South of the Himalayas lies the great alluvial plain stretching from the Jumna in the east to the Sulaimans in the west. This is one vast level, unbroken save by the wide eroded channels within which the great rivers ever shift their beds, by the insignificant spurs of the Aravalli range in the southeastern corner and by the low hills of Chiniot and Kirana in Jhang. The land between two rivers is known as doab. Between the Sutlej and the Beas lies the Bist-Jullundur doab, between the Beas and the Ravi, the Bari doab, between the Ravi and the Chenab, the Rechna doab, between the Chenab and the Jhelum, the Chaj or Jech doab and between the Jhelum and the Indus, the Sind Sagar doab. The land between the Jumna and the Sutlej is known as the Ghaggar or Sirhind plain. Large areas of the doabs between the Sutlej and the Jhelum were formerly desert wastes which, with the help of irrigation, have now been turned into prosperous agricultural settlements with wheat and cotton as the principal crops. Several canal colonies have sprung up including those of Nilibar, Montgomery, Lyallpur and Shahpur. The area between the Jhelum-Chenab and the Indus known as Thal was also a sandy waste but in the 1950s was being reclaimed by the construction of canals and tube-wells under the guidance of the Thal Development authority.

Geology.—By far the greater part of the Punjab is covered by alluvial and wind-blown deposits which constitute the Indus and the Ghaggar plains. The Salt range area forms a plateau with a steeply scarped face to the south, along which there is an axis of abrupt folding. accompanied by faulting. The rocks found in the Salt range belong to the Cambrian, Carboniferous, Permian, Triassic and Jurassic systems, while Tertiary beds cover the plateau behind. The extensive and valuable deposits of salt, from which the range takes its name, occur near the base of the Cambrian beds. Gypsum, kieserite and other salts are found. Between the Cambrian and the Carboniferous beds there is an unconformity, which, however, is not very strongly marked. in spite of the lapse of time which it indicates. At the bottom of the Carboniferous series there is usually a boulder bed, the boulders of which have been brought from a distance and scratched and striated as if by ice. It is generally admitted that this deposit indicates a southern glacial period in late Carboniferous times. Above the sandstone series at the base of which the boulder bed lies come the *Productus* and Ceratites limestones. The former is believed to belong to the Upper Carboniferous and Permian, the latter to the Trias. Jurassic beds are found only in the western portion of the range. Coal occurs both in the cis-Indus (eastern) and trans-Indus extensions of the Salt range. There are two workable seams, both in the Ranikot stage of the lower Eocene.

Climate.—Because of its subtropical position, scanty rainfall and cloudless skies and the wide expanse of untilled plains, the climate of the Punjab presents great extremes of both heat and cold. From April to September is the hot season with hot dusty winds blowing during the day, while from the begmning of October to the end of March there is a magnificent cool season, with warm bright days and cold nights. Frosts are frequent in January. In the early months of the hot season, till the end of June, a dry heat is experienced, with temperatures rising in places to 120° F. in the shade. At the end of June the monsoon arrives, the rains break in the east of the Punjab and though the heat is less intense the air is moist; and from the middle of August the temperature gradually falls. This is the most unhealthful period of the year, being exceedingly malarious. The Punjab enjoys two well-marked seasons of rainfall: the monsoon period, lasting from the end of June till the third week of September, on which the autumn crops and the sowings for the spring crops depend; and the winter rains from January to March which, though often insignificant in amount, materially affect the yield of the spring harvest. The greatest rainfall is in the outer ranges of the Himalayas, averaging about 50 in. The submontane area has about 30 in.; the central plain 20 in. to 24 in., while in the western plain Multan has only 7 in. The rainfall is heavier in the east than in the west because it is derived mainly from the Bay of Bengal monsoon current. The Arabian sea monsoon is practically exhausted over Sind and Rajasthan before it reaches the Punjab. (K. S. AD.)

History. — The history of the Punjab has been profoundly influenced by the fact that between Peshawar and Dera Ismail Khan the four frontier passes of the Khyber, Kurram. Tochi and Gomal serve as gateways from Afghanistan to the Punjab plains. For this reason it is ethnologically more closely related to central Asia than to India. Until 1922 no structural remains in India could be assigned with certainty to a period earlier than the 3rd century B.C.; later, excavations at Harappa and Mohenjo-Daro unearthed the remains of a civilization 5,000 years old bearing a general resemblance to that of Elam and Mesopotamia *(see* INDIA: *History)*. The first migration of which there is any evidence, however. is that of the Indo-European (Aryan) peoples who entered the Punjab in prehistoric times. Centuries later, within historical times. successive waves of other invaders swept through the frontier passes; and all these migrations and invasions added to the heterogeneity of the population.

The exact limits of the Achaemenian empire of Darius I cannot be determined, but probably included the Indus valley and parts of the Punjab. The earliest date known for certain in Indian history is Alexander the Great's invasion of the Punjab in 326 B.C. *(see* ALEXANDER III THE GREAT). His invasion was merely a large-scale raid and his death in 323 prevented consolidation of his power in the Punjab and the Indus valley. The history of northern India proves that the mountain barrier of the northwestern frontier seldom formed a political boundary, for the kingdoms of the Persians! Mauryas, Graeco-Bactrians, Sakas, Parthians. Kushans and Ephthalites extended from Afghanistan to the Punjab plains.

The first Moslems to penetrate into northern India were the Arabs who, in A.D. 713, extended their power to the lower Punjab; but the Moslem conquest of the Punjab was the work of Mahmud of Ghazni (971–1030), who overthrew the Hindushahiya dynasty ruling between Lamaghan and the Chenah and annexed their territories to his extensive central Asian empire. The Punjab remained in Ghaznevid hands until Mahmud's descendants were expelled by Mohammed of Ghur in 1186. It formed part of the sultanate of Delhi from 1206 until Baber's defeat of Ibrahim Lodi at Panipat in 1526 paved the way for the foundation of the Mogul empire, of which it remained a part until disintegration set in during the first half of the 18th century.

The religious intolerance of the Mogul emperors after the death of Xkbar in 1605 led to the growth of Sikh political power in the Punjab and transformed a religious sect, founded by Guru Nanak in the second half of the 15th century, into a military organization animated with undying hatred toward Moslems. The weakness of the emperors who succeeded Aurangzeb facilitated the growth of Maratha power. From 1720 onward the Maratha princes adopted a policy of territorial aggrandizement and, by 1758, had overrun almost the whole of northern India as far as Peshawar. They were gradually driven southward by the Afghans under Ahmad Shah Durrani to Panipat, where they were routed with enormous losses on Jan. 14, 1761. After the death of Ahmad Shah the various Sikh groups or *misls* began to consolidate their power in the Punjab. The most important of these *misls* were the Bhangis of Gujrat, Sialkot, Lahore and Amritsar; the Ahluwalias of Kapurthala, Jullundur and Hoshiarpur; and the Kanhyas of Gurdaspur. From 1790 onward. Ranjit Singh, the head of the Sukarchakia *misl,* rose to prominence as leader of the Sikh resistance to the Afghan ruler Zaman Shah. His attempt to establish his authority over his coreligionists, the cis-Sutlejian Sikhs, brought him into contact with the British, who had extended their power to the Jumna; and an agreement mas formed in 1809 by which the Sikh ruler accepted the Sutlej as his frontier. From this date his power increased rapidly. Between 1813 and 1821 he annexed Attock, Kashmir, Dera Ghazi Khan and Dera Ismail Khan. It was not until 1834, however, that Peshawar came under Sikh control.

After the death of Ranjit Singh in 1839 the Punjab became the scene of widespread lawlessness, and power passed to the army of the Sikh Khalsa. Suspecting the British of contemplating annexation and eager for war, the Sikhs in 1845 invaded British territory but were defeated in desperate struggles at Moodkee, Ferozeshah, Aliwal and Sobraon. By a treaty in 1846 they were compelled to surrender all lands on the British side of the Sutlej together with the Bist-Jullundur doab, to pay an indemnity and to limit the strength of their armed forces. The young maharaja, Dalip Singh, was to be guided by a council of regency presided over by Sir Henry Lawrence. The new arrangements did not prove acceptable to the Sikhs. and war broke out once more in 1848. After the battles of Chillianwalla and Gujrat the Punjab was annexed to British India on April 2, 1849. (*See* SIKH WARS.)

The newly conquered territories were placed under a board of administration until 1853, when the board's powers and functions were vested in a chief commissioner. Six years later the Punjab and its dependencies were formed into a lieutenant governorship. The annexation of the Punjab, by advancing the British administrative boundary across the Indus. brought the government of India into closer contact with the Pathan tribes of the northwestern frontier. Until 1876 relations with the tribesmen were conducted by the deputy commissioners of Hazara, Peshawar. Kohat, Bannu, Dera Ismail Khan and Dera Ghazi Khan. The system of political agencies was not adopted until 1878, when a special officer was appointed for the Rhyber. The Kurram, Malakand, Tochi and Wana agencies were created between 1892 and 1896. The tribes remained under the control of the Punjab government until the creation of the North-West Frontier province in 1901.

The response of the Punjab during World War I was magnificent: of the 1,302,000 combatants recruited throughout British India, 300,000 were provided by the Punjab, of whom more than one-half were Moslems. Between World Wars I and II communal relations in the province were embittered by the activities of the *tanzim* (orthodox) and *tabligh* movements organized by Moslems to combat the proselytizing of the Hindu *shuddi* (members of lowest caste). Far more serious than this communal strife were the political disturbances culminating in the Jallianwalla Bagh incident of 1919. (For the Punjab rebellion of 1919 *see* INDIA: *History.)*

In 1921 the Punjab was raised to the status of a governor's province. From 1922 until the passing of the Sikh Shrines act, 1925, the peace mas disturbed by the Akali Sikhs who wished to devote the revenues of certain shrines and temples to the spiritual benefit of the Sikh community. The Punjab became an autonomous province in 1937 and in World War II Punjabi troops again greatly distinguished themselves. The separation of Pakistan from India in 1947 was followed by the division of the Punjab into the state and province of East and West Punjab with Hindu and Moslem majorities respectively. (C. C. D.)

Partition set the boundary in the Punjab between India and Pakistan roughly along the line of the Sutlej up to beyond Ferozepur, and then due north between Lahore and Amritsar to the boundary of Kashmir along the line of the Ravi and the Ujh. Under British rule the Punjab was divided into the five divisions of Ambala (Umballa), Jullundur. Lahore. Rawalpindi and Multan. At the partition India received the Xmbala and Jullundur divisions and part of the Lahore division (including Amritsar district with Amritsar city, the holy city of the Sikhs). Pakistan was granted the Ramalpindi and Multan divisions and the districts of Sialkot, Gujranwala and Sheikhupura from the Lahore division in addition to part of Lahore district, including the important capital city of Lahore (pop. [1951] 849.476). The district of Gurdaspur was partitioned, and in the extreme south of the province Pakistan was allotted a small area on the east bank of the Sutlej with control of the Suleimanki headnorks on which the irrigation of the former Bahawalpur state depended.

The immediate result of partition was an outbreak of violence aith much loss of life followed by a great mass movement of population involving about 10,000,000 people. Practically all the Hindus migrated from the West to the East Punjab and practically all the Mohammedans from the East to the West Punjab.

PUNJAB (India), a state of India created out of the eastern part of the former province of the Punjab at the partition of the subcontinent between India and Pakistan in 1947. On Nov. 1, 1956. PEPSU was merged with it. (For geography and earlier history *see* the article on the former province PUNJAB above.) Partition dislocated the economy and administration of the state. Priority was given to agricultural development. The multipurpose Bhakra-Nangal project was designed to irrigate 370,000 ac., and the Nangal dam was completed. Concreting of the Bhakra dam was started in Nov. 1955, and 677 m i of main canals and 3,958 mi. of distributary canals had been constructed by 1956. One million acres had then received irrigation facilities, and on completion of the project 6,500,000 ac. would for the first time be irrigated and 3,500,000 ac. already under irrigation would receive more water. One hydroelectric powerhouse had begun to supply 34,000 kw. to the Punjab state and Delhi, and a second was expected to be ready shortly afterward. Holdings were consolidated, erosion in the southeast portion of the state was being checked, and five community projects, nine community development blocks and sixteen national extension service schemes, covering in all a quarter of the state, were formed. The result was an enormous increase in the production of food grains, cotton, raw sugar and oilseeds.

In 1951 work was begun on the construction, on modern principles of architecture, of a new capital at Chandigarh; and in Sept. 1953 government offices began to move to their new headquarters. A few cotton ginning and textile mills were constructed and the manufacture of sports goods was established at Jullundur. Oilseed crushing was undertaken on a minor scale, and a few foundries for the manufacture of agricultural implements were built. The state is served by the Northern railway line with headquarters at Delhi, uhence it is connected with the other lines of the Indian railway system. Within the state one section of the line runs north and northwest through Panipat, Ambala (Umballa), Ludhiana and Amritsar, and then links up with the North Western railway of West Pakistan. The southern section runs through Rohtak to Ferozepur and thence via Pakistan's North Western line to Lahore.

In the mid-1950s there were 8,647 primary schools, 845 middle schools, 654 high schools for boys and 86 for girls, and 63 colleges for men and 11 for women. About 40% of the children aged 6 to 11 and 25% of children aged 11 to 14 were in schools. The East Punjab university had its headquarters at Hoshiarpur.

The state comprises 19 districts and has an area of 47,062 sq.mi. Pop. 16,134,890. In the years after partition, politics in the state were confused and there was need for a time (June 1951–April 1952) of governor's rule. In the 1952 elections the Congress party gained a decisive majority; and in 1957 they secured 118 out of 152 seats, and continued in office. (S. GL.)

PUNJAB (Pakistan). With the partition of India in Aug. 1947, the old province of Punjab (*q.v.*) was divided between Pakistan and India according to the Radcliffe award. The western major portion became a province of Pakistan under the name of West Punjab which was subsequently changed to Punjab. In 1955 the province was abolished under a reorganization act. The boundary between the two Punjabs followed the Ujh and Ravi rivers to a point about 14 mi. N.E. of Lahore and then cut across the Bari doab to the Sutlej about 12 mi. N.E. of Ferozepore; thereafter it followed the Sutlej. At the extreme south a small area on the east bank of the Sutlej had been allotted to Punjab (Pakistan) to give control of the Suleimanki headworks on which the irrigation of the former Bahawalpur state depended. The boundary allotted one of the four tehsils of the Gurdaspur district, named Shakargarh, to Pakistan and half of the Kasur tehsil of Lahore district to India. The Shakargarh tehsil was incorporated in the adjoining district of Sialkot.

The Punjab province of Pakistan comprised 16 districts, grouped into three divisions, Lahore, Rawalpindi and Multan, and had an area of 62,245 sq.mi. Pop. (1951 census) 18,828,015. At the time of the 1951 census 98% of the population was Mohammedan as compared with a Mohammedan population of about 75% for the same area in 1947). When the province was merged in West Pakistan province in Oct. 1955, its capital, Lahore, became the capital of the new and much larger province.

The Punjab has an extensive system of canals which has converted large areas that were formerly desert wastes into prosperous agricultural settlements. Wheat and cotton are the principal crops where rainfall or irrigation are sufficient. Millet and gram are the chief crops in the drier western part of the province. The Salt range contains many minerals, especially salt and coal. A number of mills, especially for cotton textiles, were established after the partition, and in the Attock district the oil industry was of considerable importance.

Lahore is a great centre of trade and industry and the site of the Panjab university. The entire area is served by the North Western railway which also has its headquarters at Lahore. It connects that city with Karachi to the southwest and with Peshawar and other frontier cities to the northwest, and links up with the Northern railway in the Punjab state of India. (K. S. AD.)

PUNO, a southern sierra department of Peru, bounded north by Madre de Dios, west by Cuzco, Arequipa and Moquegua, south by Tacna and east by Bolivia. Pop. (1958 est.) 896.510. Area 27,947 sq.mi. The northern portion of the department was removed in 1912 to form a section of the department of Madre de Dios. Puno includes most of the shore of Lake Titicaca, the high plateau on which the lake stands and the mountains surrounding it on the north, east and west. Vilcanota Knot, on the border of Puno and Cuzco, constitutes the watershed dividing the enclosed lacustrine basin of Titicaca from the Amazon basin. The department is the source of the headwaters of the Amazon, notably the Tambopata and Inambari, affluents of the Madre de Dios.

Crops cultivated in the region are limited to those that mature in the cold climate; chiefly potatoes, barley and other hardy cereals. Cattle and sheep are bred there; wool, both from sheep and alpaca, is exported. The department contains one of the most important auriferous regions of the world. In addition to silver and gold which have been worked extensively, coal, salt, copper, antimony, cinnabar, arsenic, quicksilver, tin, marble, zinc, cobalt and petroleum are found. The manufacture of pottery and woolen textiles are also important industries.

The city of Puno. pop. (1958 est.) 23,227, capital of the department and province of Puno, lies at an elevation of more than 12,600 ft. above sea level, on the northwest shore of Lake Titicaca: it is the seat of a bishopric and a superior court. Puno is connected by the Southern railway with both Cuzco and the Pacific port of Mollendo and with La Paz, Bolivia by steamer across Titicaca and railway. Motor roads connect with Cuzco, Arequipa and Guaqui and northeastward to Sandia and Ollachea. Puno is 171 mi. from La Paz, 218 mi. from Arequipa and 820 mi. from Lima. (J. L. TR.)

PUNTA ARENAS, southernmost city of the world, capital of Magallanes province and department, Chile. Pop. (1952) 34,263. The city, located on the Straits of Magellan, was founded in 1849 by Col. José de los Santos Mardones. Punta Arenas' role as a port-of-call and coaling station waned after the opening of the Panama canal and fuel oil became significant in maritime movement; nevertheless, a flourishing export trade in wool and mutton, primarily with the British Isles, continues. Punta Arenas supports slaughterhouses, tallow works and wool exporting houses. The administrative and supply activities of the national petroleum company that operates in oil fields on Tierra del Fuego, the recreation requirements of its employees, the attractions of the free port to Chilean consumers and the maintenance of naval, air and army garrisons are contributing factors to the city's growth in the 20th century. Frame and corrugated metal construction predominates among the city's buildings. Surface and air communication with the north and Tierra del Fuego is good. Some lignite and placer gold are mined nearby. From 1927 to 1937 the city was called Magallanes. The name Punta Arenas means "sandy point." (J. T.)

PUNTARENAS or PUNTA ARENAS ("sandy point") a seaport on the Gulf of Nicoya on the Pacific coast of Costa Rica.

Pop. (1950) 13.272. In colonial times the city's chief function was to link Costa Rican commerce nith Panama and South America. A royal order of 1814 brought the first attempt to improve the harbour facilities: a cart road from San José was opened in the 1840s. Most Costa Rican coffee went to Europe around Cape Horn and Puntarenas was the shipping centre.

Now connected with San José by the Pacific railway, it is an increasingly important port for exporting bananas as well as coffee. There is a considerable coastal trade in rice, corn and beans. Canning and freezing fish and ship repairing are relatively new industries in Puntarenas. Most imports to Costa Rica from the west coast of the United States pass through this city. It is the capital of Puntarenas province (area 4,367 sq.mi.; pop. [1950] 88,168), a long narrow district that skirts the Pacific to the Republic of Panama. The province was the fastest growing in Costa Rica by the 1960s. Much of this was due to greatly increased activity in the banana industry as new areas opened on the Pacific coast.

(T. L. K.)

PUPIN, MICHAEL IDVORSKY (1858–1935), U.S. physicist and inventor, particularly of electrical devices, was born in Idvor, Hung. (Yugoslavia), Oct. 4, 1858. He went to the U.S. in 1874, graduating from Columbia university, 1883. The first to hold the John Tyndall fellowship (1886–88), he later studied physics and mathematics at Cambridge university and under H. von Helmholtz at the University of Berlin (Ph.D., 1889). He was instructor in mathematical physics at Columbia, 1890; and was appointed adjunct professor of mechanics, 1892, becoming professor of electromechanics there in 1901 and later director of the Phoenix research laboratories. By means of inductance coils placed at predetermined intervals of·the transmitting wire, he greatly extended the range of long-distance telephony, particularly over telephone cables. The patent for this invention was acquired in 1901 by the Bell Telephone company and by German telephone interests. He made several other inventions in electrical wave propagation, electrical resonance and multiplex telegraphy. He discovered secondary X-ray radiation in 1896 and invented in the same year means for short exposure X-ray photography by the interposition of a fluorescent screen. He wrote *From Immigrant to Inventor* (1923). He died in New York city, March 12, 1935.

PUPPETS AND MARIONETTES, jointed figures which, by various devices, are made to move in mimicry of persons or animals — usually for dramatic performances. The closely related shadows are flat cutout figures which are exhibited in silhouette against a lighted screen. The following are commonly accepted methods of producing simple types of hand puppets, rod puppets, string puppets (marionettes) and shadow figures.

Hand Puppets can be of wood, plaster, plastic wood, papier-mâché or stuffed cloth. Head and neck are in one piece with a hole running up the neck for the first finger of the operator. The arms consist of cylindrical cuffs (cardboard strengthened with cloth) which are glued or tacked to wooden hands. The operator's second finger and thumb each fit into a cuff. A small stuffed bag is suspended by tapes from a ledge at the base of the neck. Grasping this bag in the palm with the two last fingers gives a firmer control. The cuffs also are attached to the bag with tapes. This framework of the hand puppet is then concealed — the head by a mask and wig (unless the face and hair are already carved and painted on), the rest by clothing firmly attached to the ledge at the base of the neck. If desired, legs and feet can be attached.

To operate, put the doll on the hand like a glove, always keeping the forearm upright so that the puppet will stand straight. Arm and head movements are made with the fingers. The stage has no floor; a curtain or three-sided screen with an opening for the proscenium arch is required. The little roll or draw curtain is suspended from a frame or from wooden strips across the top of the screen. Painted or dyed scenery behind the dolls is similarly suspended. Puppets must be held high so that the operator's head is invisible. A ledge along the base of the proscenium arch offers a place on which to rest "properties." The stage lighting (floods or strips) should shine upon the puppets' faces, as well as upon the scenery. Humorous, lively plays are best for this grotesque, intimate type of puppet show.

String Puppets (Marionettes) are made of the same materials as hand puppets. If the head is of plaster or stuffed cloth put a wire from ear to ear with a loop at either end and another wire, twisted on to this, running down through the neck with a loop at the end. If the head is wooden, scre eyes at the sides and at the bottom of the neck are used. The torso can be one piece; but separate shoulders and hip pieces of wood with a centre section of loosely stuffed cloth give flexibility to the body. Limbs can be wooden loosely jointed,. or a wire skeleton padded or firmly stuffed cloth. The joints must be flexible: brass hinges, double screw eyes, leather or cloth straps or carved wooden joints. Hands can be of wood, plaster or wire mound with narrow tape. If the doll is of stuffed cloth the feet, lower arms and hips should be weighted with lead. Faces and hands should be painted, like theatrical make-up to carry at a distance with either oil or water-colour paints. When dressing the doll freedom must be allowed for movement of neck, elbow, shoulder, etc.

The marionette is suspended by strings from a controller held in the hand of an operator above. This controller can be a flat strip of wood about 10 in. long with a shorter crossbar. A leather strip tacked to the crossbar slips over the back of the operator's hand. The head strings are tied (from loops at the ears) to ends of the crossbar and to hold the weight of the doll. The hand strings are attached to the front end of the controller. The back string from the back waistline of the doll is attached to the rear end of the controller. A separate bar is generally used for the foot controller, and a hole in the centre of this bar allows it to be hung up, when not in use, upon a peg at the front of the main controller. The strings are attached at the knee, not foot, of the doll. Shoulder strings or extra strings for special gestures can always be added.

Practice is required for operating string puppets smoothly. To turn or bend the head, tip the controller sidewise (or pull on the shoulder strings). To seat or bow the doll, tip the controller forward or pull on the back string. To walk the puppet take the foot control in the free hand and tilt it from side to side, moving the figure on with the main controller at desired speed.

A marionette stage is a miniature replica of any stage except that the wings are left open to allow passage of dolls, strings and controllers. Operators stand on a platform directly behind and higher than the puppet stage. A strong rail, waist high, in front of this "bridge" supports the weight of the operators leaning against it. A rail at the back of the bridge is used to hang dolls upon. The bridge, the wings and the space below the puppet stage are concealed from the audience, usually by draperies. Behind these a framework forms the proscenium arch; it supports the little curtain and the front lights of the stage. Lighting and scenery must be planned not to catch the marionette's strings.

Rod Puppets are worked from below by rods. The head (of material similar to other puppets') can be made with a hole bored up the neck. A thin dowel fastened in this hole extends down below the feet and serves to hold and walk the puppet. The body usually consists of wooden shoulder and hip pieces attached horizontally at proper points to the upright dowel. Wire, or cloth stiffly stuffed with cotton, can be made to give a shape to the torso. Arms and legs are constructed as are the limbs for string puppets but the legs are generally allowed to hang without control. The arms are moved from below by thin rods of wood or mire attached to the palms. To articulate the neck of a rod puppet a more complicated construction is required. The head must be hollow and pivoted over the neck which is modeled (hollow) in one piece with the shoulders. A slender hollow metal tube is used instead of the upright dowel to allow strings attached at very precise points inside the head to drop down below the feet. By pulling these strings the operator can nod the figure's head. A convenient method of standing the puppet when not being held is to have two round disks about an inch apart fastened to the dowel just below the feet. Wooden strips must be built in just below the stage floor level at required places. These strips have slots cut into them at intervals into which the rod can be firmly set. Otherwise the stage, lighting, decor, etc., for rod puppets are similar to those for hand puppets. Rod puppets move slowly and gesture gracefully, hence are well suited for religious plays or dramas of fantasy.

Shadow Plays.—Somewhat like rod puppets, shadow plays are usually worked from below, at an opening in a screen or curtain; but this opening is covered with white cloth, drawn tight. The figures are cut in silhouette out of cardboard or tin and attached to slender staves by which they are held and moved, directly behind or in front of the cloth. Movable arms or jaws can be cut out separately, joined with brass clips and moved from below by wires or threads concealed behind the figure. Faces must be in profile. A light from behind throws the shadows plainly into view. Some suggestion of scenery can be painted upon the cloth or hung close against it. *See* DOLLS; MASK; SHADOW PLAY.

PUPPIS, one of the three southern constellations into which the large Ptolemaic constellation Argo (*q.v.*) was subdivided (*puppis,* "poop"). The bright new star Nova Puppis was visible during the winter of 1942.

PUQUINAN, a group of tribes of South American Indians, doubtfully constituting an independent linguistic stock. Their identity with the modern Uros has been much discussed. The area occupied (if this identity be accepted) would include the whole basin of lakes Titicaca and Poopo, and the Salar de Uyuni in the Bolivian plateau, together with the Peruvian-Chilean coast from about 16° to 22° S. lat. Within this area they lived in scattered small groups among the Aymaran (*q.v.*) tribes. Rivet thought that the Puquinan language (together with the Uro) is in reality a member of the Arawakan (*q.v.*) stock and that this whole group of Puquinan and Uran tribes represents a very ancient intrusion westward of the Arawakan peoples.

PURCELL, EDWARD MILLS (1912–), U.S. physicist, noted especially for his research on magnetic resonance, was born in Taylorville, Ill., Aug. 30, 1912. He received his B.S. from Purdue in 1933, and his Ph.D. from Harvard in 1938. During the war he was head of the Advanced Development group on radar problems at the radiation laboratory of the Massachusetts Institute of Technology. He became professor of physics at Harvard university in 1949. He was awarded the Nobel prize in 1952 jointly with Felix Bloch (*q.v.*) for the discovery of nuclear magnetic resonance in solids, a phenomenon observed independently for the first time at Harvard and Stanford. These investigators showed that by the absorption of radio-frequency waves in solids it is possible to detect nuclear magnetic moments. This research opened up a whole new field of physics: magnetic resonance spectroscopy. It yielded information not only on nuclear moments, but also on chemical bonds and atomic binding in liquids and solids, even supplying data on the structure of hydrocarbons useful for the oil industry. Another notable achievement of Purcell was the detection jointly uith Harold I. Ewen in 1952 of the 21 cm. line of neutral atomic hydrogen in extraterrestrial radiation. This discovery added a new dimension to radio astronomy by revealing the distribution of hydrogen in galaxies. (J. H. V. V.)

PURCELL, HENRY (*c.* 1659–1695), English composer, whose date of birth and birthplace are uncertain, is said to have been born in Westminster. His father, according to his biographer W. Cummings, was Henry Purcell, or Pursell, a gentleman of the chapel royal, whose eldest son Edward (1653–1717), became gentleman usher to Charles II, and afterward distinguished himself in the army, while Henry and Daniel, the tuo younger sons, became musicians. On his father's death in 1664, Henry Purcell was placed under the guardianship of his uncle Thomas Purcell (d. 1682), also a gentleman of the chapel and a man of extraordinary probity and kindness. (According to J. A. Westrup, Thomas was the composer's father, not his uncle.) Both he and Henry Purcell the elder sang at the coronation of Charles II. Through Thomas's interest Purcell was admitted as a chorister of the chapel and was placed under Capt. Henry Cooke (d. 1672), master of the children, an excellent teacher and a composer of anthems, to whom Samuel Pepys makes a number of references in his *Diary.* On Cooke's death Pelham Humfrey (1647–74) became master, and mas an excellent teacher as well as a musician of genius; but as a pupil of Lully he naturally stood for the French school, and in this respect failed to influence Purcell, who admired the Italian masters.

Purcell's third and last master was the distinguished composer and organist John Blow (1648–1708), to whom Purcell's great indebtedness is not always sufficiently realized. In 1673, when his voice broke, Purcell was dismissed with an ex-chorister's salary of £30 a year and presented with certain articles of dress. He was also given the appointment of (unpaid) assistant to John Kingston, keeper of the king's instruments, together with a promise to succeed him. In 1677 he was appointed "composer in ordinary for the violin" in succession to Matthew Lock. Purcell had been copyist at Westminster abbey since 1677, and in 1679 he succeeded Dr. Blow as organist.

The year 1680 was the beginning of a period of great productivity. In it he wrote the music to Nathaniel Lee's *Theodosius,* the first of a long series of dramas for which he provided incidental music, and one in which an introductory ritual scene gave him unusual scope; this was followed by Thomas D'Urfey's *Virtuous Wife.* He also produced the first of his court odes or "Welcome Songs" at this date and wrote several anthems, many of which were composed especially for the prodigious basso profundo of the Rev. John Gostling (or Gosling). a singer at Canterbury and later at the chapel royal, to whom John Evelyn alludes as "that stupendous bass." Either in 1680 or the following year he married Frances Peters, and in 1682 his eldest son was born. From 1682 he held the post of organist to the chapel conjointly with his appointment at the abbey. His first printed composition was the 12 *Sonnatas of III Parts: two violins and basse: to the organ or harpsichord.* These, though avowedly based on Italian models, show great power and originality. Purcell had now become "composer in ordinary to the king" and his official life was a very full one. For each public event he composed an ode or an anthem: some of the finest of these are the ode "Swifter. Isis, Swifter Flow" (1681); the "St. Cecilia" odes; the "Fly, Bold Rebellion" (in celebration of the suppression of the Rye House Plot, 1683); two anthems written for James II's coronation: "O I Was Glad" and "My Heart is Inditing." The *Te Deum and Jubilate,* written for St. Cecilia's Day 1694. was notable as being the first English anthem with orchestral accompaniment. It was performed annually at St. Paul's cathedral until 1712 and in alternate years with G. F. Handel's Utrecht *Te Deum* until 1743. In all his anthems there is a large proportion of instrumental music.

The opera *Dido and Aeneas,* which above all Purcell's works inspires admiration and affection in an equal degree, was written to a libretto furnished by Nahum Tate at the request of Josiah Priest, a dancing master who also kept a boarding school for young gentlewomen, first in Leicester Fields and afterward at Chelsea. The date of its composition and original performance at the school was fixed by W. Barclay Squire of the British museum as about the year 1689. In this work there is no spoken dialogue, but only recitative, and it is characterized from beginning to end by the dramatic directness which Purcell possessed in so high a degree. Dido's exquisite song of farewell is one of the flawless things in music, classical in form and in its dignified restraint, and yet of rare emotional quality. As is so often the case when he has some poignant emotion to express, Purcell chooses here to build up the song on a "ground," and the relentless reiteration of the bass contributes greatly to the dramatic effect. Graceful dance choruses, lumbering sailor dances and witches' incantations relieve the tragedy, and, avoiding an anticlimax after Dido's farewell, the composer ends with a soft and tenderly expressive chorus, "With drooping wings, ye Cupids, come," in which music and words achieve perfect union.

Although *Dido and Aeneas* stands out today as an isolated phenomenon in the age in which it is written. it was rather the peak of a movement in which Purcell's predecessors did valuable experimental work; and here, again, Blow's influence is seen, for in his only known dramatic work, *Venus and Adonis,* he sets the

CLARK, (CENTRE LEFT) HARPER AND BROTHERS; FROM BATCHELDER AND COMER, PUPPETS AND PLAYS," PHOTO BY LAURA GILPIN (CENTRE RIGHT) DETROIT INSTITUTE OF ARTS, (BOTTOM LEFT) DAVID ORCUTT, (BOTTOM RIGHT) GEORGE LATSHAW example of having every word sung and none spoken. He is no doubt also partly responsible for Purcell's skill in the use of a ground, and he probably encouraged, rather than discouraged, his pupil's audacities of harmony, since he himself was a notorious offender. Among the peculiarities of Purcell's idiom are the constant false relations and the use of the descending melodic minor in ascending passages, and vice versa. He had a marked preference for the flat minor keys. His fine feeling for rhythm, form and climax invests even his smaller pieces with a quality that is unmistakable.

In judging Purcell's scores it should be remembered that he was practically restricted to oboes and trumpets as regards wind instruments, since even the modern flute had not come into use in his time.

In 1690 Purcell wrote the music to Betterton's *Dioclesian*, which includes a masque. He was associated with Dryden in *Tyrannic Love* (1687), *Amphitryon* (1690) and *King Arthur* (1691), in all of which the music consists of separate numbers which form no integral part of the drama. In *King Arthur*, Josiah Priest was responsible for the dances. This play, which contains the famous song "Fairest Isle," had a great success and was revived on various occasions up to 1803, and once in 1842. It was first published in 1843 by the Musical Antiquarian society. The score of Purcell's songs and music to *The Fairy Queen* (an adaptation of William Shakespeare's *A Midsummer Night's Dream)* written in 1693 was discovered in 1901 and edited for the Purcell society by J. S. Shedlock in 1903.

Purcell suffered much at the hands of his editors until, in 1876, the Purcell society was founded for the purpose of bringing out a complete and authoritative edition of his works, the majority of which were still in manuscript.

Purcell died at his house in Dean's Yard, Westminster, on Nov. 21, 1695, and was buried in Westminster abbey on Nov. 26. He left a widow and three children, three others having died before him. In 1682 and 1702 she published *Orpheus Britannicus*, a collection of his works, in two parts. A famous portrait of the composer is that by Sir Godfrey Kneller, bequeathed to the National Portrait gallery, London, by Barclay Squire.

Other dramatic works by Purcell were *Don Quixote, The Indian Queen* and *Bolt duca* (all in *1695)* and many earlier works. Smaller works are the fantasias and sonatas for three or more parts, the suites and many miscellaneous pieces for harpsichord, and songs. For a detailed list, see *Grove's Dictionary* (5th ed., *1955)* and the publications of the Purcell society. Other publications include the *Chacony* for string quartet *(1926)*; *Dido and Aeneas* with English and German text, ed. by E. J. Dent, and Dennis Arundell's life, *Henry Purcell* (both by the Oxford University Press, 1928); Henri Dupré, *Purcell* (Eng. trans., 1929); the life by W. Cummings in the "Great Musicians" series *(1903)* is a standard work. *See* also J. A. Westrup, *Purcell*, "Master Musicians" series *(1937)*.

PURCHAS, SAMUEL (c. 1577–1626), English compiler of works on travel and discovery, was born at Thaxted, Essex, and studied at St. John's college, Cambridge, and at Oxford. He was vicar first of a Thames-side parish in Essex and later in London (where he was also chaplain to Archbishop G. Abbot) and met many seafarers. As an editor and compiler he sought to interest the general public of his day. In this he was very successful though his works have been severely criticized by scholars. They are however an indispensable source of information and contain many references to original accounts of voyages. His writings include; *Purchas, His Pilgrimage; or, Relations of the World and the Religion observed in all ages* (1613; other editions 1614, 1617, 1626); *Purchas, His Pilgrim. Microcosmus, or the Historie of Man* (1619); and *Hakluytus Posthumus or Purchas His Pilgrimes*, 4 vol. (1625; 20 vol., 1905–07).

See E. G. R. Taylor, "Samuel Purchas," *Geogr. J.*, vol. lxxv, pp. 536–539 (1930). (A. M. F.)

PURE LINE. A pure line consists of a self-fertilized individual and its progeny; it is a group of individuals all possessing the same hereditary constitution; in which all the factors are present in duplicate. Until W. L. Johannsen studied the effects of selection on the weights of individual seeds of the Princess bean there was no general explanation of the manner in which this process operates (*see* ANIMAL BREEDING; GENETICS; HEREDITY; INBREEDING; MENDEL, GREGOR JOHANN).

PURGATORY, according to Roman Catholic faith, a state of suffering after death in which the souls of those who die in venial sin, and of those who still owe some debt of temporal punishment for mortal sin, are rendered fit to enter heaven. It is believed that such souls continue to be members of the church of Christ; that they are helped by the suffrages of the living — that is, by prayers, alms and other good works, and more especially by the sacrifice of the mass; and that, although delayed until "the last farthing is paid," their salvation is assured. Catholics support this doctrine chiefly by reference to the Jewish belief in the efficacy of prayer for the dead (2 Macc., xii, 42 *seq.)*, the tradition of the early Christians and the authority of the church.

The state of purgatory is usually thought of as having some position in space, and as being distinct from heaven and hell; but any theory as to its exact latitude and longitude, such as underlies Dante Alighieri's description, must be regarded as imaginative.

Most theologians since Thomas Aquinas and Bonaventura have taught that the souls in purgatory are tormented by material fire, but the Greeks have never accepted this opinion. It must be inferred from the whole practice of indulgences as at present authorized that the pains of purgatory are measurable by years and days; but here also everything is indefinite. The council of Trent, while it commands all bishops to teach "the sound doctrine of purgatory handed down by the venerable fathers and sacred councils," bids them exclude from popular addresses all the "more difficult and subtle questions relating to the subject which do not tend to edification."

The Eastern Church affirms belief in an intermediate state after death, but the belief is otherwise as vague as the expressions of the pre-Nicene fathers on the subject. The Longer Catechism of the Orthodox Church (Q. 376) states:

"Such souls as have departed with faith but without having had time to bring forth fruits meet for repentance may be aided towards the attainment of a blessed resurrection by prayers offered in their behalf, especially such as are offered in union with the oblation of the bloodless sacrifice of the Body and Blood of Christ, and by works of mercy done in faith for their memory."

The efficacy of prayers for the dead, and indirectly the doctrine of purgatory, were denied by early Gnostic, sects, by Aetius in the 4th century and by the Waldenses, Cathari, Albigenses and Lollards in the middle ages. Protestants, with the exception of a small minority in the Anglican communion, unanimously reject the doctrine of purgatory and affirm that "the souls of believers are at their death made perfect in holiness and do immediately pass into glory."

Rejection of an intermediate state after death follows the Protestant idea of justification by faith as logically as the doctrine of purgatory results from the Catholic idea of justification by works.

An analogy to purgatory can be traced in most religions. Zoroaster conducts souls through 12 stages before they are sufficiently purified to enter heaven; and the Stoics conceived of a middle place of enlightenment which they called *empurosis*.

BIBLIOGRAPHY. — The principal authoritative statements of the Catholic Church on the doctrine of purgatory were made at the council of Florence *(Decret. unionis)*, and at that of Trent (Sess. vi. can. *30;* Sess. xxii, c. 2, can. 3; Sess. xxv). *See* H. J. D. Denziger's *Enchiridion;* J. Bautz, *Das Fegfeuer* (1883) and L. Redner, *Das Fegfeuer* (1856). An elaborate treatise from the Catholic standpoint is that of Cardinal Bellarmine, *De purgatorio*. The subject is discussed, moreover, in all major works on dogmatic theology. There is a representative Catholic statement in the *Catholic Encyclopaedia*, and a Protestant presentation by Rud. Hoffmann in Herzog-Hauck's *Realencyklopädie*, 3rd ed., vol. v, pp. 788–792.

PURI, a town and administrative centre of a district of Orissa state: India. is situated on the shore of the Bay of Bengal. 311 mi. S.W. of Calcutta and 776 mi. N.E. of Madras. Pop. (1951) 49,057. The old name of the town was Purushottam Puri (the city of the Greatest Being), abbreviated to Puri in common usage. William Bruton. the first European to visit the town (1633). called it "the great city of Jaggarnat." As the seat of the well-known shrine of Jagannath (see JUGGERNAUT), Puri is one of the most sacred places of pilgrimage for Hindus. The temple of Jagannath was built in the 12th century by Choda Ganga (the greatest of the eastern Ganga kings) and consists of a suite of three chambers, the dancing hall, the audience hall and the sanctuary with its images. About two miles from the temple is the Garden house (Gundicha ghara), the retreat of Jagannath to which his image, mounted on a huge car or *rath* (followed by smaller cars of his brother and sister), is pulled by enthusiastic pilgrims during the car festival each summer. The rajas of Khurda, titular descendants of the ancient Hindu monarchs of Orissa, have been in charge of the temple since 1590. The town contains the summer castle of the state governor, the palace of the raja of Khurda, a college, an observatory and many hotels and hospices (*dharamsalas*). The beach of Puri attracts many tourists.

PURI DISTRICT is a country of alluvial plains with hills and woods in the north and northeast. Pop. (1951) 1,572,262; (1961) 1,865,834. Area 4,002 sq.mi. The main river is the Kuakhai (a branch of the Katjori) which itself divides into two branches, the Daya and the Bhargavi, both flowing into Chilka lake. Chilka is one of the largest lakes in India (length 44 mi.; breadth 13 mi. in the north and 5 mi. in the south). Dotted with islands, it is saline and shallow and most suitable for fish breeding. A large quantity of fish is exported. The district is rich in antiquities. At Dhauli hill are the rock edicts of Asoka (3rd century B.C.). Sisupalgarh is a fort of 2nd–1st century B.C. and Khandagiri contains the caves and inscriptions of Kharavela (1st century B.C.). Bhubaneswar (*q.v.*) is a city of temples and at Chandrabhaga is the Konarak (*q.v.*).

Khurda is the divisional headquarters of Eastern railway, and has an arts college. There is a science college at Nirakarpur, and Satyabadi (a Brahmin village) is famous for Krishna worship (*sakhigopal*). This village in modern times was associated with the experiment of an open-air school initiated by Gopabandhu Das. At Atri is a hot sulfur spring around which a big annual fair takes place.

Puri first came under the British in 1803. Later events were the rebellion of the raja of Khurda (1804) and the rising of the *paiks* (peasant militia) in 1817–18. More than one-third of the population is said to have perished in the Orissa famine of 1866.

(MA. M.; N. K. S.)

PURIFICATION. As used in anthropology, purification denotes the preparation of individuals or communities for contact with persons or things otherwise dangerous, or to prevent the consequences of such contact. A man may unwittingly violate a tabu and such is the sense of social solidarity that the whole community feels itself menaced until he is purified. Thus. "among most or all African tribes a sin, wrong doing or breach of custom is not merely a matter demanding punishment or redress but it imparts a bane or evil influence which remains unless the necessary purification follows. The point to be emphasized is that this mysterious force affects not the evildoer but the person injured. so that it is he who must be purified. For instance, a man who is wounded is purified by the one who wounded him." (C. Dundas, *Kilimanjaro* and *Its* People, 1924, p. 155.) In primitive societies women, and sometimes their husbands, may observe ritual cleansing after childbirth—a custom with modern parallels (see CHURCHING OF WOMEN). Puberty, marriage, warfare or bloodshed, and death are other common events often marked by purifying rites, which may entail the use of water (as in baptism), mutilation (as in circumcision), fasting. prayer and confession. Food often is surrounded by tabu'and ritual in modern, folk and primitive societies. Members of totemic clans commonly abstain from the flesh of the totem animal: foods freelv eaten bv one group may be avoided by others as contaminating. The persons, objects and situations requiring purification may be regarded as sacred or as profane.

See also CIRCUMCISION; LEVITICUS; PASSAGE RITES; RELIGION; RITUAL; TABU.

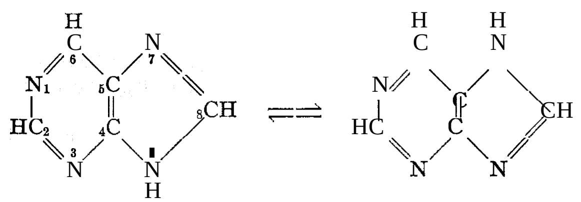
See Robert H. Lowie, *Primitive Religion* (1948); Paul Radin, *Primitive Religion* (1937).

PURIM, or the Feast of Lots, a Jenish festival celebrated on 14 Adar (February or March) and commemorating the deliverance of the Jews from the wrath of Haman, minister and favourite of the Persian king Ahasuerus. The events are related in the Book of Esther. she having been the heroine of the story. The 13th of Adar determined by lot, was set as the day on which all the Jews of Persia were to be destroyed. On that day the Jews defeated the Persians, and on the 14th they celebrated their victory and their deliverance. The Jews of Susa, who were attacked on the 14th, celebrated their triumph on the 15th; hence 15 Adar is called the Purim of Susa.

The festival is predominantly secular, having few of the religious and ethical elements of other Jewish feasts. It is celebrated with feasting, games and merriment, and since the middle ages has had a strongly carnival flavour. Purim plays, dealing often but not always with the Esther story, date from the 17th century.

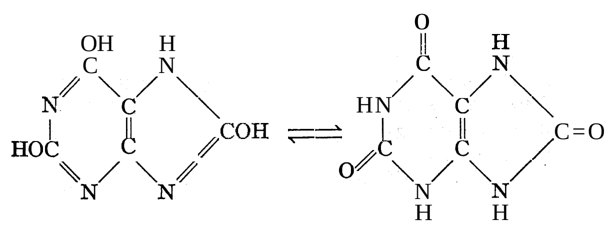
PURINES. The purines comprise a group of nitrogenous compounds, a few of which are of great importance in living cells. The first purine known was uric acid, which was discovered in human urinary calculi by the Swedish chemist, K. Scheele, in 1776. The naturally occurring purines include adenine and guanine, two essential building blocks of nucleic acids (*q* v.), a group of compounds regarded as carriers of hereditary characteristics. Another well-known purine is caffeine which, along with theobromine and theophylline, gives the stimulating effect to drinks made from coffee beans, tea leaves and cocoa beans.

Chemically, purines are structurally related to the pyrimidines. They are bases because of their nitrogen content. All purines are derived from purine itself, a substance with the empirical formula $C_5H_4N_4$. The structural formula of purine is shown in the following diagram.



Each atom is given a number, as indicated. The molecule can exist in two forms which are very readily interconvertible, a phenomenon known as tautomerization (see TAUTOMERISM). The change of structure in the tautomerization of purine consists of the migration of a labile hydrogen atom between the nitrogen atoms at position 7 and position 9.

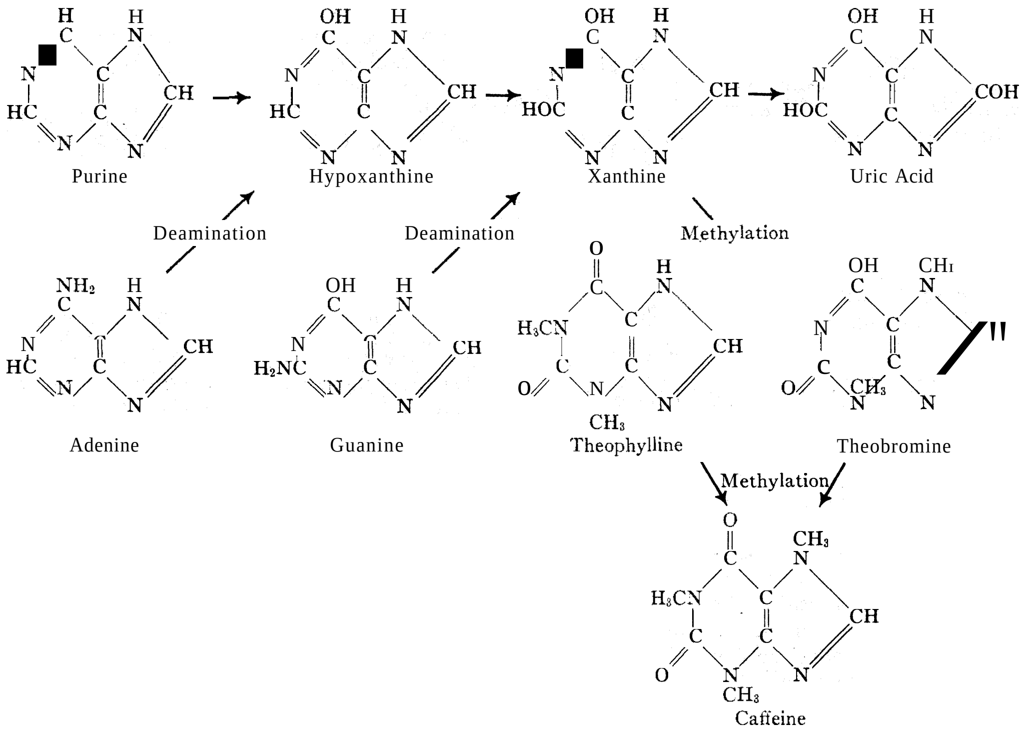
The four hydrogen atoms in purine (at positions 2, 6, 8 and either 7 or 9) may be substituted by other groups, such as hydroxyl (OH), amino-(NH_2) or methyl (CH_3) groups. When a hydroxyl group is introduced at position 2, 6 or 8, another type of tautomerization is possible, since the H of the OH group may migrate to a neighbouring nitrogen atom. For instance, uric acid, which is 2:6:8-trihydroxypurine, exists in two tautomeric forms, A and B as shown below.



A B

In form A, uric acid yields salts with metal ions, the hydrogen on oxygen being replaceable and thus making the substance an acid. Form B explains why substitution may occur on the 1 and 3 nitrogen atoms as in the methylated purines such as caffeine.

The following diagram outlines the relationships between the various naturally occurring purines. Starting with purine, and successively substituting hydroxyl groups for the hydrogen atoms attached to carbon. hypoxanthine, xanthine and uric acid are ob-



tained. Most living cells can synthesize the important purines adenine and guanine from simpler precursors *(see* NUCLEIC ACIDS). Ingested purines, as well as those formed within the cell, are eventually oxidized to uric acid.

In man, this substance is excreted in the urine as the main end-product of purine metabolism. Other mammals excrete allantoin, a degradation product of uric acid. In reptiles and birds, however, uric acid is the main nitrogenous end product of protein as well as of purine metabolism. The excrement of birds and snakes, therefore, consists mainly of uric acid.

A rich source of uric acid, guano, the excrement of certain South American sea birds, has been accumulating, with the help of a dry climate, for untold years.

Because uric acid and its monosodium salt are relatively insoluble, they are readily precipitated. Such precipitates constitute the painful nodules characteristic of the disease gout in human beings.

The pig is deficient in enzymes which convert guanine to allantoin, and consequently the pig frequently suffers from a form of gout similar in all respects to that in humans, except that the deposit in the joints consists of crystalline guanine instead of acid sodium urate.

Much of the fundamental work on purine chemistry was done by the German chemist, Emil Fischer, who coined the name purine from the Latin words *purum* and *uricum,* the latter being chosen because the best-known purine at that time, uric acid, occurs in the urine.

Any modern text book of biochemistry will give further information on this subject. (B. V.)

PURITANISM, the most dynamic form of Protestantism among English-speaking peoples during the 16th and 17th centuries. The age of Puritanism in England may be roughly defined as the century following the Reformation (*q.v.*). It extended from the first years of the reign of Elizabeth I to 1660, when the restoration of the Stuarts brought to an end the attempt to fashion a Puritan state. The Puritan age in New England dated from the first settlement in 1620 to Massachusetts' loss of the old charter and the issuance of a new one in 1691, although there was to be a brief attempt to reconstitute the old order upon a new basis during the 1730s under the leadership of Jonathan Edwards.

The term Puritan was coined as an epithet of contempt during the 1560s, and it was applied to all those persons within the Church of England who sought a more thoroughgoing reformation of the church than had been provided by the Elizabethan religious settlement. It also came to be applied to those who broke away from the Church of England in order to carry out the desired reforms without further delay. The major body of Puritans were Anglicans and remained so until the outbreak of the English Civil War in 1642 *(see* CIVIL WAR, ENGLISH). Most of them were moderate episcopalians in sympathy, although presbyterian and congregationalist sentiment was to be found among them. Even the early Congregationalists of the Massachusetts Bay colony in North America professed themselves to be loyal members of the Church of England. The small non-Anglican wing of Puritanism was composed initially of "separatist" Congregationalists and Baptists, but during the regime of Oliver Cromwell, when religious groups multiplied in a vast profusion, the Society of Friends (Quakers), constituted the extreme left of the Puritan movement.

In North America there was a varying degree of Puritan influence in all the English colonies, but the term tended to be reserved to designate the "separatist" and "nonseparatist" Congregationalists who established the Plymouth and Massachusetts Bay colonies and spread out into the rest of what was to become known as New England.

Nature of Puritanism. — Puritanism arose put of a desire for liturgical reform, being given classic definition at its earliest stage by G. M. Trevelyan: "the religion of all those who wished either to 'purify' the usage of the established church from taint of popery or to worship separately by forms so 'purified' " *(England under the Stuarts,* 16th ed., London, 1933). Questions of polity and theology later mere brought into the area of controversy, but the underlying spirit of religious and moral earnestness that had given rise to the initial demand for reform remained the most constant feature of Puritanism. As a consequence, a Puritan became identified quite correctly in the popular mind as one who followed a strict and closely regulated habit of life. Edwards gave expression to this aspect of Puritanism when he described the Christian's "practice of religion" in these words: "It may be said, not only to be his business at certain seasons, the business of Sabbath-days, or certain extraordinary times, or the business of a month, or a year, or of seven years, or his business under certain circumstances; but *the busines of his life" (The Works of Jonathan Edwards,* vol. i, p. 314, 10th ed., London, 1865). The Puritan was a spiritual athlete, characterized by an intense zeal for reform, a zeal to order everything — personal life, family life, worship, church, business affairs, political views, even recreation — in the light of God's demand upon him.

The daily routine of the Puritan usually involved private devotions at the hour of rising; family prayers with the reading of Scripture and the catechizing of children and servants; and the keeping of a spiritual diary in which the events of the day were closely scrutinized and an accounting made of moral successes and failures as well as note being taken of the signal evidences of divine grace or displeasure that had been disclosed during the course of the day. The whole thrust of Puritan preaching was designed to reinforce this systematic and carefully controlled pattern of life by sensitizing the conscience to the issues that must be faced from day to day by earnest Christians. A non-Puritan clergyman, Anthony Gilbert, in 1566 put this aspect of Puritanism vividly when he reported that his patron had said that "he could never go to any of these Genevan sermons that he came quiet home, ... there was ever something that pricked his conscience; he always thought that they made their whole sermon against him. But in the reading of Mattins and Evensong at [St.] Paul's, or in my reading of my service in his chapel, he sayeth, he feeleth no such thing, for he is never touched, but goeth merrily to his dinner."

These differing facets of the Puritan's concern make it evident that Puritanism was rooted in a vast sense of dissatisfaction with mediocre and halfhearted endeavour. This dissatisfaction, in turn, was rooted in a deep religious experience of dramatic intensity. The whole object of the Puritan mas to experience the miracle of grace himself and to produce it in others. Thus Puritanism falls within the category of a religious revival, and it is analogous in many ways to earlier revivals that sprang from the preaching of the friars and to the later revivals associated with the names of John Wesley, George Whitefield and Gilbert Tennent.

Tudor Puritanism. — Under Henry VIII the authority of the Roman papacy had been formally abolished by a series of parliamentary acts, culminating in the Act of Supremacy of 1534, which declared the king to be "the only supreme head in earth of the Church of England." The few limited reforms of the Henrician period were followed by a rapid Protestant advance under the boy king Edward VI (1547–53). This was followed, in turn, by a restoration of Roman Catholicism under Queen Mary (1553–58). Many of the more prominent Protestant leaders, including the archbishop of Canterbury, were burned at the stake during the Marian regime; the revulsion occasioned by these executions, it has been said, guaranteed that England was to be a Protestant nation in the future. Of greater importance was the fact that the exile on the continent, into which many younger men were forced, proved to be a school for training of men upon whom Elizabeth of necessity was to depend for leadership in the English Church. When Elizabeth I came to the throne late in 1558, she was hailed by the returning exiles as the English Deborah who would restore the Church of England to what they regarded as its pristine purity. She was to frustrate rather than fulfill their hopes.

Elizabeth was committed to the Protestant cause for a variety of reasons, but she detested anything that smacked of Geneva, having been alienated by John Knox's attack upon the right of women to rule and being convinced that the Genevans were "overbold with God Almighty, making too many subtle scannings of his blessed will, as lawyers do with human testaments." It was, she believed, dangerous to royal power to have private men citing Scripture against the government. Elizabeth was determined to exercise power in both state and church as her royal prerogative, and she was especially determined that the religious settlement should follow a middle course. Under pressure from the crown parliament passed an Act of Uniformity which required several observances that most Protestants regarded as popish superstitions. It was at this point, hoxever, that a division occurred. Some remembered Peter's word that one must obey God rather than men; these were to be the Puritans. Others remembered Paul's counsel that due regard must be given to constituted authority; these were to be the apologists for the Elizabethan settlement who insisted that a godly prince, after the pattern of Israel, must be obeyed in all matters not clearly proscribed in Scripture.

The initial controversy had been foreshadowed in the reign of Edward VI when Knox objected to kneeling as a practice associated with the adoration of the host and indicating a belief in transubstantiation, and when John Hooper objected to a distinctive clerical garb as representing in symbolic form a denial of the priesthood of believers. It was this latter issue that came to the front with the publication of Matthew Parker's *Advertisements* in 1566 as part of the effort to secure uniformity of clerical dress, and resulted in the label of "Puritan" being attached to the dissident party. The Puritans, of course, were seeking to reform the whole liturgy of the church that it might have greater theological integrity; and a rightly ordered worship, they believed, also involved the recovery of gospel discipline within the church. Their program was made explicit in 1572 in *An Admonition to Parliament,* which declared that "we in England are so far off from having a church rightly reformed according to the prescript of God's Word, that as yet we are not come to the outward face of the same." The "outward marks whereby a true Christian church is known," it continued, "are preaching of the Word purely, ministering of the sacraments sincerely, and ecclesiastical discipline which consisteth in admonition and correction of faults severely"; on all three counts the provisions of the Elizabethan settlement were deemed defective.

Puritan sentiment was strong enough in 1563 to come within one vote of adopting a sweeping program of reform in the Convocation of Canterbury, the legislative body for most of the Church of England. Defeated there, the Puritans turned to parliament where they were able to command majority support throughout Elizabeth's reign, but Elizabeth always claimed her prerogative and prevented parliament from dealing with the religious question. Edmund Grindal, archbishop of Canterbury, encouraged the voluntary implementation of a portion of the Puritan program, and this led to his being sequestered from office. While official efforts at reform were rebuffed by the queen, and while she was careful to prevent any widespread organization from being developed, a great deal of latitude and freedom was permitted within the parishes; and it was within the parishes, by virtue of effective preaching and pastoral example, that Puritanism continued to gain strength throughout the Elizabethan period. During this period also there were a few ardent and impetuous spirits who had become impatient with delay and who, adopting as their slogan "reformation without tarrying for any," proceeded to organize "separate" congregations. Ultimately most of these separatists were forced to take refuge in the Netherlands.

Stuart Puritanism. — Puritan confidence in the rightness of their cause may well have been the source of the optimism with which they greeted each new monarch. They were especially hopeful when after Elizabeth's death James I came to the throne in 1603. A dozen years earlier, as James VI of Scotland, he had consented to the establishment of Presbyterianism in his native land. The Puritans believed, therefore, that he might be expected to show some favour to Puritanism in England. With high expectations the Puritans presented the new king with a moderate plea for church reform known as the Millenary petition because it purported to represent the desires of more than 1.000 clergymen. The king promised a conference at Hampton court on the matter. When he met with them in Jan. 1604, he rejected the Puritan plea with scorn. James was an ardent Calvinist, but he was no presbyterian; far from restricting the power of the bishops, his dictum was "No bishop, no king."

One consequence of James's attempted repression of Puritanism was to drive additional Puritans into separatism and exile. Among these groups of exiles was the Gainsborough-Scrooby congregation, one portion of which went to Amsterdam under the leadership of John Smyth, where they became the earliest group of English Baptists. The Scrooby portion under the leadership of John Robinson went to Leiden, from which in 1620 some of their number departed to establish the colony of Plymouth in the new world. Other Puritans, unwilling to renounce all bonds of fellowship with the Church of England, adopted a middle position which has been called nonseparatist congregationalism. Chiefly under the guidance of Henry Jacob and William Ames, they developed the theory that the Church of England was in essence composed of congregational churches; this fact had been obscured but it had not been obliterated. Thus they were justified in forming independent congregations when necessary and at the same time professing themselves to be loyal members of the Church of England. Nonseparatists of this type established the Massachusetts Bay colony in 1629.

James I, however, was not an effective persecutor, and his policy was moderated by the influence of Archbishop George Abbot, who was sympathetic to the Puritan cause. By virtue of various expedients, many of the clergy were able to retain a measure of freedom in their parishes, and a system of lectureships was developed to provide for those who could not. The lectureships were preaching stations set up voluntarily, and they permitted the occupants to escape from the necessity of reading the required service. Serious trouble developed only after the accession of Charles I in 1625. Under the aegis of William Laud (*q.v.*), archbishop of Canterbury, rigorous measures were adopted to enforce conformity, lectureships were suppressed and when parliament proved to be refractory Charles embarked upon a period of personal rule that lasted through the 1630s.

Puritan Revolution. — As the result of an attempt to impose "Laud's liturgy" on the Scottish Church, Scotland rose in revolt and in 1639 invaded England. Charles was without adequate financial resources to carry on a war and was forced to summon parliament in 1640. Parliament immediately took command of the situation, refusing to grant necessary subsidies until the abuses of Charles's personal rule had been remedied. There was general agreement that the evils of prelacy should be eliminated, but when parliament abolished episcopacy the king was able to rally support; civil war broke out in 1642 (*see* CIVIL WAR, ENGLISH). The Westminster assembly of divines was summoned in 1643 to draft a new religious settlement for the nation, but its essentially presbyterian proposals were unsatisfactory for a variety of reasons to a majority of the people. The more erastian members of parliament did not look with favour upon the establishment of an independent ecclesiastical system. Large segments of the population remained strongly episcopalian in their sympathies. There had also been a vast proliferation of smaller religious groups since the lifting of the restraints of the Laudien regime. Furthermore, the Puritan preachers, who for three generations had been insisting upon the necessity for the Word of God to be freely preached, had cultivated a climate of opinion among many of their followers that was hostile to the placing of new restrictions upon the freedom to preach. Most important of all, widespread sentiment for religious toleration had developed in the parliamentary army. This was "the good old cause" that held the army together in its struggle with the king, and to the army the proposals of the assembly represented the substitution of one repressive ecclesiastical system for another. John Milton spoke for the army when he said: "New presbyter is but old priest writ large."

With parliament becoming increasingly divided and impotent, effective rule shifted to the army under the leadership of Cromwell. The royalists were brought under control in a series of battles, the king was executed and the religious problem was resolved in terms of a voluntary national establishment. Cromwell was less successful in his efforts to shift authority from the army to a stable parliamentary regime. The nation was too divided for any of the expedients he devised to succeed. After his death and the removal of his strong hand, the political situation rapidly deteriorated, and in 1660 the Puritan attempt to fashion a holy commonwealth was brought to an end with the restoration of the monarchy. The religious issue remained troublesome, however, until the adoption of the Act of Toleration in 1689.

American Puritanism. — The term Puritan has been given a much narrower definition in the United States. There was a conspicuous Puritan influence in early Virginia, and the blue laws of that colony have been said to have been even more repressive than those of New England. Moreover a Puritan influence was represented to varying degrees in all the English colonies by Baptists, Quakers and English Presbyterians. Puritanism in America, however, is generally understood to mean the early Congregationalism of New England.

Massachusetts Bay, the strongest of the New England colonies, was founded by a group of nonseparatist Congregationalists who had become convinced — as a result of the dissolution of parliament in 1629 by Charles I and the adoption of the rigorous repressive measures of Laud — that it was no longer possible to reform the Anglican Churc'n in England. Through a defect in the charter they were able to transfer the government of the colony to the new world, and throughout the Laudian decade of the 1630s a large and well-organized migration into the new colony proceeded. No colony in the history of European colonization ranked above Massachusetts Bay in wealth, station, education or capacity. The colonists were a selected people ("sifted grain") with strong clerical leadership, and their purpose was to accomplish in the new world that which they had been prevented from accomplishing at home. Their intention was to create in the American wilderness a new Zion that would become "a city set on a hill" and force by the power of its example the desired reformation in England.

The Massachusetts Bay Puritans established what they believed to be a biblical church order and with it a community that was regulated throughout by divine and natural law. The whole program was outlined in the *Cambridge Platform* of 1648. Church membership was restricted to the regenerate and their children who should "own the covenant," and only church members enjoyed political rights. Religious uniformity was enforced, and dissenters were informed that they had the right to stay away or to cross the river and take up land of their own beyond the boundary of Massachusetts. The restrictions were difficult to maintain; there were demands that the franchise be broadened and religious dissent kept appearing. When Roger Williams was banished, the settlement he established at Providence became a new source of dissidence. The second generation saw a diminution of zeal. The clergy interpreted recurrent misfortunes as signs of God's wrath with the growing laxity, but the adoption of the "halfway covenant" was evidence of clerical inability to halt the trend. The replacement of the charter in 1691 put an end to any real hope they still entertained of maintaining their holy commonwealth in its purity. The story was much the same in the other Puritan colonies of New England. Edwards briefly rallied the waning forces of Puritan zeal, and attenuated Congregational establishments lingered on in Massachusetts, Connecticut and New Hampshire until the 19th century. The Puritan heritage, however, was stamped deep in the character of the New Englanders, and with the great migration westward it became a major factor in the shaping of the American spirit.

Puritan Contributions. — One of the most conspicuous contributions of Puritanism was the sturdiness of character it produced. "The Puritan mind was one of the toughest the world has ever had to deal with. It is inconceivable to conceive of a disillusioned Puritan; no matter what misfortune befell him, no matter how often or how tragically his fellowmen failed him, he would have been prepared for the worst, and would have expected no better" (Perry Miller and T. H. Johnson, *The Puritans*, pp. 59–60, New York, 1938). The Puritan knew that the life of faith is an arduous struggle, that sin is a stubborn fact of human existence and that affliction is frequently the lot of the saints; but he was nerved and strengthened by a great devotion to God and by a great confidence in God's overruling Providence. Later generations were fed again and again from the devotional works the Puritans produced.

Curiously, the Puritans, who began as firm believers in the necessity for religious uniformity, became the architects who fashioned the principles of religious freedom. This was partly the result of the fact that the religious diversity they generated bred of necessity a spirit of toleration, but the necessity was supported by theological convictions whose implications only gradually became fully apparent. They had emphasized the necessity for the Word of God to be freely preached, and they recognized that even the best of men and churches were fallible. Who was to decide who might preach, when God might speak through the humblest of the brethern? Thus the New England Puritans could pursue measures of repression only with a lurking sense of guilt, elaborate apologetics and a tendency to make increasing concessions to dissent. More typical of the logic of Puritanism was Williams' *Bloudy Tenent of Persecution*, which became one of the great Puritan manifestoes in the English civil wars.

Many scholars have noted the contribution of Puritanism to the development of democracy. The army debates, the gathered churches, the demand for liberty and the denunciations of arbitrary power all helped create a climate of opinion favourable to the development of self-government. Even more important was the insistence upon the necessity for checks and balances if the abuse of power was to be prevented. Said John Cotton: "Let all the world learn to give mortal man no greater power than they are content they shall use, for use it they will . . . . It is necessary that all power that is on earth be limited, church power or other. . . . It is counted a matter of danger to the state to limit prerogatives, but it is a further danger not to have them limited" *(An Exposition of the Thirteenth Chapter of Revelation,* p. 72). The relationship that has been suggested between Puritanism and the rise of modern capitalism is more debatable. *See* also Index references under "Puritanism" in the Index volume.

PURITY, BRETHREN OF, the usual English designation of the IKHWAN AS-SAFA' (*i.e.,* "Sincere Brethren"), an Arabic secret confraternity who produced, probably in the second half of the 10th century A.D., a philosophical and religious encyclopaedia consisting of 52 "writings" (Arabic *rasa'il;* sing. *risala)* by different authors. The contents of this encyclopaedia appealed to the Ismailian movement, but its authors were not Ismaili themselves. As all other Islamic philosophers, they attempted to naturalize Greek philosophy in a way of their own, but they differ from other Islamic philosophers in following a more orthodox Neoplatonic line and in admitting Hermetic, Gnostic, astrological and occult sciences on a large scale. According to them, the individual human souls emanate from the universal soul and rejoin it after death; and the universal soul in its turn will be united with God on the day of the Last Judgment.

Rasa'il 1–14 deal with the preparatory sciences such as mathematics, astronomy and astrology, music, geography and the different parts of Aristotelian logic *(risala* 13 was translated into Latin in the middle ages); *rasa'il* 15–31 with the natural sciences in the order established by the later Greek commentators of Aristotle and also with man as a microcosm, with the human soul, with the influence of the stars and with the difference of languages *(see* below for *risala* 22); *rasa'il* 32–41 with the spiritual world on Neoplatonic lines, with the final destruction of the world, with the longing of the soul for God and its spiritual resurrection, etc.; and *rasa'il* 42–52 with various aspects of the revealed divine law, with the mutual duties of the brethren, with prophetic revelation and with miracles, magic, etc. There is also an important summary of the whole encyclopaedia, *Ar-Risala al-Jami'a. Risala* 22 tells the story of a dispute between animals and men before the king of the genii (in which the animals eventually lose). This story was translated into Catalan by a Franciscan friar, Anselmo de Turmeda, in 1417 (he represented it as his own original work) and into English by way of a Hindustani version, by J. Wall (1863).

Apart from Arabic editions of the whole encyclopaedia, 4 vol. (1888–89), and of the summary, critical ed., 2 vol. (1949–51), there are German translations of several of the *rasa'il* by F. Dieterici *(Die Naturanschauung und Naturphilosophie der Araber . . . ,* 2 parts, 1876–79; and *Die Abhandlungen der Ichwan es-Safa im Auswahl,* 3 parts, 1883–86). Dieterici, however, was unaware of certain Islamic aspects of the work and overrated its philosophical importance.

PURKINJE, JOHANNES EVANGELISTA (JAN EVANGELISTA PUPKYNE) (1787–1869), Czech physiologist, a pioneer in experimental physiology, histology and embryology, was born in Libochovice, near Prague, Dec. 17, 1787. In 1823 he became professor of physiology and pathology at Breslau university, where he began a course of experimental physiology, established a small laboratory and created an independent department of physiology (1839), the first of its kind. He established another after becoming professor at Prague university (1850). He died in Prague, July 28, 1869.

Purkinje's scientific work was extremely varied, the most important concerning vision and microscopy. He noticed similar granular formations in different animal tissues and drew attention to the analogy of these animal granules (Ger. *Kornchen)* with the vegetal cells (1837), and introduced the term protoplasm. Some of his discoveries bear his name: Purkinje's cells in the cerebellar cortex; Purkinje's fibres; the large heart muscle cells beneath the endocardium, forming Purkinje's network; Purkinje's germinal vesicle, the nucleus of the ovum; Purkinje's figure, the shadows of the retinal vessels; Purkinje's images, the reflections on the surfaces of cornea and lens of the eye; Purkinje's phenomenon, the change in the brightness of blue and red in the dark.

Publication of Purkinje's *Omnia Opera* began in 1918, and by 1960 eight volumes had appeared.

PURNEA, a town and district in the Bhagalpur division of Bihar state, India. The town, with a railway station, is on the little Saura river. Pop. (1951) 25,060.

PURNEA DISTRICT has an area of 4,299 sq.mi. and a population (1951) of 2,252,159. It extends from the Ganges northward to the frontier of Nepal. It is a level tract of country, traversed by several rivers flowing from the Himalayas, the greatest of which is the Kosi, which has been known to move 20 mi. in 25 years, leaving behind it a trail of sterile sand. A scheme to control its water was planned in the late 1950s. The principal crops are rice, pulses and oilseeds. Although the cultivation of indigo has declined. that of jute has greatly increased.

The district is served by the North-Eastern railway. Kishanganj (pop. [1951] 15,903) is a centre of the jute trade and a branch terminus on that railway.

PURNELL, THOMAS (1834–1889), English author, was born in Tenby, Pembrokeshire, in 1834. He studied at Trinity college, Dublin, and was assistant secretary and librarian of the Archaeological Institute of Great Britain and Ireland, 1862–66. In 1871 he published *Dramatists of the Present Day,* a reprint of his series of articles which first appeared in 1870–71 in the *Athenaeum* under the pseudonym "Q." He also edited Charles Lamb's *Correspondence and Works* (1871).

PURPLE, a shade varying between crimson and violet. Formerly it was the deep crimson colour called in Latin *purpura,* from the name of the shellfish *(Purpura)* which yielded the famous Tyrian dye. Tyrian purple during many ages was the most celebrated of all dyed colours, and possibly the first to be permanently fixed on wool or linen. Being extremely costly, robes of this colour were worn as a mark of imperial or royal rank, whence the phrase "born in the purple." In the Roman Catholic church "promotion to the purple" is promotion to the rank of cardinal.

The ancients derived their purple from the molluscs, *Purpura haemastoma,* and *Murex brandaris,* the shells of which have been found adjacent to ancient dyeworks at Athens and Pompeii. The colour-producing secretion is contained in a small cyst adjacent to the head of the animal, and this pus-like matter when spread on textile material in presence of sunlight develops a purple-red colour. P. Friedlander has shown that the dye developed from the molluscs is 6:6'-dibromoindigotin. (A. G. P.; X.)

PURPURA is the presence of large (ecchyrnoses) and small (petechiae) hemorrhages in the skin, often associated with bleeding from natural cavities and in tissues. It occurs as a result of failure of hemostasis which, in turn, has five major causes:

1. Damage to the wall of small arterial vessels (vascular purpura), due to vitamin deficiency (scurvy), bacteria, viruses, allergic reactions, etc. A hereditary disease in which the vessels appear normal but cannot contract after injury is known as pseudohemophilia.

2. Deficiency of platelets, small bodies that not only plug leakages in the vessel wall mechanically but also contain many chemicals active in the coagulation of blood. Bleeding occurs when platelets are insufficient in number (thrombocytopenia) either because they are not produced (as a result of destruction of

the precursor megakaryocytes in the bone marrow, due to invasion by leukemia or to aplasia induced by drugs or by radiation injury) or because they are too quickly destroyed by an overactive spleen or by antibodies (immunothrombocytopenia). Platelet antibodies develop in the course of other diseases (such as lupus erythematosus; *see* Lupus) or may be evoked by allergy to viruses, bacteria or certain drugs. Spleen and antibodies are usually associated in destroying platelets. In one variety of the disease (thrombocytoasthenia) the platelets are normal in number but abnormal in function.

3. Deficiency of clotting factors, either congenital as in hemophilia, Christmas disease, hypoprothrombinemia. afibrinogenemia, etc.) or acquired in the course of disease (especially of liver), administration of drugs (anticoagulants, etc.).

4. Development of circulating anticoagulants of various types (abnormal proteins, antibodies, etc.) that prevent normal interaction of the various clotting factors and are found in some blood disorders (multiple myeloma, leukemias, etc.), following reactions to drugs, in diseases of the connective tissue and in radiation injury.

5. Fibrinolysis. due to the activation of a usually dormant system that is able to destroy the blood fibrin clot; this may occur during accidents of pregnancy, delivery and surgery. A paradoxical type of bleeding is found when tissue materials (as in shock, trauma, burns, etc.) enter the blood stream and cause clotting within the vessels. As the patient is depleted of clotting factors, he becomes a bleeder. This mechanism is often found behind severe hemorrhage at delivery.

Treatment of purpura depends on the causative mechanism. ACTH and steroid hormones are effective in controlling vascular purpura and the bleeding of thrombocytopenia. Transfusion of platelets may be a useful technique for bleeding emergency, and surgical removal of the spleen is resorted to in thrombocytopenic purpura when other therapy has failed. The administration of either blood or plasma or of the fractions specifically absent (fibrinogen, antihemophilic globulin, etc.) is the basis of the treatment of acute bleeding in disorders of blood coagulation. *See* also Blood; Haemorrhage.

See M. Stefanini and W. Dameshek, *Henzorrhagic Disorders* (1955). (M. St.)

PURRAH, Purroh or Poro, a secret society of Sierra Leone, Africa. Only males are admitted to its ranks while the Bundu is strictly reserved to women.

The Purrah had its special ritual and language, markings and symbols and exercised authority by the imposition of tabus which mere enforced by various methods. In 1897 the British local government was compelled to pass a special ordinance absolutely forbidding the imposition of the tabu on all indigenous products.

See T. J. Alldridge, *The Sherbro and its Hinterland* (1901); *N.* W. Thomas, *Anthropological Report on Sierra Leone,* Part *I. (Law and Custom of the Timne and other bribes).*

PURSH, FREDERICK (1774–1820), American botanist, was born at Tobolsk, Siberia, in 1774. He received his education in Dresden. Germany. In 1799 he went to the United States where he devoted 12 years to botanical exploration and the scientific study of North American plants. In 1811 he visited England and in 1814 he brought out in London his important *Flora Americae Septentrionalis.* He then returned to the U.S. and resumed his botanical investigations. On one of his solitary tours afoot he discovered the hart's-tongue (*q.v.*), one of the rarest of the ferns in North America.

Pursh died at Montreal, Que., June 11, 1820.

PURSLANE, the common name for a small fleshy annual with prostrate stems, entire leaves and small yellow flowers, known botanically as *Portulaca oleracea,* family Portulacaceae (*q.v.*). It is a native of India, which was introduced into Europe as a salad plant, and in some countries has spread so as to become a noxious weed. Besides the common purslane, about ten other species occur in North America, chiefly in the southern United States. Some of the species of the same genus, such as P. *grandiflora* and its varieties, are grown in gardens on rockwork. The purslane is found in England but is rare.

The persistence of purslane plants is due to their ability to retain moisture and thus blossom and ripen seeds long after they have been removed from the soil. The capsules opening by a lid produce many small seeds of great longevity.

PURSUIVANT, a member of the third and lowest rank of heraldic officers, formerly an attendant on the heralds.

PURVA MIMAMSA, one of the six schools of thought to which Indian philosophers adhered in the centuries following the Epic period. *See* Indian Philosophy: *Six Systems.*

PURVEYANCE was a prerogative of purchasing goods for the royal household enjoyed by all English kings up to Charles II. Certain officers attached to the king's court were charged with the duties of buying and arranging for the cartage of goods where necessary, the ancient prerogative of the king entitling him to demand carriage services from his subjects. The possibilities of abuse were obvious. Magna Carta (*q.v.*) ordered that goods should be paid for at once and that horses and carts should not be taken for carriage duty nor timber taken for castles without the consent of the oaner. These stringent regulations were considerably modified to the king's advantage in later issues of the charter.

Many early statutes were passed against purveyance. People particularly resented the exercise of this right by royal officials and ministers for their own benefit. Statutes therefore limited its use to the immediate households of the king and queen. The name purveyor was so much hated that it was provided by statute that it should be changed to *achatour* (buyer). But statutes had little effect. In Elizabeth's reign complaints against purveyance were particularly bitter. In her early years the queen seems to have made use of her rights of purveyance to victual her navy. Later an arrangement was made by which some, if not all, counties agreed to furnish definite provisions at a fixed rate in order to get rid of the uncertainty which made the burden so much heavier. These compositions were arranged between the officers of the Board of Green Cloth and the Justices of Peace for each county at fixed prices. These fixed prices were very much lower than the market value of the goods and the difference was met by an assessment on the county. Cattle supplied in this way were kept in certain royal pastures. The parliaments of James I determined to get rid of the abuses of purveyance, and Sir Francis Bacon made a famous speech against the purveyors in the first parliament of the reign. It was held that only the abolition of the right would put an end to its abuse. The purveyors made a practice of demanding far more goods than were necessary and sold the surplus for their own advantage. They ordered goods to be taken to remote places that people might buy from them exemption from coming with their portions. There were innumerable ways in which purveyors could make dishonest profit. Despite complaints, the right of purveyance went on until it fell into disuse during the Commonwealth. Its abolition was part of the Restoration settlement, though until the end of the century it was sometimes partially revived during royal progresses. (D. M. S.)

PURVITS, VILHELMS KARLIS (1872–1945), Latvian landscape painter who introduced Impressionism into northeastern Europe, was born in Zaube rural district on March 3, 1872, and attended a secondary school in Latgale province. He later abandoned his father's milling business for painting, graduating from St. Petersburg academy in 1897; awarded a Rome prize, he traveled widely in western Europe. After teaching at Tallinn cathedral school (1906–09) he directed the Riga state art school until it was closed in 1916; from 1913, when he was elected academician of St. Petersburg academy, he was also director of the state museum and professor at Riga university.

Purvits organized the independent Latvian Academy of Arts in 1919 and was its rector and professor until 1934. In 1934–36 he edited a history of art. From Impressionism he developed the Baltic landscape style; later, his methodical compositions became more colourful and expressionistic.

Many of his pictures were destroyed by military action at Jelgava, Latvia, in July 1944; others, evacuated to Bavaria, disappeared. A refugee, Purvits died at Nauheim, Hesse, Ger., on Jan. 18, 1945.

PUSA, a village in Bihar, India, about 40 mi. N.E. of Patna. The government acquired an estate there in 1796 which was long used as a stud depot and afterward as a tobacco farm. The estate, which covered 1,280 ac., was made over in 1904 to the imperial agricultural department of the government of India, of which department it was the headquarters. In 1905 a research institute was founded with an experimental farm and an agricultural college at which officers were trained for higher posts in the agricultural departments.

The institute owed its inception to Lord Curzon, then viceroy; it rendered very useful service to Indian agriculture. A. and G. L. C. Howard produced strains of wheat which gave high yield and were of good milling quality; they had power of resistance to rust and gave good results under diverse conditions of soil and climate.

The Pusa varieties were in their day grown over large tracts of the United Provinces, the Punjab and the North-West Frontier province. E. J. Butler carried out masterly researches there on fungus pests, as did H. M. Lefroy on insect pests troublesome in India. B. P. Pal and other Indian agricultural scientists also did good work. The advantages of selective breeding of cattle were demonstrated; the milk yield of a pure herd was by this method doubled in ten years.

The institute always suffered from its isolated position, and when in 1934 an earthquake destroyed the main block of laboratories it was decided to transfer the work to New Delhi and to found a great central research institute there. This plan was duly executed, and the new Indian Agricultural Research institute was opened on Nov. 7, 1936, by the viceroy, Lord Linlithgow. The associated Central College of Agriculture is connected with Delhi university.

The road on which the institute buildings stand is called Pusa road. (E. J. R.)

PUSAN (Japanese FUSAN), a city located along a deep, well-sheltered bay at the southeast tip of Korea, facing the Korean strait. During Japanese control (1910–1945) Pusan became the major Korean port. Ferry services connected it to Shimonoseki, Japan. Rail lines through Korea to Manchuria and China terminated in Pusan. Industries, including shipbuilding, iron and steel, railroad shops and textile manufacturing were developed. Rice milling and salt refining were also carried on.

The beachhead area around Pusan was held by the United Nation forces in 1950 and the city became the temporary capital of the Republic of Korea and a port of supply and disembarkation during the first years of the Korean war. The city was swollen by refugees, whose many temporary shacks covered the hills. Disastrous fires occurred in these areas but the city was rebuilt and more permanent structures established. Industries were redeveloped and the population grew to 1,049,363 (1955 census.) (S. McC.)

PUSEY, EDWARD BOUVERIE (1800–1882), English leader of the Oxford movement, who, though remaining firm in his Anglican beliefs, headed the Catholic revival in the Church of England. mas born at Pusey on Aug. 22, 1800. His father was Philip Bouverie, whose ancestor was a Protestant refugee from the Low Countries who reached England in the 16th century. Philip Bouverie took the name of Pusey upon succeeding to the estate of that name in Berkshire. Edward was educated at Eton and Christ Church, Oxford. In 1823 he stood for a fellowship by examination at Oriel college and was elected, thus entering the brilliant common room of which John Keble and J. H. Newman (*qq.v.*) were already members.

From 1825 to 1827 he studied oriental languages and theology in Germany, where the state of German Protestantism, driven to skepticism by the rationalism of the Enlightenment, made a permanent impression upon him by way of reaction.

In 1828 Pusey's reputation as an orientalist caused the duke of Wellington to nominate him to the regius chair of Hebrew in Oxford, which carried with it a canonry of Christ Church. From the year 1833 began his association with the Oxford movement, to which he brought a decisive reinforcement. "He," wrote Newman, "at once gave us a position and a name." He contributed a tract on fasting to the Tracts for the Times in 1834 and his most noteworthy work in that series was the extensive tract upon baptism of 1835.

In 1843 Pusey preached his university sermon on "The Holy Eucharist, a Comfort to the Penitent," which asserted the doctrine of the Real Presence. For this he was suspended by the vice-chancellor (without being allowed to speak publicly in his own defense) from preaching before the university for t o years, an arbitrary act which, in H. P. Liddon's words, "sealed the doom of the old *régime*—the authority of the Heads and the old ecclesiastical polity of Oxford" and was a factor leading to university reform. Yet, after the ending of the sentence, Pusey preached in 1846 another sermon asserting another principle of the Oxford movement, the right of private confession and the existence of priestly absolution in the Church of England. Newman's secession to the Roman Catholic Church in 1845 was a crushing blow to Pusey.

Pusey's intense industry was devoted to the work of his professorial chair, to learned theological writing, to preaching and to individual spiritual direction. Nor were his activities confined to Oxford. In the cholera epidemic of 1866 he tended the sick in Bethnal Green; he preached in many parts of the country and contributed generously to church purposes, such as building St. Saviour's church, Leeds, at his own expense in 1842–45; and in addition, he was responsible for the revival of the monastic life in the Church of England, encouraging Marian Hughes to take religious vows (the first Anglican to do so since the Reformation) in 1841 and helping, in 1845, to found in London the first Anglican sisterhood,

In matters of biblical criticism Pusey was strictly conservative and to the end of his life combated the newer ideas which were becoming fashionable; his works on The Minor Prophets, with Commentary (1860) and Daniel the Prophet (1864) show a deep but old-fashioned Hebrew scholarship. Averse to the use of philosophy in theological construction, his doctrinal outlook was marked by a strong attachment to the principle of revelation interpreted by the historic authority of the church. He lacked Newman's speculative brilliance but had the intellectual strength of a well-stored and balanced mind and of a deep reverence for historic truth; he tested all current teaching by its consonance with the Bible and the mind of the early church.

Pusey's private life was marked by severe asceticism, intense personal religion, a capacity for lasting friendship and deep family affection. The death of his wife in 1839, of a daughter in 1844 and of his only son in 1880 were irreparable blows. He died on Sept. 16, 1882, at Ascot priory, the home of a sisterhood with which he was associated; he was buried in Christ Church cathedral.

Two years later his friends founded Pusey house, Oxford, as an institution for theological study and pastoral care in the university. There his library and many personal letters, papers and relics are preserved.

See H. P. Liddon, *Life of Edward* Bouverie *Pusey,* 4 vol. (1893–94), with a list of Pusey's works; and shorter biographies by G. W. E. Russell (1907) and G. L. Prestige (1933). (T. M. P.)

PUSHBALL, a game invented by M. G. Crane of Newton, Mass., in 1894. It was taken up by Harvard the next year, but never attained any considerable vogue in the U.S. In Great Britain the first regular game was played at the Crystal palace in 1902 by teams of eight. The game still is played in English preparatory and public schools, but the rules are somewhat different from those originally devised.

Pushball is played by two sides on a field usually 140 yd. long and 50 yd. wide. with a heavy, 50-lb. ball, 6 ft. in diameter. The goal consists of two uprights 18 ft. high and 20 ft. apart, separated by a crossbar 7 ft. from the ground. Scoring occurs when the ball passes the goal: 5 points for a push below the bar, 8 for heaving the ball over it. A touchdown behind the goal counts 2 for the attacking side. The sides usually number 11 each: five forwards, two goalkeepers, two right and two left wings. There are two periods of play with an intermission.

Often pushball is one of the events featured in circus performances, especially when played by teams of Indians and cowboys on horseback, perhaps representing the traditional play rivalry between these two groups. Mounted organizations seem to play the game more often than do small boys, and it seems likely to survive in countries where there are considerable numbers of horseback riders. (N. F. J.)

PUSHKIN, ALEXANDER (1799–1837), Russian poet, was born at Moscow on June 6, 1799. He belonged to an ancient family of boyars; his maternal great-grandfather was an Abyssinian general in the Russian service, ennobled by Peter the Great. In 1811 the future poet entered the newly founded lyceum of Tsarkoe Selo, situated near St. Petersburg. On quitting the lyceum in 1817 he was attached to the ministry of foreign affairs. and in this year he began to write his *Ruslan and Ly'udmila,* a romantic epic in six cantos, ahich was completed in 1820.

Meanwhile Pushkin mixed in all the gayest society of the capital, and it seemed as if he would turn out a mere man of fashion instead of a poet. But a very daring *Ode to Liberty* written by him and circulated in manuscript in St. Petersburg came to the notice of the governor, and the young author was exiled to the south of Russia where he held official positions at Ekaterinoslav and at Kishinev.

In company with General Rayevsky he visited the baths of the Caucasus for the re-establishment of his health in 1820. The Rayevskys introduced him to the poetry of Lord Byron. and the magnificent scenery of the Caucasus kindled his own poetic genius. The first fruit of the Caucasian visit was *The Captive of the Caucasus* (1822), narrating the story of the love of a Circassian girl for a Russian officer. This was followed by the *Fountain of Baklzchisarai* (1827) which tells of the detention of a young Polish captive in the palace of the khans of the Crimea. About the same time he composed the lines on Ovid, whose place of banishment. Tomi. was not far distant, and the *Ode to Napoleon.* The next long poem was the *Gipsies* (Tsygany) (1827). During his stay in southern Russia he mixed with the secret societies then rife throughout the country. In 1823 he was allowed to leave Kishinev, where the life was hateful to him, and was transferred to Odessa where he was once more on real Russian soil, and on the coast of the sea which delighted him. But he came into conflict with his official superior, and was dismissed from the service, because of an intercepted letter in which he spoke favourably of atheism. He was ordered to reside at Mikhailovskoe, near Pskov, where he soon involved himself in trouble on all sides.

In his retirement he studied old Russian popular poetry. Recollections of Byron and André Chenier gave the inspiration to some fine lines consecrated to the latter, in which Pushkin appeared more conservative than was his wont. In 1825 he wrote his tragedy *Boris Godunov,* not published till 1831, a bold effort to imitate the style of Shakespeare, thus breaking with the French traditions.

In 1825 the conspiracy of the Dekabrists broke out. Many of the conspirators were personal friends of Pushkin, especially Kuchelbecker and Pustchin. The poet himself was to a certain extent compromised, but he succeeded in getting to his house at Mikhailovskoe and burning all the papers which might have been prejudicial to him. The emperor, to whom he was presented at Moscow soon after his coronation, summoned him to Moscow and assured him of pardon and "protection." The story goes that Nicholas said to Count Bludov on the same evening. "I have just been conversing with the most intelligent man in Russia." In 1829 appeared *Poltava,* a spirited narrative poem, in which the expedition of Charles XII against Peter and the treachery of the hetman Mazeppa were described. In 1829 Pushkin again visited the Caucasus on this occasion accompanying the expedition of General Paskevich, ahich is described in *A Voyage to Arzrum* (pr. 1836). The lyrics are delightful.

In 1831 Pushkin married Natalia Goncharov, and in the following year was again attached to the ministry of foreign affairs, with a salary of 5,000 roubles. He now began his *History of the Revolt of Pugachev of 1773* (pr. 1834), an admirable piece of historical writing. While engaged upon this he wrote *The Captain's Daughter* (1836), one of the best of his prose works. In 1832 was completed the poem *Evgeni Onegin* (1825–33), again influenced by Byron.

In 1837 the poet, who had been long growing in literary reputation, fell mortally wounded in a duel (Feb. 8) with Baron George Heckeren d'Anthès, the adopted son of the Dutch minister who had married a sister of the poet's wife. Pushkin died on Feb. 10. D'Anthès was tried by court-martial and expelled from the country. In 1880 a statue of the poet was erected at the Tver Barrier at Moscow. He left four children; his widow married an officer named Lanskoi: she died in 1863.

Pushkin's poetical tales are full of drama. *Boris Godunov* and *Evgeni Onegin* are the basis of operas by Mussorgsky and Tschaikowsky respectively. Pushkin's lyrical pieces are the finest in the language Interspersed among his minor works will be found many epigrams. He was one of the earliest Russian novelists. Indeed most of his work after 1831 was done in prose. In 1831 he published a small volume of tales under the pen name of Ivan Belkin. These all show great narrative powers. The one long novel finished is *The Captain's Daughter,* a tale of the times of Catherine II, which exercised a great influence on later Russian novelists. The most famous of all his short stories is *The Queen of Spades* (1834). In the posthumous *History of the Manor of Goryukhino* Pushkin parodied Polevoy's *History of the Russian People,* and presented an amusing picture of the fictitious author of his own Tales. Ivan Petrovich Belkin.

See Prince D. S Mirsky, *Pushkin* (1926), which contains a bibliography; and the bibliography in the editions of Gennadi (7 vols, 1861), and Annenkov (6 vols. 1855).

PUSHTU, PAKHSTO, PAKKHTO (PASHTO), the language of the Afghans, belongs to the Eastern Iranian group, the oldest form of which is probably found in the Zend. Numerous terms are traceable to the Avesta. *(See* Paul Horn's *Grundriss der Neupersischen Etymologie*). The remainder of its vocabulary comes from Arabic. Persian and from the Indian Prakrits. Among the last, Sindhi takes first place. It has thus considerable claims to antiquity.

About 10% of the Afghans are able to read and write, and education is making rapid progress.

Structure. — There are nine declensions. The accusative is the same as the nominative. The agent and oblique forms are identical. The genitive, dative and locative are formed by adding suffixes to the oblique form. Most adjectives form the feminine by adding *a.* Pronominal suffixes are used as well as definite, personal, demonstrative and reflexive pronouns. The regular verb has two main tenses, the imperfect and the present. There are 37 classes of verbs, 13 intransitive and 24 transitive.

PUT AND CALL: *see* OPTIONS.

PUTEOLI, an ancient tonn of Campania (mod. *Pozzuoli, q v.).* Italy, on the northern shore of the Bay of Puteoli, a portion of the Bay of Naples. from nhich it is 6 m. W. The city was probably founded under the name of Dicaearchia by a colony of Samians from Cumae about 520 B.C., before which Misenum was the original port. In 215 the Romans introduced a garrison of 6.000 men and Hannibal besieged it in vain in 214. In 194 a Roman colony of 300 men was established. Puteoli belonged to the tribus Palatina, thus breaking the rule (the only other exception is Turris Libisonis nhich belonged to the Colluia) that *municipia* and *coloniae* were not enrolled in the four urban tribes.

The *lex parieti faciundo,* 105 B.C., relating to building works in front of the temple of Serapis, shows that Puteoli had considerable administrative independence. Sulla retired to Puteoli after his resignation of the dictatorship in 79. Cicero had a house in Puteoli itself, and a villa on the edge of the Lucrine lake (*q.v.*), and many other prominent men of the republic possessed country houses near by. *(See* AVERNO; BAIAE; LUCRINUS LACUS; and MISENUM.) In AD. 61 St. Paul landed here, and spent seven days before leaving for Rome (Acts xxviii. 13). Vespasian gave the town part of the territory of Capua, and installed more colonists

—whence it took the title Colonia Flavia.

The remains of Hadrian, who died at the neighbouring town of Baiae, were at first deposited at Puteoli, and Antoninus Pius erected a temple to his memory on the site of Cicero's villa. It was mainly, however, as a great commercial port that Puteoli was famous in ancient times. It exported iron from Elba, mosaics, pottery, perfumes, pozzolana earth (taking its name from the place), glass cups engraved with views of Puteoli, mineral dyes, etc , but its imports were considerably greater, During the Punic Wars it was a naval port, bur, in the latter part of the 2nd century B.C. it became the greatest commercial harbour of Italy and we find Lucilius about *12j* B.C. placing it next in importance to Delos, then the greatest harbour of the ancient world.

The corn supply of Rome came partly through Puteoli, partly through Ostia. Seneca (*Epist. 77*) describes the joy of the inhabitants in the spring when the fleet of corn vessels from Alexandria was seen approaching, and Statius tells us that the crew of the ship which arrived first made libations to Minerva when passing the promontory which bore her name (the Punta Campanella at Sorrento). ,

Claudius established here, as at Ostia, a cohort of *vigiles* as a fire-brigade. Brundisium was similarly protected. There was also a station of the imperial post, sailors of the imperial fleet at Misenum being apparently employed as couriers. The artificial mole was probably of earlier date than the reign of Augustus; and by that time at any rate there were docks large enough to contain the vessels employed in bringing the obelisks from Egypt. Alaric (410), Genseric *(455)* and Totila *(545)* devastated Puteoli.

The original town of Puteoli stood on the narrow hill of the Castello. The streets of the old town preserve the ancient alinement. There are also traces of the division of lands near the town into squares by parallel paths (*decumani* and *cardines*) at regular intervals of $1{,}111\frac{1}{9}$ Roman feet, postulating as the basis of the division a square with a side of 10,000 Roman feet, divided into *81* smaller squares. The market hall (*macellum*), generally known as the temple of Serapis, from a statue of that deity found there, was excavated in 1750. In the centre of the ancient city was a round colonnade with sixteen columns of Numidian marble (*giallo antico)* now in the theatre of the palace at Caserta. In the amphitheatre there were exceedingly interesting arrangements for flooding the arena, but these can only have been in use before the construction of the greater part of the subterranean portion with its cages, etc. The whole amphitheatre is 489×381 ft.; the arena 245×138 ft. Inscriptions record that it was built by the *Colonia Flavia,* i *e.,* not before Vespasian. In the older amphitheatre (426×312 feet), which was found in excavations for the new railway to Naples, Nero fought in games given in honour of Tiridates, king of Armenia. Remains of thermae also exist in various places. The cathedral of S. Proculus (containing the tomb of the musician Pergolesi, d. 1736) is built into a temple of Augustus, 6 columns of which, with their Corinthian capitals, still exist. Other ruins—of a circus, of tombs, villas. etc., exist.

Puteoli was supplied with water by two aqueducts, both subterranean, one of which, bringing water from springs in the immediate neighbourhood, is still in constant use. Puteoli was reached direct by a road from Capua traversing the hills to the north by a cutting (the Montagna Spaccata), which went on to Neapolis, and by the Via Domitiana from Rome and Cumae. There was also a short cut from Puteoli to Neapolis by the tunnel of Pausilipon, made under Augustus. In *305,* S Januaris (S. Gennaro, the patron saint of Naples). bishop of Beneventum, S Proculus, patron of Puteoli. and others, were martyrs at Puteoli,

See the study of C. Dubois, *Pouzzoles antique* (Paris, 1907) (Bibliothèque des écoles françaises d'Athènes et de Rome, fasc. 98). (T. A)

PUTNAM, FREDERIC WARD (1839–1915), U.S. anthropologist, educator and museum administrator, was born in Salem, Mass.. on April *16, 1839,* the son of a horticulturist. After studying at Harvard college under Louis Agassiz, Putnam held various museum posts in Salem and Boston; from *1869* to *1873* he was director of the Peabody Academy of Science in Salem

Putnam was curator of the Peabody Museum of American Archaeology and Ethnology at Harvard from *1874* to 1909, and he also served as curator of anthropology at the American Museum of Natural History. New York city. 1894–1903. Putnam was Peabody professor of American archaeology and ethnology at Harvard. and played an important part in establishing a department of anthropology at the University of California in the early 1900s.

Head of the department of ethnology at the World's Columbian exposition in Chicago, Ill., 1891–94, he organized various expeditions and prepared collections and exhibits that later were preserved in the Chicago Natural History museum. Putnam has been credited with increasing popular interest in anthropology and with making important contributions to museum administration. He was secretary of the American Association for the Advancement of Science for 25 years and a founder and editor of the *American Naturalist.* He died in Cambridge, Mass.. Aug 14, 191*j*.

PUTNAM, GEORGE HAVEN (1844–1930), U.S. publisher, whose chief contribution was his championship of international copyright, was born in London, Eng , on April 2, 1844, the son of the U S. publisher George Palmer Putnam (1814–1872). He attended grammar school in New York city and later studied at the Sorbonne and the University of Gottingen. Upon the outbreak of the Civil War. he returned to the United States from Germany and enlisted in the Union army. He was taken prisoner at Cedar Creek, and sent first to Libby prison and later to Danville. He later described his war experiences in several volumes. In 1872 he succeeded his father as head of one of the oldest publishing concerns in the country, the house that had introduced to American readers such authors as Washington Irving and James Fenimore Cooper.

Putnam was active throughout his long life in political organizations and civic groups, but his chief interest lay in the practical problems of authorship. He continued his father's efforts in behalf of an international copyright law and was in great measure responsible for the passage of the Copyright act of 1909, establishing more equitable copyright relations between the U.S. and Europe. He also vigorously opposed all attempts at literary censorship. His own writings deal mainly with copyright and publishing, and include *The Question of Copyright* (1891), *Authors and Their Public in Ancient Times* (1894), *A Memoir of George Palmer Putnam* (1903), *Memories of My Youth* (1914), and *Memories of a Publisher* (1915). He died in New York city, Feb. 27, 1930.

PUTNAM, GEORGE PALMER (1814–1872), U.S. publisher. was born at Brunswick, Me., on Feb. 7, 1814, and at an early age went to work in a New York city bookstore From 1841 to *1848* he sold American books in London. He also wrote articles for New York newspapers while he was in England and published a book entitled *American Facts* (1845). After his return to New York in 1848, Putnam became a book publisher and founded *Putnam's Monthly Magazine*. issued from *1853* to 1857, when he suffered financial difficulties, and again from 1868 to 1870.

After the American Civil War Putnam established the publishing house that bore his name thereafter. His son George H. Putnam (*q.v.*) succeeded him as head of the firm after his death on Dec. *20,* 1872, and continued the campaign for international copyright protection that his father had begun in the latter 1830s.

George Palmer Putnam's other children included Ruth Putnam (1856–1931), who wrote a number of books on the Netherlands, and the pioneer woman physician Mary Putnam Jacobi (*q.v.*).

PUTNAM, GEORGE PALMER (1887–1950), U.S. publisher, author and explorer, was born at Rye, N.Y., on Sept. *7, 1887,* the grandson of the publisher George Palmer Putnam (*q.v.*). He studied at Harvard university and the University of California, Berkeley, and entered newspaper work in Bend, Ore, in 1910. After serving as a lieutenant of field artillery during World War I, he became treasurer of his father's publishing firm of G. P. Putnam's Sons. Between 1930 and 1932 he was vice-president of the publishing house of Brewer, Warren and Putnam, and from 1932 to 1935 was chairman of the editorial board of Paramount Productions. During World War II he served as an officer with the U.S. army air forces in India and China. Putnam led expeditions to Greenland in *1926* and to Baflin Island the following year. In 1931 he was married to Amelia Earhart, who was the first woman to fly the Atlantic and who held women's speed and distance flight records. She was lost in the mid-Pacific during a flight around the world in 1937. He wrote her biography. *Soaring Wings* in 1939. Putnam's 12 books include his autobiography, *Wide Margins* (New York, 1941), and three volumes on Death valley. He died at Trona. Calif., Jan. 4, 1950.

PUTNAM, HERBERT (1861–1955), U.S. librarian. was born in New Tork city on Sept. 20, 1861. He graduated from Harvard college in 1883 and thereafter studied law at Columbia university, being admitted to the bar in 1886. His calling, however, proved to be that of librarian. He was librarian of the Minneapolis Athenaeum in 1884–87, of the Minneapolis Public library in 1887–91 and, after a fen years in the practice of law in Boston (1892–95), of the Boston Public library in 1895–99. He was librarian of the Library of Congress. Washington D.C.. 1899–1939, and president of the American Library association in 1898 and 1904. Putnam died Aug. 14.19jj, in Quissett. Mass.

PUTNAM, ISRAEL (1718–1790), American soldier, was born in Salem Village (now Danvers), Mass. on Jan. 7, 1718, and in 1740 removed to a farm in the vicinity of Pomfret, Conn. He was active in the French and Indian War, rising to the rank of major in 1758 News of the fighting at Lexington and Concord reached him while he was ploughing on his farm; he instantly left the plough in the furrow and hastened to Cambridge; and he was later made second brigadier of the Connecticut forces. He was with the force, commanded by Col. William Prescott, which on the night of June 16, 1775, fortified Breed's Hill, and on the next day he took a conspicuous part in resisting the British attack (*see* BUNKER HILL). After the evacuation of Boston he was in command of New York city till Washington's arrival (April 13, 1776), and then was put in general charge of the city's fortifications. Immediately before the battle of Long Island he succeeded Gen. John Sullivan in command of the troops on Brooklyn Heights, and in the battle of Long Island (of Aug. 27) he was in immediate command of the American side. In the retreat from New York city he took part in the battle of Harlem Heights (Sept. 16). In May, 1777, he took command of the Hudson highlands at Peekskill, which with Forts Montgomery and Clinton he abandoned in October, being out-manoeuvred by the British. After a few months' recruiting service in Connecticut he returned to the main army at White Plains. In the winter of 1778–79 he commanded the troops quartered near Redding, Conn. In May, 1779, he took command of the right wing on the west side of the Hudson. An attack of paralysis in Dec. 1779 terminated his active service in the war. He spent his last years on his farm in Brooklyn, Conn , where he died May 29. 1790. A bronze equestrian statue by Karl Gerhardt, over a sarcophagus, was erected at Brooklyn, Conn., by the State in 1888, and there is another statue (1874) in Bushnell park, Hartford, by J. Q. A. Ward.

Putnam was a brave, intrepid and very industrious soldier rather than a great general. His bluff heartiness has made him one of the popular heroes in American history.

See W. F. Livingston, *Israel Putnam, Pioneer, Ranger and Major-General* (1901) in the "American Men of Energy" series; I. N. Tarbox, *Life of Israel Putnam* (Boston, 1876); and *Essay on the Life of the Honorable Major-General Israel Putnam* (Hartford, 1788; enlarged ed., Boston, 1818), by David Humphreys, for a time Putnam's aide-de-camp.

PUTNAM, RUFUS (1738–1824), American soldier and pioneer, was born in Sutton, Mass., on April 9, 1738 (O.S.). He served in the French and Indian War in 1757–60; was a millwright in New Braintree in 1761–68, during which time he studied surveying; and from 1769 until the American Revolution was a farmer and surveyor. He became lieutenant colonel in one of the first regiments raised after the battle of Lexington, and served before Boston. In 1777 he served in the Northern army under Gen. Horatio Gates, commanding two regiments in the second battle of Saratoga. In 1778 he laid out fortifications, including Ft. Putnam, at West Point, and in 1779 he served under Gen. Anthony Wayne after the capture of Stony Point. After the war he returned to Rutland, Mass., where he had bought a confiscated farm in 1780. In March, 1786, he founded, with other officers of the American Revolution, the Ohio Company of Associates for the purchase and settlement of Western lands. In Nov. 1787, he was appointed by the company superintendent of its proposed settlement on the Ohio, and in 1788 he led the small party which founded Marietta, Ohio. He was a brigadier-general in the army and a commissioner to treat with the Indians in 1792–93; was surveyor general of the United States in 1796–1803; and in 1802 was a member of the Ohio State Constitutional convention. He died, in Marietta, May 4, 1824. He has been called "the father of Ohio," and greatly contributed to its development.

Campbell, *Biographical Sketches* (1838); Sidney Crawford, "Rufus Putnam, and his Pioneer Life in the North-West," vol. xii, new series, pp. 431–454, *Proceedings of the American Antiquarian Society* (1899), and Rowena Buell (ed), *The Memoirs of Rufus Putnam* (1903), in which his autobiography, journal and other papers, in the library of Marietta college, are reprinted. His *Journal, 1757–1760*, dealing with his experiences in the French and Indian War, was edited with notes by E. C. Dawes (1886).

PUTNIK, RADOMIR (1847–1917), Serbian general, was born on Jan. 25, 1847, at Kraguyevats. After serving against Turkey in 1876 and 1877, and against Bulgaria in 1889, he was made deputy-chief of the general staff, and professor at the military academy in Belgrade. The intrigues and favouritism introduced by the kings, Milan and Alexander, caused him to be placed on the retired list, but in the autumn following the military revolution of 1903 he was appointed general and chief of the general staff. In 1906 he succeeded General Gruič as minister of war, and again held that office in 1912, during the period when the military convention with Bulgaria was negotiated.

Op the outbreak of war with Turkey Putnik was made *voivode* or marshal (being the first holder of that title) and commander-in-chief, and was responsible for the rapid success of the Serbian arms at Kumanovo, Prilep and Monastir. It was largely owing to his vigilance and foresight that the treacherous night attack by which the Bulgarians opened the second Balkan War (June 29, 1913) failed as it did. When World War I broke out, he was undergoing a cure at an Austrian watering place, and was at first placed under arrest, being later released by special order of the emperor Francis Joseph and conveyed to the Rumanian frontier. Despite impaired health he resumed the position of Serbian generalissimo and inflicted upon the forces of General Potiorek three successive defeats — on the Yadar (Aug. 16-20), the Drina (Sept. 8–19) and at Rudnik, which ended on Dec. 14, 1914 with an Austrian rout and the complete evacuation of Serbia. Putnik retained the supreme command during the triple invasion of Serbia in Nov. 1915, and shared the retreat of the Serbs through Albania. When, however, the exiled government established itself at Corfu, he and most of his staff were placed on the retired list. He himself withdrew to France. He died on May 17, 1917, at Nice.

PUTTEE or **PUTTIE.** The name adapted from the Hindu *patti*, bandage (Skr. *patta*, strip of cloth), for a covering from the ankle to the knee, consisting of a long narrow piece of cloth wound spirally, and fastened by a tape, though straps may be used. For infantrymen, the winding commenced at the ankle, but mounted men reversed the process as the rubbing against the horse caused the tape to come undone. Their advantages over leggings were said to be that they were not hard on the legs, could be used as bandages or slings in case of need and occupied less space when not in wear. Worn by most armies except the German in World War I, they gradually disappeared thereafter in favour of short leggings.

PUTTENHAM, GEORGE (d. 1590), the reputed author of *The Arte of English Poesie* (1589). The book was entered at Stationers' Hall in 1588, and published in the following year. The writer of *The Arte of English Poesie* was educated at Oxford, and at the age of 18 he addressed an eclogue entitled *Elpine* to Edward VI. In his youth he had visited Spain, France and Italy, and was better acquainted with foreign courts than with his own. In 1579 he presented to Queen Elizabeth I his *Partheniades* (printed in a collection of manuscript *Ballads* by F. J. Furnivall), and he wrote the treatise in question especially for the delectation of the queen and her ladies. He mentions nine other works of his, none of which are extant. There is no direct evidence beyond Bolton's ascription to identify the author with George or Richard

Puttenham, the sons of Robert Puttenham and his wife Margaret, the sister of Sir Thomas Elyot, who dedicated his treatise on the *Education or Bringing up* of *Children* to her for the benefit of her sons.

Many later "poetics" are indebted to this book. The original edition is very rare. Edward Arber's reprint (1869) contains a clear summary of the various documents nith regard to the authorship of this treatise. The history of the Puttenhams is discussed in H. H. S. Croft's edition of Elyot's *Boke called the Governour*. There are other modern editions of the book, notably one in J. Haslewood's *Ancient Critical Essays* (1811–15).

PUTTING THE SHOT: *see* SHOT-PUT.

PUTTKAMER, ROBERT VON (1828–1900), Prussian statesman, was born at Frankfurt an der Oder on May 5, 1828. Puttkamer was the chosen instrument of the clerical conservative policy initiated by Bismarck when the growth of the Socialist movement made it expedient to conciliate the Catholic centre. As *Oberprasident* of Silesia he had mitigated the rigour of the application of the "May laws," and as minister of public worship and of the interior he continued this policy. He was also the author of the ordinance of Jan. 2, 1880, on the simplification of German orthography.

As minister of the interior, Puttkamer's temper was in harmony with the view of Bismarck and the emperor William, and with their support he tried to re-establish the old Prussian system of rigid discipline from above.

On his initiative, on Jan. 4, 1882, a royal ordinance required all officials to give the government their unconditional support at political elections. He also interfered with the liberty of public meetings and attempted to suppress strike movements by force. This "Puttkamer regime" was intensely unpopular. and when the emperor Frederick III succeeded to the throne Puttkamer was forced to resign (June 8, 1888). He was largely rehabilitated under William.

Puttkamer died at Karzin, in Pomerania, on March 15, 1900.

PUTTY, a term that generally means a cement of one of two types: whiting putty or white-lead whiting putty.

A high-grade whiting putty consists of 85% to 90% whiting (finely powdered calcium carbonate) blended with 10% to 15% boiled linseed oil. White-lead whiting putty has an admixture of 10% white lead, reducing the amount of whiting proportionately.

Prepared putty should roll freely in the hands without exuding oil. It is commonly used to secure sheets of glass in place, to fill nail holes, etc.

The term is also applied to substances resembling putty, for example, iron putty, which is a mixture of ferric oxide and linseed oil, and red-lead putty, which is composed of red and white lead and linseed oil. The term putty is also applied to certain dough-like plastic compounds. Putty is also a shortened name for putty powder (tin oxide), which is used in polishing glass, granite, metal, etc. (E. L. Y.)

PUTUMAYO RIVER, a 980 mi.-long tributary of the Amazon which rises in the Andes mountains of southern Colombia, forms the southern boundary of Colombia with Ecuador and Brazil for almost 800 mi., but for its last 100 mi. before it enters the Solimões or Amazon at Santo Antonio de Icá it flows through Brazilian territory. In Brazil it is known as the Icá river.

The area drained by the Putumayo is a vast zone of tropical rain forest where rainfall ranges upward to 140 in. a year. Except near its headwaters, in the foothills of the Andes, the population along its banks is composed largely of small groups of forest Indians.

A highway built by the Colombian government from Pasto through the Sibundoy valley to Puerto Asís on the upper Putumayo was opening the eastern flanks of the Andes to settlement in the second half of the 20th century. Another road was under construction from Ipiales toward the valley of the Rio San Miguel, which is a main affluent of the Putumayo and itself forms the Ecuador-Colombian border near its headwaters. Navigation on the Putumayo is unobstructed by rapids below Puerto Ospina, 80 mi. downstream from Puerto Asís. The only settlement of any size on the Putumayo below Puerto Ospina is Puerto Leguizamo (formerly Caucayá), from which there is a 25 mi. portage road northward to La Tagua on the Caquetá river.

The Putumayo region was the scene of the famous Putumayo rubber scandal during the height of the rubber boom which saw many Indians enslaved and killed by unscrupulous rubber operators. In 1932 there was fighting there between Colombian and Peruvian forces prior to the settlement of the so-called Leticia affair, which gave Colombia a wedge-shaped salient that extends 90 mi. south of the Putumayo to the Amazon port of Leticia. (Js. J. P.)

PUVIS DE CHAVANNES, PIERRE CÉCILE (1824–1898), French painter. was born at Lyons on Dec. 14, 1824. He occupied a rather unique position in 19th-century painting, for his work was largely independent of the major artistic currents and, perhaps for that very reason, it was approved by representatives of almost all shades of critical opinion. The son of a mining engineer, Pierre Puvis was educated at Lyons and at the Lycée Henri IV in Paris and was intended to follow his father's profession.

Puvis first studied painting under Henri Scheffer, spent some time in Italy and then frequented for a short period the studios of Thomas Couture and Eugène Delacroix. He first exhibited at the Salon in 1850 (a Pietà), but was then consistently rejected until 1858. His work was, however, esteemed by such critics as Théodore de Banville, Théophile Gautier, Charles Baudelaire and Paul de St. Victor. In 1859 he reappeared at the Salon with the "Return from Hunting" (Marseilles), an adaptation of a "Return of the Prodigal Son" executed in 1854 as part of a decorative scheme for his brother's dining room. In 1861, with the production of "War" and "Peace." he began an important series of paintings which were destined to become part of the decorative scheme for the museum at Amiens. The scheme was augmented by various gifts from the artist and finally completed with "Ave Picardia Nutrix" (1865) and the state commission for "Pro Patria Ludus" (1882).

During these years Puvis de Chavannes undertook other decorative work at Lyons, Marseilles, Poitiers and Paris, as well as exhibiting a number of important pictures such as the "Beheading of St. John" (1869), "Hope" (1872), "Family of Fisher-folk" (1875), "Women on the Seashore" (1879) and "The Poor Fisherman" (1881). The work at Lyons includes "Autumn" (Salon of 1864) and the major decorative works "The Sacred Grove." "Vision of the Antique," "The Rhône" and "The Saône" (1884–87).

In the Palais Longchamp at Marseilles are two panels representing "Marseilles as a Greek Colony" and "Marseilles, Gateway to the East" (1868–69) and in the Hôtel de Ville, Poitiers, are two decorative panels of historical subjects, "Radegund" and "Charles Martel" (1872–74). In 1876 Puvis de Chavannes was commissioned to paint a series of panels illustrating the life of St. Geneviève, for the Panthéon; although part of this task was finished and exhibited by 1880, the total scheme was completed only after the death of Puvis in Paris (Oct. 24, 1898) by pupils, under the direction of J. C. Cazin, working from the completed cartoons. Other mural decorations in Paris are those for the Sorbonne (1887–89) and for the Hôtel de Ville, which were completed in 1893. Two other important decorative commissions were those for the museum at Rouen (1890–92) and for the staircase of the public library, Boston (1894–98).

PUY, a geological term used locally in Auvergne for a volcanic hill. Most of the puys of central France are small cinder cones, with or without associated lava, while others are domes of trachytic rock, like the domite of the Puy-de-DBme. The puys may be scattered as isolated hills, or, as is more usual, clustered together, sometimes in lines. They probably became extinct in late prehistoric time. Puys are also found in the Eifel, on the Bay of Naples, in the Swabian Alps of Wiirttemberg, and, as Sir A. Geikie has shown, in Scotland.

PUY-DE-DÔME, a *département* of central France, four-fifths of which belonged to Basse-Auvergne, one-sixth to Bourbonnais, and the remainder to Forez (Lyonnais). Area, 3,095 sq.mi. Pop. (1954) 481,380. It is bounded north by Allier, east by Loire, south by Haute-Loire and Cantal, and west by Corrkze and Creuse.

The famous plain of the Limagne, watered by the Allier and its tributary, the Dore, has on its western flank the volcanic Puys and Monts Dore, while on its eastern side rises the largely granitic heights of the Forez (5,381 ft.). The Puys include a number of craters, now dead and often filled by lakes, which also occur behind lava dams in the valleys. The Puy de Sancy (6,188 ft.) is the highest crater, but the Puy de Dôme (4,806 ft.) gives its name to the de'partement and has a meteorological observatory on its summit, once crowned by a Roman temple, the ruins of which still exist.

The climate of Puy-de-Dbme is usually very severe, owing to its high level and its distance from the sea; the mildest air is found in the northern valleys, where the elevation is least. During summer the hills about Clermont-Ferrand, exposed to the sun, become all the hotter because their black volcanic soil absorbs its rays. The rainfall averages 2j to 26 in. annually; in the Limagne, around which the mountains arrest the clouds, rainfall is less. Nevertheless the soil of this plain, consisting of alluvial deposits of volcanic origin, and watered by torrents and streams from the mountains, makes it one of the richest regions of France. In the highest altitudes the rainfall attains 64 inches.

About two-thirds of the inhabitants of the Puy-de-Dôme are engaged in agriculture. The Limagne yields a variety of products and the vine flourishes on its hillsides. The high mountains provide pasture for large flocks of cows and sheep, and cheese-making is an important industry. The intermediate region is cultivated mainly for cereals, the chief of which are wheat, rye, oats and barley. Potatoes are largely grown, and peas, beans, beetroot, colza and tobacco. The Limagne produces fruit of all kinds—apricots, cherries, pears, walnuts and apples, yielding considerable quantities of cider.

The *département* possesses considerable mineral wealth. There are important coal mines at Brassac on the Allier, on the borders of Haute-Loire, at St. Elroy near the *département* of Allier, and at Bourg-Lastic on the borders of Correze. Peat, asphalt, bituminocs schists, antimony, mispickel and argentiferous lead are also worked. Of the last named there are mines and foundries at Pontgibaud on the Sioule. Amethysts and other rare minerals are found, and there are numerous stone quarries. Mont Dore, Royat and La Bourboule are watering places. The springs of St. Nectaire contain sodium and iron chlorides and bicarbonates. The waters of Châteauneuf (on the Sioule), also known to the Romans, contain iron bicarbonates; those of Châtelguyon, like the waters of Carlsbad and Marienbad, are also widely known, and there are many other mineral springs of varied character. Manufactures are grouped around Thiers, which produces a large amount of cheap cutlery, and Clermont-Ferrand, the capital. The textile industry includes wool carding and making of linen cloths, bunting, clothing, manufactories for lace and for rubber (Clermont-Ferrand), sugar-works, manufactures of edible pastes and of fruit preserves. The de'partement exports grain, fruits, cattle, wines, cheese, wood, mineral waters, cutlery, etc.

Puy-de-Dôme is served by the Orléans and P.L.M. railway companies. Many thousands of the inhabitants, chiefly of the district of Ambert, leave it during winter and find work elsewhere. The de'partement comprises 5 *arrondissements*—Ambert, Clermont-Ferrand, Issoire, Riom, Thiers — jo cantons and 473 communes. The chief towns are Clermont-Ferrand, Issoire, Thiers, Riom, Ambert, Mont-Dore-les-Bains, La Bourboule and Royat. Near Clermont-Ferrand is Mt. Gergovie (see GERGOVIA), the scene of the victory of Vercingetorix over Julius Caesar. Billom, Chamalières, Courpière, Orcival, St. Nectaire and St. Saturnin possess churches in the Romanesque style of Auvergne. 'There are interesting ruined feudal strongholds at Murols and Tournoël (near Volvic). Vic-le-Comte has a *sainte-chapelle* which is a beautiful example of the transition from Gothic to Renaissance architecture, and Aigueperse has a Gothic church of the 13th to the 15th century. Near Pontgibaud are the ruins (13th century) of the Carthusian abbey of Port St. Marie. There are a few megalithic remains in the *département.*

PUZZLE, a mechanical toy or other device involving some constructional problem. to be solved by the exercise of patience or ingenuity. Some of the oldest mechanical puzzles are said to be of Chinese origin, one of the most familiar being known as the "Chinese puzzle," or tangram (chi *ch'iao* t'ue), which consists of a square of wood or other material cut into five triangles, of different sizes, a small square and a lozenge, which can be so placed as to form over 300 figures. Another puzzle attributed to the Chinese consists of a series of rings running linked together on a bar, the problem being to take them off the bar and replace them. A common type of puzzle, the jigsaw puzzle, consists of coloured pictures cut into a number of variously shaped pieces to be fitted together.

For other forms of puzzles see LABYRINTH; REBUS; CROSS-WORD; etc.

PWLLHELI ("salt pool"), a municipal borough, seaport and market town in the Caernarvon parliamentary division of Caernarvonshire, north Wales, 20 mi. S.S.W. of Caernarvon by road. Pop. (1961) 3,642. Area 1.9 sq.mi. It has a sandy beach on the north side of Cardigan bay. The town was incorporated in 1355 by Edward the Black Prince.

The chief industries are agriculture, boatbuilding and the making of machine tools.

PYANOPSIA, an ancient festival in honour of Apollo, held at Athens on the 7th of the month Pyanopsion (October). A hodgepodge of pulse was offered to Apollo. Another offering was a branch of olive or laurel, bound with purple or white wool, round which were hung fruits of the season, pastries and small jars of honey, oil and wine. Both are old pieces of rustic magic, for which many analogies can be found elsewhere. It was carried in procession to the temple of Apollo where it was suspended on the gate by a boy whose parents were both alive. The doors of private houses were similarly adorned. The branch was allowed to hang for a year, when it was replaced by a new one, since by that time it was supposed to have lost its virtue. During the procession a chant was sung, the text of which has been preserved in Plutarch's *Theseus.*

Both offerings have been connected with the Cretan expedition of Theseus, who, when driven ashore at Delos, vowed a thank offering to Apollo if he slew the Minotaur; the offering afterward took the form of the olive or laurel branch and Pyanopsia. His comrades on landing in Attica gathered up the scraps of their provisions which explains the origin of the hodgepodge.

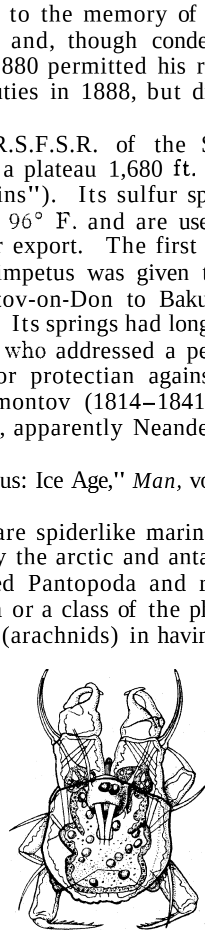
PYAPON, a town and district in Burma, on the Pyapon river. Pop. (1953) 19,174. The district, formed in 1903, lies within the delta of the Irrawaddy. It is intersected by creeks and liable to inundation at high spring tides. The jungle is being reclaimed for rice, which is the sole crop. Area, 2,076 sq.mi.; pop. (1941) 385,008, showing an increase of 50,058 in the decade. The district has no railways and few roads, communication being by water. Other urban centres, which ship the rice to Rangoon, are Kyaiklat (15,781 in 1953), and Dedayè (7,899 in 1953).

PYAT, FELIX (1810–1889), French communard, was born at Vierzon (Cher) on Oct. 4, 1810, the son of a Legitimist lawyer. Called to the bar in Paris in 1831, he threw his whole energies into journalism. The violent personalities of a pamphlet entitled *Marie Joseph Chénier et le prince des* critiques (1844), in reply to Jules Janin, brought him a six months' sojourn in La Pélagie, in the cell quitted by Lamennais. In 1848 George Sand, whom he had introduced in 1830 to the staff of the *Figaro*, now asked Ledru-Rollin to make him commissary-general of the Cher. After three months' tenure of this office he was returned by the *département* to the Constituent assembly, where he voted with the Mountain, and brought forward a motion for the abolition of the presidential office. About this time he fought a duel with Proudhon, who had called him the "aristocrat of the democracy." He joined Ledru-Rollin in the attempt of June 13, 1849, after which he sought refuge in Switzerland, Belgium, and finally in England. For a glorification of regicide at the time the Orsini attempt against Napoleon III he was brought before an English court; but acquitted, and the general amnesty of 1869 permitted his return to France, but further outbursts against the authorities compelled his return to England. The revolution of Sept. 4 brought him back to Paris, and it was he who in his paper Le *Combat* displayed a black-edged announcement of the *pourparlers* for the surrender of Metz. After the insurrection of Oct. 31, he was imprisoned for a short time. In Jan. 1871, *Le Combat* was suppressed, only to be followed by an equally virulent *Vengeur*. Elected to the National assembly, he retired from Bordeaux with Henri Rochefort and others until such time as the "parricidal" vote for peace should be annulled. He returned to Paris to join the committee of public safety, and, in Hanotaux's words, was the *âme ulcérée* of the Commune, but was blamed for the loss of the fort of Issy. He was superseded there by Delescluze, but he continued to direct the violent acts of the Commune, the overthro of the Vendôme column, the destruction of Thiers's residence and of the expiatory chapel built to the memory of Louis XVI. He escaped across the frontier, and, though condemned to death in 1873, the amnesty of July 1880 permitted his return. He was elected to the chamber of deputies in 1888, but died at Saint-Gratien on Aug. 3, 1889.

PYATIGORSK, a town in the R.S.F.S.R. of the Soviet Union, on the Podkoumok river and on a plateau 1,680 ft. above sea level, hence its name ("five mountains"). Its sulfur springs, about 15 in number, vary from 75° to 96° F. and are used for drinking and bathing and are bottled for export. The first buildings were erected in 1812 and a great impetus was given to the town when it was linked with the Rostov-on-Don to Baku railway. Its population in 1959 was 69,000. Its springs had long been known to the Circassians of the district who addressed a petition to Ivan the Terrible in 1551 asking for protectian against the Crimean Tatars. The poet M. Y. Lermontov (1814–1841) was killed here in a duel. In 1918 a skeleton, apparently Neanderthal, was reported.

See **Russ.** *Anthr. Journ.* (1922); "Caucasus: Ice Age," *Man*, vol. xxv (1926).

PYCNOGONIDA (SEA SPIDERS) are spiderlike marine animals which occur in all oceans, especially the arctic and antarctic, usually as bottom dwellers. Also called Pantopoda and rarely, Podosomata, they comprise a subphylum or a class of the phylum Arthropoda (*q.v.*) and resemble spiders (arachnids) in having the first pair of appendages characteristically arachnidlike or chelicerate. In most other respects pycnogonids are distinct from all other groups of arthropods. They are characterized by a relatively small body, excessively long legs with a patellar segment, and an additional pair of legs (ovigers) used by the male to carry the eggs about in a compact ball. The ovigers are present in all males except one New Zealand species but are lacking in the females of several genera. The sexes are usually separate, but one hermaphroditic species from Brazil has been described. Most species have eight walking legs, but species with ten legs are not uncommon in antarctic and Caribbean regions, and there is a 12-legged one in the antarctic. In addition to the walking legs and ovigers there may be a pair of pincerlike or chelate appendages (chelifores) and sensory palpi; the presence or absence of these appendages constitutes the basis of classification within the group, which includes about 50 genera divided into eight or nine families.



A PROTONYMPHON LARVA

The body of a pycnogonid consists of a cephalic segment or head region, followed by three to five trunk somites, which may be either distinctly segmented or coalesced into a compact disc, and a usually small, fingerlike abdomen with the anus at the tip. The mouth is a triangular opening at the end of an elaborate suctorial appendage (proboscis) which is often much longer and larger than the body. In such pycnogonids as *Nymphon* or *Achelia* the cephalic segment bears three pairs of appendages anterior to and in addition to the first pair of legs, the chelifores, which may or may not be chelate; the palpi, usually flanking the proboscis; and the ovigers, originating on the ventral surface. The extreme of reduction is found in *Pycnogonum,* which lacks both chelifores and palpi and has ovigers only in the males (except one species which has none). There are usually four simple eyes, located in a tubercle or elaborate process on the dorsal surface of the cephalic segment, but eyes are often lacking in deep-sea species. The digestive and reproductory systems have branches into the legs. The genital openings are usually on the ventral surface of the second joints of the last pair of legs but occur occasionally on all legs; the sexual products are stored in the fourth or femoral joints of the legs. The circulatory system is a simple dorsal heart with two or three pairs of lateral slits (ostia). The nervous system is composed of a supra-esophageal brain or ganglion and a chain of five or six ventral ganglia. There is no specialized excretory or respiratory system; secretory or cement glands occur in the males on the legs; and some species have a blood pigment of uncertain nature.

In all species of which the habits are known, the male attaches the eggs to his ovigers in masses or clusters as they are extruded from the female and carries them with him till they hatch into larvae. In some species the young larvae become attached to hydroids or polyps, in which they form galls or cysts; others are known to invade the medusa or jellyfish stage. The larval stages of a Japanese species, *Nymphonella tapetis,* are parasitic in the mantle cavity of clams; similar infestation of mussels by a California species has recently been observed. Others are associated with sea slugs (nudibranchs) and one may live within a sea cucumber (holothurian). Most species, however, are associated with coelenterates. The life cycle of deep sea forms, especially members of the genus *Colossendeis,* is unknown.

Pycnogonids occur in all oceans from the littoral zone to depths of more than 2,000 fathoms (12,000 ft.) but are especially abundant in arctic and antarctic waters. Most species are bottom dwellers, feeding on the soft parts and body juices of coelenterates and other defenseless animals? but some live on the floating or pelagic *Sargassum* in the mid-Atlantic; one, *Pallenopsis calcanea,* is bathypelagic, living at depths of 1,200–2,000 m. (about 4,000–6,500 ft.) in the Atlantic and Pacific oceans. Some species ascend to the surface to breed, swimming by treading water with their long legs. In size pycnogonids range from a spread of 3 to 4 mm. in such forms as the littoral *Tanystylum* to about 50 cm. in deep sea species of *Colossendeis.* While pycnogonids may sometimes occur in massive numbers, they are of no commercial significance and their study is untinged by economic motives.

One Devonian fossil, without discernible anterior appendages or proboscis, is considered to represent an extinct order, Paleopantopoda, while all the living species are included in the order Pantopoda. The Pycnogonida cannot be associated with the Arachnida because the sexual apertures are not restricted to the second abdominal somite (there being no such segment) as in Arachnida; the multiple gonopores are a condition not found in other living arthropods. Nor can they be considered as allied to Crustacea because they do not have antennae or biramous appendages at any stage. The patellar segment of the leg is an arachnid character, and the occurrence of both flexor and extensor muscles in the distal joint of the leg is a character of Crustacea as well as Arachnida. The musculature of the oviger is unique among arthropods: the distal division or tarsal segments are individually musculated. The chelate protonymphon larva is unique. The occurrence of supernumerary legs is not comparable with similar phenomena in other groups but seems instead to be a sort of polymorphism, possibly within a species, although the forms have been given generic names.

PYDNA, BATTLE OF (168 B.C.). The Roman operations in Greece having lingered on for some time, Lucius Aemilius

Paullus, "one of the few Romans of that age to whom one could not offer money," was sent to hasten a decision. Arriving at Heracleum he at once seized the pass of Pythium, which compelled Perseus king of Macedonia to fall back on Pydna.

The serried ranks of the Macedonian phalanx astonished and terrified Paullus, who, however, disguised his anxiety from his men, and advanced toward his enemy. The Roman vanguard was dispersed and one cohort almost annihilated. Once again the sarissa (pike) carried all before it, the Roman legions being forced back until they reached the hill upon which stood their camp. There, on account of the broken nature of the ground, the phalanx became somewhat disorganized. Paullus at once sizing up the situation "commanded his men, that wherever they should see the line of the enemy present openings, they should individually rush to these spots, and insinuating themselves like a wedge into such spaces, however narrow their extent, they should fight with impetuosity" (Livy). These tactics resulted in complete success, the phalanx being disjointed and broken up into a number of separated bodies. The 11 legion then charged the disorganized mass of pikemen and routed it. Perseus and his cavalry fled the field leaving the infantry to be slaughtered—20,000 were killed and 11,000 made prisoners. This battle was the last fought by the phalanx. The whole campaign was only 15 days. Thus perished the empire of Alexander the Great 144 years after his death.

See Livy xliv; T. Mommsen, *The History of Rome,* book iii, chap. x; H. G. Liddell, *A History of Rome* (1855). (J. F. C. F.)

PYE, HENRY JAMES (1745–1813), English poet laureate, was born in London on Feb. 20. 1745, and educated at Magdalen college, Oxford. Of all he wrote his prose *Summary of the Duties of a Justice of the Peace Out of Sessions* (1808) is most worthy of record; it is based on his own experience as a magistrate at Westminster.

Pye was made poet laureate in 1790, perhaps as a reward for his faithful support of Pitt in the house of commons. The appointment was looked on as ridiculous, and his birthday odes were a continual source of contempt. His most elaborate poem was an epic. *Alfred* (1801). He was the first poet laureate to receive a fixed salary of L27 instead of the historic tierce of Canary wine.

Pye died at Pinner, Middlesex, on Aug. 11, 1813.

PYGMALION, the name of two figures in classical literature and mythology.

1. In Greek mythology, Pygmalion was a king of Cyprus who fell in love with a statue of Aphrodite. Ovid, in the *Metamorphoses,* invents a more sophisticated version: Pygmalion, a sculptor, makes an ivory statue representing his ideal of womanhood, then falls in love with his own creation; Venus brings it to life in answer to his prayer.

Ovid's story was adapted by William S. Gilbert in *Pygmalion and Galatea* (1871), which appears to be the basis for the modern association of Galatea with Pygmalion's statue. George Bernard Shaw developed ironically the theme of the creative artist in *Pygmalion* (1912).

2. In the *Aeneid,* Pygmalion, king of Tyre, was the brother of Dido (*q.v.*) and the murderer of her husband. (Wm. S. A.)

PYGMY. Since Homer, the term has been applied specifically to a very small human race whose habitat was assumed to be the forest districts of the upper Nile; since then it has referred to a very short person (*see* Dwarfism and Gigantism). In modern anthropology the term is used as a category of size, applied to those human groups whose males do not pass 150 cm. or 59 in. in average bodily height; a slightly taller group is called pygmoid. Races of true pygmy size have not been discovered in human prehistory nor among American natives. The best known are the Twides, a generic term for three main subdivisions inhabiting the extended area of tropical Africa. (*See* also Bambute) They total probably 168,000 individuals. The Onge (Andaman Islands), the Aëta (Philippines), some portions of the Bushmen (Kalahari desert. South Africa), tribes in the mountains of New Guinea and in Indonesia also are of pygmy size. All Asiatic pygmies are known by the generic term "Negritos" (*q.v.*). Each of the tribes has its independent biological origin and enjoys a thoroughly normal development. The only characteristics they have in common are small bodily height and certain similarities in hair and face. Culturally, they still remain on the very low level of food gatherers, neglecting agriculture and stock farming. The men hunt, the women collect various kinds of small animals and roots, tubers, seeds, fruits and honey. These primitive nomads are obliged to roam around, changing their habitat every few days. Their huts are very simple, consisting of some sticks as scaffolding covered with leaves or skins. All adults wear short aprons of leaves, bark or leather, ornamentation is slightly practiced, mutilations not at all. The tribe is subdivided into many loose bands (sibs), each consisting of several families, without chief, priest or leader. The monogamic family (husband, wife, with their children) is the only form of social organization. Their principal weapon is the bow and arrow; they do not use stone or metal as raw materials. Through prayers and sacrifices they worship one Supreme Being. as the almighty ruler and author of all laws and morals. Pygmies more or less completely lack magic. animism and ancestor cult. Nearly all pygmy tribes maintain close symbiotic relations with culturally advanced tribes in their environment; consequently, they have lost their indigenous language and adopted that of their hosts.

PYLE, ERNIE (Ernest Taylor Pyle) (1900–1945), U.S. newspaperman, was one of the most famous war correspondents of World War II. Born near Dana, Ind., on Aug. 3, 1900, he studied journalism at Indiana university and left school a few months before his graduation to become a reporter for a small-town newspaper. Later, after various editorial jobs, he acquired a roving assignment for the Scripps-Howard newspaper chain. His daily experiences furnished him material for a column that eventually appeared in as many as 200 newspapers. His coverage of the campaigns in North Africa. Sicily, Italy and France brought him a Pulitzer prize in 1944. as well as several other awards. He was with the U.S. forces in the Pacific on Iwo Jima and Okinawa, during which latter campaign he visited the nearby island of Ie Shima. There, on April 18. 1945, he was killed by Japanese machine-gun fire.

Compilations of his columns appeared in book form: *Ernie Pyle in England* (1941); *Here Is Your War* (1943); *Brave Men* (1944); *Last Chapter* (1946).

See Lee Graham Miller, *The Story of Ernie Pyle* (1950).

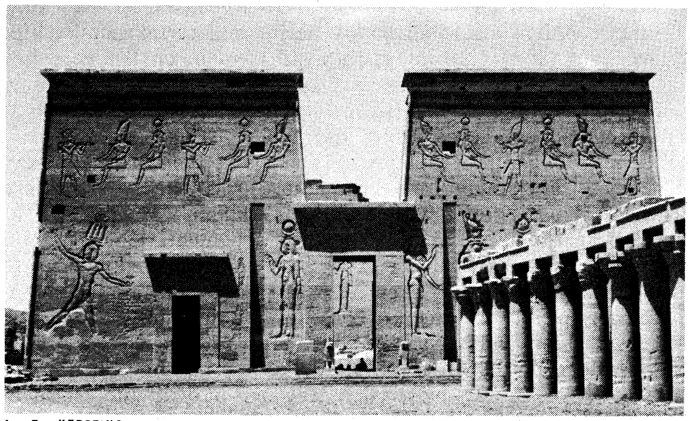
PYLE, HOWARD (1853–1911), U.S. artist and author, best known for his children's books, was born at Wilmington, Del., on March 5, 1853. He studied at the Art Students' league, New York city, and first attracted attention by his line drawings after the style of Albrecht Diirer. His magazine and book illustrations, particularly his drawings of scenes from American colonial life in New England and New Amsterdam. were of high quality. Some of Pyle's children's stories, illustrated by the author with vividness and historical accuracy, have become classics—most notably, *The Merry Adventures of Robin Hood* (1883); *Otto of the Silver Hand* (1888); and *Jack Ballister's Fortunes* (1894). Later he undertook mural paintings, executing. among others, "The Battle of Nashville" (1907) for the capitol at St. Paul, Minn.

Dissatisfied with his style in painting, he went to Italy for further study but died shortly afterward, on Nov. 9, 1911, in Florence. Pyle had established a free school of art in his home in Wilmington, where many successful American illustrators received their education.

PYLON, in architecture, originally a gate, but in modern usage applied to the huge truncated pyramidal forms, crowned with cornices, that flanked the entrances to Egyptian temples. The term is also applied to any similar large masses of masonry, often decorated with sculpture or architectural forms, used to flank the entrance to an avenue, a plaza or a bridge—especially a suspension bridge.

(*See* Bridges; Egyptian Architecture.)

A tower, usually of steel, to support a telegraph, telephone or



A. F. KERSTING

THE FIRST PYLON OF THE TEMPLE OF ISIS (PTOLEMAIC PERIOD, 332–30 B.C.), PHILAE, UPPER EGYPT

electric line over an extended span, is also called a pylon.

In aeronautics, a post or tower indicating a prescribed course of flight.

PYLOS (mod. NAVARINO), a town and bay on the west coast of Messenia, noted chiefly for the part it played in the Peloponnesian War. The bay, roughly semicircular, is protected by the island of Sphacteria (mod. Sphagia), more than 2½ mi. long. To the north lies the lagoon of Osman Aga. North of Sphagia is the rocky headland of Pylos or Coryphasium, called in modern times Palaea-Navarino or Palaeokastro, from the Venetian ruins on its summit. Most scholars have identified this with the Homeric Pylos, the home of Neleus and Nestor, and a cave on the north slope of Coryphasium is pointed out as that in which Hermes hid the stolen cattle of Apollo. But this view presents considerable difficulties, and Strabo (viii, 348 *et seq.*) argued that the Pylos of Nestor must be the place of that name in Triphylia, an important prehistoric site. After the Dorian migration Pylos declined. In 425 B.C. the Athenians sent an expedition to Sicily under command of Eurymedon and Sophocles. With them was the general, Demosthenes, who landed at Coryphasium with a body of Athenian troops and hastily fortified it. The Spartans, who were then invading Attica, withdrew their forces and attacked Pylos vigorously by sea and land, but were repulsed, and the Athenians were enabled by the arrival and victory of their fleet to blockade on the island of Sphacteria a body of 420 Spartiates with Helots. Their resistance was overcome by a rear attack directed by a Messenian, who led a body of men by a difficult path along the cliffs on the east, and the 292 Spartan survivors laid down their arms 72 days after the beginning of the blockade. Their surrender made a deep impression on the whole Greek world, which had learned to regard a Spartan surrender as inconceivable. Though Pylos should have been ceded to Sparta under the peace of Nicias (421 B.C.) it was retained by the Athenians until the Spartans recaptured it early in 409 B.C.

In the middle ages the name Pylos was replaced by that of Avarino or Navarino, derived from a body of Avars who settled there; the current derivation from the Navarrese company, who entered Greece in 1381 and built a castle at this spot, cannot now be maintained.

From 1498 to 1821 Navarino was in the hands of the Turks, save at two periods when it was held by the Venetians, who named it Zonklon. *See* NAVARINO, THE BATTLE OF.

Though differing on many points, they agree in thinking (1) that the island of Sphagia is the ancient Sphacteria, Palaeokastro the ancient Coryphasium or Pylos; (2) that in 425 B.C. the lagoon of Osman Aga was navigable and communicated by a navigable channel with the Bay of Navarino; (3) that Thucydides, if the manuscript reading is correct, underestimates the length of the island, which he gives as 15 stades instead of 24 (nearly 3 mi.), and also the breadth of the southern channel between it and the mainland. *Cf. PYM, JOHN (1584–1643), English statesman, son and heir of Alexander Pym of Brymore, Somersetshire, a member of a family which had held this seat in direct male descent from the time of Henry III. Pym matriculated as a commoner at Broadgates hall (now Pembroke college), Oxford, in 1599, and entered the Middle Temple in 1602. Through the interest of the 3rd earl of Bedford—whose agent in the west country was Pym's stepfather, Sir Anthony Rous—Pym became receiver of the king's revenue for Hampshire, Wiltshire and Gloucestershire.

Growth of Leadership.—As a member for Calne in the 1621 parliament, Pym delivered a speech on Nov. 28 to "beseech the King that there may be a commission to see the Laws here of England duly executed against Papists." When King James tried to restrict the commons' freedom of speech, Pym was a promoter of the Protestation, which was entered in the commons' journals, asserting that parliament's privileges were "the ancient and undoubted birthright and inheritance of the subjects of England." This protest the king tore from the journal. After parliament's dissolution in Jan. 1622, Pym was ordered to be confined first to his London house and afterward to Brymore, an order which remained in force for three months. In the 1624 parliament Pym sat for Tavistock, which he continued to represent for the remainder of his life. There is no evidence that he took a prominent part in this parliament or in the first parliament (1625) of Charles I. In the 1626 parliament Pym was one of the managers of Buckingham's impeachment.

The outstanding event of the 1628–29 parliament was the Petition of Right of which Pym was a leading supporter. He also spoke at length against Roger Manwaring who had preached the doctrine of nonresistance to a king, deducing that a king could levy taxes without parliament's consent. Pym was the leader in impeaching Manwaring before the lords where he delivered a speech expounding the fundamental principles of government.

During the next 11 years, when no parliament met, Pym's energies were absorbed as treasurer of the Company of Adventurers for the Plantation of the Islands of Providence, and Henrietta, incorporated in Dec. 1630. After struggling for nearly 20 years the company finally failed. Its importance was that its members were mostly leading Puritans who had already been associated with Pym in the parliamentary struggle against Charles I and would be associated again when parliaments were resumed. Hence when the Short parliament met on April 13, 1640, it included a group of resolute men already accustomed to act together and to recognize Pym as leader. On April 17 Pym spoke for two hours denouncing grievances: "The first, are those which during these eleven years interval of Parliaments, are against the Liberties and Privileges of Parliament. The Second, are innovations in matters of Religion. The Third, Grievances against the property of our goods." "That which marked Pym from henceforth as a leader of men was the moderation combined with the firmness with which every sentence was stamped." (S. R. Gardiner, *History of England,* ix, 102.) Pym was concerned in an episode which led to the parliament's abrupt end: he and others prepared a petition that the king should make terms with the Scots. To forestall this, Charles dissolved parliament May 5.

Pym now aimed at compelling Charles to call another parliament. He drew up the petition which demanded redress of grievances, peace with the Scots and a new parliament, and which 12 peers presented to the king. When writs for another parliament were issued, Pym "rode about the country to promote elections of the Puritanical brethren to serve in Parliament"—the first election campaign in parliamentary history.

The Long Parliament.—Parliament assembled on Nov. 3,

1640. Pyrn was recognized at once as the leader of the opposition to the court and his dominance grew. Believing that the earl of Strafford was set upon impeaching the popular leaders for their dealings with the Scots, and that attack was the surest defense, on Nov. 11 Pym, behind closed doors, began his denunciation of him. That same afternoon Pym carried to the lords his impeachment and a summary of the charges on which the impeachment was based. Between this date and the opening of Strafford's trial, attempts were made to win Pyrn and others over to the king by offering to them ministerial posts. Twice the king interviewed Pyrn and twice the offer was refused, presumably because Charles demanded the dropping of Strafford's impeachment as the price of Pym's appointment. On April 13, 1641, the last day of the impeachment trial, Pyrn delivered one of his most eloquent speeches, basing his attack less upon Strafford's technical breach of the law of treason than upon his betrayal of trust as the king's adviser. "Shall it be treason," he declaimed, "to embase the King's coin, though but a piece of twelve-pence or sixpence? and must it not needs be the effect of a greater treason, to embase the spirits of his subjects, and to set a stamp and character of servitude upon them, whereby they shall be disabled to do anything for the service of the King and Commonwealth?" Meantime some of Pym's associates were doubting whether the lords would convict Strafford of treason on the available evidence. On April 10, therefore, they introduced a bill of attainder. Pym never agreed with this policy, believing that the impeachment should and could be carried. But it was the attainder process which was first completed and by which Strafford was executed on May 12.

Even more important than finance or Strafford to the opposition group was the subject of religion. In this matter Pym's position was different from that of most of his associates in that he was never a Puritan but was a staunch adherent of the orthodox, pre-Laudian church. In his maiden speech (Feb. 16, 1621) he had inveighed against a member named Shepherd because of his "exasperatinge one party by that odious and factious name of Puritans." Similarly in the 1628–29 parliament he condemned Archbishop Laud's Arminianism because it contravened "the 39 Articles set forth in Queen Elizabeth's time; and the Articles set forth at Lambeth as the doctrine of the Church of England." In Dec. 1640 Pyrn moved Laud's impeachment! and on Feb. 24, 1641, presented the impeachment articles to the lords. In February the Puritan members voted that a London petition against episcopacy should be sent to a committee for report, and the Anglican members voted against this; Pyrn voted with the Puritans, but a fellow member (Edward Bagshaw) wrote: "Mr. *John Pyrn* spoke to this purpose, 'That he thought it was not the intention of the House to abolish either Episcopacy or the Book of Common Prayer, but to reform both wherein offence was given to the people'." (E. Bagshaw, *A* Just *Vindication,* 1660.) When. however, Pyrn became convinced that the bishops were merely the king's nominees to make religious changes and to preach nonresistance, he supported the abolition of episcopacy and in May 1641 voted for the Root and Branch bill. That this attitude was not due to a change of conviction is shown by his "Declaration and Vindication" of March 1643 wherein he averred: "That I am, and ever was, and so will dye a faithfull son of the Protestant Religion. without having the least relation in my beliefe to those gross errours of Anabaptisme, Brownisme, and the like."

Pyrn was a leading supporter of the Grand Remonstrance, and his speech on Nov. 22, 1641. helped to secure its passing, though by only 11 votes. This small majority was evidence of a reaction in the king's iavour. Charles thought to take advantage of it by impeaching a member of the lords and five members of the commons, including Pym (Jan. 3. 1642). Next day, Charles went to the commons to arrest the five members, only to find that "the birds are flown." This breach of privilege turned the tide decisively against Charles and made war inevitable.

The **Civil** War. — Pym had a large part in the preparations for war. On July 4 he was appointed one of the 1j members of the Committee of Safety. of whom five had been members of the Providence company. After the outbreak of war in Aug. 1642 he was the organizer who kept the parliamentary forces in the field, raising taxes and maintaining supplies. He was, in effect, the head of the executive.

At first his aim was to prevent a general war. On Nov. 9, following the battle of Edgehill, at a conference between the two houses, he urged a petition to the king for negotiations. The king refused. to receive the petition, and Pym appealed to the city for its continued support. But a few days later he was urging that both sides should disband their armies so that negotiations should not be prejudiced by their existence. When hope of negotiations iailed, Pyrn gave himself entirely to organizing for victory. In March 1643 he proposed an excise on the sale of all goods: though then rejected. the excise was levied four months later. In May he opened negotiations with the Scots. In June he reintroduced the idea — rejected the previous October — of a covenant whose signatories should pledge themselves not to lay down arms until the Reformed religion was secure. Meanwhile, negotiations with the Scots were progressing. The final terms were that the Scots would send an army into England against the king on condition that they were paid £30,000 a month and that parliament would establish presbyterianism after the war. On Sept. 25 parliament accepted these terms.

The Scottish alliance was Pym's last notable contribution to the parliamentary cause. On Nov. 7 parliament made him master of the ordnance; *i.e.,* of arms stored in the Tower. On Dec. 8 he died of cancer at Derby house, Westminster, which had been granted to him as a residence. The commons accorded him a state funeral in Westminster abbey, where his body was buried. The commons further voted a sum of £10,000 to pay his debts.

Family.—Pym's wife had been Anne Hooke (or Hooker) who had died in 1620. Of their nine children, four were sons. The eldest, Alexander, died unmarried. Charles became a baronet; his title and Pym's male line became extinct in Charles's son (also Charles) in 1688. Anthony emigrated: probably to St. Kitts.

Character. — Moderation of views in both religious and political questions, consistency of principles and administrative efficiency were Pym's outstanding characteristics, and their combination explains his supremacy in parliament. His speeches showed a sound political philosophy and logical exposition rather than rousing oratory; but they were evidently impressive and persuasive. Pym's death left a gap in the parliamentary leadership that was never again filled.

PYNCHON, WILLIAM (1590?–1662), one of the original patentees of the Massachusetts Bay company and founder of Springfield. Mass., was born in Springfield. Essex, England. In 1630 he joined the party led by John Winthrop and emigrated to New England where he settled first at Dorchester. Mass., and later at Roxbury (*q.v.*). In the early days of the colony, Pynchon served as elected assistant (1630–36) and treasurer (1632–34). In 1636 he was put in charge of a group of colonists who wanted to settle along the Connecticut river. The settlement thus founded was named Springfield. after Pynchon's English home. He served as magistrate of Connecticut (1636–38), but, after a falling out with Thomas Hooker, he turned his allegiance back to the Massachusetts Bay colony and was re-elected to the board of assistants from 1642 to 1651. In 1652, Pynchon, who had been denounced as a heretic by the Massachusetts general court because of a tract he had written attacking orthodox Puritan views, returned to England and purchased an estate at Wraysbury, near Windsor, where he died on Oct. 29, 1662.

P'YŎNGYANG, capital city of the Democratic People's Republic of Korea. is located northwest along the Taedong river, 30 mi. from the Yellow sea. The reputed grave of the Chinese sage Kija (1122 B.C.), legendary founder of the city, is north of the city. Artifacts found in graves testify to the high cuitural level of the Chinese colony established near P'yŏngyang in 108 B.C. Walls were built to reinforce the natural protection afforded by the two rivers and hills that surround P'yŏngyang. In this well-fortified area. the Koguryo dynasty (*c.* 37 B.C.–A.D. 668) had its capital, until defeated by the combined forces of China and the Silla dynasty in south Korea. Thereafter P'yŏngyang, continued to be a political and educational centre for northwestern Korea.

Connected with other parts of Korea by rail, motor road and air, commercial activities in P'yŏngyang have been of paramount economic importance. Under Japanese control (1910–45) anthracite coal mines and modern industries were developed, mainly to the south of the city where rail lines converged and to the east across the Taedong river. Hydroelectric power was supplied from plants on the Yalu river and its tributaries and from a thermal plant in the city.

In surrounding areas, heavy industries, such as the iron and steel plant at Kyŏmip'o, cement plants to the east and chemical plants to the north. were developed. In the city an arsenal was established, also railroad workshops and many light industries, for example. textiles, rubber shoes, cigarettes and corn products.

During the Korean war numerous air raids devastated P'yŏngyang. It was captured by UN forces in 1950 but subsequently was lost when Chinese Communist forces entered the war. It was reported that postwar rehabilitation restored many of the industries and that many large new apartments were built.

Pop. (1944) 368.288; (19j6 est.) 500,000. (S. McC.)

PYORRHEA is an obsolete word in dental nomenclature meaning a discharge of pus. Pyorrhea alveolaris signifies pus discharge from the alveoli (tooth sockets), but it represents only the very late stages of the disease. It is a purulent inflammation of the tissue surrounding the roots of teeth with gradual loss of the supporting bone and eventual loosening of the teeth. See also PERIODONTAL DISEASES. (EK. D. C.)

PYRACANTHA, a genus of evergreen thorny shrubs of the rose family (Rosaceae), commonly known as fire thorn. There are six species native from southeastern Europe to central China. The leathery. alternate leaves are usually minutely toothed. The white flowers are in corymbs, followed by red orange or yellow berrylike fruits. P. *coccinea,* P. *crenato-serata* and P. *crenulata* are among the best-known kinds, widely used for foundation plantings and hedges where they are prized for their brilliant fruit in autumn. The plants are easily grown in subtropical and temperate regions (P. *coccinea Lalandii* is the most hardy form) in areas of full sun or partial shade and are not particular as to soil type. (G. H. M. L.)

PYRAMID, in architecture, a monumental structure of stone or brick with a rectangular base and four sloping triangular sides meeting at an apex. Structures of this type were built at various times in Egypt, the Sudan. Ethiopia, western Asia. Greece, Cyprus, Italy, India, Thailand. Mexico and on some islands of the Pacific ocean. The most famous and in many respects most remarkable of them all are the pyramids of ancient Egypt, with which the present article will deal exclusively.

The ancient Egyptian term for pyramid is *mer*. The English word "pyramid" comes from the Greek *pyramis,* pl. *pyramides,* a word of doubtful etymology that may have been derived from the ancient Egyptian *per-em-us,* a term used in a mathematical papyrus to denote the vertical height of a pyramid.

The' pyramids of ancient Egypt were all funerary edifices. Chronologically they cover a time span of 2,700 years ranging from the beginning of the Old Kingdom to the close of the Ptolemaic period; but the time at which pyramid building reached its acme, the pyramid age par excellence, was that commencing with the 3rd dynasty and ending with the 6th (*c.* 2700 to 2300 B.C.). During that 400 years the pyramid was the regular type of royal tomb. It was not, as such, an isolated structure, but was always part of an architectural complex.

The essential components, during the Old Kingdom at any rate, were the pyramid itself. containing or surmounting the grave proper and standing within an enclosure on high desert ground; an adjacent mortuary temple; and a causeway leading down to a pavilion (usually called the valley temple), situated at the edge of the cultivation and probably connected with the Nile by a canal. About 80 royal pyramids have been found in Egypt, many of them, however. have been reduced to mere mounds of debris and were plundered of their treasures long ago.

Early Forms. — The prototype of the pyramid was the mastaba, a form of tomb known in Egypt from the-beginning of the dynastic era. It was characterized by a flat-topped rectangular superstructure of mud brick or stone with a shaft descending to the burial chamber far below it. Zoser (Djoser), the first king of the 3rd dynasty, employing Imhotep (*q.v.*) as architect, undertook, for the first time. the construction of a mastaba entirely of stone. instead of brick; it was 8 m. high and had a square ground plan with sides about 63 m. each. Once completed it was extended on the ground on all four sides. and its height too was increased by building rectangular additions of diminishing size superimposed upon its top. Thus Zoser's original mastaba became a terraced structure rising in six unequal stages to a height of 60 m., its base measuring 120 m. by 108 m. This monument, which lies at Saqqara (Sakkara), is known as the Step pyramid and is probably the earliest stone building of importance erected in Egypt. The substructure has an intricate system of underground corridors and rooms, its main feature being a central shaft 2j m. deep and 8 m. wide, at the bottom of which is the sepulchral chamber built of granite from Aswan. Zoser's Step pyramid rises within a vast walled court j44 m. long and 277 m. wide, in which are the remnants of several other stone edifices built to supply the wants of the king in the hereafter.

A structure of peculiar shape called the Blunted. Bent. False or Rhomboidal pyramid. which stands at Dahshur a short distance south of Sakkara. marks an advance in the development toward the strictly pyramidal tomb. Built by Snefru (Snofru), the founder of the 4th dynasty, it is 188 m. square at the base and approximately 98 m. high. It is peculiar in that it has a double slope; it changes its angle of inclination about halfway up its sides. the lower portion of the monument being steeper than the upper portion. It comes nearer to being a true pyramid than Zoser's terraced tomb just described. A monumental structure at Medum, also ascribed to King Snefru, was a true pyramid. though not originally planned as such. It is uncertain whether it was begun as a mastaba, like Zoser's tomb, or as a small step pyramid. The initial structure was gradually enlarged until it became a gigantic eight-terraced mass of masonry; then the steps were filled in with a packing of stone so as to form a continuous slope. The entire structure was eventually covered with a smooth facing of limestone: a geometrically true pyramid was the final result. In its ruined condition. however, it has the appearance of a three-stepped pyramid rising to a height of about 70 m. The earliest tomb known to have been designed and executed throughout as a true pyramid is the North Stone pyramid at Dahshur, thought by some to have also been erected by Snefru. though the attribution is far from certain. It is about 220 rn. wide at the base and 104 m. high; thus it is nearly as large as the celebrated pyramids of Gizeh.

Pyramids of **Gizeh.**—The three great pyramids of Gizeh stand on a rocky plateau of the desert a few miles southwest of Cairo. They were built by the 4th dynasty Pharaohs Khufu (Cheopsj, Khafre (Khefren or Chephren) and Menkaure (Mycerinus), and came to be. numbered among the seven wonders of the ancient world.

Khufu or Cheeps.-The largest and oldest of them is that of Khufu. now known as the Great pyramid and called "Horizon of Khufu" by the ancient Egyptians. Perhaps the greatest single building ever erected by man, the Great pyramid's almost perfectly square base was, when intact, 230 m. long, thus covering

PYRAMIDS OF GIZEH

Top: Aerial view of the three pyramids at Gizeh. Bottom: Section through the Great pyramid of Khufu, Gizeh, *c.* 2700 B.C.

an area of slightly over 13 ac.; it has been calculated that St. Peter's at Rome, the cathedrals of Florence and Milan, Westminster abbey and St. Paul's cathedral could all be grouped inside that area (E. B. Smith, Egyptian *Architecture* as a Cultural *Expression*). The original height was 146.59 m., reduced now to 137 m. The sides rise at an angle of 51° 52′ and are accurately oriented to the four cardinal points. The core is made of yellowish limestone blocks from the nearby Moqqatam hills, the outer casing (now mostly gone) and the inner passages are of finer limestone from Tura, while the burial chamber is built of huge blocks of granite from Aswan. Approximately 2,300,000 blocks of stone went into this stupendous structure, each weighing an average of 2½ tons.

The monument is a masterpiece of technical skill and engineering ability. The geometrical precision of its layout and the accuracy of the stonecutting are truly amazing, particularly when one considers the colossal proportions of the whole and the size and weight of the blocks employed in it. The internal walls as well as the casing stones that still remain *in situ*, some of which weigh as much as 16 tons, show finer joints than any other masonry in Egypt and possibly in the world. The question of how the pyramid was built has not received a wholly satisfactory answer. The most plausible answer is that the Egyptians. who lacked tackle and pulleys for lifting heavy weights. employed a sloping embankment of brick and earth, which was increased in height and in length as the pyramid rose, and on which the stone blocks were hauled by means of sledges. rollers and levers. According to Herodotus the road for the conveyance of building material from the river to the plateau on which the pyramid stands took 10 years to construct. while the pyramid itself took another 20 years and demanded the labour of 100.000 men. The theories that ascribe prophetic and esoteric meanings to the measurements, angles and proportions of the Great pyramid are wholly devoid of scientific foundation.

The entrance to the Great pyramid is on the north side, about 18 m. above ground level. A sloping corridor descends through the masonry, penetrates the rocky soil and ends in an unfinished underground chamber. From the descending corridor, at a point about 20 m. from the entrance! branches an ascending corridor that leads to a room known as the Queen's Chamber (a misnomer, for there is no evidence to suggest that it was designed for her) and to a great slanting gallery 8.50 m. high and 46.50 m. long. At the upper end of this gallery a low and narrow passage gives access to the burial room proper, usually termed the King's Chamber. Entirely lined and roofed with granite. the King's Chamber is 10.43 m. long. 5.21 m. wide and 5.82 m. high and stands at a perpendicular height of 42.28 m. from the ground. From the chamber two narrow shafts run obliquely through the masonry and reach the exterior of the pyramid; it is not known whether they served a religious purpose or were meant for ventilation. The King's Chamber contains nothing but an empty lidless sarcophagus of red granite without ornament or inscription. Above the room are five compartments separated by horizontal granite slabs, presumably built with a view to diverting the pressure from the ceiling of the burial chamber. There are scanty remains of the subsidiary buildings that once completed the architectural complex of the Great pyramid; they show, however, that the complex comprised the usual elements. The pyramid was surrounded by a temenos wall; attached to the east side of the wall was a temple for the mortuary service of the king, and from this a long causeway descended to the valley. It is highly probable that there was, at the lower end of the causeway. a portico or valley temple, remnants of which may still lie unearthed under the modern village of Kafr es-Sainman.

Khafre and Menkaure.—Next in size in the Gizeh group is Khafre's pyramid. which stands at a higher point of the plateau and thus appears to be taller than the larger and earlier pyramid of Khufu. It was originally 143.50 m. high, and the base 215.25 m. square. A substantial portion of its outer casing still clings round the top and consists of slabs of Tura limestone. whereas the casing blocks that remain at the bottom of the monument are of red granite. The third Gizeh pyramid, erected by Menkaure. formerly rose to a height of 66.50 m.; thus it is less than half as tall as its two towering neighbours.

Other Egyptian Pyramids.— Other noteworthy pyramids belonging to the Pyramid age are the three built at Abu Sir by kings of the 5th dynasty, of which the largest is that of Seferirkare, originally 106 m. square and 70 m. high. The other two are far smaller, but their adjoining mortuary temples appear to have been magnificent buildings decorated with excellent reliefs. some of a historical nature. The pyramids themselves were poorly constructed. and are now in a state of dilapidation.

Pyramid Texts.—The relatively small pyramids of Unas, the last monarch of the 5th dynasty, of four kings and three queens of the 6th and of an obscure 7th dynasty Pharaoh named Ibi. all of which are at Saqqara, are of particular interest because they contain. inscribed upon the walls of their inner chambers. collections of prayers. hymns and spells meant to ensure the welfare of the king or queen in the afterlife. These inscriptions, which are known as the Pyramid texts, form the world's oldest surviving corpus of religious and funerary writings.

Middle Kingdom.—The pyramids of the Middle Kingdom exhibit some structural innovations. A small pyramid mounted on a high podium surrounded by a terraced structure with a forest of columns was the dominant feature of King Nebhepetre Mentuhotep's tomb-temple at western Thebes. The pyramid was solid throughout, it had neither passages nor chambers and consisted of a rubble core cased with limestone. The core of Sesostris I's pyramid at Lisht consisted of a network of stone cross walls with the interspaces filled in with sand and loose blocks, the whole covered by a casing of dressed limestone blocks. This novel and labour-saving mode of construction was subsequently employed in other 12th dynasty pyramids at Dahshur. Illahun and Hawara, in which. however. mud brick was used for the cross walls of the core and as filling material as well. A further characteristic of the Middle Kingdom pyramids is the intricate design of the substructures.

No pyramid appears to have been constructed by any of the kings from the 18th dynasty to the 24th, with one exception: the pyramid-cenotaph erected at Xbydos for Queen Tetisheri by Ahmose I. the founder of the 18th dynasty. Royal tombs of pyramidal form were built once again by the thoroughly egyptianized Ethiopian rulers who held sway over Egypt as kings of the 25th dynasty in the 8th and 9th centuries B.C. They were buried in pyramids which they had erected for themselves in their homeland, at Nuri and Kurru, near the Fourth Cataract, in the north-' ern Sudan.

Tombs of pyramidal design were built for private persons from the Middle Kingdom onward. The earliest have been found at Abydos. They were made of coarse unbaked bricks, coated with mud plaster and whitewashed. The pyramid itself was from 3 to 4 m. high and rested on a shorter rectangular podium. The coffin was deposited in a vaulted chamber which took up most of the interior of the pyramid. In the Theban necropolis, during the New Kingdom, a rather small mud-brick pyramid, sometimes topped with an apex of limestone, was a conspicuous feature of many private tombs.

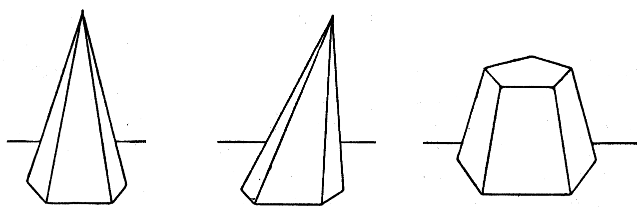
(R. A. Cs.)

PYRAMID, in geometry, a polyhedron of which one face, called the base, is any polygon and the other faces (the lateral faces) are triangles with one vertex in common. The intersections of the lateral faces are called the lateral edges of the pyramid, and their common vertex is called the vertex of the pyramid. The perpendicular distance from the vertex to the plane of the base is called the height or altitude of the pyramid. If the base is a regular polygon the centre of which coincides with the foot of the perpendicular from the vertex to the base, the pyramid is called a regular pyramid. As in the case of prisms (*q.v.*), pyramids are classified according to their bases. The portion of a



REGULAR PYRAMID, OBLIQUE PYRAMID, AND FRUSTUM OF PYRAMID

pyramid and a plane cutting all the lateral edges is called a truncated pyramid; and if the cutting plane is parallel to the base, the truncated pyramid becomes a frustum of a pyramid. The volume of a pyramid with base B and altitude a is $\frac{1}{3}aB$. The volume of a frustum of a pyramid with bases B and B' and altitude a is $\frac{1}{3}a(B + B' + \sqrt{BB'})$.

See SOLIDS, GEOMETRIC.

PYRAMIDION (diminutive of "pyramid"), an architectural term for the copper-gilt casing covering the apex of an obelisk; also its upper termination of pyramidal form.

PYRAMUS AND THISBE, the hero and heroine of a Babylonian love story told by Ovid in his *Metamorphoses*. Their parents refused to consent to their union, and the lovers used to converse through a chink in the wall separating their houses. At last they resolved to flee together. and agreed to meet under a mulberry tree near the tomb of Ninus. Thisbe was the first to arrive. but, terrified by the roar of a lioness, took to flight. In her haste she dropped her veil, which the lioness tore to pieces with jaws stained with the blood of an ox. Pyramus, believing that she had been devoured by the lioness, stabbed himself. Thisbe returned to the rendezvous, and finding her lover mortally wounded, put an end to her own life. From that time the fruit of the mulberry, previously white, was always black.

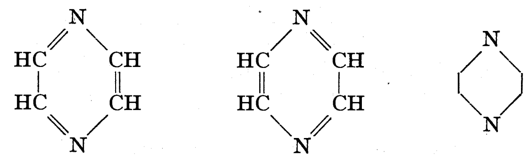
PYRARGYRITE, a mineral consisting of silver sulfantimonite, known also as dark red silver ore, is an important source of the metal. It is closely allied to, and isomorphous with. the corresponding sulfarsenite known as proustite (*q.v.*), or light red silver ore. "Ruby silver" or red silver ore (German *Rotgültigerz*) was mentioned by G. Agricola in 1546, but the two species were completely distinguished by J. L. Proust in 1804.

The composition of pyrargyrite is Ag_3SbS_3. The colour is usually grayish black and the lustre metallic-adamantine; large crystals are opaque. but small ones and thin splinters are deep ruby red by transmitted light; hence the name, from the Greek words for "fire" and "silver." The streak is purplish red, thus differing markedly from the scarlet streak of proustite and affording a ready means of distinguishing the two minerals. The mineral occurs in metalliferous veins with calcite, argentiferous galena, native silver, native arsenic, etc.

The best crystallized specimens are from St. Andreasberg in the Harz mountains and Freiberg in Saxony, Ger., and Guanajuato, Mex. It is found at Cobalt, Ont., and is not uncommon in silver mines in the U.S., in Colorado, Nevada. New Mexico and Idaho, but rarely as distinct crystals; and it has been found in Cornish mines.

PYRAZINES (PIAZINES or PARADIAZINES), in organic chemistry, nitrogenous compounds containing a ring composed of four carbon atoms and two nitrogen atoms, the latter being in the 1:4 relationship.

Pyrazine, $C_4H_4N_2$, crystallizes from water in colourless prisms having a heliotrope odour; it melts at 55° C. and boils at 115° C. Its structure, which is analogous to that of benzene (*q.v.*), may be described as a resonance hybrid between I and II (*see* RESONANCE, THEORY OF).



I II III

As with benzene, the structure is commonly expressed by the conventional symbol III.

Important derivatives of pyrazine include: hexahydropyrazine, or piperazine; the diketopiperazines or amino-acid anhydrides, which are obtained by the elimination of alcohol from the esters of a-amino acids; and the various groups of azine dyes. *See* DYES.

(G. W. WD.)

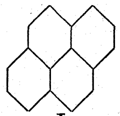
PYRAZOLES, in organic chemistry a series of compounds containing a five-membered ring with three carbon atoms united to two adjacent nitrogen atoms arranged as in formula I, which represents the structure of pyrazole itself.

I II

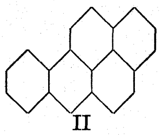
The application in medicine of such pyrazole derivatives as antipyrine and pyramidone, and the production of synthetic dyes of the pyrazoione type, lends a special interest to this chapter of organic chemistry. (G. T. M.; X.)

PYRENE, an aromatic hydrocarbon found with chrysene, in the coal-tar distillate boiling above 360° C. and also in "Stupp" fat, a by-product from the working up of mercury ores in Idria. It was long considered to be yellow but is now known to be colourless when pure. It melts at 156° C. and boils above 360° C.

Chromic acid oxidizes it successively to pyrene-quinone and pyrenic acid; permanganate oxidizes the latter substance to naphthalene-1:4:5:8-tetracarboxylic acid, which confirms the structure I ascribed to pyrene, $C_{16}H_{10}$.



I



II

1,2-Benzopyrene, II. occurs in coal tar to the extent of at least 0.003% and is of interest in that it is apparently the factor mainly responsible for the carcinogenic activity of the tar (*see* CARCINOGENIC CHEMICALS).

BIBLIOGRAPHY.—A. E. Everest, *The Higher Coal-Tar Hydrocarbons* (1927); L. F. Fieser, *The Chemistry of Natural Products Related to Phenanthrene* (1936). (*G. W.* WD.)

PYRENEES, a range of mountains in southwest Europe (Span. PIRINÉOS. Fr. PYRÉNÉES), separating the Iberian peninsula from France, and extending for about 273 mi.. from the Bay of Biscay to Cape Creus, or, if only the main crest of the range be considered, to Cape Cerbltre, on the Mediterranean sea. The main crest constitutes the Franco-Spanish frontier; except in the case of the valley of Aran, which belongs orographically to France but politically to Spain. The Pyrenees are conventionally divided into three sections, the central, the Atlantic or western and the Mediterranean or eastern. The central Pyrenees extend eastward from Canfranc to the valley of Aran. and include the highest summits of the whole chain, Aneto or Pic de Néthou (11.168 ft.) in the Maladetta ridge, Posets (11,073 ft.) and Mont Perdu or Monte Perdido (11,007 ft.). In the Atlantic Pyrenees the average altitude gradually diminishes westward; while in the eastern Pyrenees, except for one break at the eastern end of the Pyrénées Ariégeoises, the mean elevation is maintained, till a rather sudden decline occurs in the extreme eastern portion, the Albères. This threefold division is only valid so far as the elevation of the Pyrenean chain is concerned, and does not represent its geological structure or general configuration. The southern versant of the mountains is the more important. It is recognized that the range must be regarded as an elevated part of the earth's crust, the culminating portion of which is composed of a series of chains which do not coincide with the watershed, but cross it obliquely. Maps by Schrader and de Margerie (*Ann.* du Club *Alpin français,* 1891 and 1892) show the orderly arrangement of these chains. The primitive formations of the range are shown to be almost all continued diagonally on the Spanish side, and the central ridge thus presents the appearance of a series of wrinkles with an inclination (from northwest to southeast) greater than that of the chain as a whole. Other less pronounced wrinkles run from southwest to northeast and intersect the former series at certain points, so that it is by alternate digressions from one to the other series that the irregular crest of the Pyrenees acquires its general direction. Far from having impressed its own direction on the orientation of the chain at large, this crest is merely the resultant of secondary agencies by which the primitive mass has been eroded and lessened in bulk, and though its importance from a hydrographic point of view is still great, its geological significance is practically nil.

Geology.—The Pyrenees are divided into a number of longitudinal zones. The central zone (central Massifs) consists of Primary rocks, Archaean, Cambrian. Ordovician, Silurian, Devonian and Lower Carboniferous (Dinantian) together with great masses of granite. It forms most of the higher summits, but west of the Pic d'Anie it disappears beneath an unconformable covering of Cretaceous deposits. On the French side the central zone is followed by: (1) the zone of Arikge, consisting of Lower Cretaceous and Jurassic beds, together with granitic masses; (2) the zone of the Petites Pyrénées, Upper Cretaceous and Eocene; a thin outcrop of Jurassic and (3) the zone of Aragon, Eocene, and Primary rocks. On the Spanish side, from north to south, are: (1) the zone of Mont Perdu, Upper Cretaceous and Eocene with a thin outcrop of Jurassic; (2) the zone of Aragon, Eocene and (3) the zone of the Sierras, Trias. Cretaceous and Eocene. Although the number of zones is the same on the two flanks, they do not correspond. The zone of the Corbières has no equivalent in Spain, while in France there is no definite zone of Eocene like that of Aragon. The zone of the Petites Pyrénées, however. is clearly homologous with that of the Sierras. On the northern side granitic masses occur in the zone of Arikge among the Jurassic and Lower Cretaceous beds. On the southern side they are not found except in the axial zone, and the Jurassic and Lower Cretaceous deposits are reduced to a narrow band. In spite of these differences between the two flanks. the structure is to some extent symmetrical.

The tectonics of the Pyrenees are still only imperfectly understood. Some authorities consider the structure to be that of a fan, while others have shown that the phenomena of *recouvrement* play an important part there. Large masses of rock have been brought forward upon thrust planes over the edges of other beds with which they originally had no connection. Several cases have been described, but denudation has been carried further than in the Alps, and accordingly the masses overlying the thrust planes have been more completely removed.

The Pyrenean axis was outlined by the Hercynian movement and folding took place along it at the close of the Dinantian epoch and again before the Permian. Later the chain was completely submerged until early Cretaceous times, when the earth movements which raised the present mountains commenced and continued into the Oligocene period. The uplift of the Pyrenees was therefore completed before that of the Alps.

The arrangement of the Pyrenees in chains gently inclined near the centre but longitudinal everywhere else, is illustrated by the courses of the streams which flow down toward Spain. On the French side most of the longitudinal valleys have disappeared, except at the eastern end. On the south the principal streams, after cutting their way through the highest zone at right angles to the general direction of the range. become involved halfway to the plains in great longitudinal folds, from which they make their escape only after traversing long distances.

The total area of the Pyrenees is estimated at 21,044 sq.mi., two-thirds of which is on the southern versant. The mean elevation is placed at 3,930 ft.. while the highest summit Pic de Néthou, is 11.168 ft. above sea level. The passes show a greater altitude than those of the Alps.

Gaves.—Four features of Pyrenean scenery are the absence of great lakes, as in the Alps; the rarity and great elevation of passes; the large number of the mountain torrents locally called *gaves,* which often form lofty waterfalls, surpassed in Europe only by those of Scandinavia; and the frequency with which the upper end of a valley assumes the form of a cirque. The highest waterfall is that of Gavarnie (1.384 ft.), at the head of the Gave de Pau; the Cirque de Gavarnie, in the same valley, is perhaps the most famous example of the cirque formation. Low passes only occur at the two extremities of the range, where the principal highroads and railways run between France and Spain; a third railway (Pau to Jaca via the pass of Somport) was opened in 1928. In the mountains themselves there are only five passes practicable for motors—the Col de la Perche. Col du Pourtalet, Col de Somport, Roncevalles road and the road through the Baztan valley.

Projects for further railway construction. including the building of tunnels on a vast scale, have been approved by the French and Spanish governments.

The metallic ores of the Pyrenees are not important. There are considerable iron mines at Vicdessos in Arikge and at the foot of Canigou in Pyrénées-Orientales. Coal deposits capable of being profitably worked are situated chiefly on the Spanish slopes and the French side has numerous beds of lignite. Mineral springs are abundant and specially noteworthy are the hot springs. The latter, among which those of Bagnkres de Luchon and Eaux-Chaudes may be mentioned, are sulfurous and mostly situated high, near the margin of the granite. The lower springs, such as those of Bagnkres de Bigorre (Hautes-Pyrénées), Rennes (Aude) and Campagne (Aude). are mostly selenitic and not very warm. The use of hydroelectric power has been developed in the 20th century.

The amount of the precipitation, including rain and snow, is much greater in the western than in the eastern Pyrenees, causing a marked contrast between these sections of the chain in more than one respect. In the first place, the eastern Pyrenees are without glaciers, the quantity of snow falling there being insufficient. The glaciers are confined to the northern slopes of the central Pyrenees, and do not descend far down in the valleys, but have their greatest length in the direction of the chain. They form, in fact, a narrow zone near the crest of the highest mountains. There, as elsewhere in Europe, there are evidences of a much wider extension of the glaciers during the Ice Age. The best known glacier is that in the valley of Argelès. The snow line varies in different parts of the Pyrenees from 8,800 to 9.200 ft. above sea level.

A more marked effect of the high rainfall in the west is seen in the vegetation. The lower mountains in the extreme west are very well wooded, but the extent of forest declines eastward, and the eastern Pyrenees are peculiarly wild and naked, more so because there the granite massifs occur. There is a change, moreover, in the type of flora in passing from west to east. In the west the flora, at least in the north, resembles that of central Europe, while in the east it is distinctly Mediterranean in character. The Pyrenees are relatively as rich in endemic species as the Alps, and among the most remarkable instances of this is the occurrence of the sole European species of *Dioscorea* (yam), the *D. pyrenaica,* on a single high station in the central Pyrenees, and that of the monotypic genus *Xatardia,* only on a high pass between the Val d'Eynes and Catalonia. The genus most abundantly represented in the range is that of the saxifrages, several species of which are there endemic.

In their fauna also the Pyrenees present some striking instances of endemism. There is a distinct species of ibex *(Capra pyrenaica)* confined to the range, while the Pyrenean desman or water mole *(Mygale pyrenaica)* is found only in some of the streams of the northern slopes of these mountains, the only other member of this genus being confined to the rivers of southern Russia. Among the other peculiarities of the Pyrenean fauna are blind insects in the caverns of Ariège, the principal genera of which are *Anophthalmus* and *Adelops.*

The ethnology. folklore. institutions and history of the Pyrenean region form an interesting study: see ANDORRA; ARAGON; BASQUE; BEARN; CATALONIA; NAVARRE.

Bertrand, *Sur la structure géol. des Pyre'ne'es* (1911); L. Carez, *Resume' de la géologie des Pyrénées* (1912); on the climate and flora, T. Cook, *Handbook to the Health Resorts of the Pyrenees* (1905).

PYRÉNÉES-ORIENTALES, a *de'partement* of southwestern France, bordering on the Mediterranean and the Spanish frontier, formed in 1790 of the old province of Roussillon and of small portions of Languedoc. Population (1954) 230,285, including many Spaniards. Area, 1,600 sq.mi. The *de'partement* is bounded north by Ariège and Aude, east by the Mediterranean, south by Catalonia and west by the republic of Andorra. Its borders are marked by mountain peaks, on the north by the Corbières, on the northwest and southwest by the eastern Pyrenees, on the extreme southeast by the Albères, which end in the sea at Cape Cerbera. The coast is low lying, with large lagoons. In the lowlands the climate is Mediterranean, with mild winters, dry summers and short and sudden rainstorms. Amélie-les-Bains is much frequented on account of its mild climate and sheltered position. The temperature ranges from 85° to 95° F. in summer, and in winter only occasionally falls as low as 26° or 27° F. The mean rainfall is 27 in. on the coast, but increases toward the hills. The most common wind is the tramontane from the north-northwest. as violent as the mistral of Provence and extremely parching. The marinada blows from the south-southeast.

On the Canigou massif to an altitude of 1,400 ft. are found the orange, the aloe, the oleander, the pomegranate and the olive; the vine grows at an altitude up to 1,800 ft.; next come the chestnut (2.625 ft.), the rhododendron (from 4,330 to 8.330 ft.), pine (6,400) and birch (6,560); while stunted. junipers grow to the summit. The cultivated land in Pyrénées-Orientales is devoted to winegrowing, market-gardening and fruit culture, the production of cereals being comparatively unimportant. The main source of wealth to the *de'partement* is its wine, of which some kinds are strongly alcoholic and others are in request as liqueur wines (Rivesaltes, Banyuls). Early vegetables are grown in the irrigated lowlands, and fruit-growing is chiefly carried on in the river valleys. In iron Pyrénées-Orientales is one of the richest *départements* in France, the greater part of the ore being transported to the interior. Lignite and various kinds of stone are worked. The mineral waters are popular. Amélie-les-Bains has hot springs, chalybeate or sulfurous. In the *arrondissement* of Céret there are also the establishments of La-Preste-les-Bains, near Prats de Mollo, with hot sulfurous springs, and of Le Boulou, the Vichy of the Pyrenees. Near Prades are the hot sulfurous springs of Molitg, and a little north of Mont Canigou are the hot springs of Vernet, containing sodium and sulfur. In the valley of the Ter the sulfurous and alkaline springs of Thuès reach a temperature of 172° F. The baths of Les Escaldas, near Montlouis, are hot, sulfurous and alkaline.

The chief route (Southern railway) across the Pyrenees is from Perpignan through Montlouis, a fortified place, to Puigcerda in the Spanish province of Gerona, through the pass of La Perche, skirting in the French *de'partement* an enclave of Spanish territory. Three other roads run from Perpignan to Figueras through the passes of Perthus (defended by the fort of Bellegarde), Banyuls and Balistres, the last-named being traversed by a railway. The chief towns of the three *arrondissements* are Perpignan, Céret and Prades: there are 18 cantons and 233 communes.

The *de'partement* constitutes the diocese of Perpignan under the archbishop of Albi, and is attached to the appeal court and the *acade'mie* (educational division) of Montpellier and to the region of the 16th army corps.

Perpignan, the capital town and a fortress of the first class, Amélie-les-Bains-Palalda and Elne are the chief towns.

Rivesaltes ([1954] 5,059) is the most populous town after Perpignan (63,863).

PYRETHRUM, formerly considered a genus of the composite family (Compositae) but now regarded as belonging to the genus *Chrysanthemum* of the same family.

The type form, the perennial C. *coccineum,* is the florists' pyrethrum, commonly called painted lady. Large daisylike flowers—deep rose-coloured petals surrounding the yellow centre or disk—are borne on long simple stems above the crown of finely cut leaves. Modern varieties are remarkable for the colours of their flowers—white, lilac and shades of red. They are most welcome ornaments for the flower borders and as cut flowers.

The powdered flower heads of C. *coccineum* and *C. anethifolium* are the source of Persian insect powder, and *C. cinerariaefolium* and *C. marschalli* yield Dalmatian insect powder. Both powders are important insecticide ingredients, commonly called pyrethrum. The active substances in pyrethrum—pyrethrins I and II and cinerins I and 11—are contact poisons for insects and cold-blooded vertebrates. The concentrations of pyrethrum powder used in insecticides are nontoxic to plants and higher animals; therefore, these insecticides find wide use in household and livestock sprays as well as in dusts for edible plants. Pyrethrum is the insecticidal basis of many aerosol "bombs" developed during and since World War II.

These highly aromatic plants, native to southwestern Asia, are now widely cultivated as fine hardy perennial garden subjects; they are grown for pyrethrum powder in Japan, Kenya and California. Seeds sown in the spring in ordinary well-drained garden soil in full sun will produce plants that bloom the following year; plants may be increased by division of the crown after flowering.

(N. TR.)

PYRGI, an ancient town of Etruria, Italy, on the southwest coast, 9 mi. W.N.W. of Caere. The name is Greek (*pyrgoi,* "towers"), and the place of considerable antiquity. Remains of its defensive walls exist in polygonal blocks of limestone and sandstone, neatly jointed. They enclosed a rectangular area about 200 yd. in width and at least 220 yd. in length, and there was a small harbour.

A rich temple of Leucothea there was plundered by Dionysius in 384 B.C. Later it became dependent on Caere, though it was not originally its harbour, for Alsium is a good deal nearer (5 mi. S.). The Romans planted a colony there about 200 B.C.

PYRGOS, a town of Greece. in the department of Elis and Achaea. 43 mi. S.S.W. of Patras. It is connected with its harbour, Katakolon, 7½ mi. distant, with Patras. Olympia and Kalamata (Kalámai), by rail. It has frequently been damaged by earthquakes. Pop. (1951) 17,996. Axis troops occupied it during World War II.

PYRIDINE, a colourless, liquid, nitrogenous base with a pungent odour, belongs to the class of heterocyclic aromatic bases and is the most fully investigated member of that class. It is obtained primarily from the noncondensable coke-oven gases together with the homologous methylpyridines, the picolines. Structurally, pyridine (C_5H_5N) may be regarded as benzene in which one CH group is replaced by N, and in analogy with benzene there is an entire series of compounds derived from pyridine as the parent compound. Although the pyridine nucleus does not occur so frequently in natural products as the derived condensed systems quinoline (*q.v.*) and isoquinoline, it is found in the alkaloids of the pomegranate, lobelia, hemlock, areca and tobacco species and in the B-complex vitamins. nicotinic acid and pyridoxine, compounds of great physiological and commercial significance. Pyridine, the picolines and the higher homologues such as the lutidines (dimethylpyridines) and collidines (trimethylpyridines), which are found in the light-oil and middle-oil fractions from coal tar, are known as the pyridine bases. These bases were first isolated and characterized by T. Anderson in England (1846–57) in his investigation of the oil formed in the dry distillation of bones. α-picoline, the first of these bases to be isolated as a pure substance, had been obtained from the basic constituents of coal tar in 1846. Pyridine and several of its homologues were obtained from bone oil shortly thereafter. Since their formation occurs on dry distillation only if the bones still contain unsaponified fat, they are regarded as end products of the interaction of acrolein formed from the glycerol of the fat and the ammonia from the nitrogenous constituents.

In addition to limited supplies from bone oil, pyridine bases have been commercially available from the condensation products of the coking of coal since 1860. With the advent of the successful use of the by-product oven in Germany in 1881 and its introduction later into the U.S. and England. the coal-tar industry was firmly established, but it was not until spurred by the demands of the growing pharmaceutical industries that, around 1920, the production of pyridine bases from coal tar began to expand rapidly. The pyridine and pyridine bases produced in the coking process are recovered from the ammonia saturator liquor from the ammonium sulfate .crystallization process at the by-product coal-carbonization plant and from a low-boiling fraction (middle oil) of the coal tar at the refining plant. The mother liquors from the distillation of the middle oil, after removal of naphthalene by centrifugation, are extracted with caustic soda, the residual oil distilled. the distillate treated with sulfuric acid, the acid solution neutralized with ammonia. the crude wet pyridine bases dried by azeotropic distillation with benzene and refined by fractional distillation to give some pyridine and picolines, but mainly the higher alkylated pyridine and quinoline bases. The ammonia saturator liquors, containing about 60% of the 0.15 lb. of total pyridine and quinoline bases per ton of coal coked, are saturated with ammonia in a continuous neutralizing still and distilled to give crude pyridine bases containing 15%–20% water, dried by azeotropic distillation with benzene and fractionated to yield pyridine, α-picoline, a β-picoline fraction and a mixture of higher alkylated pyridines.

Synthetic Processes. — The inherent limited production of pyridine bases from the coking industry encouraged commercial development of synthetic processes to meet the increasing demands for intermediates for the manufacture of pharmaceuticals, copolymers and detergents.

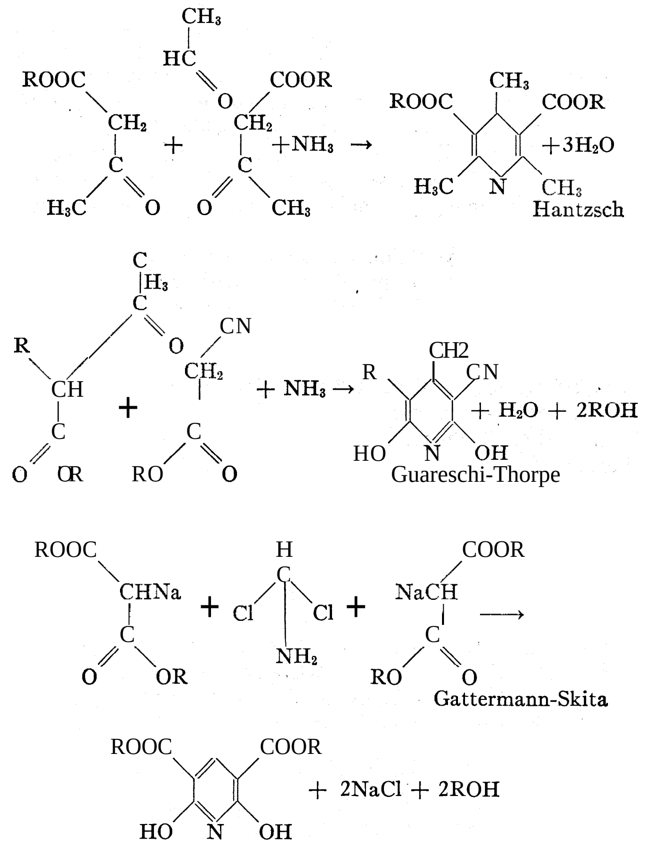
Examples of such processes are given:

1. Since pyrolysis of bones, shale and coal is actually a synthesis of pyridine bases, various pyrolytic syntheses by the vapour-phase reaction of ammonia with acrolein, acetylene derivatives, acetaldehyde or ethyl alcohol and hydrogen by passage of the mixed gases over metal oxide catalysts at 350°–500° C. have been investigated.

2. The reaction of paraldehyde with aqueous ammonia at 200°–250° C., the so-called Chichibabin synthesis, gives 70%–80% yields of 2-methyl-5-ethylpyridine (MEP, aldehyde collidine) with 5%–10% of α-picoline as by-product. MEP is oxidized to the corresponding dicarboxylic acid, which loses carbon dioxide at high temperatures and gives 75% yields of nicotinic acid. Catalytic dehydrogenation of MEP in the presence of an inhibitor gives 2-methyl-5-vinylpyridine (MVP), a valuable monomer for the preparation of synthetic rubbers and acrylonitrile polymers.

3. The classical Hantzsch pyridine synthesis (1882) involves the condensation of two moles of acetoacetic ester with one mole of aldehyde and ammonia (β-aminocrotonic esters can substitute for a mole of acetoacetic ester and ammonia). The dihydropyridine derivatives formed are readily oxidized to a substituted pyridine derivative. or the ester may be hydrolyzed and decarboxylated to bases such as 2.6-lutidine or collidine. Many modifications of this classical synthesis have been developed; the Knoevenagel-Fries condensation substitutes a mole of malonic ester for a mole of acetoacetic ester; the Guareschi-Thorpe modification involves the use of cyanoacetic acid derivatives; and the Gattermann-Skita method employs compounds of the type of dichloromethylamine reacting with diethyl sodiomalonate.

4. The pyridine ring can also be formed by condensation of hydroxylamine with 1,5-diketones, by replacement of the ring oxygen atom of pyrones with an N atom and by expansion of the five-membered ring of pyrroles.



Pyridine syntheses

Properties.—Pyridine is a stable. flammable, colourless liquid volatile with steam, m.p. −42° C.; b.p. 115.3° C. It readily adsorbs moisture to form an azeotrope corresponding to $C_5H_5N.3H_2O$, b.p. 92°–3° C. It is an excellent solvent for most organic compounds and gives conducting solutions with silver, copper, lead, mercury and iron halides, nitrates and acetates. It is a completely water-soluble, weak base (K_b 2.3 × 10^{-9}) forming salts with strong acids and as a tertiary amine yields typical quaternary salts.

The higher alkylpyridinium halides such as N-cetylpyridinium chloride are valuable cationic germicides. Pyridine, toxic to humans in daily doses of 1.8–2.5 c.c. per day, is detoxified in the dog by conversion to N-methylpyridinium hydroxide. Like ammonia it combines with the metals of the transitional groups of the periodic table to give stable co-ordination compounds whose study has been important in the development of the theory of co-ordination and in the stereochemistry of the metals. Oxidation of quinoline to quinolinic acid, in which the benzene ring is destroyed while the pyridine ring remains intact, shows the extreme stability of the ring to oxidation. Consequently, pyridine can be used as a solvent for oxidations and the pyridine homologues are oxidized to the corresponding pyridinecarboxylic acids. Degradation of alkaloids containing pyridine, quinoline and isoquinoline rings by vigorous oxidation often provides valuable structural information.

The similarity of behaviour of pyridine to that of benzene led to the adoption of a formula for pyridine similar to the Kekulé formula for benzene, but, at present, pyridine is considered to be a resonance hybrid of a number of structures which differ in their electronic distribution.

Pyridine is readily reduced catalytically, electrolytically or by sodium in alcohol to the saturated hexahydro derivative piperidine, $C_5H_{11}N$, m.p. −9° to 17° C., b.p. 106° C., d_4^{20} 0.8622, K_b 1.6 × 10^{-3}. It is a colourless liquid with a characteristic ammoniacal odour miscible with water and most solvents. It forms salts, ring-substituted derivatives and well-known N-derivatives such as N-acetyl- and N-benzoylpiperidines. Piperidine can be obtained by the hydrolysis of the alkaloid piperine, occurring in various peppers, and is present in coniine. the poisonous principle of hemlock. as the ester 2-propylpiperidine. In addition to the various synthetic anesthetics such as eucaine, prepared from 4-piperidone, the analgesic meperidine hydrochloride is an important derivative of piperidine. The elucidation of the structure of the pyridine carboxylic acids was an important stage in determining the structure of many alkaloids. The more commercially important carboxylic acids are the vitamin nicotinic acid, and isonicotinic acid, whose hydrazide has found use as an antitubercular agent. A synthesis of isonicotinic acid from citrazinic acid, produced by the amidation of citric acid, has been commercially developed. Other important pyridine derivatives of pharmaceutical interest in addition to vitamin B_6 and sulfapyridine are the urogenital analgesic 2.6-diamino-3-phenylazopyridine hydrochloride, the x-ray contrast materials sodium iodomethamate and iodopyracet and the antihistaminic 2-benzyl (2-dimethylaminoethyl) amino pyridine hydrochloride. In addition to the above-mentioned MEP and MVP, 2-vinylpyridine, used as a monomer for copolymerization with butadiene. styrene and acetonitrile, and the water-repellent stearamidomethylpyridium chlorides, produced by heating stearamide, paraformaldehyde and pyridine hydrochloride in pyridine, are important commercial pyridine base derivatives.

(C. R. AL.)

PYRIMIDINES: see NUCLEIC ACIDS.

PYRITE or IRON PYRITES, also known as fool's gold, is a naturally occurring iron disulfide. This compound is dimorphous, existing both as orthorhombic marcasite (white iron pyrites) and as cubic pyrite (see also MARCASITE). The name pyrite comes from the Greek *pyr,* "fire," in allusion to the fact that it emits sparks when struck by steel.

Nodules of pyrite have been found in prehistoric burial mounds, suggesting their use as a primitive means of producing fire. Wheel-lock guns. in which a spring-driven serrated wheel rotated against a piece of pyrite, were used for a period before the development of the flintlock.

Pure pyrite contains 46.67% iron and 53.33% sulfur. Nickel and cobalt may replace some of the iron, but the frequent presence of gold and copper is probably because of microscopic inclusions of other minerals containing these metals. In some localities auriferous pyrite is an important source of gold, and a considerable quantity of copper is obtained from certain pyrite deposits. In addition to the gold and copper which it may contain, the chief commercial use of pyrite is as a source of sulfur and sulfur dioxide (SO,), used for bleaching and in the manufacture of sulfuric acid (*q.v.*).

Unlike most sulfide ores, which have to be roasted to obtain the SO„ pyrite contains such a high percentage of sulfur that when reasonably pure, and in finely divided form, it will sustain its own combustion without the aid of an external source of heat. For the manufacture of sulfuric acid it is desirable that the ore be as free as possible from arsenic. Because of the availability of much better sources of iron (hematite, goethite and magnetite), pyrite is not generally used as an iron ore, although small quantities of sinter, or cinder from the burning of pyrite, may be mixed with the higher-grade ores.

For many years Spain was the largest producer, the large deposits at Rio Tinto being important also for copper. Other important producers are Japan, the United States (Tennessee, Virginia, California), Canada, Italy, Norway, Portugal and Czechoslovakia. Beautiful crystals are found in many localities, including Cornwall in England; Westphalia in Germany; St. Gotthard in Switzerland; Elba and Piedmont in Italy; and Colorado, New Jersey, Pennsylvania, Arizona and Utah in the United States. (See also NATURAL RESOURCES: Nonmetallic Minerals.)

Pyrite crystals are common and sometimes are beautifully developed. The commonest forms are the cube, octahedron and pentagonal dodecahedron (pyritohedron), either separately or in various combinations. The cubes frequently have very characteristic striations parallel to the cube edges. Penetration twins also occur. The hardness of pyrite is 6 to 6.5 and the specific gravity about 5, varying somewhat with composition. A conchoidal fracture is usually conspicuous on crystals and on coarse-grained material. It sometimes has an iridescent tarnish. The lustre is bright metallic and the streak greenish-black. The colour is brass yellow. In comparison marcasite is a paler yellow, while chalcopyrite (copper pyrites) is much deeper yellow as well as softer.

Pyrite weathers rapidly to hydrated iron oxide, goethite or limonite; pseudomorphs of goethite after pyrite are common. They vary from a thin coating of goethite on the pyrite crystals to those which have been completely altered. This weathering produces a characteristic yellow-brown stain or coating, such as is observed on rusty quartz or in the residual iron deposits, or "gossan" capping on exposed sulfide ore bodies.

Pyrite is a mineral of very wide distribution and it occurs under extremely varied conditions of mineral formation; thus it is said to be a "persistent" mineral. It has been reported as resulting from magmatic segregation; it occurs as an accessory mineral in igneous rocks and has been found as a sublimation product at Vesuvius. Especially important are the hydrothermal deposits, from medium- to high-temperature solutions. Pyrite is very common in vein deposits with other sulfide minerals and with quartz. It is common in sedimentary rocks, such as shale, coal and limestone. Pyritized fossils are of frequent occurrence in these rocks.

Pyrite is found in large deposits in contact metamorphic rocks. Deposits of copper-bearing pyrite are widely distributed and often of great size. They usually occur in or near the contact of eruptive rocks with schists or slates, the presence of the igneous rocks probably being connected genetically with the origin of the ore. Well-developed cubes of pyrite occur with magnetite in a chlorite schist at Chester, Conn.

Pyrite Group.——Pyrite has the composition FeS_2 and is the most important member of the pyrite group, an isomorphous series which also includes bravoite $(Ni,Fe)S_2$; laurite, RuS_2; sperrylite, $PtAs_2$; hauerite. MnS_2; and penroseite, $NiSe_2$. It is also closely related structurally to the cobaltite group, which consists of cobalt and nickel minerals in which the sulfur pairs (S_2) of pyrite are replaced by arsenic-sulfur (AsS) and antimony-sulfur (SbS), resulting in lower symmetry. (L. S. RL.)

PYROGALLOL or PYROGALLIC ACID, a trihydroxybenzene, 1,2,3-$C_6H_3(OH)_3$, first prepared by K. W. Scheele in 1786 by heating gallic acid. It is used as a photographic developer and also as an oxygen absorbent in gas analysis. It has antiseptic properties and is employed medicinally in the treatment of psoriasis. The process of manufacture is still based on Scheele's procedure. Gallic acid with half its weight of water is heated in an autoclave until the pressure reaches 12 atm. and the temperature registered is 175° C. Steam and carbon dioxide are then allowed to escape, leaving in sufficient water to keep the pyrogallol liquid. The cooled solution is decolorized with animal charcoal and evaporated down until the volatile pyrogallol has distilled over into flat iron receivers. The solidified material is purified by repeated distillation or sublimation. Pyrogallol crystallizes in colourless leaflets or needles, melts at 134° C. and is easily sublimed; it distills at 309° C. under the ordinary pressure with partial decomposition. It dissolves in $2\frac{1}{4}$ parts of water at 13° C., and its aqueous solution develops a blue colour with ferrous sulfate containing a little ferric salt.

Its alkaline solution. when exposed to air, rapidly becomes black because of the absorption of oxygen with the production of complex coloured substances. (G. T. M.)

PYROLUSITE, a mineral composed of manganese dioxide of great importance as an ore of manganese. It is used in the manufacture of steel and manganese bronze, as an oxidizing agent in the manufacture of chlorine and in dry cells, in glass, ceramics and paint pigments. It is mined in the U.S.S.R., Germany, Brazil, India, the United States (West Virginia, Georgia, Tennessee, the Lake Superior district and California), Cuba, French Morocco. Ghana and the Union of South Africa. This compound, which has the formula MnO_2, is dimorphous, occurring both as an orthorhombic form: ramsdellite, and as the tetragonal form pyrolusite. The latter is isomorphous with rutile and cassiterite, TiO_2 and SnO_2. Crystals are rare and have a hardness of 6 to 6.5, with a specific gravity of about 5, and have been called polianite because of the mistaken belief that they were essentially different from the commoner massive varieties. Pyrolusite is usually fine grained, often fibrous or powdery, and thus appears to be soft, as low as 2, and marks paper. Because of the fine-grained nature it may contain adsorbed water. The fine fibrous masses. sometimes radially arranged, are very characteristic. The soft powdery material. sometimes called wad (*q.v.*), may or may not be pyrolusite; likewise, harder dense material in crusts or nodules may be pyrolusite or may be one of the psilomelane (*q.v.*) type of minerals. Pyrolusite is formed by the alteration of other manganese ores, such as rhodochrosite and rhodonite, and frequently occurs as a pseudomorph after manganite. Black dendritic growths of manganese dioxide are frequently found in limestones and in moss agate quartz.

See also MANGANESE. (L. S. RL.; X.)

PYROMETER, an instrument for measuring high temperatures (Gr. *pyr*, "fire," *metron*, "a measure"). The term was first used by P. van Musschenbroek to denote an instrument wherein the expansion of a metal rod measured the temperature. Discontinuous thermoscopes, depending on the fusion of a metal or salt, have also been employed.

Prinsep prepared a series of alloys of silver and gold and of gold and platinum whose melting points, as determined by accurate instruments, covered a range of temperature from 954° C. to 1,775° C.. at intervals of from 25° C. to 30° C. By placing ingots in a furnace and observing which one melted a fair idea of the temperature was obtained. Carnelley and Williams employed certain salts of known melting point; however, the Seger's cones, employed in porcelain manufacture, depend on the softening of small cones made of clay.

The instruments employed today depend either on electrical effectsproduced in wires inserted in the furnace and so raised to its temperature, or upon measurements made on the radiation emitted by the furnace.

See also THERMOMETRY for scientific forms.

PYROMORPHITE, a mineral with the composition of lead chlorophosphate sometimes occurring in sufficient quantities to be mined as an ore of lead. Pyromorphite results from the alteration of galena in the oxidized portions of metalliferous veins and is frequently found in the upper levels of lead mines. The name is from the Greek pyr, "fire" and *morphē*, "form"; when a fragment is fused the globule assumes a faceted form on solidifying.

Crystals are common and have the form of a hexagonal prism terminated by the basal planes, often barrel shaped and sometimes hollow at the ends; globular and reniform masses are also found. The formula is $Pb_5Cl(PO_4)_3$ and all gradations in composition exist between pyromorphite and the isomorphous lead chloroarsenate, mimetite (*q.v.*). The resemblance in external characteristics is so close that as a rule it is possible to distinguish them only by chemical tests. Likewise, it is closely related to vanadinite (*q.v.*), in which the PO, is replaced by VO,. Pyromorphite is usually bright green, yellow or brown. sometimes orange-red and rarely colourless and transparent. The lustre is resinous to subadamantine.

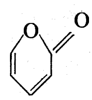
The hardness is 3.5 to 4 and the specific gravity about 7. (L. S. RL.)

PYROMUCIC ACID (FUROIC ACID): *see* FURFURAL.

PYRONES, a term used in organic chemistry to describe a group of six-membered heterocyclic compounds. Pyrones are of tno main types derived from 1:2-pyrone (I) or 1:4-pyrone (II); these two groups are often described as a-pyrones and y-pyrones respectively.

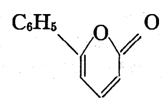
Pyrones are not in general degraded by acids, but in some cases show quite a strong basic character and yield oxonium salts with acids. Like esters, pyrones are hydrolyzed by alkali and this reaction is frequently of importance in the determination of their structure. They do not usually show ketonic properties. but possess a stability similar to that of aromatic compounds and may be regarded as heterocyclic analogues of benzene.

The main interest in the chemistry of pyrones has developed from the recognition that quite a large number of naturally occurring organic compounds are derivatives of either a- or y-pyrones. Thus 6-phenyl-1:2-pyrone (III) has been isolated from cotobark and about 70 natural products are known which are derived from 3:4-benz-1:2-pyrone (coumarin) (IV). Coumarin (*q.v.*) itself (IV) occurs in tonka beans, lavender oil and sweet clover and its pleasant fragrant odour has led to its use in perfumery and in foodstuffs. Umbelliferone (7-hydroxycoumarin) is present in many plants and is obtained by the distillation of the resins from various umbelliferae. Umbelliferone absorbs ultraviolet light and is used in some sun-screen lotions and creams.

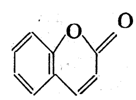


I

II

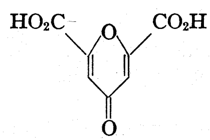


III

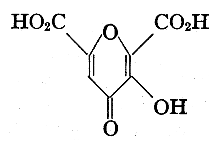


IV

Derivatives of 1:4- or y-pyrone occur very widely in plants and to illustrate the variety of structure which is possible, the structures of chelidonic acid (V) from the lily of the valley and the celandine (*Chelidonium majus*), meconic acid (VI) from opium, maltol (VII) from malted barley and kojic acid (VIII) produced by the growth of the mold, *Aspergillus niger*, may be compared.



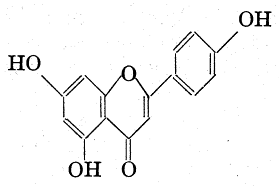
V



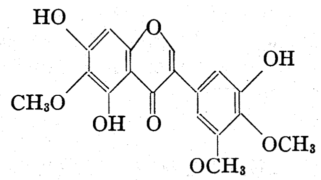
VI

VII VIII

In determining the structure of these natural products advantage is often taken of their reaction with aqueous sodium-hydroxide. The following example illustrates the general method. The structure of chelidonic acid (V) was indicated by its alkaline cleavage yielding acetone and oxalic acid. This structure was confirmed synthetically by condensing acetone with diethyl oxalate. using sodium ethoxide. and then subjecting the intermediate ester ($EtO_2C.CO.CH_2.CO.CH_2.CO.CO_2Et$) to dehydration and acid hydrolysis.



IX



X

More complicated derivatives of 1:4-pyrones occur naturally and are probably the most widely occurring oxygen heterocyclic derivatives. They include flavones, e.g, apigenin (IX) from parsley, isoflavones, *e.g.*, irigenin (X) from orrisroot and xanthones. (W. D. Os.)

PYROPHORIC ALLOYS are groups of alloys nhich when filed or scratched give off bright sparks. Alloys containing about 15% iron and mixtures of rare-earth metals with small amounts of antimony, bismuth, copper and silicon are used in various lighters.

PYROPHORUS, a material which inflames spontaneously on contact with air. Homberg's pyrophorus (Gr. *pyr*, "fire," *phorein*, "to bear"), one of the earliest known, was prepared by heating alum with finely divided carbon or organic material (lampblack, starch or flour) in a closed tube. The product, a mixture of potassium sulfide, aluminum sulfate and carbon, is spontaneously inflammable.

PYROPHYLLITE, a mineral species composed of hydrous aluminum silicate. It resembles talc (*q.v.*) and has long been used in slate pencils and tailor's chalk.

Pyrophyllite was carved by the Chinese people into small images and ornaments and has also been included with talc and under the names agalmatolite and pagodite.

The production and uses of pyrophyllite expanded greatly in the second half of the 20th century. Major uses were in the manufacture of insecticides, ceramics, refractories, roofing, rubber and plaster products.

The most extensive commercial deposits of pyrophyllite are in the Cnited States in the Deep river region of North Carolina, the leading producing state. Pyrophyllite is also mined in California and in Canada. A massive variety produced in the Cnion of South Africa is marketed under the name of "wonderstone." Pyrophyllite occurs in shear zones in highly metamorphosed acid volcanic rocks. Pale-green foliated masses, very like talc in appearance, are found in the Urals, in Switzerland and in other localities.

Pyrophyllite is one of the silicates having a sheet structure, like the micas and chlorites. The composition is $Al_2(OH)_2Si_4O_{10}$; it is isomorphous with talc, $Mg_3(OH)_2Si_4O_{10}$, and the two minerals have similar properties as well as uses.

Both are soft and have a soapy feeling; pyrophyllite occurs in foliated and massive varieties corresponding to foliated talc and soapstone (steatite).

The folia of pyrophyllite have a pronounced pearly lustre and have a perfect cleavage parallel to their surfaces. They are flexible but not elastic and are usually arranged in fanlike or radiating groups.

The foliatkd variety, when heated, exfoliates and swells up to many times its original volume, hence the name pyrophyllite from the Greek *pyr*, "fire" and *phyllon*, "leaf." The colour of both varieties is white or pale green, grayish or yellowish. The specific gravity is 2.8 to 2.9. (L. S. RL.; X.)

PYROTECHNICS: *see* FIREWORKS.

PYROXENE, in mineralogy, the metasilicate group of minerals. Pyroxenes form one of the principal minerals in many common rock types, such as gabbro, norite, peridotite, pyroxenite and basalt. and occur as an accessory mineral in some granites, syenites, diorites and andesites. The pyroxenes are commonly dark green to black, but in the absence of iron they can be light-coloured to white. The physical aspects of the pyroxenes are characterized by two planes of well-developed cleavages 87° or 93° apart. Except for the sodium-containing varieties, which are usually needlelike, the pyroxenes usually occur as short, stubby, prismatic crystals or mineral grains. Some crystal faces are usually present so that, as the crystal is viewed parallel to the cleavages, the crystal outline is commonly an octagon.

Species.—Mineral names are given to the ideally pure compounds. The naturally occurring minerals usually are composed of mixtures of two or more of the ideal compounds because of the extensive degree to which different metal ions are accepted into the structure of a single crystal. The pyroxenes are subdivided into two groups according to the symmetry of their crystals. Orthorhombic symmetry characterizes the enstatite ($MgSiO_3$) to orthoferrosilite ($FeSiO_3$) series. Bronzite and hypersthene are mixtures of enstatite and orthoferrosilite. Monoclinic symmetry characterizes all other pyroxenes, of which diopside. $CaMg(SiO_3)_2$; hedenbergite, $CaFe(SiO_3)_2$; jadeite or jade, $NaAl(SiO_3)_2$; acmite (aegirite), $NaFe^{3+}(SiO_3)_2$; and spodumene, $LiAl(SiO_3)_2$; johannsenite. $CaMn(SiO_3)_2$; and the clinoenstatite ($MgSiO_3$) to clinoferrosilite ($FeSiO_3$) series are representative. The monoclinic pyroxenes augite and pigeonite can be considered as mixtures of the diopside-hedenbergite series with the clinoenstatite-clinoferrosilite series. plus some aluminum.

Spodumene (*q.v.*), as ceramic material and a source of lithium, and jadeite, as an ornamental stone (see JADE), are the only economically important pyroxenes. Crystals of diopside sometimes have been cut as gem stones.

Formations.— Most of the pyroxenes can be formed over a wide range of temperatures; *e.g.*, enstatite, $MgSiO_3$, can be formed theoretically by naturally occurring reactions as low as 95° C. ($MgCO_3 + SiO_3 \rightarrow MgSiO_3 + CO_2$ at 1 atm. CO_2 pressure) and by other natural reactions as high as 1.557° C. Diopside, $CaMg(SiO_3)_2$, can be formed theoretically by naturally occurring reactions as low as 135° C. [$CaMg(CO_3)_2 + SiO_2 + CaMg(SiO_3)_2 + CO$, at 1 atm. CO_2 pressure] and by other natural reactions up to 1,391° C. However, in the high-temperature metamorphic, igneous and volcanic environments the stability fields of the pyroxenes are relatively larger and, therefore, pyroxenes are commoner in these environments and are relatively rare in low-temperature environments.

The formation of pyroxene over a wide range of compositional environments is possible because of its ability to accept a large variety of different metal ions into its structure; it is, therefore, found associated with almost any of the other common silicate minerals. Pyroxenes are found in metamorphic, igneous and volcanic rocks as well as in pegmatites, ore deposits, as in the diamond mines of South Africa (see ECLOGITE), and many meteorites.

Chemical Structures.— In terms of chemistry the pyroxenes are characterized by the structure of the Si-0 groups in the crystal. The relative ionic sizes of Si^{4+} and O^{--} are such that Si^{4+} closely fits in the central space between four O^{--} ions arranged at the corners of a tetrahedron; thus, silicon always surrounds itself with four oxygen ions. Silicon can furnish only four of the necessary eight electrons needed to satisfy the four oxygen ions, and this results in an excess oxygen problem. The various ways in which this oxygen problem is solved form the basis of subdivision of the silicate group of minerals (see also AMPHIBOLE). The pyroxenes are characterized by the following type of solution: If each silicon ion shares two of its four oxygen ions with two other silicon ions, an endless chain results:

```
   O    O    O    O
   |    |    |    |
O–Si–O–Si–O–Si–O–Si–O
   |    |    |    |
```

The remaining demands of the unshared oxygen ions for one electron each can be satisfied by the formation of bonds with other electron-donating ions. In this manner parallel Si-O chains are bonded together by rows of metal ions parallel to the chains. Almost any of the two-valent metal ions or mixtures of them, or a combination of a three- and a one-valent metal ion. are able to bind the chains together. The difference in the ionic sizes oi the metal ions causes slight angular adjustments in the relative position of one Si-O chain to another which result in the two different symmetry classes for the pyroxene group of minerals. Pure nickel, cobalt, zinc or iron pyroxenes or mixtures of them are not known to form, although these elements can be present in small amounts. The reason for the absence of such pyroxenes is that the pyroxene structure becomes unstable in the presence of large amounts of these high bonding energy ions.

For discussion of mineralogical and crystallographic concepts used in this article *see* MINERALOGY.

See also GEOCHEMISTRY: *Geochemistry of the Lithosphere: Crystallization of Magma;* SILICON: *The Silicates.*

(G. W. DEV.; X.)

PYROXENITE, a rock consisting essentially of minerals of the pyroxene group, such as augite and diallage (a diopside), hypersthene, bronzite or enstatite. Names have been given to members of this group according to their component minerals; *e.g.,* pyroxenite (augite), diallagite (diallage), hypersthenite (hypersthene), bronzitite (bronzite) and websterite (diallage and hypersthene).

Closely allied to this group are the hornblendites, consisting essentially of hornblende.

PYRRHO OF ELIS *(c.* 365–275 B.C.), the Greek philosopher from whom Pyrrhonism takes its name, had as a teacherrinaxarchus of Abdera, from whom he learned the view—a one-sided development of the system of Democritus—that every perception and judgment of value is relative. He joined the expedition of Alexander the Great and reached India, where he was able to see for himself, in the fakirs, an example of the total indifference to circumstances for uhich the Greek philosophers often yearned. About 330 B.C. he established himself as a teacher in his native Elis. His reputation spread to other parts of Greece, and later sceptics looked to him as their founder. Other philosophers before him had proclaimed that nothing is knoun with certainty; Pyrrho seemed to have carried doubt to its logical extreme. He wrote nothing, but some impression of his arguments can be gained from the fragments of the poems of Timon of Phlius (*q.v.*). The aim of the wise man is to become imperturbable and proof against the changes of fortune; he must utterly abstain from judgment and be prepared to doubt even sense-perception, for this is not the infallible test of truth which others have supposed it to be; however, he must equally not distrust perception on principle, for this would imply that it is known or judged to be false. A placid acceptance of things as they appear. fortitude against pain and indifference to external fortune seem to be the practical consequences. The sceptics of the New Academy (Arcesilaus and Carneades) professed to derive their scepticism from Socrates, not from Pyrrho.

See also SKEPTICISM. (D. J. A.)

See L. Robin, *Pyrrhon et le scepticisme grec* (1944).

PYRRHOTITE, a mineral species consisting of iron sulfide. Small amounts of nickel and cobalt are often present; the nickeliferous pyrrhotite of Sudbury, Ont., with its associated pentlandite (*q.v.*), is the most important source of nickel. The name is from the Greek *pyr,* "fire," and *rhotes,* "redness." The formula is $Fe_{1-n}S$, in which n may vary from o to 0.2. The variety troilite, having a composition near FeS, has been identified as an important constituent of some meteorites *(see* METEORITES: *Mineralogical Composition).* Crystals of pyrrhotite have the form of hexagonal plates bounded at their edges by faces of a hexagonal prism and pyramids, which are deeply striated horizontally More frequently, however, the mineral is massive, with a familiar or granular structure. It is magnetic, sometimes with polarity, and is therefore often called magnetic pyrite. The colour is bronze yellow, the lustre metallic and the streak grayish black. The hardness is 4 and the specific gravity 4.58–4.64. Pyrrhotite occurs in metalliferous veins and as grains and plates disseminated through various rocks. *See* also NICKEL.

PYRRHUS *(c.* 318–272 B.C.), king of Epirus in ancient Greece, whose costly military successes gave rise to the phrase, "Pyrrhic victory," nas the son of Aeacides and a member of the royal family of the Molossians. He claimed descent from Pyrrhus, the son of Achilles, and was also connected with the royal family of Macedonia through Olympias, the mother of Alexander the Great.

While still a boy, he became king of the wild mountain tribes of Epirus, and learned the art of war in the school of Demetrius Poliorcetes and his father Antigonus. He fought by their side at the battle of Ipsus in Phrygia (301), in which they were decisively defeated by the combined armies of Seleucus Nicator and Lysimachus. Soon afternard he was sent to the court of Ptolemy of Egypt at Alexandria as a pledge for the faithful carrying out of a treaty of alliance between his brother-in-law Demetrius and Ptolemy. Through Ptolemy, whose stepdaughter Antigone he married, Pyrrhus was enabled to establish himself firmly on the throne of Epirus, and became a formidable opponent to Demetrius, who was now king of Macedonia and the leading man in the Greek world. He defeated one of Demetrius' generals in Aetolia, invaded Macedonia and forced Demetrius to conclude a truce with him For some time he occupied most of Macedonia under the terms of the truce, but in 286 Lysimachus defeated him at Edessa and drove him back into Epirus.

In 281 Tarentum, in southern Italy, asked his assistance against Rome. Pyrrhus went with about 25,000 men, and might, with more wholehearted assistance from the Greek cities, have been a fatal obstacle to the growth of Rome, faced with Etruscans and Gauls in the north as well as this reinforced opposition in the south. Greeks and Romans met at Heraclea (280), and Pyrrhus, with the advantage gained by his cavalry and elephants, completely defeated the consul M. Valerius Laevinus, but at the cost of very heavy losses. He advanced on Rome through Latium, but the towns uere all garrisoned, and though the senate was inclined to agree to terms, the speech of Appius Claudius the censor decided them against it. Cineas, Pyrrhus' minister, was sent back with a refusal to negotiate as long as Pyrrhus' troops were in Italy

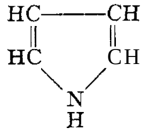
In 279 Pyrrhus won another costly victory at Asculum in Apulia. He then went to Sicily with the idea of driving the Carthaginians out; his military operations were successful, and Rome and Carthage united in an alliance against him, nhile his despotic methods alienated the Sicilian cities. He stayed three years in Sicily and then returned to Italy, but the Greek cities now entirely failed to support him and he was completely defeated at Bcneventum in 275. He left Italy, saying, "what a battlefield I am leaving to Rome and Carthage"—a remark of some insight. The rest of his life was passed in wars at home. including a victory over Antigonus Gonatas, and an unsuccessful expedition into Sparta at the invitation of Cleonymus in 273. He was killed in 272 in a night skirmish in a street in Argos.

Pyrrhus wrote a history of the art of war, which is praised by Cicero and quoted by Dionysius of Halicarnassus and Plutarch, the chief ancient authority for his life.

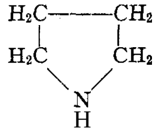
PYRROLE. A colourless oil whose existence in coal tar was surmised by the German chemist F. F. Runge in 1834 but which was first isolated and studied by the Scottish chemist Thomas Anderson in 1857. The name is derived from Greek and Latin roots meaning "fiery oil." from the fiery red colour imparted by pyrrole to a wood splint previously moistened nith acid Pyrrole is of great historical interest because of the fact that one of its derivatives, indole (q *v.*), is the fundamental building block of the regal dye of the ancients, Tyrian purple. as nell as of the most important ancient and medieval dye, indigo. Pyrrole is also the structural unit of chlorophyll, the green portion of the pigment of leaves; of heme, the red portion of the pigment of blood, of the pigments of the bile; and of the pigments of numerous types of bacteria, algae and other living organisms. Pyrrole pigments are found in coal. petroleum and similar substances derived from plant and animal sources.

The colouring matters derived from pyrrole are the objects of extensive scientific investigations because their functions in plants and animals are so critically important to life. Atmospheric carbon dioxide, fixed by photosynthesis involving chlorophyll, is the ultimate source of most of our food and fuel, and the efficiency of transportation of oxygen by the blood pigment hemoglobin is indispensable to the rapid motions of higher animals. In addition, these pyrrole pigments are probably produced by living organisms in greater tonnage than any other class of pigments. Derivatives of pyrrolidine, which is completely reduced pyrrole, occur in alkaloids, such as cocaine and nicotine, and as building blocks of proteins in the form of the amino acids proline, hydroxyproline and tryptophane.

Pyrrole boils at 131° C., is slightly lighter than water (density 0.9669) and has the composition C_4H_5N. It is sparingly soluble in water but dissolves in alcohol, ether and many other solvents. Its structural formula was assigned correctly by the German chemist Adolf von Baeyer in 1870 in the course of his classical investigations on the structure of indigo. It is conventionally represented as in diagram I; diagram II is the formula for pyrrolidine:



I



II

Pyrrole is characterized by great chemical reactivity, being slowly destroyed by air with the formation of a brown pigment. It is also destroyed by strong acids, being partially converted into indole, and it enters into combination with a wide variety of chemical reagents. It has been obtained from bone oil and by destructive heating of proteins but is now available commercially from acetylene, formaldehyde and ammonia. Pyrrole is moderately toxic, acting as a nerve poison. Certain of its derivatives have found a limited application in medicine. Their main use is in organic chemical synthesis for the study of the structure and functions of the naturally occurring pigments.

The most important pyrrole derivatives are the porphyrins (from the Greek for purple) and the chlorines (from the Greek for yellow-green) and their metallic compounds. A typical iron-porphyrin compound is hemin, the oxidized form of the coloured portion of the blood pigment.

See Hans Fischer and Hans Orth, *Die Chemie des Pyrrols* (1934–40). (A. H. Cn.; X.)

PYRUVIC ACID or Pyroracemic Acid is an extremely reactive organic acid which occupies a central place in cellular metabolism. Formed duirng sugar fermentation, it may be oxidized to acetic acid or it may be reduced: (1) to lactic acid (glycolysis); (2) to ethyl alcohol (alcohol fermentation) through decarboxylation to acetaldehyde; (3) to malic acid by CO_2 fixation; or (4) to alanine by NH_3 fixation. The oxidation of pyruvic acid in living cells requires the presence of vitamin B_1 (thiamine) and its concentration in the blood increases in vitamin B_1 deficiency.

Pyruvic acid, $CH_3COCOOH$, is best prepared by heating together a mixture of six parts of fused potassium hydrogen sulfate and four parts of tartaric acid at 210°–220° C. The distillate is fractionated under reduced pressure, the yield being 50%–55%. Pyruvic acid was first obtained by J. J. Berzelius in 1835 by the dry distillation of tartaric acid. It is a colourless liquid boiling at 75°–80° C./25 mm. and at 165° C./760 mm. with partial decomposition; on redistillation at 60° C./10 mm. it forms crystals which melt at 13.6° C. With phenylhydrazine it gives crystalline phenylhydrazone and it combines additively with prussic acid and with alkali bisulfites. It forms mercaptals with mercaptans and is oxidized to acetic acid with hydrogen peroxide in neutral and with ceric sulfate in acid solutions. Its most characteristic reaction with aldehydes and aromatic amines (Doebner's reaction) leads to the production of arylcinchonic acids. It can be tested for by reduction to lactic acid through the action of magnesium and an acid.

PYRZYCE (Ger. *Pyritz*), a town in the province of Szczecin, Pol., formerly in the Prussian province of Pomerania, Ger., 16 mi. S.W. of Starogród by the railway to Kostrzyn. Pop. (1939) 11,200, (1950) 2,694. It became a town in 1150. Near the town was the spring in which Otto, bishop of Bamberg, baptized the first Pomeranian converts to Christianity in 1124.

PYTHAGORAS (fl. 5th century B.C.), a noted Greek sculptor of Rhegium, a contemporary of Myron and Polyclitus and their rival in making statues of athletes. One of these, that of the boxer Euthymus of Locri, can be dated at 472 B.C. He was born at Samos and migrated in his youth to Rhegium, in Italy. He made a statue of Philoctetes notable for the physical expression of pain, an Apollo shooting the Python at Delphi and a man singing to the lyre. His technical improvements went far to ending archaic stiffness. No existing work can be certainly attributed to him, but the "Apollo on the Omphalos" at Athens and the "Choiseul-Gouffier" Apollo in the British museum have been identified as copies of his statue of Euthymus.

PYTHAGORAS AND PYTHAGOREANISM. The Greek philosopher Pythagoras, who was active *c.* 530 B.C. and gave his name to an order of scientific and religious thinkers, was born in Samos. Reputed by legend to have travelled extensively, he was certainly in contact with ideas native to Asia Minor. The historically important part of his career begins with his migration to Crotona, a Dorian colony in southern Italy, about the year 529. According to tradition, he was driven from Samos by the tyranny of Polycrates. At Crotona he became the centre of a widespread organization which was, in its origin, a religious brotherhood or an association for the moral reformation of society rather than a philosophical school. The Pythagorean brotherhood had much in common with the Orphic communities which sought by rites and abstinences to purify the believer's soul and enable it to escape from the "wheel of birth." Although its aims may have been primarily those of a religious order rather than a political league, it actively supported aristocracies. Indeed it gained control over many Western Greek colonies; and it was politics which led in the end to the dismemberment and suppression of the society. The first reaction against the Pythagoreans, led by Cylon, was able to bring about the retirement of Pythagoras to Metapontum, where he remained until his death at the end of the 6th or the beginning of the 5th century. The order appears to have continued powerful in Magna Graecia until the middle of the 5th century B.C. when it was violently trampled out, its meetinghouses being everywhere sacked and burned. Those Pythagoreans who survived took refuge abroad: Lysis went to Thebes, where he became the instructor of Epaminondas; and Philolaus, who according to tradition wrote the first exposition of the Pythagorean system, also lived at Thebes at the end of the 5th century. Philolaus, however, and some others were afterward able to return to Italy. Tarentum (Taras) then became the chief seat of the school: Archytas, the friend of Plato, was prominent there both as a philosopher and as a statesman in the first half of the 4th century B.C. About the middle of that century, however, the Pythagoreans disappeared as a philosophic school.

Philosophical Beliefs.—There seems to have been a split in the school, dating from about the middle of the 5th century B.C. On the one hand, there were "the mathematicians," represented by such names as Archytas and Aristoxenus, who were interested in scientific studies, particularly in mathematics and in musical theory; on the other, there were the more conservative members of the school, who concentrated on the moral or religious precepts and were called *akousmatikoi* (from *akousmata*, "oral traditions"). It is probable that both the scientific and the religious elements were present from the start in Pythagoreanism. Most of the evidence for the beliefs of Pythagoras himself is doubtful. It was customary for his later disciples to claim the master's authority indiscriminately; and Aristotle speaks only vaguely of "the so-called Pythagoreans," "the Italians," and so on. The doctrines that can reasonably be attributed to Pythagoras may however be summarized as follows:

1. First and foremost is his account of the soul. He believed in the transmigration of the individual soul from one body to another, even of a different species. "Do not hit him," he once

said to a man who was beating a puppy, "it is the soul of a friend of mine. I recognized it when I heard it cry out." But if a man led a pure life, his soul might be released from all flesh. It is possible that this held good only for the exceptional man, a seer such as Pythagoras himself or Empedocles (*q.v.*). But the view of the body as the tomb or prison of every soul, with philosophy as the meditation of death and the release from the body, seems to be attributed to a Pythagorean in Plato's Phaedo (61 D ff.). Its importance in the history of religion need not be underlined. All this must be set in the framework of the belief, brought to the Greeks from Asia Minor. which ascribed to souls a future life in the starry heavens. For nearly all Pythagoreans the actual composition of the soul (*e.g.*, out of fire or air. the warmth or breath of life) gave it a natural affinity with the stars or the sky.

2. The pure life consisted in obeying precepts which are mostly recognizable as primitive taboos; *e.g.*, not to eat beans, not to poke a fire with iron. More strictly moral were the three questions which had to be put to oneself every evening: In what have I failed? What good have I done? What have I not done that I ought to have done? Of external aids to purification one of the most important was music.

3. The fascination of numbers for the school must go back to its founder. His greatest discovery was probably the dependence of the musical intervals on certain arithmetical ratios of lengths of strings at the same tension, 2:1 giving the octave, 3:2 the fifth and 4:3 the fourth. It must have contributed powerfully to the idea that "all things are numbers." Though not necessarily to be attributed to Pythagoras, this idea was the philosophical kernel of Pythagoreanism. Early forms of it probably did not distinguish between things being numbers, having numbers and merely resembling them. But in Aristotle's account of it (Metaphysics, i. ch. j and 8) numbers were the elements of everything. in the way that fire, water, etc. had been for other thinkers. The whole heaven formed a '(musical scale and number"; and even such things as reason, justice and marriage were identified with distinct numbers. The elements of numbers themselves were "the odd" and "the even" or "limit" and "the unlimited." which in Aristotle's view represent a primitive insight into the notions of form and matter. These two pairs headed a list of ten pairs of fundamental "opposites." the remaining eight being "one" and "many," "right" and "left," "male" and "female,)' "rest" and "motion," "straight" and "curved," "light" and "darkness." "good" and "evil," "square" and "oblong." It was a philosophy of metaphysical and moral dualism: but it came to see the universe as a harmony of opposites, in which "the one" generated the number series, or "limit" successively imposed itself on "the unlimited."

Thus music and the belief in a stellar heaven (especially if this had originally been associated with Babylonian astrology) are two links between the religious content of Pythagoras' outlook and the mathematical and astronomical studies made later by the scientific wing of his school. The first to have made a comprehensive system may have been Philolaus. Thereafter the three doctrines outlined above would have been common to the *akousm*-atikoi and to the "mathematicians" alike. Their development by the latter can be seen in what follows. Much of it had been known to the Babylonians.

Pythagorean Arithmetic. — The unit or 1 (which was not strictly a number) was assigned or equated to the point, 2 to the line, 3 to surface and 4 to solid. The assertion of J. Burnet and many others, that numbers were regularly held to be spatially extended, is open to question. The normal account seems to have been that the point "flowed into" the line, the line into surface, and so on. But numbers were certainly represented by arrangements of pebbles in triangles, squares, etc.; and the practice assisted the geometrical expression of arithmetical theorems. which was due fundamentally to the existence of both rational and irrational fractions, since these contradicted the strict definition of numbers as magnitudes. The holy tetractys, by which the later Pythagoreans used to swear, was a figure of this kind  representing the triangular number 10 and showing at a glance its composition as $1+2+3+4$. To add a row of five dots gives the next triangular number nith j as the side, and so on. showing that the sum of any number of the series of natural numbers beginning with 1 is a triangular number. The sum of any number of the series of odd numbers beginning with 1 is similarly seen to be a square; thus 3 and 5 added successively to 1 give figures of the kind  called gnomons. If we take the series of even numbers, we see that the sum of any number of them beginning with 2 makes an oblong number 
The successive odd numbers after 1 were themselves called gnomons because the addition of each to the sum of the preceding ones (beginning with 1) makes a square number into the next larger square. If the gnomon added to a square is itself a square number, there is a square number which is the sum of two squares; thus $1+3+5+7=16$ or 4^2, and the addition of 9 ($=3^2$) gives 25 or 5^2, that is, $3^2+4^2=5^2$. Pythagoras himself is credited with a general formula for finding two square numbers the sum of which is also a square, namely (if m is any odd number). $m^2+\{\frac{1}{2}(m^2-1)\}^2=\{\frac{1}{2}(m^2+1)\}^2$. This connects itself with the theorem of the square on the hypotenuse of a right-angled triangle, which tradition universally associates with the name of Pythagoras. In the case of the isosceles right-angled triangle the ratio of the hypotenuse to either of the other sides is what is written as $\sqrt{2}$, which is irrational in the sense that its value cannot be expressed exactly as a ratio between numbers. It was the Pythagoreans who discovered the irrationality of $\sqrt{2}$ and not only this but also the method of finding ever closer approximations to the value of $\sqrt{2}$ by forming the series of the so-called side and diagonal numbers that satisfy one or other of the two equations $zx^2-y^2=+1$ and $ax^2--y^2=-1$, when x stands for the length of one of the equal sides and y for that of the hypotenuse. The method depends on the proposition $2x^2-y^2=(2x+y)^2-2(x+y)^2$, whence it follous that, once one set of values for x and for y has been found such that $2x^2-y^2=+1$, then $2(x+y)^2-(2x+y)^2=-1$. the higher numbers $x+y$ and $2x+y$ in the latter equation taking the place of the x and of the y in the original; then, vice versa. with the higher numbers substituted, we may proceed from $2x^2-y^2=-1$ to $2(x+y)^2-(2x+y)^2=+1$, where $x+y$ and $2x+y$ stand for a second set of higher numbers; and so ad *infinitum*. Hence is derived the infinite series $\frac{1}{1}, \frac{3}{2}, \frac{7}{5}, \frac{17}{12}, \frac{41}{29} \ldots$ giving progressive approximations to $\sqrt{2}$.

Contributions **to Geometry.**—Other contributions to geometry were made by the Pythagoreans. In the first place Pythagoras. it is said. himself formulated definitions in geometry. Secondly, the Pythagoreans proved that the sum of the three angles of any triangle is equal to tno right angles: there is their proof, which, like Euclid's, uses the property of parallels; hence they knew the theory of parallels. Thirdly, they discovered the powerful method in geometry of the application of areas (cf. Eucl. i. 44, 45), including application with excess and defect (cf. Eucl. vi. 28. 29), which amounts to the geometrical solution of any quadratic equation in algebra having real roots. Fourthly, they discovered the theory of proportion, together with the arithmetic, the geometric and the harmonic means. The theory and the arithmetic mean appear in the middle terms of the proportion $a : \frac{a+b}{2} = \frac{2ab}{a+b} : b$, a particular case being $12:9=8:6$, from the terms of which the three musical intervals can be obtained. The Pythagorean theory of proportion was arithmetical (after the manner of Euclid, book vii) and did not apply to incommensurable magnitudes; it must not therefore be confused with the general theory due to Eudoxus, which is expounded in Euclid v. Fifthly, it was claimed that Pythagoras discovered the construction of the five regular solids. It was more probably Theaetetus who (as we read elsewhere) discovered the octahedron and the icosahedron; but the Pythagoreans were clearly acquainted with the pyramid or tetrahedron and the dodecahedron. The construction of the dodecahedron requires that of a regular pentagon. which again depends (as in Eucl. iv, 10, 11) on the problem of Eucl. ii. 11, about the division of a line in extreme and mean ratio. a particular case of the application of areas. The assumption that the Pythagoreans could construct a regular pentagon is confirmed by the fact that the pentagram, the triple interwoven triangle, or the star-pentagon, was used as a symbol of recognition between the members of the school and was called by them health. Sixthly, the Pythagoreans discovered how to construct a rectilineal figure equal to one and similar to another rectilineal figure.

To sum up, it may be said that Pythagorean geometry covered the bulk of the subject matter of Euclid's books i, ii, iv, vi (and probably iii), with the qualification that the Pythagorean theory of proportion was inadequate in that it did not apply to incommensurable magnitudes.

Pythagorean Astronomy.—It remains to speak of the Pythagorean astronomy. Pythagoras was one of the first to hold that the earth and the universe are spherical in shape. He appreciated that the sun. the moon and the planets have a motion of their own independent of the daily rotation and in the opposite sense. It is improbable that Pythagoras himself was responsible for the astronomical system known as Pythagorean, which deposed the earth from its place in the centre and made it a planet like the sun. the moon and the other planets; for Pythagoras apparently the earth was still at the centre. The later Pythagorean system is attributed alternatively to Philolaus and to Hicetas, a native of Syracuse. The system may be thus described. The universe is spherical in shape and finite in size. Outside it there is infinite void. which enables the universe to breathe, as it were. At the centre is the central fire, wherein is situated the force which directs the movement of the universe. Within the universe bodies revolve around the central fire as follows: nearest to the central fire is the counterearth, which always accompanies the earth; next in order (reckoning from the centre outward) is the earth, then the moon, then the sun: then the five planets and then. last of all, the sphere of the fixed stars. The counterearth, revolving in a smaller orbit than the earth, is not seen by us because the hemisphere in which we live is always turned away from the counterearth. This part of the theory involves the assumption that the earth rotates about its own axis in the same time as it takes to complete its orbit around the central fire; and as the latter revolution was held to produce day and night, it is a fair inference that the earth was thought to revolve around the central fire in a day and a night, or in 24 hr. The counterearth may have been invented to explain the comparative frequency of lunar eclipses. The system amounts to a first step toward an anticipation of the Copernican hypothesis, and Copernicus himself referred to it as such.

Later **Pythagoreanism.**—A survival (sometimes called Neopythagoreanism) of Pythagorean practices and doctrines, particularly that of immortality, is attested in Rome from the 1st century B.C. As a philosophical theory it merged with Platonism. But it was also a kind of cult; and the frescoes in the underground basilica of the Porta Maggiore have been claimed as Pythagorean. In imperial times there were Pythagoreanizing philosophers and mathematicians in Alexandria, in Syria and elsewhere. Plato's immediate successors had already made a partial return to more purely Pythagorean theory; and Neoplatonists. such as Iamblichus in the 4th century A.D., drew on them as well as on more recent, forged Pythagorean writings (*e.g.*, the *Orphic Hymns*).

For Christian Fathers, such as Ambrose, Pythagoras was an authoritative figure because he was thought to have been a Jewish intermediary between Moses and Plato. By the 16th century he was liable to be reckoned, and his beliefs cited, according to the interests of the writer, as a poet, as a magician, as the father of the Cabbala, as a mathematician or as a champion of the contemplative life. He is depicted, characteristically an old man, among the philosophers, in Raphael's "School of Athens." *See* ARCHYTAS; PHILOLAUS.

(T. L. H.; A. C. LD.)

PYTHEAS OF MASSALIA (Marseilles), Greek explorer and geographer of *c.* 300 B.C., was the first Greek to visit and describe the Atlantic coast of Europe (including Britain). His main work, *On the Ocean,* is lost; citations in later authors do not give a coherent picture of it or even show exactly how far he traveled. There is one fragment of a second work, perhaps a complementary description of the Mediterranean coast of Europe. Pytheas' writings were extensively used by later geographers, notably Eratosthenes and Poseidonius; but he was attacked as a Munchhausen by equally eminent men, particularly the historian Polybius (followed by Strabo). Modern scholars have rehabilitated him, often to excess. He certainly visited some northern countries, and his comments on small points, *e.g.,* on the native drinks made from cereals and honey and on the use of threshing barns (contrasted with open-air threshing in the Mediterranean sun), show acute observation. His scientific interests appear from his calculation of the ratio of the hand of a sundial to its shadow at the summer solstice, and from his notes, sometimes rather puzzling, on the length of the longest day as he traveled northward. These observations were used by his successors (not, it seems, by Pytheas himself) for establishing parallels of latitude. He also noticed that the Pole star is not at the true pole and that the moon affects the tides.

Pytheas is at his worst in giving measurements, whether in day's journeys (five from Cadiz to Cape St. Vincent, three from Ushant to the French coast) or in stadia (40,000, *i.e.,* over 4,000 mi., for the circumference of Britain). His Thule—the northernmost inhabited island, six days' sail from northern Britain and extending at least to the Arctic circle—cannot be identified. It may be Norway (but not Iceland).

Pytheas was too ready to believe what he was told: the story of the Stagnant sea bounding the earth in the far north—a mixture of earth, air and water, like a "sea-lungs" (jellyfish?)—deserves Polybius' ridicule. His work laid a valuable foundation for greater men, though, as Polybius saw, he often misled them.

(E. BA.)

PYTHIAS, KNIGHTS OF, a fraternal and benevolent order of secret character, founded in Washington, D.C., Feb. 19, 1864, and chartered by a special act of congress. In the second half of the 20th century the order maintained more than 50 grand lodges or grand domains in the states of the United States and in provinces of Canada. There were also about 3,000 local or subordinate lodges. The governing body is the Supreme Lodge. There were four recognized auxiliary bodies, the military department, the Dramatic Order Knights of Khorassan, the Junior Order Princes of Syracuse and the Pythian Sisters which, founded in 1888, was open to all women relatives of members of the Knights of Pythias.

PYTHIUS (PYTHIOS, PYTHEOS), noted Greek architect of the 4th century B.C. With the architect Satyrus he built the great Mausoleum at Halicarnassus (353 B.C.), one of the seven wonders of the world, ordered by Queen Artemisia as a tomb for her husband. Mausolus. A number of restorations of the mausoleum were made in the 19th century. Pythius cultivated the Ionic style, in which he also constructed the temple of Athena at Priene. The dedicatory inscription, which is in the British museum. records that the founder was Alexander the Great. Pythius is mentioned by Pliny and Vitruvius.

PYTHON, a snake of the family Pythonidae, and more especially any one of the species of the genus *Python.* The snakes of this genus are large, and its various species are found throughout the tropics of the old world. The snakes of the python family are distinguished from the boas (*q.v.*), with which they are often confused, by the presence of the supraorbital bone in the skull. As in the boas, vestiges of the hind limbs are present, visible externally as a pair of claws adjacent to the anal cleft. The teeth are strong and adapted for catching and holding the prey. There is no venom or venom-conducting apparatus.

Killing of the prey is effected by constriction; one or more coils of the body are thrown around the victim, following up the stroke of the head, and pressure is applied by the powerful body muscles. The pressure exerted by a large python must be terrific. Thk prey is killed, however, by suffocation rather than by any actual crushing of the ribs. During the swallowing process much saliva is secreted, and should the prey be disgorged, as may happen if the snake is disturbed, it will be found to be covered with this secretion. This evidently accounts for the fable that pythons cover their prey with saliva before swallowing it.

There can be no doubt that large pythons are strong enough to kill an animal the size of an ox, but stories of their killing and eating cattle and horses are not to be credited. The prey is swallowed whole, and though the mouth is greatly distensible, it cannot be stretched beyond the calibre of a moderate-sized pig. Authentic accounts of attacks on man are extremely few.

Most pythons are partly arboreal and are likely also to be found in the vicinity of water, in which they lie and soak. Reproduction is by means of leathery shelled oval eggs, of which there may be a hundred or more in a clutch. The eggs are laid in a heap and are guarded and incubated by the mother, who coils herself around them, and who is known from observation in zoological gardens to have a higher body temperature than the surrounding air while so occupied.

The largest species is the reticulated python (Python *reticulatus)* of the Malay region, which occasionally reaches a length of 30 ft. The Indian python (P. *molurus)* is frequently seen in zoological gardens, as is the African rock python (P. sebae). Other members of the python family include the remarkable arboreal green python of New Guinea (Chondropython viridis) and various other Australasian types. Two species (*Loxocemus*) inhabit western Mexico, as the only American members of the family. (H. W. P.; K. P. S.)

PYTHON, a huge serpent, nameless and female in the earliest account (Hymn. Homer iii, 300 et seq.), which was killed by Apollo at Delphi (older name Pytho), either because it would not let him come near the oracle—in one version (Hyginus, *fab.* 140), it used itself to give oracles—or because it persecuted his mother Leto during her pregnancy. It is generally said to be the child of Earth, and in all probability is to be connected with the reliable tradition that there was an oracle of Earth at Delphi before Apollo came.

In Hellenistic belief, a python was a spirit which possessed certain persons and prophesied unknown to them through their mouths.

See Farnell, *Cults of the Greek States,* iii, 9; iv, 180; also Preller-Robert, i, 239.

PYTHONOMORPHA, the mosasaurs, a group of large marine lizards of Upper Cretaceous age.

See REPTILES.

PYX, a term for various forms of receptacles, from the Greek. *pyxis* ("a box" or "chest"). In ecclesiastical usage it is the sacred vase or tabernacle in which the Host is reserved. In the English mint the pyx is the chest in which are placed one coin from every 15 lb. of newly coined gold and one from every 60 lb of newly coined silver to await the "trial of the pyx" (see MINT). This chest was formerly kept in the Chapel of the Pyx in Westminster abbey.

Q THIS letter corresponds to Semitic Ϙ (koph), which may derive from an earlier sign representing the eye of a needle, and to Greek Ϟ (*koppa*). The form of the majuscule has been practically identical throughout its known history. In the form found on the hloabite stone the vertical stroke extended to the top of the loop, and the same is the case with an early form φ from the island of Thera. The Etruscan form was identical with the Greek. The Latin alphabet had two forms, Q and Q.

In the minuscule form the stroke has moved to the right side of the letter owing to the speed of writing. This produced the cursive form q occurring in the 6th century A.D. Uncial writing also had the form q and the Carolingian form nas practically identical.

In Semitic the sound represented by the letter was an unvoiced guttural pronounced farther back than that represented by the letter *kaph*. In Greek the letter was largely redundant. and in the eastern alphabet was entirely superseded by *kappa*. In the Chalcidic alphabet, however, it lingered and spread from there. probably through the Etruscan. into the Latin alphabet. where it was used only with a following *u*, the combination representing the unvoiced labiovelar sound in such words as *quaero*. The combination of these two letters holds to the present day. and in modern English *q* is not used unless followed by *u*, even if, in words such as "oblique," the sound is a simple velar and not a labiovelar. The most usual position of the sound is initial in words such as "queen." "quick." Q is used apart from *u* only very rarely in words of iorrign origin. especially to represent a Semitic guttural, as in "Qabala," "Iraq." (B. F. C. A.; J. W. P.)

QAIN is the administrative headquarters of the district of Qainat, province of Khurasan, in Iran. Camels are reared and the principal products are grain, saffron, wool and opium.

The town of Qain (pop. [1956] 4,416) is about 200 mi. S. of Meshed in a broad valley. The cultivation of saffron is a specialty of the neighbourhood. The chief industries are the making of felts and carpets. Southeast of the town are the ruins of a great fort. Qain was built by Shah Rukh to replace an older town which he is said to have destroyed. After a time the Uzbegs took possession of and held the place until Shah Abbas I (1587–1629) expelled thern. In the 18th century it fell under the sway of the Afghans and was a dependency of Herat until 1851.

(P. Z. C.; X.)

QAIRWAN (KAIROUAN, KAIRWAN), the sacred city of Tunisia, 36 mi. S.W. from Sousse, and about 80 mi. due south from Tunis. Pop. (1956) 33,968 (commune). The chief buildings are the mosques, which are open to Christians.

In the northern quarter stands the great mosque founded by Sidi 'Oqba ibn Nafi, containing his shrine and the tombs of many Tunisian rulers. It was several times rebuilt; that which subsists dates from the period of the Aghlabites (3rd century of the Hegira, 9th century of the Christian era). In the northern side of the courtyard rises a massive square minaret.

The Mosque of Sidi 'Oqba is the prototype of many other notable mosques. (*See* MOSQUE.) Of greater external beauty than that of Sidi 'Oqba is the Mosque of the Three Gates. Cufic inscriptions on the facade record its erection in the 9th and its restoration in the 15th century A.D. Internally, the mosque is a single chamber, supported by 16 Roman columns. One of the finest specimens of Moorish architecture in Qairwan is the *zawia* of Sidi Abid-el-Ghariani (d. c. A.D. 1400), one of the Almoravides, in whose family is the hereditary governorship of the city. The entrance, a door in a false arcade of black and white marble, leads into a court whose arches support an upper colonnade. The Mosque of the Companion (*i.e.*, of the Prophet), outside the walls to the northwest, is also important. This mosque is specially sacred as possessing what are said to be three hairs of the Prophet's beard, buried with the saint, who was one of the companions of Mohammed. (This legend gives credence to the belief that the tomb contained the remains of Mohammed's barber.)

The town is the centre of fairly active trade and industry, especially in leather goods and carpets.

The legend says that 'Oqba in AD. 671 (A.H. 50) determined to found a city as a rallying point for the followers of Mohammed in Africa He led his companions into the desert and, having exhorted the serpents and wild beasts, in the name of the Prophet, to retire he struck his spear into the ground exclaiming "Here is your Qairwan" (resting place). In the 8th century Qairwan was the capital of Ifrikia province. Later it became the capital of the Aghlabite princes, thereafter following the fortunes of successive rulers of the country. *See* TUNISIA: *History*. (P. W. I.)

QAIS, an island in the Persian gulf lying about 10 mi. off the mainland of Iran is the site of a trade emporium of great importance in former times. The island, measuring 9 mi. by 5 mi., rises 120 ft above sea level to a plateau and is bare of vegetation except for small patches of cultivation and a few date groves and stunted herbage. It is surrounded by a reef and pearl banks. Pop. (1954 est.) 1.686.

In the Mohammedan period it formed a part of the province of Fars. but it was only in the later middle ages that the place attained importance. when a prince of south Arabian origin obtained possession of it, built a fleet there, and gradually extended his power. He captured Siraf (modern Tahiri) which was then the principal emporium of the Persian-Indian-Chinese trade. Siraf gradually—in the first half of the 11th century—became more and more deserted under the suzerainty of the princes of Qais, and finally Qais supplanted Siraf.

At its period of greatest power. the dynasty of Qais also ruled over the district of Oman on the opposite Arabian shore. The Rabbi Benjamin of Tudela visited Qais between A.D 1164 and 1173, and noted the rich market of the island whose chief business was the exchange of Persian. Mesopotamian, Arabian and Indian manufactures and produce. The site of the old city is marked by the ruins known as Harira on the north coast. Qais in turn lost its importance—for what reason is not precisely known—somewhere in the 14th century, and its trade passed to Hormuz.

(P. Z. C.)

QARO (or CARO), **JOSEPH BEN EPHRAIM** (1488–1575), codifier of Jewish law, whose code is still authoritative with the mass of Jews, was born in 1488. As a child he shared in the expulsion from Spain (1492), and like most prominent Jews of the period was forced to migrate from place to place. In 1535 he settled in Safed, Palestine, where he spent the rest of his life. Safed was then the headquarters of Jewish mysticism. Qaro's mysticism did not take the form of a revolt against authority, but was rather the spiritual flower of pietism. It is, however, as a legalist that Qaro is best known. In learning and critical power he was second only to Maimonides in the realm of Jewish law. He was the author of two great works. In the earlier and greater book, in the form of a commentary (entitled *Beth Yoseph*) on the *Turim* (*see* JACOB BEN ASHER) designed exclusively for specialists, Qaro shows an astounding mastery over the Talmud and the legalistic literature of the middle ages. He felt called upon to systematize the laws and customs of Judaism in face of the disintegration caused by the Spanish expulsion. But the *Beth Yoseph* is by no means systematic. Qaro's real aim was effected by his second work: the *Shulhan Arukh (Table Prepared)*. Finished in 1555, this code was published in four parts in 1565. The work gradually became the almost unquestioned authority of the whole Jewish world. 'Its influence was to some extent evil. It "put Judaism into a strait jacket." Independence of judgment was inhibited, and the code stood in the way of progressive adaptation of Jewish life to the life of Europe. But its good effects far outweighed the bad. It was a bond of union, a bar to latitudinarianism, an accessible guide to ritual, ethics and law. It sanctified the home, it dignified common pursuits. When, however: the era of reform dawned in the 19th century, the new Judaism assumed an attitude of hostility to Qaro's code.

QATAR, an independent sheikhdom on the Persian gulf coast of Arabia. Area approximately 8,500 sq.mi. Pop. (1957 est.) 30.000. Its boundaries with Saudi Arabia and the neighbouring sheikhdom of Abu Dhabi are undefined. It is a peninsula about 90 mi. by 40 mi., stretching northward into the gulf between Salwa bay and the Khor 'Udaid. Structurally it is a limestone upfold. Its surface is a gravelly, almost waterless desert crossed by low ridges with a maximum height of over 250 ft. and without vegetation except for a little scrub in the depressions. Water supplies are mainly obtained from distillation plant. Its main resources formerly were pearling (greatly declined) and fisheries. The development of the country from the late 1940s onward resulted from the exploitation of its oil resources, which proved to be much greater than those of the neighbouring island of Bahrein. An artificial port for oil loading was created at Umm Said on the east.

The only town is Doha (pop. [1957 est.] 20,000) with a market and anchorage for dhows. (T. HER.)

QENA, a town of upper Egypt on a canal about 1 mi. E. of the Nile and 380 mi. S.S.E. of Cairo by rail. Pop. (1957) 46.091 (mun.). Qena, the capital of a province of the same name. was called by the Greeks Caene ("New Town") in distinction from Coptos (Qift. Quft), 15 mi. S., to whose trade it eventually succeeded. It is noted for the manufacture of the porous water vessels used throughout Egypt. Its earlier extensive commerce with Arabia and India had been reduced to trade with Arabia in dates and grain. but during World War II revived. (A. J. AL.)

Q FEVER (also known as BALKAN GRIPPE; Ger. QUEENSLAND FIEBER or Q FIEBER; Fr. FIÈVRE Q or MALADIE DE DERRICK-BURNET; Ital. FEBBRE Q) is an acute, self-limited. systemic disease caused by Rickettsia burneti (Coxiella burneti), a microorganism of the family Rickettsiaceae. The rickettsiae approximate the smaller bacteria in size and appearance but are obligate intracellular parasites, as are the viruses. Biologically, the rickettsiae occupy a position between the bacteria and the viruses.

History.—Q fever was first recognized as a new disease in 1935 in Queensland. Austr., by E. H. Derrick. According to him. Q stands for "query," an appellation applied because of the many unanswered questions posed by the new disease at the time of its first description. The term "Queensland fever" is therefore unjustified historically (or geographically). The causal organism was originally designated Rickettsia *burneti* by Derrick. after F. M. Burnet, who isolated it. It is frequently referred to also as Coxiella burneti, after H. R. Cox, who found that Montana ticks were infected by a rickettsia later shown to be indistinguishable from that recovered in Australia, and who uncovered evidence of the possible existence of Q fever in the United States.

The disease, originally encountered almost entirely among abattoir workers, cattle ranchers and dairy farmers in Australia, and just recently among sheep ranchers, was thought for many pears to be restricted to that continent. However, several outbreaks of pneumonitis. later shown to be outbreaks of Q fever, occurred among Axis and Allied troops in the eastern Mediterranean during the minter of 1944–45. These were the first naturally occurring outbreaks of Q fever recognized outside Australia; the disease thereafter was reported from various parts of the world.

Transmission. — While many species of ticks in various parts of the world have been found to be naturally infected, the role of this arthropod in the dissemination and maintenance of the rickettsiae is unclear. It seems likely that some small mammal, perhaps a rodent, serves as a reservoir of the rickettsiae and that ticks keep the infection alive in nature by spreading the rickettsiae from animal to animal within the host species. Man and his livestock (viz., cows, goats and sheep) are not necessary to survival of the rickettsiae in nature and are infected only accidentally.

Tick-transmitted Q fever appears to be rare in man and, in some parts of the world at least, in domestic livestock as well. Since the rickettsiae are excreted in the milk of dairy cows and goats. ingestion of infected dairy products may play a role in the infection of man and livestock. Inhalation of infected material, however. appears to constitute the common mode of infection. The infected animal sheds the rickettsiae through the milk, excreta and, most importantly, through the placenta and the birth fluids. Contamination of the environment leads to air-borne dissemination of the rickettsiae and subsequently to infection of persons in close contact with livestock, contaminated clothing, etc.

Symptoms, Treatment and Prevention. — The incubation period of the disease is from two to four weeks, averaging about 18 to 21 days. The onset of the illness may be gradual but generally is sudden, and the disease is ushered in by fever, chills or chilly sensations, headache. muscle aches, loss of appetite, disorientation and profuse sweating. Symptoms referable to the upper respiratory tract may be present but generally are infrequent and minimal, and pneumonia, even uhen relatively extensive, may be detectable only by X-ray examination. Although Q fever is, on the whole, a mild disease, it can sometimes result in a severe and protracted illness The outlook for recovery is excellent; the mortality rate is believed to be less than 1%. The disease is amenable to therapy with wide-spectrum antibiotics, which are highly effective.

Since Q fever appears to be, in large part. an infection associated with occupation, vaccines prepared from killed R. burneti can be used to protect those persons exposed to infection. Milk, whether used for table purposes or for manufacture of dairy products should be pasteurized. See also RICKETTSIAE. (E. H LEN.)

QIFT (Arabic, KUFT, ancient COPTOS, KOPTOS), a small village in Egypt on the east bank of the Nile. 25 mi. N. of Luxor, known to the ancient Egyptians as Qebti. The town was an early dynastic foundation, the predynastic settlements having been at Ombos (ancient Nubyt) on the west bank of the river which the early routes followed. Qebti owed its importance to the gold and porphyry mines in the district; inscriptions there show that they were being worked in the 1st and 2nd dynasties Just outside Qift Flinders Petrie excavated a temple dedicated to Min of the Desert Routes and containing three important archaic statues of the god. The town was also associated with Isis, who was said to have found Osiris's body there. By Old Kingdom times Qebti was a place of some importance; both Pepi I and II built and restored temples there, and it was the starting point of expeditions for Punt. By the time of Thutmose III the importance of the city had declined, but it revived in the Ptolemaic period through trade with the east. Queen Asinoe was banished to Qebti by Ptolemy Philadelphus, and held her court there for some years. A rebellion directed against Diocletian's taxation on the transit trade led to the destruction of the city in A.D. 292, but later it became the centre of a thriving Christian community and the Christian inhabitants of Egypt, the Copts, derived their name from the town. It retained its influence during the middle ages, until replaced as the caravan trade terminal by Kus (Qus) Largely as a result of Petrie's work there. Qift has supplied skilled workers for all major excavations in Egypt and neighbouring countries. (M. V. S.-W.)

QISHM, also pronounced Jishm and sometimes styled by the Arabs al-Jazirat al-Tawilah (Long Island), is the largest island in the Persian gulf It lies parallel to the coast between Lingeh and Bandar Abbas and is separated from the Persian mainland by a channel known to mariners as Clarence strait. It is 68 mi. long and has a very irregular outline, with an average breadth of about 10 mi. although it exceeds 20 mi. abreast of Hanjam Island. The coast is generally rocky but the southeastern and western shores have sandy bays and the northwestern is fringed by mud flats. Irregular table-topped hills almost cover Qishm. The geological formation resembles that of the adjacent coast; upper strata of coarse sandstone grit and conglomerate supported by blue Lias marl interrupted by salt hills. Salt is mined on the southeastern coast and there are naphtha springs. Cereals. vegetables, melons and dates are gronn near the villages in the north and around the coasts. The main occupations of the inhabitants are fishing and boatbuilding with some camel breeding, stock raising and weaving. Wild goats, partridges and rock pigeons are found in the hills, and some gazelle in the plains. The population in 1954 was about 15.000; 5,781 live in Qishrn town. They are mainly of Arab origin and are administered by a sheikh of the Bani Ma'in tribe on behalf of the Iranian government. (K. C. B.)

QUACKERY, the characteristic practice of quacks or charlatans, who pretend to knowledge and skill that they do not possess, particularly in medicine. The quack makes exaggerated claims as to his power to heal disease, generally for financial gain. The conditions usually treated by quacks are those for which specific methods of treatment, or "cures," have not yet been developed; those particularly feared, such as cancer, venereal diseases and, in the past, tuberculosis; those nith frequent remissions and recurrences, such as arthritis, neuritis and migraine; and mental disturbances. People yield to quackery in times of great stress, pain or sorrow. In the absence of exact knowledge, and sometimes even in its presence in the face of insurmountable difficulties, the credulous person craves a miracle. He is ready to be overwhelmed by the personality and the claims of the charlatan.

The typical quack may be a man or a woman, but is likely to be striking in appearance and personality. In the past crippled persons, such as hunchbacks; rulers, such as high priests and kings; mystics and mentally disturbed persons were believed to possess special powers in healing disease. The modern charlatan in his announcements features an alphabetical appendage, indicating the possession of academic degrees that, however, were not conferred by any recognized scientific organization or university. The charlatan originally may be self-deluded as to his powers, but sooner or later he becomes aware of his failures. He then continues in his practice, consciously deluding those who depend upon him. He is aided by the reluctance of persons who have consulted him with disadvantage to acknowledge the fact, and by magnification of his apparent successes. Advances in psychosomatic medicine have helped to explain some of the healings recorded by quacks.

Techniques. — Whenever a new discovery is made in any field of science, the charlatan may take advantage of public interest and lack of information to utilize it with exaggerated claims. Lack of general knowledge encourages occultism, and the characteristic claim of the auack is the possession of a formula. method, device or product unknown to other physicians or scientists. At the time of the American Revolution. for example, a quack named Elisha Perkins (1741–99), aware of public interest in the recently discovered electricity, invented "metallic tractors" to draw disease out of the body. These were two rods of brass and iron, about three inches long, one of copper, zinc and gold, the other of iron with some other metals; they cost 1*s.* to manufacture and sold for $5. James Graham (1745–94) in England set up a temple of healing in which he burlesqued the principle of electricity, promising cures and rejuvenation.

Knowledge of powerful drug substances derived from plants (digitalis, belladonna. cascara, quinine and castor oil) or from metals (mercury, arsenic and particularly gold) led to the development of nostrums that mere exploited with false, misleading or exaggerated claims to cure such diseases as tuberculosis, syphilis, cancer. kidney diseases and gynecological, digestive and rheumatic disorders. Sometimes the quack or purveyor of nostrums did not trouble to include a potent drug but merely used any bitter-tasting, dark herb or vegetable with common salt or sulfur. Toward the end of the 19th century alcohol was used as a solvent, and it yielded its typical effects to the satisfaction of the users. Many modern nostrums depend principally on aspirin.

With the discovery of radium, claims were made for mixtures said to contain this substance. In a few instances some radium actually was included, and users died years later from the effects of radium on the bones. Radium was said to be incorporated in magical magnetic belts, and radium plasters with infinitesimal amounts of radioactivity were purveyed.

Increasing knowledge of the glands of internal secretion gave rise to preparations for rejuvenation, beautification and sexual power. Vitamins have been incorporated in preparations for growing hair or preventing grayness, without any real evidence that they could be helpful. Indeed, in the realm of cosmetology, quackery and nostrums seem destined forever to reap a pecuniary harvest.

Because peopie believe in "nature," uncooked foods, systems of exercise, recital of ritualistic codes, manipulation of bones, muscles and tendons, complicated machines of no particular merit. heat, cold, baths, lights (plain and coloured), static electric currents and even radiozctivity have been vaunted as useful in the control of disease and the promotion of health.

With the development of techniques for advertising and promotion, the quacks thrived until legislative controls were broogh tinto action. As early as 1843 a leader in advertising said that pain or the fear of pain attracted the greatest interest in mankind, and that for this reason medical advertising took most of the space available in the press. Vanity had the next strongest appeal Education of the public in physiology, anatomy and hygiene have not served to dispel gullibility. Quack advertising still relies on blatant exaggeration, use of unusual terms (such as "dyskinesia" for constipation), creation of fear, promise of secrecy and financial saving (actually the employment of nostrums and quackery invariably results in greatly increased and prolonged expense). With the coming of radio, some quacks secured radio stations to sell promised cures, and even television has been so employed.

Legislation.—In the United States. quackery varies from state to state according to the limits permitted by law. In some states it is limited almost entirely to the sale of drugs and herb preparations. In other states institutes or sanatoriums are conducted by quack doctors.

In Great Britain a violator is held liable if he holds himself out as a "listed" or recognized medical practitioner or if a death occurs associated with his ministrations; there the law considers that a person consults a quack at his own risk. The continental European countries have not been successful in curbing quackery. In Germany during World War II the unlicensed healers were actually encouraged and formed an association which received governmental recognition. In Latin America quackery is rampant.

In the United States the Food and Drug act of 1906 eliminated the widely advertised quack cures for cancer, tuberculosis and other serious diseases; thereafter the same preparations were sold as cures for coughs, colds, pains and aches and minor complaints. Labels were required to carry information as to content of certain ingredients, warning as to hazards and, in some instances, references to diseases that would not be helped by the preparation. The Federal Food, Drug and Cosmetic act of 1938 and the Wheeler-Lea act (also 1938) provided a certain amount of governmental control over claims made in advertising, in newspapers and magazines, over radio and television, in circulars and on labels. Such controls are exercised, however, only on products in interstate commerce. Individual states vary in the amount and kind of control they exert. More recently new drugs, devices or cosmetics may not be released until submitted with evidence to the appropriate governmental agency. Finally, the post office department has authority to forbid the use of the mails when convinced that they are being used fraudulently.

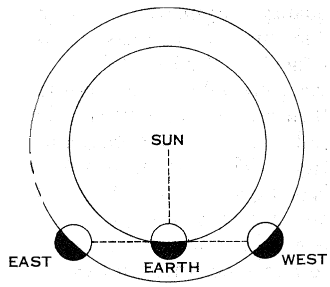
Organizations concerned with such conditions as cancer and heart disease conduct continuous campaigns of public education, warning against the depredations of medical quackery and the sellers of nostrums, and the United States public health service also has undertaken such activities. The state medicai licensing boards, medical societies and Better Business bureaus also are concerned with the protection of the public in these fields.

For these reasons quackery has steadily diminished, and the depredations of quacks have been severely limited. Nevertheless the nature of the human mind is such that charlatans will no doubt continue to appear and wreak damage from time to time until society with a social conscience and legal controls catches up with them. See also FRAUD.

See Morris Fishbein, *Fads and Quackery in Healing (1932)*; Grete de Francesco, *The Power of the Charlatan (1939).* *(M. Fi.)*

QUACK GRASS (Agropyron *repens*), a perennial grass of the barley tribe (Hordeae), called also couch grass or quitch grass. It is native to Europe, common in northern Europe and widely naturalized in North America. Quack grass has bright-green, smooth, stiffly erect stems. one to four feet high; leaves with flat or inrolled blades; and terminal flowering spikes, two to six inches long, composed of numerous, usually five-flowered spikelets, which often bear short awns. Sometimes it is grown for forage, but it is better known as a troublesome weed in cultivated fields, especially on rich soil, spreading rapidly by its creeping rootstocks. The best method to eradicate it is to plow the land, after it has been left in sod two or more years, just after the flowers appear, and to harrow at weekly intervals for about six weeks.

QUADRATURE (Lat. quadratura, a making square), in astronomy, that aspect of a heavenly body in which it makes a right angle with the direction of the sun. The moon at first or last quarter is said to be at east or west quadrature, respectively. A superior planet (outside the earth's orbit) is at west quadrature when its position is 90° W. of the sun (see drawing). It rises around midnight, reaches the south meridian near sunrise and sets near noon. At east quadrature the planet is near the meridian at sunset and sets near midnight. At both quadratures, the planet is at gibbous phase, but only in the case of Mars does it show up conspicuously gibbous.

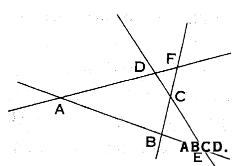


QUADRATURE OF A SUPERIOR PLANET

In mathematics, quadrature is the determination of a square equal to the area of a curve or other figure. Integration by quadratures means calculation by a step-by-step process when no analytical expression for the integral is available. (H. M. Lo)

QUADRILATERAL, in geometry, a figure formed by four straight lines. It is said to be plane or skew according to whether the four lines do or do not lie in one plane.

Let us consider the plane figure bounded by four lines terminated at the vertices. A line joining a pair of opposite vertices is called a diagonal. The area of such a quadrilateral is half the product of the length of one diagonal by the sum of the perpendiculars drawn to this diagonal from the other two angular points. The sum of the squares of the four sides of such a quadrilateral is equal to the sum of the squares of its diagonals increased by four times the square of the line joining the midpoints of the diagonals. If the vertices of such a quadrilateral lie on a circle, the product of the diagonals is equal to the sum of the products of the opposite sides. It is in projective geometry that the quadrilateral plays its most interesting role. If A, B, C, D are four points in a plane no three of which are collinear, then the lines AB, BC, CD, DA, each taken to be of indefinite extent, form a quadrilateral (see figure). These sides intersect in pairs not only in the four given points (called vertices) but also in a point E on both AB and CD, and in a point F on both BC and AD. The points E and F are also called vertices. Then each side of the quadrilateral contains three vertices. Two vertices not on the same side are called opposite. A line joining two opposite vertices is called a diagonal. The configuration so described is called a complete quadrilateral. The dual figure is called a complete quadrangle. These figures are of fundamental importance in projective geometry (*q.v.*).



ALL LETTERED POINTS ARE VERTICES

QUADRILLE, a lively dance, executed by four couples arranged in a square. A form of contredanse known by 1710, the quadrille crystallized about 1815 in the general form popular since then, and consisting of five figures: *le* pantalon, *l'été,* la poule, la pastourelle or la trknise, and the finale. The music was often based on operatic melodies; dance patterns were subject to great variation. Although steps and figures have undergone considerable modification, quadrilles such as the Lancers are still among the most popular square dances. In theatrical terminology, quadrille has denoted: (1) small groups of dancers in 18th-century ballet; (2) Paris night-club dancers of the 1890s, immortalized by Henri de Toulouse-Lautrec; (3) divisions of ensemble dancers at the Paris opera in the 20th century. (LN. ME.)

QUAESTOR (Lat. quaerere, "to investigate"), a Roman magistrate whose functions, in the later times of the republic, were principally financial, although he was originally concerned with criminal jurisdiction. The quaestorship was probably instituted in 509 B.C. simultaneously with the consulship. The number of quaestors, originally two, was successively increased until Julius Caesar raised it to 40 (45 B.C.); Augustus reduced it to 20, which remained the regular number under the empire. When the number was raised from two to four in 421 B.C., the office was thrown open to the plebeians. The quaestorship was the lowest of the great offices of state, and hence the first sought by aspirants to a political career (*cursus* honorum). The candidate was bound to have completed his 30th year before he entered office, but Augustus lowered the age to 25. Quaestors were elected by the comitia tributa (see COMITIA) under the presidency of a consul or another of the higher magistrates. They held office for one year, but, like the consuls and praetors, they were often continued in office. It was a rule that the quaestor attached to a higher magistrate should hold office as long as his superior; hence, when a consul presided over the city for one year and afterward as proconsul governed a province for another year, his quaestor also held office for two years. A peculiar burden laid on the quaestors, as a sort of fee exacted from all who entered on the political career, was the paving of the high roads, for which the emperor Claudius substituted the exhibition of gladiatorial games.

Various classes of quaestors may be distinguished:

Urban **Quaestors.**—Originally the duties of the quaestors, like those of the consuls, were undefined; the consuls were the superior magistrates of the republic, the quaestors their assistants. From a very early time, however, the quaestors possessed criminal jurisdiction; political crimes only seem to have been excepted. The criminal jurisdiction of the quaestors appears to have terminated only when trial by permanent courts (quaestiones *perpetuae*) was extended to criminal cases.

The quaestors had also charge of the public treasury (*aerarium; q.v.*) in the temple of Saturn, and this was in later times their most important function. They kept the keys of the treasury and had charge of its contents, the coin and bullion, the military standards and a large number of public documents, which comprised all the laws as well as the decrees of the senate. Their functions as keepers of the treasury were withdrawn from urban quaestors by Augustus and transferred to other magistrates.

Military **Quaestors.**—These were instituted in 421 B.C. and were clearly distinguished from the urban quaestors by the fact that a nonurban quaestor was assigned as an assistant or adjutant to every general in command. whose name or title the quaestor usually added to his own. Originally they were the adjutants of the consuls only, afterward of the provincial praetors and still later of the proconsuls and propraetors. The governor of Sicily had two quaestors; all other governors and commanders had but one. Between the quaestor and his superior a close personal relation existed, and was not severed when their official connection ceased. The duties of the military quaestor, like those of the treasury quaestor, were primarily financial. Moneys due to a provincial governor from the state treasury were often, perhaps regularly, received and disbursed by the quaestor; the magazines seem to have been under his charge; he coined money, on which not infrequently his name appears alone. But, though his duties were primarily financial, the quaestor was the chief assistant or adjutant of his superior in command, and was invested with a certain degree of military power. When the general left his province before the arrival of his successor, he usually committed it to the care of his quaestor, and, if he died or was incapacitated from naming his successor, the quaestor acted as his representative.

Italian **Quaestors.**—The subjugation of Italy occasioned the institution (267 B.C.) of four new quaestors, who appear to have been called quaestores classici because they were originally intended to superintend the building of the fleet (classis); their functions, however, are very imperfectly known.

QUAGGA, an animal of the genus *Equus* (E. quagga), allied to Burchell's zebra, formerly met with in vast herds on the great plains of South Africa between Cape Province and the Vaal river, but now extinct, the last having died in 1872 in the London zoo. The colour of the head, neck and upper parts of the body was reddish brown, irregularly banded and marked with dark-brown stripes, stronger on the head and neck, and gradually becoming fainter until lost behind the shoulder. There was a broad, dark, median dorsal stripe. The undersurface of the body, the legs and tail were nearly white, without stripes. The crest was high, surmounted by a standing mane, banded brown and white. *See* ZEBRA.

QUAHOG, also spelled QUAHAUG or QUAUHOG, is a corruption of the word paquahock used by the New England Indians for the hard-shell clam Mercenaria *mercenaria* in the family Veneridae. The name quahog is used only on the Atlantic seaboard of the United States and particularly in New England. The shell of this clam is large, thick and solid, marked with concentric growth lines and ridges. It is a dirty gray in colour outside; inside it is often marked with purple, and it was from this that the Indians made their purple wampum. The quahog has short siphons and so does not burrow deeply into the sand; often a portion of the valves is protruding, or the shell may lie on the surface. It ranges from the intertidal zone out to depths of several fathoms and is found on sandy muddy bottoms. This clam was an important item of food to the Indians and the early settlers and continues to support an important industry on the Atlantic coast from Nova Scotia to Maryland. The young clams, known as cherrystones, are eaten raw; the larger ones are cooked in a variety of ways, though chowder is perhaps the commonest. The black, mahogany or ocean quahog, *Arctica* islandica, has a heavy dark covering on the outside of the shell. This edible species lives in deeper water and is dredged in quantity off the New England coast. Young of both species are important food for bottom feeding fishes. *Mer*cenaria campechiensis, the southern quahog, is also fished commercially. See also CLAM. (R. D. T.)

QUAIL, a game and table bird known throughout Europe, Asia and Africa. The common quail (Coturnix *coturnix*) varies in colour, but in general is reddish-brown above marked with dark brown and buff and pale buff below, passing into white on the belly. Essentially migratory, the quail breeds on the ground, laying 9 to 15 yellowish eggs spotted with dark brown. Immense numbers are netted during the autumn migration in Mediterranean countries. The quail is now rare in Great Britain. It feeds largely on weed seeds and insects and is decidedly a beneficial species. Related forms include the rain quail (C. coromandelica) of India, the African quail (C. delegorguei) and the Australian stubble quail (C pectoralis). The North American quails belong to a different subfamily of the Phasianidae. They include the bobwhite (Colinus *virginianus*) and the California tufted quail (Lophortyx californica).

The button quails (Turnix), lacking the hind toe in most species, are now regarded as related to the cranes. Turnix sylvatica ranges from Spain to the East Indies, with various races. (K. P. S.)

QUAKERS, originally a cant name applied in derision to the members of the Society of Friends, but now used without any contemptuous significance. It was used as early as 1647, and arose from the physical manifestations of religious emotion characteristic of many early Friends.

See FRIENDS, SOCIETY OF.

QUALITIES. The word "quality" has, both in philosophy and ordinary speech, a long history. It appeared in English as a translation of the Latin qualitas, a word coined by Cicero to translate the Greek poiotes; and this Greek word had itself been coined by Plato (*Theaetetus*, 182a), with apology for its barbarous character. and employed as a technical term by Aristotle in his doctrine of categories (*see* CATEGORY). In spite of this highly artificial beginning, the word "quality" soon became acclimatized in ordinary English; in philosophy, however, its uses have been various and somewhat obscure.

The ordinary uses of the word (which cannot here be exhaustively dealt with) may be broadly distinguished under two headings. First, the word is sometimes employed as a synonym of "property" or "characteristic": in this sense it would cover almost anything that might be ascribed to an object for the purpose of describing it—its colour, shape, dimensions and so on. In the same sense honesty, prudence. obstinacy, etc., may be spoken of as "qualities of character." Second, the word is used, perhaps more commonly, in contexts where merit, grade or value is in question. Where, for example, two kinds of cloth are said to differ "in quality," it would usually be meant not merely that they differ but that one kind is better (by the appropriate standards) than the other; it might indeed be said to be of better, or higher, quality. Similarly, when Emerson'wrote that "there is more difference in the quality of our pleasures than in the amount," he undoubtedly meant to convey that some of our pleasures are better, more valuable, and not merely more intense or more prolonged than others. It is usually in this way that the word "quality" is to be understood when a contrast is stated or implied with "quantity." The word is also often employed by itself in the sense of "good quality," as in the old phrase "persons of quality" or in such advertisers' phrases as "quality groceries." In view of the existence and, perhaps, prevalence of this second use, it is important to remember that (in the first sense) a "quality of character," for example, is not necessarily good or desirable. Cowardice is as truly a quality of character as bravery.

Qualities and Relations.—The traditional distinction betaeen qualities and relations, so common that it can hardly be regarded as technical or philosophical, has sometimes been attacked as being philosophically unimportant. It cannot be denied, however. that there is such a distinction, or that it is sometimes convenient to employ it. What the distinction is can be roughly indicated by examples. Colour would be said to be a quality, since, in saying of what colour an object is, nothing need be mentioned other than that object to which the colour is ascribed. Proximity. on the other hand, would be said to be a relation, since, in employing the phrase "is close to," two objects must be mentioned, one of which is said to be close to the other. Similarly, a statement of the form "*Y* is between X and *Z*" might (rather artificially) be said to assert the relation of intermediacy—a "three-term" relation, since mention must be made in the statement of three things, one being said to be between the other two. A connected and sometimes convenient notion is that of "relational quality." For example, it might be said that being tall is a relational quality since, though it is clearly not a relation (the sentence "Jones is tall" is complete in itself), it could be held that in calling someone tall a comparison is implied between his height and (roughly) that of most other men.

Qualities and Predicates.—The foregoing brief distinction between qualities and relations might suggest the view that, in all subject-predicate (as distinct from relational) statements, the predicate is employed to ascribe a quality to that which the subject-expression is used to designate. It would be usual, however, and seems desirable, not to accept such a general principle without qualification; for there are many expressions. properly used as predicates and not obviously complex, which are yet used so differently from others that it seems inadvisable to regard them all as alike in standing for qualities. It would, for example, be reasonable to deny that the word "real" stands for a quality. For whereas the word "yellow," for instance, is ordinarily (literally) employed in just one way, namely in ascribing a particular colour, and so might be said always to stand for the same quality, the force of the word "real" varies greatly from context to context. It would be most unnatural to insist that a real (as opposed to a pantomitne) horse and a real (as opposed to an illusory) advantage share a single quality, reality; the word "real" takes its particular force in each context from the implied contrast, and in this respect, if in no others, the cases differ completely.

Nonnatural Qualities.—An instance which has aroused more controversy, though it is not perhaps of greater importance, is that of the predicate "good." G. E. Moore, in his influential *Principia Ethica* (Cambridge, 1903), launched an attack on what he called the naturalistic fallacy. He distinguished in the course of his argument between the "natural qualities" of objects—for example their colour. shape, texture or weight—and "nonnatural qualities," of which his primary instance was goodness: and the naturalistic fallacy. he claimed was committed by anyone who sought to define a nonnatural quality in terms of a natural quality or qualities. Doubts nere soon expressed, both by Moore himself and by others, about the meaning to be attached to his expressions "natural" and "nonnatural." But other critics were inclined to question whether goodness was a quality at all. of any variety; and some insisted that it was not. (*Cf.* the symposium "Is Goodness a Quality?" in the Aristotelian society's *Supplementary Volume XI,* London, 1932.)

Now this denial might seem surprising in the light of the ordinary use of the word "quality." For one of its most common uses, as remarked above. is in contexts where merit goodness or badness. is at Issue: good apples are of better quality than bad ones. Moreover, it seems entirely natural to say that goodness of heart is an admirable quality of character. If so, it would seem that there could be no objection to the assertion that goodness is a quality.

The philosophical objections to this assertion are somewhat complex but may be summarized as follows. It has been urged that to classify goodness as a quality reveals. or at least invites, misunderstanding of the distinctive character of value judgments. To say that anything Q is a quality, it is said, is to imply that a statement of the form "*X* is (or possesses) *Q*" gives a description of X, or states a fact about X; and it has commonly been held that descriptions or statements of fact, properly so called, must be sharply distinguished from judgments of value (or, that describing an object must be distinguished from expressing commendation or condemnation of it). Hence, Moore's distinction between "yellow" as standing for a natural quality and "good" as standing for a nonnatural quality was held to be Inadequate; for it implied that judgments of value were no more than a special kind of statements of fact, or statements of a special kind of facts, thus obscuring the supposedly more fundamental distinction between statements of fact, of whatever sort and judgments of value. Moore's argument was also held to raise needless apparent problems about the ways in which judgments of value could be supported or attacked, disputed or justified; for it appeared that nothing clear and satisfactory had been said. or could be said about the way in nhich the presence or absence of nonnatural qualities could be detected.

However, this criticism of Moore is inconclusive. For it is not in fact the case, as has often been assumed, that descriptions or statements of fact must be evaluatively neutral. It is proper to say that a man may be *described* as dishonest, though thereby his character is condemned; it may be a *fact* that he is dishonest and hence a statement of fact to say so. But if so, to say that goodness is a quality and to concede that the assertion "*X* is good" may be a statement of fact or a description does not oblige one to misrepresent the peculiar character of value judgments. One may say that, in stating the fact that X is good or in describing X as good, one is necessarily also commending X—that goodness is precisely the quality which commendable things are said to possess. Those philosophers who have distinguished so sharply between "descriptive" and "evaluative" terms might well be held themselves to have misstated the same distinction which Moore was accused of misstating, in his distinction between natural and nonnatural qualities.

A better reason for denying that goodness is a quality might be found in the extreme generality of the word "good" (*cf.* Aristotle, *Nicomachean Ethics,* I, v). It would be unplausible to maintain that the word is actually ambiguous; but if it is not ambiguous and if it stands for a quality, one must hold that, whatever things are called good, the same quality is thereby ascribed to them. But this in its turn seems most unnatural. Can good arguments, good apples, good deeds and good cricketers be plausibly said to share one common quality of goodness? If so, should one not expect a sound judge of cricketers to be thereby equipped to judge apples also, or arguments? But this is obviously contrary to facts. It is noteworthy that the "admirable quality of character" mentioned earlier was not in general goodness but in particular "goodness of heart." It seems that some such particularization of goodness is essential if it is to seem natural to speak of it as a quality. Moore, indeed, when he said that goodness was a nonnatural quality, had restricted his discussion to the alleged special use of "good" in moral contexts. But this restriction seemed somewhat arbitrary, nor is it clear how his argument could be extended if the restriction were dropped. It could not well be held that "good" in other contexts stands simply for natural qualities; but if not, it is not clear how Moore could distinguish between moral and other contexts, nor why he should be at such pains to do so.

Primary and Secondary **Qualities.**—Locke's celebrated distinction between primary and secondary qualities (*Essay Concerning Human Understanding,* ii, ch. 8), of which some notice must be taken here, in fact exhibits the disconcerting feature that some of those things between which he thus distinguishes would not naturally be regarded as qualities at all. The primary qualities of matter, he says, are "solidity, extension, figure, motion or rest, and number"; the secondary qualities are "colour, sounds, tastes, etc."—the "etc." being evidently designed to cover at least smells and warmth and cold. Of these "motion or rest" would usually be spoken of as states, not qualities—partly at least because an object that was at rest, being set in motion, would not be said itself to undergo alteration, as would be implied by saying that it had lost one quality and acquired another. Number also is not commonly thought of as a quality: yellow flowers are all individually yellow, but ten flowers are not all individually ten. To this it might be replied that the quality of being ten belongs not certainly to the members of a collection of ten things but simply to the coilection itself. There are further objections to this reply (*cf.* G. Frege, *Foundations of Arithmetic,* Eng. trans. by J. L. Austin, Oxford and New York, 1950, p. 39e *ff.*); but here it will be sufficient to appeal to the obvious difference between the question "Of what sort? (*qualis?*)" and the question "How many?" as a sufficient reason for refusing to classify number as a quality. From the list of secondary qualities, sounds at least seem to be similarly misclassified. It is clear enough that an actual sound is not a quality of that which makes it, though the capacity, tendency or disposition to make that sort of sound or to be concerned in the making of it might well be so regarded.

Apart from these perhaps minor points, Locke's own account of his important distinction is regrettably confused. He says that our ideas of primary qualities "resemble" those qualities ("their patterns do really exist in the bodies themselves") but that our ideas of secondary qualities are wholly unlike that in objects which causes us to have them. Sometimes, apparently confusing qualities with ideas, he says that secondary qualities, unlike the primary, would not exist at all in the absence of suitably sensitive observers. Sometimes he seems to contend that our ideas of secondary qualities are so various and fluctuating that we cannot say that any such qualities are really "in" objects themselves. He certainly comes very close to saying, and by Berkeley was understood to mean, that our ideas of secondary qualities are only a "false imaginary glare," tempting us to ascribe to objects qualities which really they do not possess at all. It is accordingly necessary to inquire what it was that he was seeking, though unsuccessfully, to convey; and here we must take notice of two different distinctions, with both of which Locke was evidently concerned, though he does not clearly indicate that they are two and different.

First, he was clearly influenced strongly by current scientific accounts of the process of perception. He officially regards the qualities of matter as the causes of our "ideas of sensation" and hence is led to think of matter as really characterized by those qualities required in the current explanatory theory. Now the theory current in Locke's time was a mechanical one, "corpuscles" being supposed to act "by impulse" on the sense organs; it is accordingly not surprising that his list of primary qualities includes all and only those features that are of mechanical importance—solidity, shape, size, motion and number. The secondary qualities, perception of which is accounted for by the action of corpuscles supposed to have primary qualities only, are thus thought of as an almost irrelevant intrusion, making their appearance because and only because the world happens to contain appropriately sensitive organisms.

But, second, Locke also says that primary qualities are those which "the mind finds inseparable from every particle of matter"; and he later suggests that they constitute the "red essence" of matter. Now here his case seems to be founded not on scientific but on logical or conceptual considerations. He seems to say that possession of the primary qualities is, and possession of secondary qualities is not, essential to being "material" — that the concept of materiality includes the primary qualities but not the secondary. And this view, though baldly stated, seems to be right. It is clear enough that anything that we should regard as a material object must be individually distinguishable from other things (countable); must have some shape and dimensions; must be moving or at rest in space; and must be "solid" (in the sense at least of excluding other things from the volume of space occupied by itself). It is equally clear that a material thing is not logically required to make any sound, or to have any taste or smell. The case of colour is more controversial. For sight is in practice the most important of our senses, and it might be urged that any material object must be at least so far coloured as to be visible, accessible to the important sense of sight.

It appears, however, that visibility is actually less important than this would suggest; there is, for example, no conceptual difficulty in the idea of the Invisible Man. By contrast, an "intangible man" would be thought of not as a genuine though peculiar kind of man but rather as not a man at all—as a ghost, a vision or a hallucination.

Many other questions of intricacy and interest are suggested by Locke's distinction, though not raised by Locke himself—questions, for example, about the importance and limitations of measurement in our dealings with material things and about the relation between actual or conceivable metrical scales and the (usually) rough "qualitative" distinctions marked in everyday speech.

There is also a large family of questions which might be grouped under the heading "appearance and reality." It is, however, impossible to pursue these topics in the present context.

Qualities and Substance. — Something perhaps should be said here of the not wholly obsolete question, whether a material object can be identified with the sum of its qualities, or whether we must (as Locke held) "suppose always something besides" the qualities, in which they inhere or to which they belong — something to which he and others have given the name of substance (*q.v.*). The disagreement on this question appears to be a case of cross-purposes. On the one hand. an object clearly cannot be simply identified with a collection of qualities: for it is an elementary point of logic that qualities must be qualities of something — that there must indeed be something which they qualify. On the other hand, there is no need to reach Locke's conclusion that this is always a "something we know not what," for which "substance" is simply an arbitrary name. For that in which. say, the qualities of a table inhere is of course a table. a something we know quite well. Historically. the controversy on this issue seems to have arisen from a *prima facie* perverse but in fact not unpersuasive tendency to regard the ultimate possessor of qualities as an essentially characterless and hence unperceivable and indescribable stuff; while the justified opposition to this line of thought expressed itself by reaction in the mistaken form of a denial that anything but qualities need be admitted.

To escape from the dilemma it is necessary to see that. while qualities must certainly inhere in or belong to substances (or at any rate things which are not themselves qualities'). there is no need to suppose the existence of a single characterless stuff in which all qualities ultimately inhere. A thorough removal of the difficulty could probably be best secured by an examination of the related but contrasting roles of substantival and adjectival expressions, together with some investigation of such pedestrian expressions as "stuff." "matter" and "something."

Quality of Propositions. — A specialized use of "quality" has long been made by logicians in the Aristotelian tradition. Under this heading propositions are classified as either affirmative or negative. The term "quality" is employed in this way in contrast with a technical use of "quantity" — the three quantities of propositions being "universal," "particular" and "singular." Kant attempted to introduce, symmetrically with the three headings of quantity, a third quality which he called "infinity"; but this alleged further distinction was not well founded and did not find favour.

(G. J. WK.)

QUANTICS, the study of homogeneous algebraic functions of two or more variables which generally contain only positive integral powers of the variables. *See* ALGEBRAIC FORMS.

QUANTITY THEORY OF MONEY, a theory concerning the relationship between the amount or supply of money and the purchasing power or value of one unit of money. Since the value of one unit of money varies inversely nith prices of things for which it is exchanged, the quantity theory has to do with the relationship between the amount of money and the average price, or price level, of things other than money.

In its extreme variant, the quantity theory alleges that the price level changes because the amount of money changes, in the same direction and in the same proportion. This implies that the total amount of money remains constant in value however many units of money there may be.

The quantity theory of money is typically deduced from one form or another of quantity equation. The equations in commonest use have been $MV=PT$ and $\frac{N}{K}=P$. The former is the Fisherian equation. named in honour of Irving Fisher: the latter is the Cambridge equation developed principally by Alfred Marshall and A C Pigou at Cambridge university

M and N in these equations are the supply of money. commonly defined as the sum, expressed in a nation's monetary unit. of coin and paper currency and bank deposits subject to check. P in both equations is an average or index of prices for the marketable goods and services that are measured hv T and K Current usage is to include in T and K only the goods and services that comprise national product or national income. omitting the stock of existing wealth and all securities. PT and PK, then, are aggregate market values of goods and services currently produced and exchangeable for money.

V and K are related reciprocally, and express the desire of persons, firms and governments to have money rather than things included in T and K. The Fisherian equation is relevant to a period of time. and its V is the frequency during the period with which the average unit of money is spent. This frequency is low if money users wish to retain money for relatively long periods in relatively high proportion to income. high if they dispose of it quickly after receipt. MV is evidently spending of money during a period of time, as PT is the value of goods on which it is spent. The Cambridge equation is relevant to a moment of time. and its K is the real or physical amount of goods which money users do without in order to hold N money. If K is relatively high at each moment of time, the spending of money or V is low over a succession of moments.

The derivation statistically of either quantity equation is difficult. There is no unambiguous measurement of the real goods T or K or of the price levels at which they are traded for money. V is measurable only as the quotient of PT divided by M. Finally, there is disagreement as to whether the money supply should include not only coin, currency and checking deposits but also savings accounts and similar claims on banks and other institutions. For these and other reasons the quantity equation is not actively employed in empirical analysis of price levels and other economic variables.

The quantity theory of money, that price levels vary as a result of and in proportion to changes in the supply of money, specifies that T and V or K should be stable. Otherwise. the effect of, say. an increase in M in inflating P would be either suppressed or magnified by changes in the flow of goods or in the desire of money users to have money rather than goods and services that money buys.

The theory may be expressed more conservatively, that changes in the money supply tend to affect the price level proportionately, and that the tendency will work itself out if factors quite independent of money and the price level do not concurrently disturb T and V or K.

The quantity theory implies a process by which changes in the supply of money can influence prices. This process is an adjustment of the demand for money by money users to the supply of money. The demand for money may be visualized as $M'=\frac{PT}{V}$ demand M' depends positively on PT and negatively on V; that is. on the value of goods to be exchanged for money and on the frequency with which each unit of money is used in buying these goods. The supply of money M depends not on money users but on the ability and willingness of the monetary system to create money. There is equilibrium when $M'=M$. If equilibrium is disrupted by an increase in M, the excess supply of money is spent on goods and services. If the flow of goods and services is given, and if both old money and new circulate at the same V, commodity prices P must rise until M' is once more equated with M and the excess supply of money is dissipated by price inflation. In the process of adjusting demand to supply, prices have risen less than in proportion to the increment of money, but when the process is done and a new equilibrium established the price inflation is proportional.

The quantity theory that proportional changes in price levels adjust the demand for money to the supply has been an integral part of some formal systems of economic reasoning. These bodies of doctrine, not infrequently brought to bear on economic problems of the 20th century, presume to explain the behaviour of the entire economic system. They assume that V is stable, or very slow to change. reflecting persistent habits of money users in holding money balances and making money payments. They assume, further, that T is determined by such nonmonetary factors as the labour force, labour productivity and the relationship of wage rates to prices of output. The composition of T and the ratios of individual prices to each other reflect ,comparative costs of different goods and their comparative utilities to buyers. Everything that is real is determinable independently of money. hloney merely determines. via quantity-theory reasoning, rhe absolute level at which price relationships are established. In this view, money is a veil which in equilibrium may obscure but does not affect real determinants of economic welfare. Moreover. it should be the goal of monetary policy to keep money in this neutral role.

Neutral money. the argument continues. may be distorted by unsound policies on the part of treasury or monetary system. Monetary expansion will lead to both intermediate and ultimate consequences that are socially objectionable. The intermediate consequences are a fall in interest rates below "natural" levels that maintain stable full employment and stable prices. An excessive demand for goods and services ensues that will eventuate in cumulative and unlimited inflation of price levels if the excess supply of money is stubbornly replenished. If monetary expansion ceases, the high level of demand for goods and services collapses, and economic recession follows. The outcome of continuous inflation is maldistribution of income and wealth, perhaps a catastrophic paralysis of the economic and social structure. The outcome of abbreviated inflation is the business cycle, with its various wastes of scarce resources.

It is concluded that, in the transitional phases of inflation or of cyclical movement, the quantity theory of money does not apply precisely. In these phases. when the demand for money is adjusting to an altered supply, both V and T are subject to change. According to neutral-money doctrine, the quantity theory does explain differencesin price levels between states of general economic equilibrium. Since the quantity of money affects only price levels and not welfare in equilibrium, and since changes in the quantity of money reduce economic welfare in transitional phases, the optimal policy regarding money is to stabilize its quantity. Even in economic recession, "cheap" or "easy" money should not be adopted as one aspect of recovery policy.

The quantity theory has been brought to bear on other issues of policy. As developed by John Locke in the 17th century, David Hume in the 18th century, and others, it was used to attack the doctrines of mercantilism. If the accumulation of money by a nation merely raises prices. the mercantilist goal of export surpluses and imports of monetary metals for enhancement of national wealth must be illusory.

In the 19th century the quantity theory contributed to the gains of free-trade doctrine over protectionism. If the intermediate effect of import duties is to create an export surplus of goods and services, the ultimate effect is that the export surplus stimulates imports of gold. an expansion of the supply of money and a rise in domestic price levels that nullifies the trade restriction. The duties are eventually self-defeating.

In the 20th century the quantity theory played a part not only in analysis of inflation and business cycles but also in analysis of foreign-exchange rates and international commerce. The doctrine of purchasing-power parity, as developed primarily by Gustav Cassel, emphasizes that monetary expansion within a single country results in domestic price inflation. The inflation of prices. in turn, implies a decline not only in the internal purchasing power of the currency but also in the purchasing power of the inflated currency over money balances of other countries. The corrective for a depreciating exchange rate is stabilization of the supply of money and of the domestic level of prices.

From its primitive antecedents in the economic literature of Greece and Rome to its modern formulations, the quantity theory of money has been an important strand in the development of economic thought.

In the modern consensus, especially as a result of the influence of Lord Keynes, the tendency is to dispense with the Fisherian and Cambridge equations and to regard as a very special case the circumstances under which a proportional change in prices would follow a change in the supply of money.

It is widely agreed among economists that a change in prices may initiate disturbance, with subsequent adaptation of the supply of money: the causal sequence may be reversed. It is agreed. furthermore. that changes in V and T over both short periods and long may be expected typically to minimize or aggravate the impact of money on prices. The changes in V and T may be independent of developments in the realm of money or may alternatively be induced by monetary change. In any specific case, the effect of change in the money supply depends on the public's response in the spending of money and on the availability of goods to buy with money at alternative price levels.

The inflation of prices as the money supply expands, is probable when money users are expecting prices to rise. Then, reluctant to hold money as it depreciates, the public spends money balances more rapidly, increasing V. Inflation is probable, too. nhen the nation's capacity to produce goods and services is in intensive use. Then a rise in money and in money spending meets on the markets an inelastic supply of goods and services T. When either of these circumstances or both prevail in extreme degree an especially violent inflation may surpass the prediction of quantity theory and reduce even toward zero, rather than leave constant, the purchasing power of the total money supply. When opposite circumstances prevail. as in deep recession or depression. expansion of the money supply notoriously fails for at least limited periods to stimulate money spending at rising prices. In more commonplace circumstances productive growth and relatively stable price expectations provide a powerful antidote for the inflationary potential of increasing amounts of money.

There has been some disposition, on the basis that prices do not vary as quantity theory predicts, to minimize the effect of changes in the money supply on money spending and hence on either value of output PT or on prices alone. Correspcndingly monetary policy and techniques of managing the money supply have been reduced to a subsidiary role, at various times in different countries, in comparison with fiscal techniques for regulating money spending, the demand for goods and services and the levels of employment and prices.

QUANTUM MECHANICS. Following are the main sections and divisions of this article:

I. INTRODUCTION

Throughout the 19th century most physicists regarded Newton's dynamical laws as sacrosanct. During the 20th century, however, it became increasingly clear that many phenomena, especially those connected with radiation, defy explanation on Newtonian principles. It is well recognized that two major innovations are essential. One of these is the introduction of the principle of relativity. The relativistic corrections are important only for bodies moving with velocities comparable with that of light, and as a result experimental confirmation is possible only in very special types of laboratory experiments or in the cosmological field. The other innovation is quantum mechanics. Although rather less publicized than relativity, the quantum concepts have equally drastic philosophical implications and furnish richer and more diversified fields for investigation in the laboratory.

Quantum mechanics is the mechanics governing phenomena which are so small-scaled that they cannot be described in classical terms. Thus quantum rather than Newtonian dynamics must be used in dealing with the motions of electrons or nuclei inside atoms and molecules. In the equations of quantum mechanics, Max Planck's element of action, $h = 6.625 \times 10^{-27}$ erg sec., plays a central role. This constant, which is one of the most important in all of physics, has the dimensions

$$\text{mass} \times \text{length}^2/\text{time}.$$

The term "small-scale" used to delineate the domain of quantum mechanics should not be literally interpreted as relating necessarily to extent in space. A more precise criterion as to whether quantum modifications of the Newtonian laws are of importance is whether or not the phenomenon in question is characterized by an "action" (time integral of the kinetic energy) which is large compared to Planck's constant. Thus, if a great many quanta are involved, the Planck idea that there is a discrete, indivisible quantum unit loses importance, just as to a millionaire it would make little difference whether the smallest unit of currency is the cent or the dollar. This fact explains why our ordinary physical processes appear to be so fully in accord with the laws of Newton. Planck's element of action is, for example, far too fine-grained to have any bearing on the driving of an automobile. Since ultimately all matter is built out of atomic or small-scale ingredients, it must be possible to describe the properties of even large-scale bodies by means of quantum mechanics. In other words, Newtonian dynamics must represent a special case of quantum dynamics appropriate to cases where the action is very large compared to the elementary quantum. This is indeed true; it should be emphasized, however, that quantum mechanics is really an extension of classical statistical mechanics rather than of the deterministic laws of Newton. As a result, one of the most important philosophical implications of quantum mechanics concerns the apparent breakdown of the causality principle in atomic phenomena. (See UNCERTAINTY PRINCIPLE, THE.)

The history of quantum mechanics may be divided into three main periods. The first of these began with Planck's theory of black-body radiation in 1900, and may be described as the period in which the reality of Planck's constant of action was demonstrated, but its real meaning was rather obscure. The second period began with the Bohr quantum theory of spectra in 1913. Niels Bohr's ideas gave the correct formula for the frequency of spectral lines in many cases, and were an enormous help in the codification and understanding of spectra. Still they did not represent a consistent, unified theory, as he himself recognized, but rather a sort of patchwork affair in which classical mechanics was subjected to a rather extraneous set of so-called "quantum conditions," which restrict the constants of integration to certain particular values. The true quantum mechanics appeared in 1926, reaching fruition almost simultaneously in a variety of forms, *viz.*, the matrix theory of Max Born and Werner Heisenberg, the wave mechanics of Louis V. de Broglie and Erwin Schrodinger, and the transformation theory of Paul A. M. Dirac and Pascual Jordan. These different formulations are in no sense alternative theories, but rather they are different aspects of a consistent body of law.

Near mid-20th century the status of quantum mechanics was aptly described as follows (from Dirac in *Proceedings of the Royal Society, A*, vol. cxxiii): "The general theory of quantum mechanics is now almost complete, the imperfections that still remain being in connection with the exact fitting in of the theory with relativity ideas. These give rise to difficulties only when high-speed particles are involved, and are therefore of no importance in the consideration of atomic and molecular structure, and ordinary chemical reactions. . . . The underlying laws necessary for the mathematical theory of a large part of physics and the whole of chemistry are thus completely known, and the difficulty is only that the exact solution of these laws leads to equations much too complicated to be soluble." It should be added perhaps that quantum mechanics makes no pretense of describing completely what goes on inside the nucleus. In other words, the details of the short-range dynamics of the neutrons, protons, etc., of which the nucleus is composed are not known, although quantum mechanics has been a help in understanding many nuclear phenomena. such as the emission of alpha particles and photodisintegration, and although the rather intricate field theory of quantum mechanics has provided some insight into the properties of mesons, particles of transient life which are of interest mainly in connection with nuclear phenomena. In short, by the second half of the 20th century the theory of nuclear physics was in a more or less embryonic stage comparable, say, with extranuclear quantum theory in its early days.

Thus, quantum mechanics gave us the appropriate laws of nature down to distances of the order 10^{-10} cm., but we still do not know the rules in detail when we seek to probe below nuclear radii of the order 10^{-12} cm.

II. QUANTUM THEORY PRIOR TO THE BOHR ATOM

First will be described the earlier investigations in quantum theory which anteceded the discovery of the true quantum mechanics in *1926*. This procedure is not merely an attempt to preserve historical order, but is also advisable because some of the primitive theories describe some subjects fairly well and help in the visualization of the later. more recondite developments.

1. Black-Body Radiation. — The quantum of action had its birth in the studies of black-body radiation in *1900* by Planck, professor of physics at the University of Berlin. All black (*i.e.,* perfectly absorbing) bodies heated to a given temperature should emit radiation having the same spectrum. The latter can be shown to be identical with the spectral distribution of energy in a so-called *Hohlraum; i.e* , a cavity whose radiation is in thermal equilibrium with matter. *(See* BLACK BODY.) According to classical physics, the density of radiant energy should be proportional to the square of the frequency, and so increase without limit as the wave length is made progressively shorter. This prediction is sometimes called the "ultraviolet catastrophe," and the corresponding analytical formula for the energy density is called the Rayleigh-Jeans law. It yields the dashed curve of fig. 1. The observed distribution is that indicated by the solid curve, which Planck was able to deduce theoretically by making a quantum hypothesis.

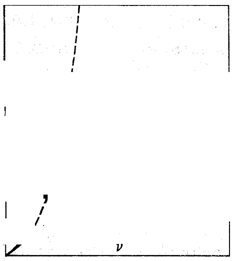

FIG 1.—THE ENERGY DENSITY (ρ_ν) OF BLACK-BODY RADIATION AS A FUNCTION OF FREQUENCY (ν). CLASSICAL AND QUANTUM THEORIES GIVE RESPECTIVELY THE DASHED AND CURVES

We shall now indicate how the Rayleigh-Jeans and Planck radiation laws can be derived and shall formulate them mathematically. The method which we sketch is a well-known but rather formal one. It may be characterized as the application of classical equipartition *(see* KINETIC THEORY OF MATTER) or of classical statistics to the degrees of freedom of the ether. It is not presumed that a material ether really exists; this term is used merely to indicate that the standing electromagnetic naves in an enclosure are handled by the same type of statistical procedure as those of a material medium. The first step is the enumeration of the different types of standing waves or modes of vibration of the ether in a rectangular parallelopiped of volume V. Just as a rope with fixed ends can vibrate only in certain ways, represented by the fundamental and the various harmonics, so also in the three-dimensional case only certain modes of oscillation are compatible with the boundary conditions. If the edges of the parallelopiped are large compared to the wave length, the number of possible vibrations in the frequency interval ν, $\nu + d\nu$ can be shown to be

$$(8\pi\nu^2 V/c^3).d\nu, \tag{1}$$

where c is the velocity of light. Let the mean energy of an oscillation of frequency ν be denoted by ϵ_ν. Then the density of radiant energy in the irequency range $\nu, \nu + d\nu$ is $\rho_\nu d\nu$ with

$$\rho_\nu = \epsilon_\nu \cdot (8\pi\nu^2/c^3). \tag{2}$$

It is now necessary to evaluate ϵ_ν. This is done by treating each characteristic mode of vibration as a harmonic oscillator. According to classical statistical mechanics,

$$\epsilon_\nu = KT, \tag{3}$$

where k is Boltzmann's constant 1.38×10^{-16} erg/degree. Equation (3) is a direct consequence of the classical theory of equipartition. The latter demands that the mean kinetic energy per degree of freedom be $\frac{1}{2}kT$, and a harmonic oscillator has equal mean kinetic and potential energies, so that the total energy is kT. Substitution of (3) in *(2)* yields the Rayleigh-Jeans law

$$\rho_\nu = 8\pi\nu^2 kT/c^3. \tag{4}$$

The fact that ρ_ν increases without limit when ν is made arbitrarily large is the ultraviolet catastrophe mentioned above.

In quantum theory, however, the mean energy of a harmonic oscillator is taken to be

$$\epsilon_\nu = \frac{h\nu}{e^{h\nu/kT} - 1}. \tag{5}$$

This formula is obtained by assuming that the energy of a harmonic oscillator is restricted to the "quantized" values $0, h\nu, 2h\nu, 3h\nu, \ldots$. The mean energy is calculated by weighting these values in accordance with the usual Boltzmann factor, so that

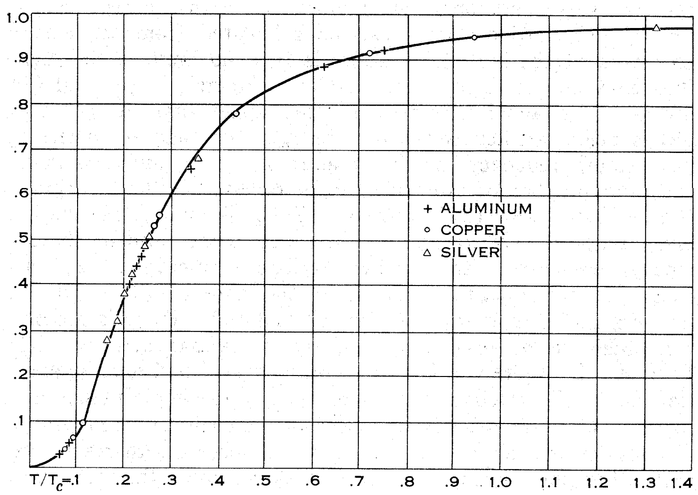
$$\epsilon_\nu = \frac{h\nu e^{-h\nu/kT} + 2h\nu e^{-2h\nu/kT} + \cdots}{1 + e^{-h\nu/kT} + e^{-2h\nu/kT} + \cdots}. \tag{6}$$

The series in the numerator and denominator of (6) are readily summed, and the result is (5). Substitution of (5) in (2) gives

$$\rho_\nu = \frac{8\pi h\nu^3}{c^3} \cdot \frac{1}{e^{h\nu/kT} - 1}. \tag{7}$$

This is the celebrated Planck radiation formula. This represents essentially one approach used by Planck. He also had other ways of obtaining his formula, but most of these have been discarded. The best present derivation of the Planck radiation formula is probably one due to Albert Einstein in 1916, which is based on so-called detailed balancing for a system of matter and radiation.

2. Specific Heats. — Another early success of quantum theory was in the field of specific heats, where it explained the deviations from the law of P. L. Dulong and A. T. Petit. This law states that the specific heat per gram atom is very nearly the same, about six calories, for many solid elements. Honever, there are many exceptions. Also. if the temperature is lowered sufficiently, the specific heat approaches zero, instead of remaining constant, as predicted by the law. The behaviour of three metals, for instance, is shown in fig. *2.* The law of Dulong and Petit is a direct consequence of the classical theory of equipartition, provided the latter is applied to the atom as a whole and no attempt is made arbitrarily to apply classical statistics to the motion of the electrons inside the atom. The specific heat is then independent of temperature, and so in fig. *2* would be represented by a horizontal straight line of unit height in the scale employed there. Debye's quantum model, on the other hand, yields the solid curve, which is in good agreement with experiment. This curve approaches unity if the temperature is raised sufficiently. More generally, all classical and quantum theories of specific heats



ADAPTED FROM T PRESTON THEORY OF HEAT (MACMILLAN)

FIG 2 —SPECIFIC HEAT OF A MONATOMIC SOLID AS A FUNCTION OF TEMPERATURE THE CURVE IS CALCULATED FROM DEBYE'S QUANTUM THEORY. THE SCALE OF ORDINATES IS SO CHOSEN THAT CLASSICAL THEORY GIVES UNITY

agree asymptotically at high temperatures. On the other hand. the vanishing of the specific heat at the absolute zero is a characteristic quantum phenomenon.

In the mathematical analysis the difference between the classical and quantum theories of the specific heats of solids parallels closely that between the proofs of the Rayleigh-Jeans and Planck laws for radiation. Instead of considering the electromagnetic vibrations of the ether, it is necessary to deal with the vibrations of the atoms composing the solid with respect to each other. If the forces binding the atoms to their equilibrium positions obey Hooke's law, the vibrations are simple harmonic. The dynamical system represented by the aggregate of atoms constituting the solid obviously is exceedingly complicated, but, in principle, modes of vibration can be sorted out according to frequency. Let there be $n_\nu d\nu$ such modes in the interval ν, $\nu + d\nu$. Let the mean energy of a harmonic vibration be denoted by ϵ_ν, which, as before, has the value (3) or (5) depending on whether classical or quantum theory is used. The total energy is obtained by integrating over all frequencies, and the specific heat c_V is the temperature derivative of the energy. Hence

$$c_V = \frac{d}{dT}\left[\int_0^\infty n_\nu \epsilon_\nu d\nu\right]. \tag{8}$$

The determination of the factor n_ν specifying the distribution of vibration frequencies represents an exceedingly difficult problem, as n_ν is no longer given by the simple expression (1) which applied in the radiative case. However, if the classical result $\epsilon_\nu = kT$ is employed, it is not necessary to determine n_ν, as kT is merely a constant factor, which can be taken outside the integration. The integral can then be immediately evaluated from the relation

$$\int_0^\infty n_\nu d\nu = 3N, \tag{9}$$

which states that the total number of independent modes of oscillation, or in other words the total number of degrees of freedom, must be three times the total number of atoms N. Hence, according to classical equipartition,

$$c_V = 3Nk. \tag{10}$$

This is essentially the law of Dulong and Petit. If we take an amount of material equal to a gram atom, so that N becomes the Avogadro number, and if we express the specific heat in calories rather than in ergs, then (10) gives a specific heat of 5.96 cal. per degree.

In quantum theory, on the other hand, it is necessary to evaluate n_ν. Peter J. W. Debye assumed a distribution law for n_ν analogous to that (1) for the radiative case, but with allowance for transverse and longitudinal vibrations with different velocities of propagation, which can be calculated from the elastic constants of the material. There is then no limit to the high-frequency end of the spectrum, and the integrals in (8) and (9) diverge. To avoid this difficulty the upper limit in (8) and (9) is rather artificially taken to be ν_c rather than ∞, where ν_c is a "cutoff frequency" so chosen as to satify (9) and thus make the total number of vibrations equal to $3N$. With this model, Debye found $c_V = f(T/T_c)$, where $f(T/T_c)$ is a universal function of a "reduced temperature" T/T_c, which is the ratio of the ordinary temperature to a "characteristic temperature" T_c calculable from the elastic properties of the material. This reduced temperature is used for the abscissa in fig. 2. Debye's method for obtaining n_ν originally appeared somewhat artificial, but Born and Theodore von Kármán showed that it had some dynamical basis. The Debye model applies only to simple monatomic solids. When the solid is composed of molecules, it is necessary to consider the vibrations not only of molecules with respect to each other but also the vibrations of atoms inside the molecules. As emphasized by Einstein, the latter effect gives sharp maxima of n_ν at certain frequencies. Improved methods of calculating n_ν have been developed, and the theory correspondingly refined. So far only solids have been referred to. There is also considerable literature on the specific heats of gases. Here again, quantum theory explains deviations from the classical theory of equipartition, especially at low temperatures, which are particularly pronounced for hydrogen.

3. Photoelectricity.—Nowhere, perhaps, is the inadequacy of classical theory revealed more strikingly than in the subject of photoelectricity, which is concerned with emission of electrons by an illuminated body. (See PHOTOELECTRICITY.) Photoelectric phenomena exhibit two main features: (1) no emission occurs at all unless the frequency ν of the incident radiation exceeds a certain critical value, called the threshold frequency; and (2) the kinetic energy of the ejected electrons depends on the frequency of this radiation, and not on its intensity. In other words, if a light source is removed farther and farther from the body which it illuminates, the emitted electrons are undiminished in their velocity of escape, but are decreased in number. Such a state of affairs was a complete conundrum at the turn of the century, since in classical electromagnetic theory, diminished incident intensity implies a lowering of the energy traversing the absorbing "target area," and as a result of the lower energy flow, the velocity imparted to the electron should be decreased, contrary to experiment. In 1905 Einstein showed that the observed behaviour could be explained if in the emission of the electron a quantum of energy $h\nu$ is picked up by matter from the radiation, regardless of the latter's intensity. The process merely becomes less likely when the intensity is low. Just how such a corpuscular model was to be reconciled with the undulatory features of light, such as interference, was something not understood for two decades or so, but was finally clarified by the Heisenberg uncertainty principle and by Bohr's theory of complementarity. From the less sophisticated outlook of 1905, Einstein showed that if the conflict with the wave viewpoint was ignored, his picture did indeed account for the salient factors of photoelectricity. The kinetic energy of escape of the electron will not in general be the same as the quantum $h\nu$ absorbed from the radiation inasmuch as part of the energy is consumed in liberating the electron from the metal. This portion is called the thermionic work function, and will be denoted by the letter ϕ. Einstein's equation for determining the velocity of escape v of an electron is thus

$$\tfrac{1}{2}mv^2 = h\nu - \phi. \tag{11}$$

Since the kinetic energy $\frac{1}{2}mv^2$ is necessarily positive, emission is possible only if $\nu > \phi/h$. Hence ϕ/h is the threshold frequency.

Closely related to the photaelectric effect is the Compton effect (*q.v.*), which also reveals the need of the quantum hypothesis.

III. BOHR ATOM

A signal advance in quantum theory was achieved when the Danish physicist Niels Bohr propounded his theory of the spectrum of hydrogen, in 1913. By that time there was no doubt as to the validity of the Rutherford picture of the atom as a miniature solar system, with the nucleus and electrons playing respectively the role of the sun and the planets. (See ATOM.) The number of electrons in the neutral atom is the same as the chemists' atomic number, one for hydrogen, two for helium, etc. Therefore, the dynamics of the orbits of the electrons in the various atoms will be very complex except in the hydrogenic case, for the mathematical difficulties associated with even a three-body problem (*e.g.,* neutral helium, with one nucleus and two valence electrons) are enormous. By a hydrogenic atom is not necessarily meant a hydrogen atom, but any other atom which has been stripped of all but one valence electron as a result of ionization. Examples are singly ionized helium, doubly ionized lithium, etc. Clearly, the study of the spectrum of hydrogen, because of its comparative simplicity, should be the most likely starting point of any attempt to decipher the complexities of atomic spectra.

1. Balmer Formula.—It has long been known that there are some remarkable regularities in the spectrum of hydrogen. As early as 1885, J. J. Balmer showed that the wave lengths λ of many lines are well represented by the empirical formula

$$\frac{1}{\lambda} = RZ^2\left[\frac{1}{n'^2} - \frac{1}{n''^2}\right], \tag{12}$$

in which n', n'' are integers, and R is a constant, the so-called Rydberg constant. If, for instance, one takes $n' = 2$ and $n'' = n' + 1, n' + 2, \ldots$, the expression (12) gives the wave lengths of the lines in what is called the Balmer series. The choices $n' = 1$, 3, 4 and 5 yield respectively the Lyman, Paschen, Brackett and Pfund series, which were discovered later. Since the atomic number Z is unity for hydrogen, the factor Z^2 in *(12)* is unnecessary for present purposes, but is included to permit later extension to atoms of higher nuclear charge.

2. Postulates of the Bohr Theory.—For many years, the *raison d'être* for the formula (12) was completely obscure. It is not surprising that the subject of line spectra was a closed book to the classical physicist. As some one has said, the task of constructing a model of the atom merely from knowledge of its spectra radiated under violent electrical or thermal excitation is comparable with trying to learn about a piano merely from the noise emitted when it is dropped downstairs. Bohr, however, showed that the behaviour *(12)* could be explained by means of two postulates, as follows:

1. The existence of stationary states: In every atom there is a discrete succession of states, in any one of which the electrons can move without appreciable radiation, and which can be identified by a set of integers, usually called quantum numbers. The designation of these states as stationary refers to the absence of radiation from the orbits, in contravention of classical electrodynamics, and does not imply a static atom. Except for omission of the radiation corrections, the motion of the electrons in the stationary states is assumed to conform to the laws of classical mechanics.

2. The Bohr frequency condition: It is assumed that an electron can sometimes pass discontinuously from one allowed orbit to another. In such a transition, the initial and final states will have different amounts of mechanical energy E'' and E'. To secure conservation of energy, the change in the mechanical energy must be counterbalanced by the absorption or emission of a light quantum, whose energy is $h\nu$ if the frequency is ν. This requirement yields the so-called Bohr frequency condition

$$h\nu = E'' - E'. \tag{13}$$

The analogy to Einstein's photoelectric equation *(11)* is obvious.

In connection with the first postulate it is necessary to formulate the quantum conditions which restrict the energies of the atoms to certain particular values. The easiest case to handle is that of a simply periodic system, where the orbit repeats itself after a given interval of time τ. Here the quantization is effected by the relation

$$\overline{T} = \tfrac{1}{2}nh\nu_0, \tag{14}$$

in which n is an integer, $\overline{T}$ is the mean kinetic energy of the system (*i.e.,* the average of the kinetic energy T over a period) and $\nu_0 = 1/\tau$ is the frequency with which the orbit repeats itself. It is to be emphasized that the orbital frequency ν_0 is in general not the same as that ν given by the Bohr frequency condition (13). This nonidentity of the orbital and radiated frequencies is a celebrated paradox of the Bohr atom, as according to classical mechanics or actual observations on large-scale phenomena there is no distinction between the frequencies of motion of a system and those of the waves which it radiates. It should be mentioned, however, that in the Bohr theory there is an asymptotic agreement of the two frequencies for large quantum numbers, which is usually termed the "correspondence principle for frequencies."

3. Derivation of the Balmer Formula From the Bohr Theory.— It will now be shown that the Balmer expression *(12)* is a consequence of the quantum condition *(14)* and the Bohr frequency condition. This derivation is such a simple and classic one that it seems worth giving, even though in a sense it is outmoded by later but more intricate calculations by means of wave mechanics, which also yield the result *(12)* with identically the same value of the Rydberg constant R as that obtained from the Bohr theory.

To simplify the calculations, it will be assumed that the orbit is circular but it can be shown that the energy levels are no different in the general case of ellipses. Let the mass of the nucleus and electron be denoted by M and m respectively, and let the nuclear and electronic charges be Ze and $-e$. Here e has the value 4.80×10^{-10} in electrostatic units. and Z is the atomic number. The centre of gravity, which may be supposed stationary, divides the line connecting the two particles in the inverse ratio of their masses. Hence. the electron and nucleus revolve around this centre in circles of radii $Ma/(m + M)$ and $ma/(m + M)$ respectively. where a is the distance from the nucleus to the electron. Since the angular velocity is $2\pi\nu_0$, the kinetic energy is

$$T = \tfrac{1}{2}\left[m\left(\frac{M}{m+M}\right)^2 + M\left(\frac{m}{m+M}\right)^2\right](2\pi\nu_0)^2a^2. \tag{15}$$

This equation can also be written as

$$T = \tfrac{1}{2}\mu(2\pi\nu_0)^2a^2, \tag{16}$$

where μ is the so-called reduced mass, given by

$$\mu = mM/(m + M). \tag{17}$$

As T is constant in time, there is no distinction between T and $\overline{T}$. Thus application of the quantum condition (14) gives

$$(2\pi\nu_0)\mu a^2 = nh/2\pi. \tag{18}$$

In other words, the angular momentum of the system is an integral multiple of $h/2\pi$ The equality between the centriiugal force on the electron and the Coulomb attraction due to the nucleus yields a further relation

$$\mu a(2\pi\nu_0)^2 = Ze^2/a^2. \tag{19}$$

When equations (18) and (19) are solved for a and ν_0, the result is

$$a = n^2h^2/4\pi^2Ze^2\mu, \qquad \nu_0 = 4\pi^2\mu Z^2e^4/n^3h^3. \tag{20}$$

The first relation of (20) shows that the allowed or "quantized" values of the radius of the atom form a progression of the form $a_0, 4a_0, 9a_0, \ldots$, where a_0 is a fundamental unit $h^2/4\pi^2\mu Ze^2$ called the Bohr radius, and having the numerical value 0.53×10^{-8} cm. if $Z = 1$ (hydrogen). Substitution of (20) in (16) gives

$$T = 2\pi^2\mu Z^2e^4/n^2h^2,$$

while the potential energy is

$$V = -Ze^2/a = -4\pi^2\mu Z^2e^4/n^2h^2.$$

Hence the total energy $E = T + V$ is

$$E = -2\pi^2\mu Z^2e^4/n^2h^2. \tag{21}$$

When we substitute this value of E in the Bohr frequency condition (13) and remember that $\lambda = c/\nu$, we have indeed the Balmerformula (12), provided the Rydberg constant R has the value

$$R = 2\pi^2\mu e^4/ch^3. \tag{22}$$

The question immediately arises whether (22) yields a value of R in agreement with the optical measurements, when the numerical values of the constants e, h, μ, c are substituted. The answer is that there is certainly agreement within the precision with which these constants are known, for e, h, μ are known only to one part in a thousand or so. On the other hand, since optical wave lengths are known so very accurately. the Rydberg constant R can be determined to within less than *1* part in *1,000,000*. *A* valuable cross-check on the values of the various atomic constants is thus provided. namely. use of *(22)* along with the spectroscopic determination of R permits determination of one of the four quantities e, **h**, μ, **c** if the other three are known. It is thus possible to increase the accuracy with which the value of the particular one of the four constants is known (viz., h) which otherwise cannot be as precisely determined as the other three.

4. Correction for the Motion of the Nucleus, and Spectroscopic Determination of e/m.—If we neglect the motion of the nucleus. or in other words consider the mass M of the nucleus to be infinite, then equation (17) shows that the reduced mass becomes identical with the mass m of the electron. When allowance is made for the finite mass of the nucleus, μ will differ slightly from m. The neutral hydrogen atom and ionized helium atom resemble each other in having only one electron, so that formula (22) should be applicable to either. However, the different masses of the hydrogen and helium nuclei will make the Rydberg constant slightly different for the two. Just this state of affairs is found experimentally: the best spectroscopic value of the Rydberg constant for hydrogen is $R_H = 109677.58$ cm.$^{-1}$, while that for helium is $R_{He} = 109722.27$ cm.$^{-1}$ (Du Mond and Cohen's figures). The corresponding value for a hydrogenic atom of infinite nuclear mass in $R_{H\infty} = 109737.31$ cm.$^{-1}$.

Equation (22) shows that the ratio of the Rydberg constants for hydrogen and ionized helium is equal to the ratio of the reduced masses, the other constants canceling out. When (17) is used,

$$\frac{R_{He}}{R_H} = \frac{1 + m/M_H}{1 + m/xM_H}, \tag{23}$$

where x is the ratio M_{He}/M_H of the mass of the helium nucleus to that of hydrogen. This ratio can be regarded as known from determinations of atomic weights, since practically all of the atom's mass arises from the nucleus. Hence, by means of (23) and the spectroscopic determinations of R_H, R_{He}, it is possible to evaluate the ratio m/M_H of electronic to protonic mass. Furthermore, it is possible to go a step farther and determine e/m spectroscopically, inasmuch as one has $e/m = (e/M_H)(M_H/m)$ and as the value of e/M_H is known from electrolysis; *i.e.*, from the so-called electrochemical equivalent. In this nay, the shift between the Rydberg constants for hydrogen and ionized helium furnishes perhaps the most accurate means of determining elm In the early 1930s there appeared to be a discrepancy between the values of e/m determined spectroscopically and by more direct deflection methods. This difficulty has disappeared, and the generally accepted value of elm is 1.759×10^7 e.m.u.

During the first years of Bohr's theory, the only known hydrogenic atoms (i e., those with one valence electron) were H and He+. Subsequently. X-ray measurements at Uppsala, Fin., revealed lines due to Li^{2+}, Be^{3+}, B^{4+} and C^{5+}. These lines are particularly useful because they furnish wave-length standards in the X-ray region. Another subsequent development was the discovery of the hydrogen isotope deuterium, nhich has about double the value of M for ordinary hydrogen and hence a slightly different Rydberg constant. This difference, in fact, historically furnished the first means of demonstrating the existence of deuterium with certainty.

5. Relativity Fine Structure. — A great triumph of the Bohr atom was the theory of the relativity fine structure in hydrogen, which was developed by Arnold Sommerfeld in 1916. In the preceding discussion. the problem was treated by means of Newtonian mechanics. When the relativity corrections are introduced, the orbits cease to be periodic, and the quantization becomes more complicated. It is necessary to introduce two quantum conditions, mathematical details of which will be omitted here except for mentioning that they restrict the values of certain so-called "phase integrals" to integral multiples of Planck's constant. If the nuclear mass is treated as infinite, the formula for the energy can be shown to be

$$E = mc^2\left\{\left[1 + \left(\frac{\alpha Z}{n - k + g}\right)^2\right]^{-\frac{1}{2}} - 1\right\}, \tag{24}$$

where

$$\alpha = 2\pi e^2/hc, \qquad g = (k^2 - Z^2\alpha^2)^{\frac{1}{2}}. \tag{25}$$

If (24) be expanded as a power series in α^2, and terms beyond α^4 are disregarded, the expression for E takes the form

$$E = -\frac{2\pi^2 mZ^2e^4}{n^2h^2}\left[1 + \frac{\alpha^2Z^2}{n^2}\left(\frac{n}{k} - \frac{3}{4}\right) + \cdots\right]. \tag{26}$$

Since $m = \mu$ if $M = \infty$, the first term of (26) is the same as the Newtonian result (21). and involves only the principal quanturn number n. The remainder of (26) is due to the relativity corrections, and involves a second quantum number k, which is the so-called azimuthal quantum number. Its physical significance is that the angular momentum is $kh/2\pi$, and the range of values for k is $1, 2, \cdots n$. The dependence of the energy on k is only a minor effect because of the smallness of α $(= 1/137.0)$, but it causes lines which would otherwise coincide to be slightly separated so as to form the components of a multiplet. A decomposition is indeed found experimentally, and on the whole the observed spacing of the components agrees nell with theory.

6. Stark Effect. — Still another quantitative success of the Bohr theory of the hydrogen spectrum is provided by the Stark effect, or splitting of the energy levels and hence of the spectral lines by means of an electric field. The separation and number of the components accords with theory in a remarkable fashion. The formulas for the displacement in frequency involve Planck's constant h, and so classical theory was powerless to explain any of the features of the Stark effect. On the other hand, in the alternative phenomenon of the Zeeman effect (separation of lines in a magnetic field), Planck's h cancels out of the final formula for the shift in frequency, and so classical and quantum theories give identical results for the normal Zeeman effect (*q.v.*).

7. Moseley's Relation. — In attempting to apply the Bohr concepts to nonhydrogenic atoms, the mathematical complexities are so great that the permitted energy levels or frequencies cannot be exactly determined. Nevertheless, certain successes of the theory should be stressed. One of these is the explanation of Moseley's relation in X-ray spectra. wherein the frequencies of the K lines—*i.e.*, the hardest lines (lines of shortest wave length or highest frequency) — are proportional approximately to the square of the atomic number. This is simply an expression of the factor Z^2 in (21). The result (21) applies approximately to an interior electron of a nonhydrogenic atom if the screening of the nucleus by the other electrons is so poor that the field is substantially that of the bare nucleus. This approximation will be a good one only for electrons which are deep-seated in the atom, such as are responsible for the emission of X-rays.

8. Relation Between Critical Potentials and Spectral Frequencies. — By electron bombardment it is possible to "excite" an atom from one stationary state, say of energy E', to another of higher energy E''. To be able to do this, the impinging electron must have at least a kinetic energy equal to $E'' - E'$, as otherwise conservation of energy cannot be secured. The energy which an electron acquires in falling through a difference of potential V is Ve. Hence, the minimum or "critical" accelerating potential required for the excitation is given by $Ve = E'' - E'$. Alternatively, the Bohr frequency condition states that $h\nu = E'' - E'$. Thus, $Ve = h\nu$, and this relation holds as a useful consequence of the theory, even though the mechanics of the many-body problem is so intricate that it is not possible to calculate theoretically the energy levels E', E''.

9. Stern-Gerlach Effect. — The application of the quantum conditions to an atom in a magnetic field shows that its component of angular momentum in the direction of the field should be "quantized" and equal to an integral multiple of $h/2\pi$. The corresponding magnetic moment, which is proportional to the angular momentum, should hence likewise acquire only discrete values. Otto Stern and Walther Gerlach verified this prediction by observing the deflections of atoms in an inhomogeneous magnetic field. We cannot overemphasize how beautifully the existence of only certain particular deflections in their experiments demonstrates the reality of the quantized positions which are the essence of quantum theory. It is true that the explanation of the precise quantitative values of the deflections found by Stern and Gerlach requires inclusion of electron spin and the refinements of quantum mechanics in certain cases. However, the broad outlines of the phenomenon were clear even in the days of the Bohr theory, especially the complete contradiction between the classical continuous distribution of orientations and quantum discreteness. The Stern-Gerlach experiment decided unequivocably in favour of the latter.

10. Harmonic Oscillator and Rotator — Molecular Spectra. — There are two very simple schematic models which are particularly easy to quantize and which are rich in physical applications. They are the harmonic oscillator and the rigid rotator or "rotating dumbbell."

For a particle which is harmonically bound (*i.e.,* subject to a linear restoring force) the mean kinetic energy is equal to the mean potential energy. Hence the total energy, which is the sum of the kinetic and potential, is equal to twice the mean kinetic energy. Furthermore, the frequency ν_0 of a harmonic oscillator is independent of the initial conditions. Therefore, application of (14) immediately yields the result

$$E = nh\nu_0. \tag{27}$$

The quantized values of the energy of a harmonic system given in (27) are the same as those used above in discussing black-body radiation and specific heats.

For a rigid rotator, there is no potential energy, and the kinetic energy has the constant value $\frac{1}{2}I(2\pi\nu_0)^2$, where I is the moment of inertia, and ν_0 is the rotation frequency. The quantum condition (14) yields $2\pi\nu_0 I = nh/2\pi$. The quantization thus consists in equating the angular momentum to an integral multiple of $h/2\pi$. The corresponding quantized value of the energy is, since E = T,

$$E = n^2h^2/8\pi^2I. \tag{28}$$

These formulas have a direct application to the spectrum of a diatomic molecule such as HCl. As a first approximation, the energy of the molecule can be divided into contributions from (1) the electronic motion relative to the two nuclei regarded as fixed attracting centres, (2) the vibration of the two nuclei along the line connecting them, and (3) "end-over-end" rotation of the molecule as a whole. Effects (2) and (3) are respectively portrayed by the harmonic oscillator and the rotator. The quantum numbers associated with (2) and (3) are not, of course, the same, and so the letters v, J are used for them instead of n. The total energy of the molecule is thus

$$E = E_e + vh\nu_0 + J^2h^2/8\pi^2I. \tag{29}$$

The electronic term E_e will be a function of numerous quantum numbers other than v, J, but is too difficult to compute explicitly because of the complexities of the many-body problem. The dependence on the rotational and vibrational quantum numbers a, J predicted by (29) agrees nicely with experiment.

11. Intensities and Transition Probabilities in the Bohr Theory.— The theory so far presented is one-sided, as it tells how to calculate the frequency but nothing about the intensity. In order to have information about the latter, it is necessary to know the transition probability. It is a fundamental concept of the Bohr theory that radiation takes place sporadically and discontinuously, when an electron passes from one stationary state to another, rather than continuously as in classical theory. The transitions between states are governed by the statistics of random processes. like radioactive decay. Thus, if an electron is initially in a state l, there is a certain probability $A_{l\rightarrow m}$ that it will pass to another state m. Let us denote by $\nu(lm)$ the frequency associated with this transition, which by (13) is the same as $(E_l - E_m)/h$. Since an amount of energy $h\nu(lm)$ is radiated in each transition, the total rate at which energy is radiated in the frequency $\nu(lm)$ is

$$I_{l\rightarrow m} = h\nu(lm)A_{l\rightarrow m}N_l, \tag{30}$$

where N_l is the number of atoms in the state l.

Part of the contribution to $A_{l\rightarrow m}$ in the case of emission, and all in the case of absorption, will come from transitions induced by a radiation field. Even in the absence of the latter, however, there is a certain probability of "spontaneous radiation," provided the energy E_m of the final state is less than that E_l of the initial one. For simplicity, only the spontaneous effect will be considered.

The problem is now to calculate the transition probability in the absence of a radiation field. Here the Bohr theory gave no clear-cut answer. The best that could be done was to make an approximate estimate by means of the so-called correspondence principle, which has been described as a "magic wand which enables one to borrow the results of classical theory for quantum theory." According to classical electrodynamics, an electron moving in a periodic orbit described by Fourier series such as

$$x = \sum_{\tau=-\infty}^{\infty} x_\tau e^{2\pi i\tau\nu_0 t}$$

radiates energy in the harmonic $\tau\nu_0$ at a rate

$$(4e^2/3c^3)(2\pi\tau\nu_0)^4[|x_\tau|^2 + |y_\tau|^2 + |z_\tau|^2].$$

The correspondence principle for frequencies shows that if the difference in quantum number between the initial and final states is τ, the quantum frequency $\nu(lm)$ approaches asymptotically the classical overtone $\tau\nu_0$ if the quantum number is large. Hence. a formula by which the transition probability can be estimated qualitatively or asymptotically is

$$A_{l\rightarrow m} = (4e^2/3hc^3)(2\pi)^4\nu(lm)^3[|x_{l-m}|^2 + |y_{l-m}|^2 + |z_{l-m}|^2]. \tag{31}$$

It is to be emphasized that (31) never gives a clear-cut and unambiguous answer, as there is no way of telling whether the Fourier coefficients should be evaluated for the initial or the final orbit of the transition, or should represent some sort of compromise between the two.

IV. ADVENT OF TRUE QUANTUM MECHANICS

Although the Bohr theory had the many triumphs indicated above, still as time progressed, especially in the early 1920s. it became increasingly apparent that it was not adequate. With much labour it was possible to determine the energy levels of the neutral helium atom, a three-body problem, and these did not accord with experiment. Unjustifiable half-quantum numbers (*i.e.,* half rather than whole integers) kept appearing in the empirical description of band spectra. Numerous other difficulties could be recited. It was clear that the trouble was simply that the "old" or Bohr quantum theory was a patchwork doctoring of classical mechanics, wherein the quantum conditions were added in a rather artificial way. What was needed was a rational, self-consistent quantum mechanics, which started afresh and evolved a mathematical framework and philosophy all its own This was discovered in 1926, which was thus an epoch-making year in the history of quantum theory.

This remarkable new mechanics cannot be regarded as the product of any one man, and was instead the result of the impact of mind on mind among the leading theoretical physicists of the time. It was developed in a diversity of mathematical forms, which present a rather confusing array to the student beginning the subject. However, these various formulations, though different in superficial mathematical structure, are basically in harmony with each other. The three main mathematical forms are the following: (1) the matrix theory of Born, Heisenberg and Jordan; (2) Schrodinger's wave mechanics. the outgrowth of De Broglie's concept of "phase waves"; and (3) the so-called transformation theory. based on kinetical indeterminism, developed by Dirac and Jordan, and interpreted by Heisenberg.

A. Wave Mechanics

1. Hamiltonian Analogy and De **Broglie Waves.**—We shall begin with the "wave" formulation, as this is the version most universally used, and perhaps the easiest to understand The impetus to the development of this form of quantum mechanics nas furnished by De Broglie's interpretation of the classical Hamiltonian analogy between optics and dynamics This analogy, which is readily demonstrated from Fermat's principle in optics and the principle of least action in mechanics, establishes a formal similarity between the path of a particle in a mechanical system and a hypothetical optical system in which the refractive index is correlated in a rather arbitrary nay with the potential energy $V(x, y, z)$ in the mechanical problem. This comparison always seemed highly artificial because the velocity in the optical system was different from that in the mechanical one. However if somehow it is possible to introduce the concept of wave length into the analogy, so that it is meaningful to talk about dispersion, then besides the phase velocity there is also a group velocity, which is the velocity with which signals or modulations are propagated. De Broglie showed that although the velocity of the mechanical particle differed from the phase velocity, it became identical with the group velocity, provided the wave length has the value

$$\lambda = \frac{h}{\sqrt{2m(E - V)}} = \frac{h}{mv}. \tag{32}$$

The second form of (32) is obtained by noting that the energy constant E is the sum of the kinetic energy $\frac{1}{2}mv^2$ and the potential energy $V(x, y, z)$. Formula (32) gives the celebrated De Broglie wave length which occurs so characteristically in quantum-mechanical diffraction problems. When De Broglie first propounded his ideas in 1925, it was not clear whether they had much physical significance, but only a year or so after his paper, the existence of the De Broglie wave length was confirmed in a most striking fashion in the experiments of Clinton J. Davisson and Lester H. Germer on the diffraction of electrons by a crystal. They showed that beams of electrons passing through a crystal were diffracted in many ways like X-rays, but with the wave length given by the formula $\lambda = h/mv$.

2. Schrodinger Wave Equation.— Prior, however, to the Davisson-Germer experiments, Schrodinger recognized the great portent of the De Broglie wave length, and by means of it was led to the fundamental equation of wave mechanics, usually called the wave equation. Schrodinger conjectured that true quantum mechanics stands in the same relation to ordinary classical mechanics that physical optics does to geometrical optics. Just as the ray-tracing characteristic of the latter is unable to explain the phenomena of diffraction and interference, so, Schrödinger reasoned, ordinary mechanics could not explain atomic phenomena, the reason in each case being that the dimensions are not large compared to the wave length. Hence he sought to establish a procedure analogous to that used in physical optics. Now the fundamental "wave equation" of the latter is

$$\frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2} = \frac{1}{u^2}\frac{\partial^2 f}{\partial t^2}. \tag{33}$$

Here the phase velocity u may be a function of x, y, z. In the monochromatic, or periodic, case, the solutions can be written in the form $f = \psi(x, y, z)e^{2\pi i\nu t}$, where the space factor ψ satisfies the equation

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} = \frac{4\pi^2}{\lambda^2}\psi, \tag{34}$$

with $\lambda = u/\nu$. For the wave length λ, Schrodinger inserted the De Broglie value (32). Then (34) becomes

$$\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \frac{\partial^2 \psi}{\partial z^2} + \frac{8\pi^2 m}{h^2}(E - V)\psi = 0. \tag{35}$$

This is the Schrodinger wave equation. One immediately wonders how quantized phenomena can be extracted from (35), as a partial differential equation suggests things continuous rather than discrete. The answer is that one must confine one's attention to the "physically admissible," or, colloquially, "civilized" solutions of (35), which meet certain requirements of continuity, single-valuedness, etc. Solutions which fulfill these demands are called characteristic functions, proper functions or eigenfunctions. The precise conditions that these physically admissible solutions need to meet vary somewhat with the physical nature of the problem. It is usually sufficient that ψ be single-valued, continuous, together with its first derivatives, and finite, except perhaps at a few points at which ψ becomes infinite in such a way that

$$\iiint |\psi|^2 dv \text{ and } \iiint \left\{\left|\frac{\partial \psi}{\partial x}\right|^2 + \left|\frac{\partial \psi}{\partial y}\right|^2 + \left|\frac{\partial \psi}{\partial z}\right|^2\right\} dv$$

exist. Also, ψ must vanish at infinity. Now, to be sure, (35) possesses an infinity of solutions, since the latter involve arbitrary constants of integration and even arbitrary functions. Nevertheless, it often happens that not one of these solutions has the properties demanded of a characteristic function. Instead, an admissible solution is usually obtained only if E is given certain particular values, called characteristic values, proper values or eigenvalues. These values of E are those which are to be substituted into the Bohr frequency condition (13).

3. Rotator and Harmonic **Oscillator.**—A simple illustration of how the condition that the solution be physically admissible limits the parameter E is provided by the two-dimensional rotator; *i.e.*, the rotating dumbbell whose motion is confined to a plane. Here the wave equation analogous to (35) is

$$\frac{\partial^2 \psi}{\partial \varphi^2} + \frac{8\pi^2 IE}{h^2}\psi = 0, \tag{36}$$

as is seen by specializing (35) to one co-ordinate, with $V = 0$, and noting that in a rotational problem the moment of inertia I and angle φ replace the mass and a linear displacement. The solution of (36) is

$$\psi = A\cos[(8\pi^2 IE/h^2)^{\frac{1}{2}}\varphi - \epsilon], \tag{37}$$

where A and ϵ are arbitrary constants. The requirement of single-valuedness as a function of position on the circular path of rotation demands that $\psi(\varphi + 2\pi) = \psi(\varphi)$. This is possible only if the coefficient of φ in the argument of the cosine is an integer n. Thus

$$E = n^2h^2/8\pi^2 I. \tag{38}$$

This is exactly the same formula for the energy of a rotator as that (cf. equation [28]) obtained with the old quantum theory. It would thus at first appear that the new quantum mechanics did not remove the difficulty that half rather than whole integers are required to obtain agreement with experiment on rotational energy levels. Actually, however, the end-over-end rotation of a molecule should be represented by a rotator not confined to a particular plane, and so associated with a three- rather than two-dimensional space. When this extra degree of freedom is added, it is found that the factor n^2 in (38) is replaced by $(n + \frac{1}{2})^2 - \frac{1}{4}$, so that, apart from an unimportant additive constant, the result is the same as though half quantum numbers were used in the Bohr theory. Details of the analysis are omitted here, but it is essentially the same as that in classical potential theory where it is shown that the characteristic values of the differential equation for surface harmonics are proportional to $n(n + 1)$.

Of course, in most problems the mathematical analysis is more complicated than in this purposely simple illustration of the rotator. When exact, closed expressions are obtained for the characteristic values of a system with one degree of freedom, they are usually derivable by the so-called polynomial method. In this, the solution is expressed as a power series, and it is shown that if the series does not terminate, the solution is not physically admissible. The termination condition then usually restricts the energy parameter E to certain particular or "characteristic" values.

The polynomial method may be illustrated by the one-dimensional harmonic oscillator. Here the wave equation (35) takes the form

$$\frac{d^2\psi}{dx^2} + \frac{8\pi^2 m}{h^2}(E - \tfrac{1}{2}ax^2)\psi = 0. \tag{39}$$

On the introduction of the following abbreviations and changes of variable,

$$A = \frac{4\pi E}{h}\left(\frac{m}{a}\right)^{\frac{1}{2}}, \qquad u = \frac{m^{\frac{1}{4}}a^{\frac{1}{4}}(2\pi)^{\frac{1}{2}}}{h^{\frac{1}{2}}}x, \qquad \psi = e^{-u^2/2}g, \tag{40}$$

equation (39) becomes

$$\frac{d^2 g}{du^2} - 2u\frac{dg}{du} + (A - 1)g = 0. \tag{41}$$

A series solution is assumed:

$$g = c_k u^k + c_{k+2}u^{k+2} + c_{k+4}u^{k+4} + \cdots. \tag{42}$$

After the indicated operations are performed, the entire left side of (41) can be expressed in the form of a series. The coefficient of each power of u in the latter must vanish if (41) is satisfied. The vanishing of the coefficient of the lowest power (viz., u^{k-2}) requires either $k = 0$ or $k = 1$. On equating to zero the coefficient of u^n, one obtains the recurrence formula

$$\frac{c_{n+2}}{c_n} = \frac{2n+1-A}{(n+1)(n+2)}$$

for determining the ratio c_{n+2}/c_n. The series *(42)* will terminate at the term $c_n u^n$ if $A = 2n + 1$ or, in other words, by (40) if

$$E = (n + \tfrac{1}{2})h\nu_0, \quad \text{with} \quad \nu_0 = \frac{1}{2\pi}\left(\frac{a}{m}\right)^{\frac{1}{2}}. \tag{43}$$

It can be shown that if the series does not terminate, then ψ increases without limit as x becomes arbitrarily large, and the solution is not physically admissible. Hence, the only characteristic values of the harmonic oscillator are those given by (43). Comparison with (27) shows that the new quantum mechanics gives the same energy levels for the harmonic oscillator as does the old Bohr theory, except for an additive constant which is equivalent to the use of half quantum numbers in (27). Usually it is unimportant whether the extra term $\frac{1}{2}h\nu_0$ is included, but by study of the shift between the electronic spectra of diatomic molecules differing only in being composed of different isotopes. it is possible to decide experimentally between (27) and (43), and the results unequivocably favour the latter.

4. Hydrogen Atom. — The focal point of the old Bohr theory was its success with the hydrogen atom, and one is naturally anxious to know whether these triumphs are reproduced by wave mechanics. It turns out that the Schrodinger theory usually gives exactly the same energy levels for a hydrogenic atom as did that of Bohr. This remarkable coincidence holds even inclusive of the corrections for the motion of the nucleus, and in the first-order Stark effect. Thus, all the standard achievements of the old Bohr theory regarding the Rydberg constant, hydrogen-helium shift, spectroscopic determination of *elm*, etc., are reproduced with wave mechanics. When second powers of the electric field are included in the Stark effect, the results are slightly different with wave mechanics, and the experimental results favour the new formula, though observation of the effect of the second-order corrections requires such high field strengths that precision is difficult. The details of the mathematical analysis will not be given here, but a few salient points will be cited. The calculation for hydrogen is unlike the illustrations of the rotator and oscillator given above, inasmuch as there are three degrees of freedom rather than only one. A problem involving more than one co-ordinate is exactly soluble in wave mechanics as a rule only if the variables are separable; *i.e.*, if co-ordinates can be found such that the wave equation admits a solution which can be resolved into products of factors. each of which involves only one co-ordinate. Fortunately such a decomposition is possible for the hydrogen atom. Variables can be separated by using polar co-ordinates, and the wave function then takes the form

$$\psi = A R_{nl}(r) P_l^{|m_l|}(\cos\theta) e^{im_l\varphi}. \tag{44}$$

Here $P_l^{|m_l|}$ is an associated Legendre function (in which $|m_l|$ is the absolute value of m_l), and R_{nl} is the product of an exponential factor and a polynomial in r (a derivative of the so-called Laguerre polynomial). The constant A is arbitrary, while n, 1. m_l are integers. The mathematical problem is very similar to the familiar one of the solution of Laplace's equation in polar co-ordinates, except that the differential equation satisfied by the radial factor is different, no longer admitting a solution in the form of a simple power of r as in the Laplacian case. For the Stark effect, the separation of variables is achieved by using parabolic rather than polar co-ordinate. Both of these types of co-ordinates are special cases of elliptical co-ordinates. and Eisenhart showed generally that if the Schrodinger equation for a single particle admits separation at all, it must be with elliptical co-ordinates.

5. Continuous Spectra. — So far the impression has been given that the characteristic values form a discrete rather than continuous manifold. However, there are certain ranges within which any value of the energy is allowable. The simplest example is furnished by the hydrogen atom. Here, in addition to any of the discrete negative values (21), any positive value of the energy is allowable. The reason for this distinction is the following The differential equation satisfied by the radial factor of the wave function for the hydrogen atom has two singular points; viz., the origin and the point at infinity. There is always one solution which is regular at the origin, but it will in general increase without limit at infinity if $E < 0$ Only certain special negative values of E avoid this catastrophe, and these are the characteristic values. When, however, the energy constant E is positive, all solutions vanish at infinity, and so the solution which behaves properly at the origin also necessarily does the same at infinity. Hence any positive value of E is a characteristic value. This remark applies even to nonhydrogenic atoms if the origin of the energy is chosen at ionization The existence of this continuous manifold of positive energy values is reflected experimentally in the continuous absorption beyond the series limit. In fig. 3 the transitions from a fixed lower state to upper states with larger and larger values of n give rise to lines which crowd closer and closer together. Because there can also be transitions to states in the continuum there is a continuous spectrum beyond the limit corresponding to $n = \infty$. There can also be transitions between two values of the energy in the continuous domain, and it is by this mechanism that the continuous X-ray spectrum is emitted from the anode of an X-ray tube.

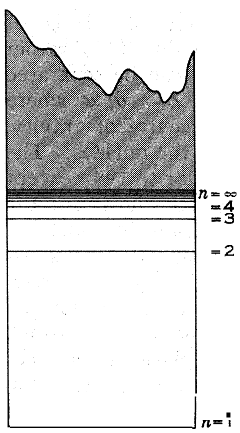


FIG 3 — DISCRETE AND CONTINUOUS ENERGY LEVELS OF HYDROGENIC ATOM

6. More General Form of the Wave Equation. — So far, in (35), we have given the form of the wave equation for a conservative system consisting of a single particle and having a definite energy. We need a rule for forming the wave equation in other cases, involving either more than one particle or an indefinite energy, or both. In classical theory a conservative system necessarily has a definite, constant energy, but in quantum mechanics this need not be so, as is discussed below more fully in connection with the Heisenberg uncertainty principle. As a result, it is no longer redundant to say that a conservative system has a definite energy. The more general scheme for forming the wave equation given here also applies to the nonconservative case in which the potential energy V contains the time explicitly.

The procedure is as follows. First of all, the Hamiltonian technique is to be used; *i.e.*, the system is to have associated with it a classical Hamiltonian function $H(q_1, \ldots, q_f, p_1, \ldots, p_f, t)$, which is a function of the co-ordinates and momenta. We replace p_k by the operator $\frac{h}{2\pi i}\frac{\partial}{\partial q_k}$, and in this fashion we can form a linear differential equation

$$\left[H\left(q_1, \cdots, q_f, \frac{h}{2\pi i}\frac{\partial}{\partial q_1}, \cdots, \frac{h}{2\pi i}\frac{\partial}{\partial q_f}, t\right) + \frac{h}{2\pi i}\frac{\partial}{\partial t}\right]\Psi = 0. \tag{45}$$

This is the general wave equation. One is led to it primarily by comparison with other forms of quantum mechanics, especially transformation theory, rather than through the De Broglie and Schrödinger interpretation of the Hamiltonian analogy.

In case the system is conservative, so that t does not enter explicitly, (45) will admit a solution of the form

$$\Psi = e^{-2\pi i E_m t/h}\psi_m(q_1, \cdots, q_f), \tag{46}$$

where ψ_m is independent of t and satisfies the equation

$$\left[H\left(q_1, \cdots, q_f, \frac{h}{2\pi i}\frac{\partial}{\partial q_1}, \cdots, \frac{h}{2\pi i}\frac{\partial}{\partial q_f}\right) - E_m\right]\psi_m = 0. \tag{47}$$

However, (46) does not represent the most general solution of *(45)* for a conservative system, which is

$$\Psi = \Sigma_m c_m e^{-2\pi i E_m t/h}\psi_m, \tag{48}$$

where the summation is over all the characteristic values E_m and where the c_m are arbitrary constants. The expression (46) presupposes that the energy has a definite value, whereas (48) does not involve this restriction.

Equation (47) reduces to (35) for a one-particle system, where the classical Hamiltonian function is $(p_x^2 + p_y^2 + p_z^2)/2m + V$. To include the correction for the motion of the nucleus, it is necessary to add to this Hamiltonian function an extra term $(p_\xi^2 + p_\eta^2 + p_\zeta^2)/2M$, where M and p_ξ, p_η, p_ζ are respectively the mass and components of momentum of the nucleus. It is, of course, then necessary to use the general equation (47) rather than (35). It can be shown that the variables can be separated by changing them from x. y, z, ξ, η, ζ to X, Y, Z, r, 0, φ where X. Y, Z are the Cartesian co-ordinates of the centre of gravity, and r, θ, φ are polar co-ordinates with origin at the nucleus. The solution of the wave equation takes a form similar to (44) except that there is an extra factor $e^{ik_1X}e^{ik_2Y}e^{ik_3Z}$ which allows for the motion of the centre of gravity of the system, and in which k_1, k_2, k_3 are arbitrary constants. The differential equation satisfied by the "internal" part of the wave function (*i.e.*, the part depending on r, 0, φ) can be shown to be the same as for the one-body problem, in which the nuclear motion is disregarded, except that the reduced mass (17) appears in place of the electronic mass m. The total energy—*i.e.*, the characteristic value of (47)—is the sum of the internal energy given by (21) and an extra term $(k_1^2 + k_2^2 + k_3^2)h^2/8\pi^2(m + M)$ which represents the translational kinetic energy of the centre of gravity of the system. In the discussion of the Bohr theory above, this translational energy was omitted, but its inclusion in the Bohr frequency condition introduces a correction to the frequency nhich is essentially the quantum analogue of the classical Doppler effect, and yields results substantially equivalent to the latter.

An important property of (47) is that its solutions can be shown to be orthogonal. provided the operator is of the so-called self-adjoint type. This condition is one which can practically always be met. If, in addition, the arbitrary proportionality constants in the wave function are so chosen that they are normalized to unity, one has the relation

$$\int \psi_l^* \psi_m d\tau = \delta^l_m, \tag{49}$$

where $d\tau$ is a volume element embracing the co-ordinate space of all the particles (of dimensionality $3n$ if there are n particles), and where the integration is over all the co-ordinates. The expression δ^l_m is the usual Kronecker delta, and has the meaning that $\delta^m_m = 1$ and that $\delta^l_m = 0$ $(l \neq m)$. The asterisk is used here and elsewhere to denote the complex conjugate. It is necessary to distinguish between ψ_m and its conjugate ψ_m^*, because the solutions of the Schrodinger wave equation are not necessarily real. In (49) the case $l \neq m$ expresses the orthogonality, and $l = m$ embodies the normalization.

B. Matrix Form of Quantum Mechanics

A few months prior to Schrodinger's discovery of wave mechanics, another, superficially very different approach to quantum mechanics was developed by Born and Heisenberg. The impetus to this other approach was Born's repeated emphasis to his colleagues at Gottingen that the reason the old quantum theory was then (1925) failing was that it sought to use the same kinematical concepts of space and time within the atom as in ordinary measurable large-scale events. After all, the concepts of space and time have a meaning only when we tell how they can be measured, and obviously at atomic distances we cannot use ordinary measuring rods or clocks. Guided by this philosophy based on the so-called operational viewpoint, Heisenberg discovered his matrix mechanics. He did not originally recognize his formulation as a matrix one—Born was the first to see that the equations were best interpreted in the language of matrices.

The basic idea of the matrix mechanics is that the co-ordinates and momenta associated with the electrons in the atom are to be treated as matrices rather than as quantities having a definite numerical value. A matrix is an array of the form

$$\boldsymbol{a} = \begin{Bmatrix} a(11) & a(12) & a(13) & \dots \\ a(21) & a(22) & a(23) & \dots \\ a(31) & a(32) & a(33) & \dots \\ \dots & \dots & \dots & \dots \\ \dots & \dots & \dots & a(nn) \end{Bmatrix}$$

The matrices involved in quantum mechanics are infinite ones; *i.e.*, have an infinite number of rows and columns.

The Heisenberg matrix elements are quantities which are intimately connected with the concept of the transition probability in the old quantum theory, and alternatively with Fourier coefficients in classical mechanics. For simplicity consider a system with only one degree of freedom. Then the matrix index can be identified with the quantum number, and a matrix element $a(lm)$ is correlated with a transition between states of quantum numbers 1 and m. The exact matrix expression replacing (31) is

$$A_{l\to m} = (4e^2/3hc^3)\,(2\pi)^4\nu(lm)^3[|x(lm)|^2 + |y(lm)|^2 + |z(lm)|^2]. \tag{50}$$

Here $x(lm)$ refers to an element of the x co-ordinate matrix, etc., and is the quantum analogue of the Fourier coefficient x_{l-m} involved in the rough formula (31) arrived at by means of the correspondence principle. As presented here. and as Heisenberg reasoned historically, (50) is obtained by analogy with classical theory, but it should be mentioned that (50) can also be derived independently from the Dirac radiation theory, which applies quantum mechanics to the degrees of freedom of the ether. By means of (50) the intensity of a line can be calculated if the Heisenberg matrices are known.

In order to compute the matrix elements needed for use in (50), it is necessary to transcribe atomic mechanics into the mysterious matrix language, and for this a matrix algebra and calculus are necessary. The sum of two matrices is formed by adding corresponding elements, so that $(a + b)(lm) = a(lm) + b(lm)$. Matrices are multiplied together in the same way as determinants; *i.e.*,

$$(ab)(lm) = \Sigma_n a(ln)b(nm). \tag{51}$$

There is, however, the difference that whereas a determinant has a numerical value, a numerical meaning is attached only to the individual entries of a matrix and not to its entirety. This loss of numerical value corresponds to the abandonment of ordinary kinematical relationships within the atom. The multiplication is in general noncommutative; *i.e.*, $(ab)(lm) \neq (ba)(lm)$ or more symbolically $\boldsymbol{ab} \neq \boldsymbol{ba}$, if boldface type is isued to designate the entire matrix rather than a single entry.

By repeated additions and multiplications it is possible to construct functions of matrices which are in turn matrices, and thus develop a matrix algebra. In order to transcribe atomic mechanics into the mysterious matrix language, it is necessary to have some sort of rule for constructing the derivative of one matrix with respect to another. A consistent mathematical framework is obtained if one defines the derivatives of a function $f(q_1, \dots, q_f, p_1, \dots, p_f)$ in the following way:

$$\frac{\partial f}{\partial p_k} = \frac{2\pi i}{h}(fq_k - q_k f), \quad \frac{\partial f}{\partial q_k} = -\frac{2\pi i}{h}(fp_k - p_k f). \tag{52}$$

The special cases $f = p_j$ or q_j yield the so-called quantum conditions

$$\begin{aligned} p_k q_k - q_k p_k &= (h/2\pi i)1, \qquad p_k q_j - q_j p_k = 0 \qquad (k \neq j) \\ p_k p_j - p_j p_k &= 0, \qquad q_k q_j - q_j q_k = 0. \end{aligned} \tag{53}$$

A diagonal matrix is one which has vanishing entries except down the principal diagonal—*i.e.*, $a(lm) = 0$, $1 \neq m$—while a unit matrix has the additional property $1(ll) = 1$. A diagonal matrix is the quantum analogue of a Fourier series which contains nothing but a single constant term. Hence, in a conservative system with a definite energy. the energy matrix must be a diagonal one.

It should be pointed out that the Heisenberg matrices are infinite ones in the sense that they involve an infinite number of rows of columns. Namely, each index (number of row or column) is correlated with a stationary state, and there is an infinite number of such states. Furthermore, in connection with fig. 3 me have seen that often the permitted stationary states form a continuous rather than discrete manifold. In the continuous region it is necessary to introduce the rather recondite concept of a matrix with continuously varying indices, so that it cannot then even be tabulated in terms of rows and columns. When there is a continuum, the summation in (51) must be replaced by an integration. Similarly, in the expansion (48) the summations are to be construed as including integrations over the continua when these are present.

1. Relation of Matrix and Wave Theories.—It is possible to work out the energy levels of the harmonic oscillator, rotator, hydrogen atom, etc., by means of pure matrix theory, and the results are always the same as those obtained with wave mechanics. One immediately suspects that the two approaches are interrelated. This is indeed the case. If the Schrodinger wave functions are known, the Heisenberg matrix elements can be computed by a straightforward integration. Suppose that we desire the matrix elements of a function $f(q_1, \ldots, q_f, p_1, \ldots, p_f)$ of the co-ordinates and momenta. Then the appropriate formula is

$$f(lm) = \int \psi_m{}^* f\left(q_1, \cdots, q_f, \frac{h}{2\pi i}\frac{\partial}{\partial q_1}, \cdots, \frac{h}{2\pi i}\frac{\partial}{\partial q_f}\right)\psi_l d\tau, \qquad (54)$$

where the integrand contains an operator f formed by replacing each p_k by $\frac{h}{2\pi i}\frac{\partial}{\partial q_k}$. We shall not attempt to prove (54) but shall note one or two simple consequences. In the first place, the quantum conditions (53) are satisfied. For instance, if $f = p_k q_k - q_k p_k$, then

$$f\psi_m = \frac{h}{2\pi i}\left[\frac{\partial}{\partial q_k}(q_k\psi_m) - q_k\frac{\partial \psi_m}{\partial q_k}\right] = \frac{h}{2\pi i}\psi_m,$$

and except for a factor $h/2\pi i$, the integral (54) becomes identical with (49), so that we have $f(lm) = (h/2\pi i)\delta_m^l$. This result agrees with the first relation of (53), since the elements of a unit matrix are equivalent to a Kronecker delta. The remaining relations of (53) are obviously satisfied. The third relation, for instance, follows since $\partial^2\psi/\partial q_j\partial q_k = \partial^2\psi/\partial q_k\partial q_j$.

Satisfaction of the wave equation (47) for a conservative system with definite energy is tantamount to making the energy a diagonal matrix. To see this we note that by (47) the operator H is equivalent to multiplication by a constant E_m. Hence, if f in (54) is taken to be the Hamiltonian operator H, the integral differs from (49) merely by a constant factor and so has the value $E_m\delta_m^l$.

If one is wedded to the extreme matrix viewpoint, one regards the wave functions merely as mathematical auxiliaries used to compute the Heisenberg matrix elements by means of the "matrix computing machine" (54). Such a viewpoint is undoubtedly too one-sided, and is offensive to physicists nho take comfort from the parallelism of wave mechanics to classical mathematical physics, and to optics, in particular.

2. Intensities and Polarizations of Spectral Lines.—By combining (54) (as applied to f = x, y, z) with (50), it is possible to compute the intensities of spectral lines. Furthermore, by examination of the relative magnitudes and phases of the corresponding x, y, and z components involved in (50), predictions can also be made regarding the polarization behaviour. In this fashion, for example, the intensities in the various components in the Stark effect for hydrogen can be calculated. Also, and even more important, it is possible to derive the various so-called "selection rules," which forbid certain quantum numbers changing except by a specified number of units. It can be demonstrated, for instance, that the quantum number for a harmonic oscillator cannot change by more than one unit. With the restriction $n'' - n' = \pm 1$, the quantum-mechanical frequency v obtained by substituting (43) in (13) becomes identical with the classical frequency ν_0. Without the restriction, v could be any multiple of ν_0, a highly unreasonable situation since classically overtones are always absent for a simple harmonic system.

A particularly important case of the selection principle is that for the so-called azimuthal quantum number 1, which is involved in the relativistic hydrogen atom and especially in Newtonian nonhydrogenic atoms with one valence electron. By means of (54) it can be proved that 1 cannot change except by one unit. The quantum number 1 plays a vital role in interpreting the spectra of alkali atoms. (See SPECTROSCOPY.) An energy level is classified of the s, p, d, f character according as $l = 0, 1, 2, 3$. The selection principle $l' - l'' = \pm 1$ materially limits the "combinations" of the terms; *i.e.*, the possible transitions between the different energy states. The predictions are strikingly confirmed by experiment.

C. Statistical Significance of Quantum Mechanics

1. Interpretation of the Wave Function.—We have not as yet given sufficient emphasis to the physical meaning of the solution of the Schrodinger wave equation, as distinct from its relation to the matrix formalism. The wave function satisfying the general equation (45) has an important physical interpretation. The square of its modulus is proportional to what may be called a statistical charge density. Let us consider first a system with only one particle. Then the probability that the particle will be in the volume element dxdydz at time t may be taken to be

$$|\Psi|^2 dxdydz, \qquad (55)$$

provided the total probability is normalized to unity; *i.e*,

$$\iiint |\Psi|^2 dxdydz = 1. \qquad (56)$$

This scheme of interpretation is a consistent one, as it can be shown that it is a consequence of the differential equation (45) that the integral on the left-hand side of (56) is independent of time. Otherwise the normalization condition (56) could not be imposed. Similarly, when there are n particles, $|\Psi|^2$ determines the probability in a $3n$ dimensional space whose volume element $d\tau$ is $dx_1, \ldots, dz_n$.

It is to be emphasized that the density given by (55) is inherently statistical in character. We do not say that the particle is in the element dxdydz at time t, but merely that there is a certain probability of the particle being there. In the particular case of a conservative system in a definite stationary state, the relation $|\Psi|^2 = |\psi_m|^2$ is satisfied by virtue of (46), and then the probability becomes independent of time. The places where $|\Psi|$ or $|\psi_m|$ is large are those where the particle is likely to be located, but it is never possible to say when it is there. The situation may be compared to the information obtainable from the time exposure of a firefly on a dark night. Where the photographic plate reveals the most brightness is where the firefly has spent most of the time, but one cannot infer just when the insect was at a particular spot. Similarly in quantum mechanics, the information about particles is inherently restricted because of its statistical nature.

When quantum mechanics was first discovered, there was considerable controversy as to whether it was necessarily statistical in character. For a while many physicists maintained that a deterministic picture was possible, in which the electron was considered to be a fluidlike affair whose density distribution is governed by (55). It is now, however, generally conceded that such attempts are untenable and involve the same fallacy as reasoning from the time exposure of the firefly that the latter is a luminous fluid rather than a discrete insect. It should be regarded as an advantage rather than a drawback that quantum mechanics must be interpreted statistically. When atomic experiments are analyzed from the "operational" viewpoint, it is found that the measurements always involve statistical features inasmuch as some of the parameters are distributed over a range of values and are not determined with complete precision. It is not the co-ordinates alone which must be statistically interpreted, but also other dynamical quantities, such as energy, momentum, etc.

2. Probability Distribution in Momentum Space.—Again confining attention to one particle, it is possible, for instance, to inquire concerning the probability that its components of momentum fall within a certain range at time t. The symmetrical roles of co-ordinates and momenta in the Hamiltonian technique suggest that there is a function χ such that

$$|\chi(p_x, p_y, p_z, t)|^2 dp_x dp_y dp_z \qquad (57)$$

determines the probability that the momenta are in the element $dp_x dp_y dp_z$ at time t. There is indeed such a function, and the relation between the two functions Ψ, χ is similar to that between a function and its Fourier transform. Namely, it can be shown that

$$\Psi = h^{-3/2}\iiint \chi(p_x,p_y,p_z,t)e^{2\pi i(p_xx+p_yy+p_zz)/h}dp_xdp_ydp_z, \tag{58}$$

$$\chi = h^{-3/2}\iiint \Psi(x,y,z,t)e^{-2\pi i(p_xx+p_yy+p_zz)/h}dxdydz. \tag{59}$$

Equation (58) has intuitively a very reasonable form, as it is natural to regard any disturbance as being built up of a superposition of De Broglie waves, each of the structure $e^{2\pi ipx/h}$ in one dimension or $e^{2\pi i(p_xx + p_yy + p_zz)/h}$ in three. In any principle of superposition in physics, the square of the amplitude governs the intensity, and so it is natural to assume that $|\chi|^2$ gives the probability. It can be shown from the mathematical theory of Fourier transforms (Plancherel's theorem) that

$$\iiint |\Psi|^2dxdydz = \iiint |\chi|^2dp_xdp_ydp_z. \tag{60}$$

If (60) were not satisfied, the physical interpretation given 9, χ would lack consistency, for it is necessary that the total probability for either co-ordinate or momentum distribution be unity; or in other words, the normalization (49) in co-ordinate space must imply a corresponding normalization in momentum space. Another relation which can be established, and which shows the intimate relation between momentum and the operator $\frac{h}{2\pi i}\frac{\partial}{\partial x}$, is

$$\iiint p_x{}^n|\chi|^2dp_xdp_ydp_z = \iiint \Psi^*\left(\frac{h}{2\pi i}\frac{\partial}{\partial x}\right)^n\Psi dxdydz, \tag{61}$$

where n is an integer. Also there is a symmetrical relation

$$\iiint x^n|\Psi|^2dxdydz = \iiint \chi^*\left(-\frac{h}{2\pi i}\frac{\partial}{\partial p_x}\right)^n\chi dp_xdp_ydp_z. \tag{62}$$

Clearly (62) and (61) give respectively the mean value of the nth power of the x-component of displacement and of momentum.

3. Interference of Probability Amplitudes.— In ordinary probability theory, probabilities are compounded in accordance with the law

$$P(b) = \int P(b,\, a)P(a)da, \tag{63}$$

where $P(a)$ is the probability of occurrence of a, and $P(b,$ a) is the probability of occurrence of b when a is given. On the other hand, since $|\Psi|^2$ or $|\chi|^2$ is the density in position or momentum space, the functions involved in the compounding relation (58) are the square roots of probabilities and are spoken of as "probability amplitudes." The function $e^{2\pi i(xp_x + yp_y + zp_z)/h}$ is essentially a De Broglie wave and is called the probability amplitude connecting co-ordinates and momenta. The fact that in quantum mechanics there exists a compounding relation analogous to (63) with $P^{\frac{1}{2}}$ rather than P is sometimes called the phenomenon of the "interference of probability amplitudes." Although no logical inconsistencies are ultimately involved, still this somewhat curious way of associating probabilities leads to many paradoxes which look rather strange from the standpoint of large-scale statistical mechanics. There is a certain amount of parallelism to the unintelligibility of interference phenomena in optics, wherein amplitudes rather than intensities are added, to a person who has been versed only in geometrical optics, ray tracing, and perhaps the corpuscular theory of light. It is now well recognized that radiation has both corpuscular and undulatory aspects. The former, for instance, stands out clearly in the photoelectric effect. As emphasized in Bohr's principle of complementarity, the two aspects are not contradictory but instead play complementary roles. So also, matter has both corpuscular and undulatory features. The type of compounding involved in (58) implies use of the wave amplitude in much the same way as in optics. It is well knoan that interference phenomena in the latter must be treated by superposing wave amplitudes rather than intensities or the number of corpuscular light quanta.

D. Transformation Theory

1. General.— The general interpretation of quantum mechanics as essentially a theory of probability amplitudes has been developed particularly by Jordan and by Dirac. The details of this so-called "transformation theory" are too intricate and abstract to be treated here, but their formulation of quantum mechanics has elegance. generality and a unifying influence on the interpretation of the various other viewpoints. The Schrodinger wave equation, from the standpoint of transformation theory. may be regarded as an equation for finding the probability amplitude for distribution-in-position when the energy is known. One might ask for the probability amplitude for the distribution of other functions than positional co-ordinates—for instance, momenta—and the known quantity might not necessarily be the energy, as certain experiments correspond to fixation of other quantities than the energy. Such more general problems can be solved by means of transformation theory.

2. Uncertainty Principle.— It is to be noticed that in (55) or (57) expressions have been given for the probability of the particle being in an element of volume dxdydz of position space. or in an element of momentum space, but that there is no probability function for a concurrent occurrence of given values of position and momentum associated aith a volume element $dxdydzdp_xdp_ydp_z$. This fact takes us to the heart of the Heisenberg uncertainty principle. The latter limits the accuracy with which it is possible to specify simultaneously the values of a co-ordinate and its canonically conjugate momentum. If Δp_x and Δx be the limits of precision within which p_x and x can simultaneously be determined, there exists the inequality

$$\Delta x\Delta p_x \geqq h/4\pi. \tag{64}$$

For illustrations of this concept, see Uncertainty Principle, The. It is meaningless to talk about the probability of a simultaneous occurrence of a given value of a co-ordinate and its conjugate momentum, for by (64) there is infinite uncertainty in a momentum if the position is known with complete precision, or vice versa.

The uncertainty principle should not be regarded as an additional hypothesis artificially injected into quantum mechanics. Instead, it is something which can be proved as a consequence of the latter, along the following lines. By proper choice of the origin for position and velocity, the mean position and velocity can be made zero; in other words, $I_{61}{}^{(1)} = I_{62}{}^{(1)} = 0$, where $I_{61}{}^{(n)}$, $I_{62}{}^{(n)}$ denote respectively the integrals (61) and (62). The uncertainty in position and momenta can then be regarded as measured by the root mean square displacement and momentum, so that we can take $\Delta p_x{}^2 = I_{61}{}^{(2)}$, t ~ = $I_{62}{}^{(2)}$ provided Ψ is normalized in accordance with (56). Now it can be shown by pure mathematics, largely by the aid of the so-called Schwarz inequality, that any function Ψ normalized in accordance with (56) and satisfying the requirements of continuity, etc. required of a physically admissible wave function satisfies the identity $I_{61}{}^{(2)}I_{62}{}^{(2)} \geqq (h/4\pi)^2$. The uncertainty principle is hence proved for the type of system under consideration. The equality sign in (64) corresponds to the minimum possible value of the product of the two errors, and this is achieved only when the probability functions have a Gaussian distribution.

It can be shown that the time is canonically conjugate to the energy. Hence, if we make an experiment whose span in time is limited, as is always the case, the energy cannot be known with complete precision, and so the appropriate wave function is (48), in which there is a dispersion of energy values, rather than (46), in which it is supposed that the energy is completely determinate. Wave functions of the general form (48), in which a number of stationary states are superposed and thus co-exist, are sometimes spoken of as "wave packets." It is through the construction of the latter that classical and quantum theories merge when the amount of action is large.

V. ELECTRON SPIN

4 very important development practically concomitant with the advent of the true quantum mechanics was the discovery of electron spin. The basic idea of the latrer is that the electron has an extra degree of freedom which may be likened to the spin of a top about an axis. Or, if the electron moving about the nucleus is compared to the earth in the solar system, then there is an obvious analogy of the spin of the electron to the diurnal rotation

of the earth about its own axis. The important features of the spinning electron were first presented by two young Dutch physicists, George E. Uhlenbeck and Samuel A. Goudsmit, in 1925, although some of the earlier literature did contain suggestions of a rotating electron in rather different connections.

The various dilemmas of spectroscopic theory and magnetism which are resolved by the introduction of electron spin are many. One of them is the existence of multiplets in molecular spectra. The simplest and most familiar example of a multiplet is provided by the two components of the D lines of sodium, which arise because the energy level of the upper state is double; *i.e.,* consists really of two stationary states. A single level, however, is obtained if the ordinary theory of a point electron is used. It is hence necessary to introduce a fourth quantum number, whose values subdivide the energy levels more than if only the quantum numbers associated with the external degrees of freedom of the electron were introduced.

If an electron model without spin is used, then there are three quantum numbers per electron. If the force field is dominantly central, as is usually the case even in nonhydrogenic atoms, then these three can be interpreted as the principal quantum number n, the azimuthal quantum number l, and the "magnetic" or "equatorial" quantum number m_l. The range of values of l is $0, \ldots, n-1$, and that of m_l is $-l, \ldots, +l$. The azimuthal quantum number l has the physical significance of specifying the angular momentum of the electron, in multiples of $h/2\pi$, while m_l fixes the component in a particular direction. The mathematical significance in terms of the indices of Tesseral harmonics involved in the wave function is that revealed in equation *(44)*.

1. Pauli Exclusion Principle. — Wolfgang Pauli proposed that besides n, l, m_l there be a fourth quantum number, or index m_s, which can take on the values $\pm\frac{1}{2}$. He then (1925) introduced his famous exclusion principle, for which he was awarded the Nobel prize in 1945. This principle states that no two electrons can have all four quantum numbers n, l, m_l, m_s the same. From this, the properties of the chemists' periodic table flow out automatically, including the existence of the "long" periods containing the iron, platinum and palladium groups, and of 14 rare earths. For instance, the choice $n = 1$ for the principal quantum number corresponds to the first or hydrogen-helium period, which has two elements, and $n = 2$ to the second or lithium-neon period. Namely, if $n = 1$, we can have $l = 0$, $m_l = 0$, $m_s = \pm\frac{1}{2}$, two possibilities in all, whereas if $n = 2$, we can have $l = 0$, $m_l = 0$, $m_s = \pm\frac{1}{2}$ and also $l = 1$, $m_l = 1$, $m_s = \pm\frac{1}{2}$; $l = 1$, $m_l = 0$, $m_s = \pm\frac{1}{2}$; $l = 1$, $m_l = -1$, $m_s = \pm\frac{1}{2}$ giving eight possibilities all told. In this general fashion the numbers of elements in the different rows of the periodic table are deduced by a simple enumerative process.

When Pauli published his celebrated paper in 1925, the significance of the fourth quantum number was a complete mystery. The great contribution of the theory of Uhlenbeck and Goudsmit, which appeared less than a year later, was to show how naturally the spinning electron accounts for the Pauli formalism. The two choices $m_s = \pm\frac{1}{2}$ are interpreted as determining the two possible orientations of the spin angular momentum relative to the axis of quantization. In order that there be two choices, and no more, it is necessary to postulate that the electron has a "half quantum" $\frac{1}{2}(h/2\pi)$ of spin angular momentum.

2. Interpretation of the Exclusion Principle in Terms of Antisymmetric Wave Functions. — The spin hypothesis of Uhlenbeck and Goudsmit furnished an explanation of the fourth quantum number. It did not, however, give any indication of why it is that no two electrons have all four quantum numbers the same. Heisenberg was the first to point out that the Pauli exclusion principle has a rudimentary interpretation in terms of the symmetry properties of wave functions. When one solves the wave equation for a system of several like particles, their identity introduces special properties of symmetry, and permits classification of the solution according to symmetry characteristics, the precise codification of which involves complicated group theory. For the very simple special case of only two identical particles, for instance, the solutions are either symmetric or antisymmetric, as regards interchange of the corresponding co-ordinates of the two particles. In other words, the wave function is either invariant or reverses sign when the electrons are permuted. When there are more than two electrons, there are many types of symmetry intermediate between the symmetric and antisymmetric cases, which represent two extremes but which still have a meaning. Furthermore, the antisymmetric solution can never be constructed when the electrons are in identical states (*i.e.,* have all four quantum numbers the same) for then the wave function would have to reverse sign as a result of an operation which does not change the arguments, an obvious impossibility. Hence, the Pauli principle is an automatic consequence of the formalism of quantum mechanics if it is postulated that only those solutions of the Schrodinger equation which are antisymmetric under permutation of the electron co-ordinates are physically realizable. In other words, nature somehow has a penchant for antisymmetric wave functions. In this connection it is to be understood that all four co-ordinates are to be permuted; *i.e.,* the spin co-ordinate as well as the three ordinary orbital ones x, y, z. The spin co-ordinate, unlike the variables x, y, z, which are continuous, assumes only the two values which correspond to the two possible orientations of the spin angular momentum relative to the axis of quantization. The wave function, on the other hand, need not be antisymmetric with respect to permutation of the orbital co-ordinates alone. In fact, no rigorous delineation of symmetry types under purely orbital permutation is possible, although it can be shown that symmetry characteristics associated with the orbital part of the problem determine the multiplicity of a spectral term; *i.e.,* whether it is a singlet, doublet, triplet, etc. The purely orbital forms of the wave equation given in (35) or (45) do not take cognizance of the spin. Inclusion of the latter introduces certain small magnetic interaction terms involving spin operators in the Hamiltonian function, and requires that the arguments of the wave function include spin variables as well as the ordinary orbital co-ordinates $q_1, \ldots, q_f$.

3. Electron Spin and Magnetism. — Electron spin plays a leading role in the theoretical interpretation of magnetic phenomena. A fuller description will be found in the article on MAGNETISM; only two points will be mentioned here. One is that ferromagnetism arises almost entirely from spin rather than from orbital magnetic moment, for in the solid state the crystalline electric fields usually quench the orbital contributions to the magnetic moment. The other is that in the Uhlenbeck-Goudsmit model of electron spin the ratio of magnetic moment to angular momentum is taken to be e/mc, whereas the classical value of the ratio which applies to the orbit is $e/2mc$. In other words, the so-called gyromagnetic ratio has an anomalous factor 2 when applied to the spin. This anomaly is confirmed not only by measurements on the gyromagnetic effect (rotation of a body by magnetization, or magnetization by rotation). but also by those on the anomalous Zeeman effect. In the latter the so-called Landé g-factor expresses the fact that part of the contribution to the magnetic moment is of the normal orbital type, and part of the anomalous spin variety. *(See* ZEEMAN *EFFECT.)*

VI. DIRAC ELECTRON

1. General. — In the Uhlenbeck-Goudsmit theory, the half quantum of spin angular momentum and the anomalous factor 2 in the gyromagnetic ratio are introduced in a purely ad *hoc* fashion. Another approach, which avoids this arbitrariness, was developed by Dirac in 1928. In the original Schrodinger theory without spin, the behaviour of an electron was described by a single second-order differentia! equation. The spin properties assumed by Uhlenbeck and Goudsmit involved two different possible settings of space-quantized spin angular momentum, and were interpreted by means of the matrix theory. Pauli, however, soon showed how the Schrodinger wave theory could be generalized to include the spin, by introducing two wave functions, ψ_1, ψ_2, which satisfy two simultaneous second-order differential equations. Dirac had the revolutionary idea that the electron be described by four wave functions, $\psi_1, \psi_2, \psi_3, \psi_4$, which satisfy four simultaneous first-order differential equations. If the electron is subject to an electrostatic potential $\varphi(x, y, z)$ and vector potential A, these equations are as follows:

$$\begin{aligned}(p_0 + mc)\psi_1 + (p_1 - ip_2)\psi_4 + p_3\psi_3 &= 0,\\ (p_0 + mc)\psi_2 + (p_1 + ip_2)\psi_3 - p_3\psi_4 &= 0,\\ (p_0 - mc)\psi_3 + (p_1 - ip_2)\psi_2 + p_3\psi_1 &= 0,\\ (p_0 - mc)\psi_4 + (p_1 + ip_2)\psi_1 - p_3\psi_2 &= 0,\end{aligned} \tag{65}$$

where

$$p_0 = \frac{h}{2\pi ic}\frac{\partial}{\partial t} + \frac{e}{c}\varphi, \qquad p_1 = \frac{h}{2\pi i}\frac{\partial}{\partial x} + \frac{e}{c}A_x,$$

$$p_2 = \frac{h}{2\pi i}\frac{\partial}{\partial y} + \frac{e}{c}A_y, \qquad p_3 = \frac{h}{2\pi i}\frac{\partial}{\partial z} + \frac{e}{c}A_z.$$

When first viewed, these equations certainly look arbitrary and artificial. Space will not permit description of how, to the first approximation in the dimensionless constant $(2\pi e^2/hc)^2$, they are equivalent to the more conventional theory based on second-order differential equations. It was this equivalence that first led Dirac to hit upon the equations of the structure (65). If the solutions are normalized to unity in the sense that

$$\iiint [|\psi_1|^2 + |\psi_2|^2 + |\psi_3|^2 + |\psi_4|^2]dxdydz = 1,$$

then $(|\psi_1|^2+|\psi_3|^2)dxdydz$ and $(|\psi_2|^2+|\psi_4|^2)dxdydz$ are respectively the probabilities that the electron be in the volume element $dxdydz$ with spin parallel or antiparallel to the axis of quantization. It can further be shown that the simultaneous equations (65) have the proper invariance under a Lorentz transformation, so that the requirements of the special theory of relativity are satisfied. This is not true of the simple Schrödinger equation (35), which is essentially Newtonian in character. The relativistic transformation properties of ψ_1, ψ_2, ψ_3, ψ_4 are those appropriate to a pair of spiriors, each of which has two components. This result is rather surprising, as one's first conjecture would be that the ψ's would transform like the components of a four-vector.

All the properties of electron spin, including the proper amount of angular momentum, relativistic fine structure and even the gyromagnetic ratio: flow out of the Dirac formalism in an almost miraculous fas ion suggestive of a magician's extraction of rabbits from a silk hat. Of course! some mathematical calculation, omitted here, is required to demonstrate that these various properties are indeed implied in (65), but it should be emphasized particularly that when (65) is used, no additional postulates are necessary as in the original theory of Uhlenbeck and Goudsmit. Thus (65) can be regarded as the basis of a relativistic electron, with spin as a by-product. In fact, the discovery of (65) and related methodology must be regarded as one of the most brilliant achievements in the whole history of mathematical physics.

When the Dirac equations (65) are used, the expressions for the energy levels of a hydrogenic atom have exactly the same form (24) as in the original relativistic Bohr-Sommerfeld theory. This identity of results must be regarded as one of the strangest coincidences in all of physics. In other words, the new quantum mechanics with spin is equivalent to the old theory without spin. Unless the spin is included in some form, either explicitly through the Uhlenbeck-Goudsmit model (which, however, is reliable only to the approximation [26]) or implicitly through the more refined Dirac equations, relativistic wave mechanics gives results different from (24j and not in accord with experiment. There is an important difference between the new and old interpretations of (24). The integer k no longer has the significance of being the azimuthal quantum number, as in the old quantum theory, but rather is equal to $j + \frac{1}{2}$, where j is the so-called inner quantum number which takes on half-integral values. The selection principles allow transitions in which the inner quantum number is unaltered as well as those in which it changes by ± 1, whereas only the ± 1 changes are allowed for the azimuthal quantum number. Hence, even though the energy levels are exactly the same, more spectral lines are allowed in the new than in the old interpretation of the relativistic fine structure. The extra components are confirmed experimentally, although the resolution is generally inadequate to detect them except as satellites of other lines.

Another success of the Dirac model is that it yields the so-called Klein-Nishina formula for the scattering of X-rays, which, unlike previous expressions, agrees well with experiment.

2. Negative Energy States and the Positron.— To this point, only the triumphs of the Dirac theory have been stressed. Some of its difficulties should also be mentioned. One is that it is uncertain how the relativistic theory should be extended to include the interaction between electrons found in nonhydrogenic atoms. A more serious trouble is the existence of the so-called negative energy states. It is convenient and hence customary in relativity to include, as will be done henceforth, the so-called rest energy mc^2 of the electron in the total energy. This inclusion is equivalent to omitting the term -1 from the brace in (24), and with this modification the energy levels given by (24) are all positive. The dividing line between the discrete and continuous levels in fig. 3 then comes at $E = mc^2$. The equivalence of energy levels in the old and new theories mentioned above applies only so long as attention is confined to states of positive energy. The old quantum theory gave no negative ones. However, it can be shown that with the Dirac equations (65) there is a continuum of states of negative energy, filling the entire range of energies below $-mc^2$. The rest energy mc^2 is enormously greater than the binding energy of the hydrogen atom, represented by the span of the discrete levels in fig. 3. The interval between the lowest positive state and the highest negative one is thus very approximately $2mc^2$, or about 1,000,000 ev. To show even the highest negative energy level, it would be necessary to extend fig. 3 about two miles below the bottom of the page. the intervening interval being void, and from there down to minus infinity the figure should be shaded to indicate a continuum. (By contrast it should be noted that the relativity fine structure, first revealed by the second member of the expansion [26] of [24], also cannot be shown in fig. 3, but for a different reason, as on the scale of fig. 3 the splitting would amount to only about a millionth of an inch.)

The states of negative energy are obviously supernumerary and superfluous if viewed in a conventional fashion, and to get a theory that has a meaning, they must somehow be stricken off the books. Dirac suggested that the negative states are to be regarded as filled, each having the one electron allowed by the Pauli exclusion principle. This idea, of course, mould not work with conventional Boltzmann statistics without the exclusion principle, as then there would be an overwhelming probability that the electrons be in states of negatively infinite energy. As there is a nondenumerable infinity of negative energy levels, there would be an infinite number of electrons housed in such states, even with the limitations imposed by the Pauli rule. Since the electron has a negative charge, there would hence be an infinite negative charge density. Dirac proposed that the charge is not to be counted in computing the charge density to be used in the Poisson law. etc.

According to this apparently fantastic conception, if an electron were somehow taken from one of the normally filled states of negative energy and placed in one of the conventional ones of positive energy. not only mould an electron be created, but also a particle of equal mass but positive charge, now called the positron. Namely, a deficit in the full complement of negative charge, carried, so to speak, at zero on the books, is equivalent to a corresponding surplus of positive charge. (Dirac suggested originally that the shortage might coi-respond to the proton, but this idea is now considered untenable as, for one thing, no explanation is given of the diversity of mass between electron and proton.) Fantasy turned to reality, however, when Anderson obtained cloud chamber photographs showing the existence of positrons; *i.e.*, particles equal to the electron in mass but positively charged. They should not be confused with protons, which are almost 2.000 times heavier. Unlike the protons, which are stable! positrons are extremely short-lived, as there is always the possibility that an electron will be captured out of a state of positive energy and fill the gap in the negative one. Raising of an electron from a negative to a positive level is equivalent to the creation of an electron and a positron, or in other words to "pair production." The minimum energy involved in such a transition is' very approximately $2mc^2$.

Hence, the absorption of gamma-rays can give rise to pair production if, and only if, their frequency exceeds $2mc^2/h$. In the experimental confirmation of this phenomenon, an apparent difficulty of the Dirac theory is turned into a triumph.

A positron and electron which are near each other move about their common centre of gravity in much the same fashion as do the electron and proton in the hydrogen atom but without the disproportionality in mass between the two constituents. The quasi-atom thus formed is called positronium and is highly ephemeral. The existence of positronium was definitely, though rather indirectly, confirmed in the experiments of Martin Deutsch in 1951.

By analogy with antielectrons (*i.e.*, positrons) one wonders whether antiprotons exist as well. Such particles, which have the same mass as the proton but a charge of opposite sign, and which can be regarded as holes in a continuum of positive charge, were first detected in 1955 by Owen Chamberlain, Emilio Segrè, Clyde E. Wiegand and Thomas Ypsilantis.

VII. QUANTUM ELECTRODYNAMICS

So far the impression has been given that the relativistic fine structure of hydrogen agreed with the Dirac theory within the limits of accuracy of the measurements. Beginning in 1934, however, there mas some indication that the separation between the two peaks of the H a doublet in hydrogen was smaller than predicted by theory. (Each peak of the doublet results from a number of unresolved components, and rather careful analysis is necessary to evaluate properly their combined effect.) Whether there was a real discrepancy was for a number of years a matter of controversy, but painstaking spectroscopic measurements by L. Giulotto and others in 1947–48 made it clear that the discrepancy was real.

At about the same time it occurred to a number of theoretical physicists that an explanation of the discrepancy was that there are corrections because of the interaction of the electron mith the electromagnetic field, which is represented in quantum mechanics by a series of quantized oscillators. This is a tricky subject, for the energy associated nith this interaction turns out to be infinite, a difficulty nhich had been appreciated since 1930 and which is known as the divergence in the self-energy of the electron. Nevertheless, by a proper system of bookkeeping, not without elements of arbitrariness and inconsistency, it is possible to compute the differences in the electrodynamic corrections for the various states of the hydrogen atom, and these turn out to be finite. The differential effects agree well with experiment. and so, despite its bothersome divergences, there is more physical reality in the quantum-mechanical formalism of the electromagnetic field than was realized before 1947.

Most of the experimental verification of the quantum electrodynamical theory is concerned aith the fine structure of the levels in hydrogen for which the principal quantum number has the value 2. Without the electrodynamical corrections, there are two such levels, given by (24), with $n = 2$ and $k = 1$; or $n = 2$ and $k = 2$. In the uncorrected theory the level $n = 2, k = 1$ actually consists of two coincident states, called $2^2S_{\frac{1}{2}}$, $2^2P_{\frac{1}{2}}$ in the terminology of the spectroscopists; while $n = 2, k = 2$ is designated as $2^2P_{\frac{3}{2}}$. (The subscript gives the value of J, and the letters S, P mean that the so-called azimuthal quantum number has respectively the values 0, 1). The electrodynamical corrections prove to be practically the same for the two P levels but differ for the S state. As a result the two coinciding levels $2^2S_{\frac{1}{2}}$, $2^2P_{\frac{1}{2}}$ are split apart, and $2^2S_{\frac{1}{2}}$ is displaced toward $2^2P_{\frac{3}{2}}$, a phenomenon known as the Lamb shift. This decomposition is too small to resolve by conventional optical experiments, but makes the apparent doublet width separating the $J = \frac{3}{2}$ state from the $J = \frac{1}{2}$ state smaller than the difference calculated from (24) with the choices $k = 1$ or $k = 2$. The discrepancy with the best optical measurements is thus explained.

Much more quantitative—in fact, spectacular—tests of the electrodynamic corrections have been made, however, with the microwave and molecular beam techniques, which make possible the direct observation of the small energy differences represented by the transitions $2^2S_{\frac{1}{2}} - 2^2P_{\frac{1}{2}}$ and $2^2S_{\frac{1}{2}} - 2^2P_{\frac{3}{2}}$. With ordinary optical measurements, where the wave length is of the order 0.0001 rather than 10 cm., these intervals can be observed only as small fine structures or modulations in the Balmer series. The microwave measurements require intricate and difficult detection techniques, which Willis E. Lamb, Jr.. and Robert C. Retherford successfully devised and instrumented in 1950.

The Lamb shift for hydrogen. $2^2S_{\frac{1}{2}} - 2^2P_{\frac{1}{2}}$, calculated from the electrodynamical corrections is 0.035264 cm.$^{-1}$ (1057.19 mc.), while Lamb's most recent experimental value is 0.035283. For deuterium (heavy hydrogen) the corresponding figures are 0.035307 and 0.035324. The large number of significant figures for such small energy differences reveals graphically the high precision of microwave and molecular beam spectroscopy. It is a particular triumph both of theory and experiment that there is such good accord (0.000043 *v.* 0.000041 cm.$^{-1}$) between the calculated and observed difference in the shift for hydrogen (H^1) and deuterium (H^2), obviously a delicate, high-order correction.

In 1947 Julian Schwinger showed that the electrodynamical corrections make the magnetic moment of the electron somewhat greater than the conventional expression $eh/4\pi Mc$. The most accurate theoretical value, inclusive of fourth-order electrodynamical corrections computed by Robert Karplus and Norman M. Kroll, introduces an extra factor 1.0011454. The molecular beam experiments of Polykarp Kusch and collaborators give 1.001146 ± 0.000012. The work of Lamb and Kusch in confirming quantum electrodynamics won them joint award of the Nobel prize for physics in 1955.

A field theory analogous with that of quantum electrodynamics is used to describe the properties of mesons. transient particles of intermediate mass used in the mechanics of the interior of the nucleus.

VIII. WHAT QUANTUM MECHANICS HAS ACCOMPLISHED

By way of summary, it is perhaps well to list some of the outstanding contributions which quantum mechanics has made to the understanding of atomic physics.

1. The old Bohr theory owes its success to quantum mechanics. The great triumph of the original Bohr version of quantum theory was its ability to explain the spectral frequencies of hydrogenic atoms; *i.e.*, hydrogen, ionized helium, etc. This is done equally well by wave mechanics—in fact, better in some respects.

2. Quantum mechanics has provided a procedure for calculating the intensities rather than merely the frequencies of spectral lines.

3. Qualitative explanation of the spectra of nonhydrogenic atoms is now possible. The reason that quantitative precision is usually not possible is simply that when there is more than one electron the wave equation becomes too complicated mathematically to solve exactly. In the particular case of the neutral helium atom, which involves a three-body problem, it is possible to calculate the energy levels very accurately after considerable labour. The computed energy of the ground state of the neutral helium atom agrees mith the observed energy to within 1 part in 10,000. This atom, on the other hand, was a stumbling block of the old Bohr theory.

4. Electron spin has played an important part in understanding of the phenomena of magnetism.

5. A quantum theory of the chemical bond has been formulated. Although chemical processes are so complicated that one cannot hope to calculate accurately from theory the heats of the reactions, still quantum mechanics does enable one to understand the salient features—why valence rules are as they are, why there should be saturated bonds, etc. The Pauli exclusion principle is the key to the interpretation. The spin quantum number of an atom is intimately connected with its valence. Atoms aith spins other than zero can be regarded as having unsaturated valences. The bonding is not due to any large magnetic coupling between the spins, and usually arises from the so-called exchange energy, which is electrostatic in character but which is correlated with spin alignment because of the constraints imposed by the Pauli exclusion principle. As a rule, the exchange energy is favourable to bonding when the spins are antiparallel. Besides codifying

valence numbers, quantum mechanics has furnished a qualitative understanding of the directional valence characteristic of stereochemistry. It has also introduced the concept of resonance energy in chemical bonds. Previously the molecule was thought of as having a fixed structure, but quantum mechanics shows that it can coexist in several states at once, and a lower energy is often obtained if a molecule resonates among a variety of configurations.

6. A quantum theory of the solid state has been formulated. Thanks to quantum mechanics. it can be explained in a general way how atoms are held together in solid bodies. Various properties of solids, such as compressibility, thermal and electrical conductivity, specific heat, etc., also can be explained. Because solids involve more complicated aggregates of atoms than do individual molecules, the difficulties in the way of a strictly rigorous numerical computation are even greater than for the calculation of chemical binding. Nevertheless, semiquantitative as well as qualitative predictions are sometimes possible.

7. Quantum mechanics provides the basis. for the interpretation of ionization potentials, capture phenomena and especially questions connected with the scattering of electrons or other particles (neutrons, protons, etc.) when they come near atoms or molecules.

8. Numerous phenomena associated with the interaction of radiation with matter were first adequately explained by quantum mechanics. Examples are the Compton effect or the photoelectric effect, and various questions connected with absorption and emission. By means of the so-called Kramers formula. a far more profound and realistic description of dispersion is provided than in classical theory.

9. Quantum mechanics provides an explanation of the existence of the positron and antiproton.

10. A quantum electrodynamics, describing many phenomena associated with radiation and with the coupling of electrons, has been formulated.

11. Finally, the philosophical implications of quantum mechanics must not be forgotten. The Heisenberg uncertainty principle, which shows that there is a limit to the precision with which nature can be observed, is particularly important in this respect.

QUARANTINE AND ISOLATION. Quarantine is the complete or partial limitation of the freedom of movement of well persons or animals that have been exposed to a communicable disease; its purpose is to prevent further transmission of the disease Segregation of a sick person or carrier is also commonly called quarantine but is more properly designated isolation.

Venice in 1374 imposed nhat was probably the first quarantine by hanning travelers suspected of having been infected with bubonic plague. In 1377 the Adriatic port of Ragusa (modern Dubrovnik, Yugos.) required all travelers from plague districts to remain for a month at one of two designated points before entering the city. The first quarantine station was erected in 1383 in Marseilles, where all travelers from infected ships were detained for 40 days.

It is from this 40-day period of detention that the term quarantine is derived (It. *quaranta*, "forty").

The purpose of isolation is to prevent transmission of the infectious agent from the infected person or animal to a susceptible person by placing the person or animal under such conditions that the possibilities of transmission are minimized. Strict isolation of the patient for the period of communicability (which is determined by experience) is necessary in diseases such as smallpox. In other diseases, such as malaria, the patient need only be protected by screens from the mosquito vector. In still other diseases isolation is not utilized nowadays, either because the method of transmission is not fully understood or because it has been discovered that isolation of the few frank cases of the disease does not prevent further transmission from much larger numbers of mild, unrecognized cases.

Modified isolation may be carried on voluntarily by a person's remaining at home when he has a mild infectious disease such as a cold.

While isolation to be effective must be imposed until the end of the period of communicability, the exposed person or animal, called a contact, must not be permitted to expose healthy susceptible persons during the incubation period of the disease. The incubation periods of different diseases or of different cases of the same disease vary in length; but for purposes of quarantine the periods are considered to be the longest usual intervals between first exposure and development of the first signs of infection. Quarantine is often modified so that those contacts who are presumed to be immune because of their ages or histories may be permitted to go about their usual business. Quarantine also is being superseded to some extent by surveillance. the practice of close supervision of contacts so that they may be isolated at the first signs of illness without restricting their freedom prior to that.

Ships usually are no longer quarantined in the earlier manner; the word of the ship's physician is accepted that there are no cases of communicable disease on board. Rapid travel by air, however, has necessitated the institution of new types of quarantine. For example. travelers from an area in which yellow fever is prevalent may be required to remain in quarantine until the end of the incubation period; otherwise they may become sources of infection to the people in the country of their destination.

Quarantine and isolation may be voluntary or official; the latter is enforceable by the government. Official quarantine or isolation is not invoked so often as in the past because in some diseases there are so many unrecognized or missed cases that the identity of the majority of cases and contacts is unknown. When quarantine is employed, it usually is enforced to a greater degree against the more susceptible groups in the population or against those who may be dangerous to public health if they become infected; *e.g.*, schoolteachers or food handlers. More efficient methods of controlling communicable disease, such as vaccination (when available) or control of vehicles or vectors of disease, have to a great extent replaced isolation and quarantine.

See American Public Health Association, *Control of Communicable Diseases in Man*, 8th ed. (1955); H. R. Leavell and E. G. Clark (eds.), *Textbook of Preventive Medicine* (1953). (H. J. SY.)

QUARE IMPEDIT, in English law, a form of action by which the right of presentation to a benefice is tried. It is so called from the words of the writ formerly in use, which directed the sheriff to command the person disturbing the possession to permit the plaintiff to present a fit person, or to show cause "why he hinders" the plaintiff in his right.

QUARITCH, BERNARD (1819–1899), English bookseller and collector, born at Worbis, Ger., on April 23, 1819, went to London in 1842. In 1847 he started a bookseller's business off Leicester square and in 1860 moved to Piccadilly. About 1858 he began to purchase rare books. In 1873 he published the *Bibliotheca Xylographica, Typographica et Palaeographica*, a remarkable catalogue of early productions of the printing presses of all countries, and from time to time published a variety of other catalogues of old books. Quaritch developed the largest trade in old books in the world. He died at Hampstead on Dec. 17, 1899.

QUARLES, FRANCIS (1592–1644), English religious poet remembered for his *Emblemes and Hieroglyphikes,* the most notable emblem book in English. Born at Romford, Essex, he was baptized on May 8, 1592. He was educated "at schoole in the Countrey," at Cambridge, taking his degree from Christ's college in 1609, and at Lincoln's Inn, London. In 1618 he married Ursula Woodgate, and made his home in London. He had private means, and was happiest living in scholarly seclusion. He began his literary career with a series of lugubrious biblical paraphrases, the first, *A Feast for Wormes*, appearing in 1620. These were collected as *Divine Poems* (1630), his most substantial volume. About 1626 Quarles went to Ireland, where he became secretary to Archbishop Ussher. There he completed his first secular work, *Argalus and Parthenia* (1629), a heroic romance based on a story from Sir Philip Sidney's *Arcadia.* By 1633 he had settled in Essex.

With *Emblemes* (1635) Quarles produced a new type of emblem book. Most of the 79 plates for it, and some of his ideas, were borrowed (though he was a devoted member of the Church of England) from two Jesuit manuals. But his characteristic use of conventional material and the merit of his verse gave the emblem book its initial claim to serious consideration as literature. *Emblemes* was so successful that Quarles produced another emblem book, *Hieroglyphikes of the Life of Man* (1638). Printed together in 1639, *Emblemes and Hieroglyphikes* became the most popular book of verse of the 17th century.

The last years of Quarles's life were overshadowed by poverty. Probably for this reason he obtained the post of chronologer to London in 1640, and virtually abandoned poetry to employ his pen more lucratively. His first prose work, *Enchiridion* (1640), became the most popular book of aphorisms of its time.

Civil war found Quarles unhappily conscious of conflicting loyalties, yet a staunch Royalist. He is said to have suffered for his allegiance and for writing *The Loyall Convert* (1644). a pamphlet defending the king's position. Quarles died on Sept. 8, 1644 His wife, with 9 of 18 children who had been born to them. was left in want.

QUARRYING, the art of obtaining stone from the earth's crust. Rocks that are quarried for commercial use fall into three great groups: igneous, sedimentary and metamorphic. Granite is the most important of the igneous type. The sedimentary rocks, the most important of which are limestones, sandstones and shales, are sometimes termed stratified because they have been deposited in successive layers. The third group, metamorphic, contains rocks of both igneous and sedimentary origin that have been changed by tremendous mountain-building forces.

There are two main products of the quarrying industries—dimension stone and crushed and broken stone. The term dimension stone is applied to blocks or slabs of natural stone that are cut to definite shapes and sizes. Crushed and broken stone includes irregular fragments produced by passing the stone through crushers or by grinding the rock to a fine powder.

Dimension Stone.—Although rock deposits are abundant, only in certain places have they the necessary qualities that make them suitable for use as dimension stone. Generally the rock must be uniform in grain size and coloration, and must have attractive colours. Most rock deposits are intersected by natural partings called joints. If the joints are closely spaced the rock is valueless. The most favourable deposits are those in which the joints are vertical, in two more or less parallel systems at right angles to each other and spaced four or more feet apart.

When a rock deposit is located the first step is to clear the surface of soil, gravel or other debris—a process known as stripping. After the surface of the rock has been cleared, the next step is to separate masses of rock from the parent ledge. It is important in quarrying dimension stone to avoid the use of powerful explosives that would shatter the rock and destroy its usefulness. Blocks must be removed with care to preserve their strength and weather resistance. The first operation is to make a cut or channel which will separate a block from the solid bed. For the softer rocks such as limestones and sandstones. the channeling machine generally is used. This has a cutting tool consisting of several chisel-edged steel bars clamped together. As the power-driven machine travels back and forth on a track it cuts a channel 2 to $2\frac{1}{2}$ in. wide and several feet deep.

In the harder rocks such as granites, channeling machines cannot be used. One method of making primary cuts in granite, and sometimes in marble and slate, is to drill a row of closely spaced holes to a depth of eight or ten feet, and to cut the webs or cores between them with a flat broaching tool, thus making a continuous channel. Another method is to use a wire saw. This consists of a three-strand or single-strand wire rope about $\frac{3}{16}$ in. in diameter which runs as a belt, and cuts by abrasion when fed with sand or other hard grains in water.

When the primary cuts have been made, if floor seams are absent, the mass of rock must be separated at the quarry floor. Horizontal holes may be drilled beneath the blocks, and the blocks then can be broken loose by driving wedges in the holes. The masses of rock thus set free may be very large. In limestone they may be 80 or 100 ft. long, 8 or 10 ft. high and 4 ft. wide. These large blocks are subdivided into smaller sizes generally by the plug and feather method. The blocks are marked out to desired sizes with square and straightedge. A man with a compressed-air hammer drill then sinks a row of shallow holes along the chalk line. Separation is made by wedging. The so-called feathers are strips of iron flat on one side for contact with the wedge, and curved on the other to fit the wall of the drill hole. The plug is a steel wedge which is driven between each pair of feathers. When the plugs are sledged lightly in succession the force generated is so great that the rock breaks. The separated blocks are conveyed to mills where they are sawed into slabs, shaped to desired dimensions or turned on lathes into columns. They are then rubbed or polished to give the desired surface finish.

The principal uses of dimension stone are for both exterior and interior building construction. Granites and marbles are also used extensively for memorials ranging from simple markers and headstones to elaborate mausoleums. Slate is used for roofing, stair treads. blackboards and many other applications. Sandstones are used as building stone and for abrasive wheels such as grindstones. Quartzites are used chiefly for flagging.

Crushed Stone.—Although the use of stone in fragmentary form is a comparatively recent development, the crushed stone industry has far outstripped the dimension stone industry in tonnage. The chief varieties of rock used are limestone, sandstone, granite and basalt (traprock). As the purpose is to obtain small fragments, explosives are used for shattering.

The first operation is to drill deep holes in rows. The churn drill or well drill is widely used to sink holes 6 in. or more in diameter and 50 or more feet deep. The distance of the row of holes from the quarry face is known as the burden; it is commonly 20 to 30 ft. The distance from one hole to another in the row is known as the spacing and is usually less than the burden. In large quarries a row of 15, 20 or more holes, and two or more rows may be drilled for a single blast. The size of the charge in each hole is calculated according to the toughness of the rock. When the explosive charge is in place the upper part of the hole is tamped with sand or rock dust. The charges are fired simultaneously and a single blast may throw down 20.000 or more tons of broken stone, which is then conveyed to the crushers where it is reduced to a maximum size of about six inches. The fines are separated by screening, and the larger sizes are reduced in smaller secondary crushers. Crushed stone is used chiefly for road building, concrete aggregate and railroad ballast. Limestone has special uses such as fluxing stone in blast furnaces and for many chemical applications.

QUARTER DAYS, the days that begin each quarter of the year; in England, March 25 (Lady day), June 24 (Midsummer day), Sept. 29 (Michaelmas day) and Dec. 25 (Christmas day). They are the days on which it is usually contracted that rents should be paid and houses or lands entered upon or quitted. In Scotland there are two legal terms, May 15 (Whitsunday) and Nov. 11 (Martinmas); these, together with the two conventional terms, Feb. 2 (Candlemas) and Aug. 1 (Lammas), make up the Scottish quarter days. In the Scottish burghs, however, the removal terms are May 28 and Nov. 28. In the United States the quarter days are, in law, the 1st of January, April, July and October.

QUARTERMASTER. In the U.S. army this term denotes a member, usually a commissioned officer, of the quartermaster corps. This corps is responsible for the procurement and supply of food, clothing, fuel, and individual and housekeeping types of equipment (but not weapons), the collection and interment of war dead and the maintenance of national cemeteries.

The term quartermaster has a long history in European warfare, dating back at least to the 15th century. In general, quartermasters superintended arrangements for the quartering. and sometimes the subsistence and movement, of troops. In Europe. quartermaster officials on the staffs of higher commanders had evolved by the 18th century into something like the modern chief of staff, or chief of the general staff. In Great Britain and the United States, by contrast, the quartermaster remained a specialized administrative and logistical functionary. (See LOGISTICS.)

The U.S. army's quartermaster corps traces its beginnings back to June 1775, when the army itself was first established. From the beginning, the basic function of the quartermaster organization mas to help plan marches, lay out camps and provide the army's transportation. In 1812 the quartermaster department (as it was then called) acquired broad though ill-defined purchasing responsibilities that conflicted with those assigned to the commissary general of purchases.

By 1842, however, the quartermaster's department was procuring and distributing to the army all its noncombat supplies and equipment except food, which was the responsibility of the subsistence department. During the Civil War the quartermaster general was responsible for all the army's transportation, on water as well as land, and including all its animals with their forage and equipage. He was also responsible for providing clothing; for the operation of utilities at military camps; for military real estate and construction, except fortifications and railway bridges; for operation of military telegraphs; and for interment of war dead. His control of military railroads and military telegraphs was purely nominal, however, as both these services were operated as virtually independent agencies directly under the secretary of war.

On the eve of World War I the quartermaster corps (now so designated) absorbed the functions of the subsistence and pay departments. During the war, all supply and transportation functions were temporarily concentrated in the general staff, but under the National Defense act of 1920 the corps was re-established with most of its old responsibilities (except the pay function). World War II brought a significant reduction in the scope of these responsibilities through creation of a separate transportation corps and assignment of most types of military construction to the corps of engineers. By 1950 the quartermaster corps had thus become essentially a supply service, feeding, clothing' and fueling the army and providing much of its noncombat equipment. Under a broadening system of interservice pooling of logistical responsibilities, some of these functions were also performed for the navy and the air force.

The U.S. quartermaster corps has no exact counterpart in the British service. The royal army service corps (R.A.S.C.) stores and issues expendable noncombat supplies such as food, forage and fuel. The R.A.S.C. is also responsible for most transportation except that organic to units. The royal army ordnance corps stores and issues equipment, clothing, ammunition and explosives and certain motor vehicles. The civilian ministry of supply, rather than the military services, handles procurement of supplies. In British army staff organization, the quartermaster general's branch, or "Q" staff, has co-ordinating responsibility for supplying the material needs of troops and for all military movement (except operational, which is controlled by the "G" or general staff branch). Personnel administration is the responsibility of the adjutant general's branch, or "A" staff.

In the naval service, both American and British, quartermasters are petty officers or selected seamen who perform certain navigational and administrative duties under supervision of the captain, navigating officer or officer of the deck, including manning the wheel while at sea.

See Erna Risch, *The Quartermaster Corps: Organization, Supply, and Services*, vol. i (1953); Erna Risch and Chester L. Kieffer, *The Quartermaster Corps: Organization, Supply, and Services*, vol. ii (1955). (R. M. LN.)

QUARTER SESSIONS, COURT OF, in English law, the name for the justices of the peace of any county, riding, parts, division or liberty of a county, or of any county of a city or county of a town, in general or quarter sessions assembled; it includes the court of the recorder of a municipal borough having a separate court of quarter sessions. The word "general" in this context is contrasted with "special" or "petty." The court is a local court of record having a limited criminal jurisdiction, and also to some extent civil jurisdiction. As a court of record it has, in addition to its other jurisdiction, power to punish summarily without the assistance of a jury contempts committed in its presence, such as insults to the justices or disturbance of its proceedings. At the present time the whole of England and Wales is within the local jurisdiction of some court of quarter sessions.

The court derived its name from the direction in a statute of 1388 that the "justices shall keep their sessions in every quarter of the year at the least." By s. 22 of the Criminal Justice Act 1925, general quarter sessions for any county must be held at such times within the period of 21 days immediately preceding or immediately following March 25, June 24, Sept. 29 and Dec. 25 in every year as may be fixed. The justices are free to sit oftener by adjournment of the quarterly sessions to another time, and even to another place, in their county, or to hold additional sessions. All the sessions thus held are "general," though not all may be "quarter" sessions. The Assizes and Quarter Sessions Act 1908 gave the useful power of dispensing with the holding of quarter sessions if there is no business to transact, and under the Criminal Justice Act 1925 there' is power to dispense with the grand jury where all persons committed have pleaded guilty.

In all the counties, except that of London, the justices in the commission elect a chairman and vice-chairman, neither of them necessarily a lawyer, to preside at the sittings of the court. In the county of London there are a paid chairman and deputy chairman, who must be barristers of at least ten years' standing, and are appointed by the Crown. Under the Quarter Sessions Act 1858 the court may sit in two divisions of at least two justices at the same time and place, but not simultaneously in separate parts of the same county.

The jurisdiction of the court of quarter sessions of a borough does not depend upon the commission of the peace, but upon the Municipal Corporations Act 1882. Before the Municipal Corporations Act 1835, many boroughs had criminal jurisdiction under their charters. Under that Act and the Act of 1882 a grant of quarter sessions to a city or borough is made by the crown in council on petition of the town council. The recorder (*q.v.*), a barrister of not less than five years' standing appointed by the Crown, is sole judge of the court.

The city of London is not subject to the Municipal Corporations Act 1882, and its court of quarter sessions is created by the city charters, and is held before the mayor and aldermen with the recorder. It does not now sit to try indictments, which all go to the Central Criminal Court.

Criminal Jurisdiction.—Courts of quarter sessions in counties and boroughs have both original and appellate jurisdiction depending on the commission of the peace and on legislation beginning in 1344. This jurisdiction is derived in counties from the commission of the peace The jurisdiction of quarter sessions is governed chiefly by the Quarter Sessions Act 1842, and they are forbidden to try the following offences: treason or misprision of treason; murder, capital felony or any felony (except burglary) which is punishable on a first conviction by penal servitude for life; offences against the king's title, prerogative, person or government, or against either House of parliament; offences against the Official Secrets Acts 1911 and 1920; offences subject to the penalties of praemunire; blasphemy and offences against religion, and composing or publishing blasphemous, seditious or defamatory libels; and various other offences prohibited by statutes. But their jurisdiction has been extended by the Criminal Justice Act 1925 and certain offences under the Perjury and Forgery Acts and other statutes and the so-called "long firm" frauds are cognisable by quarter sessions Trials before the court with a jury are governed by the same procedure as trials on indictment in a court of assize. Under the Vagrancy Act 1823 and amending Acts, they have special powers of sentencing incorrigible rogues sent to them by courts of summary jurisdiction

An appeal lies to quarter sessions from convictions by a court of summary jurisdiction only where such an appeal is expressly given by statute. (See SUMMARY JURISDICTION)

Civil Jurisdiction.—By legislation in and since 1888 most of the administrative powers and duties of justices in general and quarter sessions have been transferred to the incorporated and elective councils of counties, boroughs and urban and rural districts. But the justices still possess certain original, civil or quasi-civil jurisdiction with respect to licensing and as to closing highways. Most of the civil jurisdiction of quarter sessions is now appellate, *i.e.*, with reference to orders made by justices.

Rating appeals, although they are still made to quarter sessions, are heard by a committee of the justices of the county appointed by such sessions (Rating and Valuation Act 1925). The procedure as to each form of appeal depends partly on the statute by which it is given and partly on the general provisions of the Summary Jurisdiction Acts. Decisions on law may be reviewed by the High Court (king's bench division) by means of *certiorari, mandamus* or prohibition. Convictions on indictment before courts of quarter sessions are within the provisions of the Criminal Appeal Act of 1907, except convictions on indictments for obstruction or non-repair of a public bridge, highway or river, from which an appeal lies to the court of appeal in the same way as in the case of civil actions tried at assizes. Persons dealt with as incorrigible rogues are also within the Act of 1907. Quarter sessions can state a case on a point of law on an appeal to them against a conviction by a court of summary jurisdiction, and if they decline to do so may be ordered to state a case by the High Court (Criminal Justice Act 1925).

(W. F. C.; W. DE B. H.)

United States.—There are one or two courts of quarter sessions in the United States but in general, courts of other names, differing in the various jurisdictions, perform its functions

QUARTER SQUARES. The product of two numbers is equal to the difference of one fourth the squares of their sum and their difference: $ab = \frac{1}{4}(a+b)^2 - \frac{1}{4}(a-b)^2$. This fact has been used to reduce multiplication to addition with the aid of tables of quarter squares, or using other methods of generating quarter squares. The quarter square of an odd number always has a fractional part $\frac{1}{4}$, which can be ignored in applying the formula. The method is very old and many tables of quarter squares have been prepared, but few are easily available. The most extensive table lists quarter squares of integers not exceeding 200,000. Various mechanical and electrical applications have been suggested. The method is still frequently useful and economical.

See J. Blater, *Tafel der Vzertel-Quadrate aller ganzen Zahlen von 1 bis 200,000* (1887). For reference to other tables *see* A. Fletcher, J C P. Miller, L. Rosenhead, *An Index of Mathematical Tables* (1946 and later) and mathematical review journals.

(C. B. To)

QUARTERSTAFF, a staff of wood from six to nine feet in length. used as a means of attack and defense; originally, no doubt, it was the cudgel or sapling with which many heroes are described by early writers as being armed. Egerton Castle (Schools and *Masters* of *Fence*) says that the staff was the "foil," or practice substitute for the long sword or two-hander. In earlier times it may also have been used as a practice weapon for the spear and bill. It was usually made of oak, the ends often shod with iron, and was held with both hands, the right hand grasping it one quarter of the distance from the lower end (whence the name) and the left at about the middle.

The quarterstaff attained great popularity in England in the middle ages, and was still in use in the 17th century.

(A. R. H.; X.)

QUARTON (CHARONTON, CHARRETON), **ENGUERRAND,** French religious painter, famous for his "Coronation of the Virgin," was born in the diocese of Laon and was active in Provence (1444–66). His real name was transformed in the south into Charreton or Charretier and in modern times, with no reason, into Charonton or Charenton He is one of the best-documented French medieval artists and details exist of six commissions for important paintings, two of which have survived: the "Virgin of Mercy" (1452, Chantilly), an altarpiece the predella of which, painted in collaboration with Pierre Villate, is missing; and the "Coronation of the Virgin" (1453–54, Hospice de Villeneuve-les-Avignons), the contract for which is one of the most complete and interesting documents on medieval art. showing that the composition was minutely prescribed. Both paintings reveal a very original style, partly northern (showing affinities with the tapestries of Arras and sculptures from Picardy) and partly southern (a sort of "Cubist," sharp, sculptural stylization of figures, folds and rocks). Exactly the same style is to be found in the famous "Avignon Pietà" (shortly before 1457? now in the Louvre), which is most probably the work of Quarton.

Quarton is in the first rank of French painters. He is full of imagination. creating very original types of Virgin and saints; his drawing is precise and graceful, his composition majestic and rich. Like Jean Fouquet. Quarton combines the grandeur of monumental decoration with the subtlety of book illumination.

(C. SG.)

QUARTZ, a widely distributed mineral species, consisting of silicon dioxide, or silica (SiO_2). It is one of the commonest minerals and is found in many varieties and with very diverse modes of occurrence. The various forms of quartz have attracted attention from the earliest times, and the water-clear crystals were known to the Greeks as *crystallos,* "clear ice," being supposed by them to have been formed from water by the intense cold of the Alps; hence the name crystal, or more commonly rock crystal, applied to this variety. The name quartz is an old German word of uncertain origin. first used by Georg Agricola in 1530.

Following a description of the uses, occurrence and general properties of quartz this article deals with its crystallography, the varieties of quartz, electrical properties and optical properties and discusses the changes, known as inversions, quartz undergoes when heated.

Uses.—Quartz is a mineral of great economic importance. Many varieties are in popular use as gem stones, such as agate, amethyst, aventurine, bloodstone, cairngorm or smoky quartz, carnelian, chrysoprase, citrine, onyx (for cameos), rock crystal, rose quartz and tigereye (see also GEM). In localities where satisfactory material is available, sandstone, composed mainly of quartz, is an important building stone. Large amounts of sand are used in the manufacture of glass and porcelain. Sand is widely used for foundry molds for casting metals. Quartz is an abrasive, as in sandpaper, sandblasting, millstones and grindstones. Quartz brick is a high-grade refractory (see INVERSION, below) and quartz is used as a flux in smelting calcareous ores. Both quartz and silica glass transmit ultraviolet light and are used optically for this purpose. Because of the low coefficient of expansion and the refractory nature, tubing and various vessels of fused quartz have important laboratory applications: fibres are used in extremely sensitive weighing devices (see BALANCE: Ultramicrobalance). Thin plates cut from quartz crystals are used for frequency control in electronic communications equipment (see Electrical Properties, below).

Occurrence. — Quartz occurs as a primary and essential constituent of igneous rocks of acidic composition. such as granite, quartz porphyry and rhyolite. It is an abundant mineral in pegmatite~,sometimes making up the major part, and often being intergrown with feldspar (graphic granite). It is a common constituent in many gneisses and crystalline schists. By the weathering of silicates, silica passes into solution and is redeposited as quartz in cavities, crevices and along joints of rocks of all types.

Extensive veins of quartz are frequent in schistose rocks. Quartz veins, of economic importance as a matrix of gold, are probably related to igneous action. In mineral veins and lodes, quartz is often the most abundant gangue mineral. Quartz, being a mineral very resistant to weathering, forms the bulk of sands and sandstones, the latter being sand cemented with calcite, gypsum or hematite. A siliceous cement gives an orthoquartzite, while such a rock after being metamorphosed and recrystallized is called metaquartzite. Quartz occurs as pseudomorphs. replacing other minerals, and frequently is the petrifying material in petrified wood.

For ordinary uses, quartz is abundant and cheap. However, lack of adequate supplies of suitable crystals for electrical use has led to many attempts to grow synthetic quartz. Successful methods have been found. and good crystals, free from twinning, have been produced.

General Properties. — Quartz is a hardness standard, being 7 on Mohs' scale; it cannot be scratched with a knife. The specific gravity is 2 6j. There is no distinct cleavage, but plunging a heated crystal into cold water may develop planes of separation parallel to the rhombohedra1 and prism faces. A conchoidal fracture is characteristic of most varieties Coarse-grained varieties have a vitreous to greasy lustre; fine-grained varieties may be waxy or dull. The mineral is a nonconductor of electricity; it is not attacked by acids, except hydrofluoric, and is only slightly dissolved by solutions of caustic alkalies. It is infusible in the ordinary blowpipe flame. but will fuse in the oxyhydrogen flame to a clear colourless glass.

Crystallography. — Quartz crystallizes in the trigonal trapezohedral class of the hexagonal system. The crystals possess no planes or centre of symmetry, but only axes of symmetry. The vertical (c) axis is a threefold axis, and the three lateral (a) axes are twofold and polar; that is, the opposite ends are not alike. Usually, however, this lower degree of symmetry is not indicated by the face development of the crystals. Many crystals are bounded only by the faces of a hexagonal prism m $(10\bar{1}0)$ and what appears to be a hexagonal bipyramid (fig. 1), although sometimes the prism is absent (fig 2). Frequently the crystals are distorted (fig. 3), with similar faces varying in size but still having their proper angular positions. If the distortion is extreme,

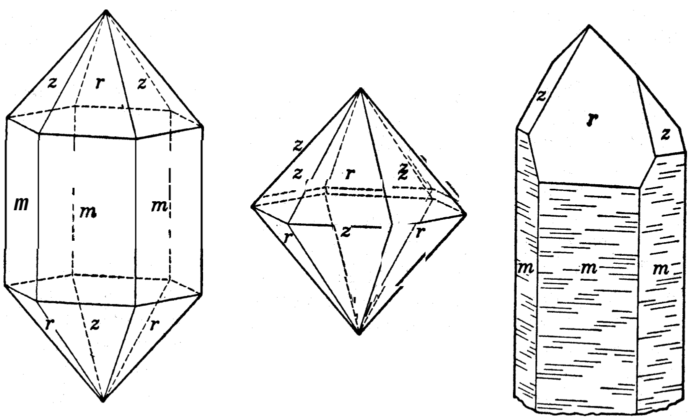

FIG 1, 2 AND 3 —QUARTZ CRYSTALS SHOWING RELATIONSHIPS OF FACES AND CHARACTERISTIC STRIATIONS

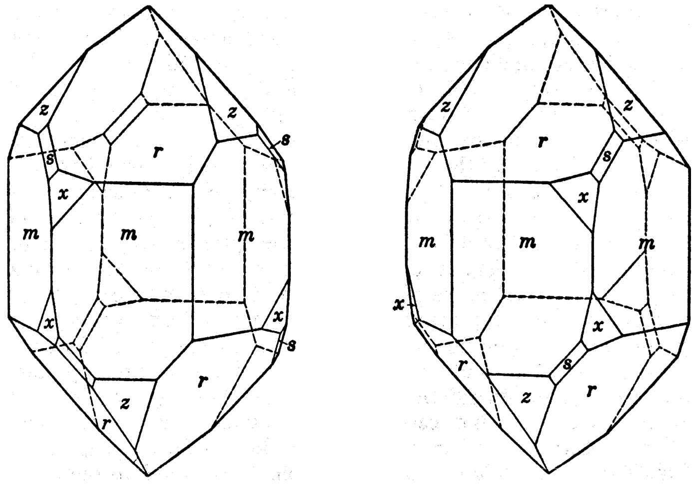

FIG. 4 AND 5.— LEFT-AND RIGHT-HANDED QUARTZ CRYSTALS ILLUSTRATING MIRROR IMAGE SYMMETRY

at first glance the crystals may be difficult to interpret, but they can usually be oriented by aid of the very characteristic horizontal striations on the prism faces. These striations (fig. 3) are parallel to the edges of intersection between the prism and terminal faces, and are due to the frequent oscillatory combination of these forms. The apparent hexagonal bipyramid is really a combination of two rhombohedrons, one positive, *r* $(10\bar{1}1)$, and the other negative, z $(01\bar{1}1)$. Although many exceptions occur, *z* is usually smaller than *r* (fig. 4 and 5) and sometimes completely absent. The six small faces *s* $(11\bar{2}1)$, situated on alternate-corners, are those of a trigonal bipyramid, while the faces *x* (5161) are those of a trigonal trapezohedron. The latter are of comparatively rare occurrence, except on crystals from a few localities. These *x* faces clearly distinguish between the two types of quartz crystals, left-handed (fig. 4) and right-handed (fig. 5). Such crystals are said to be enantiomorphous. They are not superposable, but one is the mirror reflection of the other, like the right and left hands. In some cases the *s* faces are striated parallel to their intersection with r; this serves to distinguish *r* and z, and thus show the right- or left-handed character when the *x* faces are missing. Numerous other faces have been observed on quartz, but they are of rare occurrence. The basal plane, so common on many crystals, is of the greatest rarity on quartz, and when present appears only as a small rough face formed by corrosion of the crystal. Natural etching, or artificial etching by hydrofluoric acid, produces etch figures, which are small pits or depressions of characteristic shape. As would be expected, the etch figures are different on the *r* and *z* faces, and on right-handed crystals the etch figures are reversed in position with respect to left-handed, thus clearly revealing the true symmetry and enantiomorphous character. This feature of the crystals is of course related to the internal grouping of the atoms, which actually consists of a spiral arrangement that may be either right- or left-handed.

Twin crystals of quartz are very common; in fact those without twinning are rare. The twinning may not be obvious unless the *s* or the *x* faces are present. Penetration twins are the commonest, with the prism planes of both individuals coinciding, and may be of two types. Dauphine or electrical twins consist of two right-handed or two left-handed crystals intergrown so that the *r* faces of one coincide with the z faces of the other, which brings the *x* and *s* faces on all six corners, both above and below. The contact between the two portions may be very irregular, or there may be a complicated patchwork of the two orientations. Brazil or optical twins are intimate intergrowths of right- and left-handed quartz, laminae or polygonal inclusions of one being enclosed within the other. These twins are readily detected by use of polarized light. Both types of twinning may be present in the same crystal. Dauphiné twinning is revealed by etching with hydrofluoric acid, and sometimes, probably as a result of natural etching, it is possible to trace the twin boundaries between duller *z* and brighter *r* areas in the same plane. In a rarer type in which the twin plane is $(11\bar{2}2)$, two individuals are united in juxtaposition with their vertical axes nearly at right angles (84° 33'). Such twins have been found in Isère, in the former province of Dauphine. France, and in Japan they are fairly abundant.

Varieties. — Quartz crystals have many interesting variations. They may show a skeletal development, or they may have a helical twist. They may have successive layers of growth. If transparent, the outlines of the inner layers may be faintly visible, giving a "phantom" crystal. In "cap" quartz, the successive layers may separate. "Sceptre" quartz has a short. thick crystal perched in parallel position on a longer slender crystal. Many crystals have cavities. usually filled with a liquid (water. carbon dioxide or a hydrocarbon) and containing a movable bubble of gas. Among the many varieties of quartz are amethyst, rose, milky and smoky quartz, which have characteristic colorations. In addition to the pink colour, properly cut rose quartz may show a star-shaped figure (asterism). Citrine is a yellow variety. Some types of quartz contain inclusions of other minerals, such as rutilated quartz, which has long needles of rutile. Aventurine contains glistening scales of mica, hematite or chlorite; moss agate has inclusions of manganese oxide or chlorite. Tigereye is a replacement of asbestos, and retains the fibrous structure; hence it has a beautiful chatoyant (cat's-eye) lustre when cut and polished. There are many fine-grained varieties of quartz. Chalcedony has a waxy lustre, and occurs in botryoidal and stalactitic forms. Agate and onyx are banded, being formed by the successive deposition of very thin layers. Many agates used for ornaments have been artificially coloured. Carnelian is red; chrysoprase and plasma are green; bloodstone is green with red spots. Basanite or touchstone is black. and was formerly used for testing precious alloys by means of the colour of the streak they left when rubbed on the stone. Jasper is impure, and coloured red, brown or yellow by iron oxide. Flint and chert are gray and occur as nodules in chalk and limestone. For particulars concerning the appearance, properties, occurrence, etc., of varieties of quartz *see* AGATE; AVENTURINE; BLOODSTONE (or heliotrope); CARNELIAN; CAT'S-EYE; CHERT AND FLINT; JASPER; MOCHA STONE (or moss agate); ONYX.

The reader is also referred to the listings under quartz and variety names in the index volume.

Electrical Properties. — Quartz is piezoelectric; that is, a crystal develops positive and negative charges on alternate prism edges when it is subjected to pressure or tension. The charges are proportional to the change in pressure. The pyroelectric effect supposedly observed on quartz is actually attributable to differential expansion during heating, hence is really a piezoelectric effect. This behaviour is related to the low symmetry, especially to the polar character of the lateral axes. Because of the piezoelectric property, a quartz plate can be used as a pressure gauge, as in depth-sounding apparatus. Moreover, if compression and tension produce opposite charges, the converse effect is that alternating opposite charges will cause alternating expansion and contraction. A section cut from a quartz crystal, with definite orientation and dimensions, has a natural frequency of this expansion and contraction (*i.e.,* vibration) which is very high.

Properly cut plates of quartz may have frequencies measured in millions of vibrations per second, and are used for frequency control in radio and other electronic communications equipment and for crystal-controlled clocks. Quartz plates for this purpose must be from portions of a crystal free from twinning (electronic grade); otherwise the vibrations would be in opposition in the two twin areas.

Optical Properties. — In its optical behaviour, quartz is also of interest, since it shows rotary polarization. This phenomenon is related to the enantiomorphous character of quartz. A ray of plane-polarized light traversing a right-handed crystal in the direction of the vertical axis has the plane of polarization rotated to the right, while a left-handed crystal rotates it to the left. A section one millimetre thick, cut perpendicular to the vertical axis of a quartz crystal, rotates the plane of yellow light (D line) through 22° and of blue light (G line) through 43°. Such a section when examined between crossed nicols with the petrographic microscope shows an interference figure with a coloured centre, there being no black cross inside the innermost ring (this is not shown in very thin sections). Superimposed sections of right- and left-handed quartz, as may be present in twinned crystals. exhibit interference figures with Airy spirals. The indexes of refraction of quartz for yellow light (D) are $o = 1.5442$ and $e = 1.5533$; the optic sign is therefore positive.

See also LIGHT: *Refraction and Double Refraction: Natural Optical Gyration.*

Inversion. — When heated, quartz undergoes a series of remarkable changes. At ordinary temperatures it exists as a-quartz, but at 573° C. it passes over into β-quartz, with a change from trigonal trapezohedral to hexagonal trapezohedral symmetry and an alteration in other properties. At 867° C. this β-quartz changes to β-tridymite, and again at 1,470° C. changes to β-cristobalite. These changes are known as inversions. The inversion from a- to β-quartz is reversible, so that quartz is always the a-form at ordinary temperatures. After β-tridymite or β-cristobalite are formed, they remain as tridymite or cristobalite, but upon cooling they invert to metastable a forms, which may exist for indefinitely long periods. Accordingly, all three α forms are found in nature. The six crystalline modifications have closely related structures, in which each silicon atom is surrounded tetrahedrally by four oxygen atoms. Adjacent tetrahedrons are linked by sharing of oxygen atoms, and the various modifications differ only in the arrangement of these linked tetrahedrons. 'The change from quartz to tridymite at the inversion temperature is very sluggish. This is of practical importance in the manufacture of silica refractory brick. The original quartz brick must be heated well above the inversion temperature if the inversion is to be completed in a reasonable time. This is necessary before the brick can be used in a furnace lining, since there is about a 15% increase in volume in the inversion from quartz to tridymite. Cristobalite, on the other hand, has nearly the same volume as tridymite, so that it does not matter which is present in the finished brick. For additional information on inversion *see* SILICA.

For discussion of crystallographic and mineralogical concepts used in this article *see* also MINERALOGY. (L. J. S.; L. S. RL.)

QUARTZITE is a sandstone which has been converted into a solid quartz rock. Unlike sandstones, quartzites are free from pores and have a smooth fracture; if struck with a hammer they break through the sand grains, whereas in sandstones the fracture passes through the cementing material and the rounded surfaces of the grains are exposed, giving the broken surface a rough and granular appearance. Conversion of sandstone to quartzite may be accomplished by precipitation of silica from interstitial waters (hydrous metamorphism) at no great depth and under ordinary pressures. In contrast with these rocks, termed orthoquartzites, those produced by recrystallization under high pressure and elevated temperatures are called metaquartzites.

In microscopic section the clastic structure of some quartzites is well preserved; the rounded sand grains are seer, with quartz overgrowths deposited in crystalline continuity so that the optical properties of the grains are similar to those of the material which surrounds them: a line of iron oxides or other impurities may indicate the boundary of the original sand grain. Many quartzites, however, have been crushed and the quartz consists in large part of a mosaic of small crystalline fragments of irregular shape with interlocking margins; these are the "sheared quartzites"; and if they contain white mica in parallel crystalline flakes they become more fissile and pass into quartz schists.

The term quartzite implies not only a high degree of induration or "welding" but also a high content of quartz. Rocks of like induration but containing appreciable quantities of other minerals and rock particles are impure quartzites, more appropriately called graywacke, etc. Most quartzites contain 90% or more of quartz, and in some the quartz content exceeds 99%. These constitute the largest and purest concentrations of silica in the earth's crust. Quartzites are snowy white. less often pink or gray; they commonly have a fine angular jointing and break up into rubbie under the action of frost. They yield a thin and very barren soil, and because they weather slowly tend to project as hills or as mountain masses. Many of the prominent ridges in the Appalachian mountains are the topographic expression of highly resistant tilted beds of Paleozoic quartzite. The Pre-Cambrian rocks of the Lake Huron and Lake Superior regions include thick and very pure quartzites. The Baraboo quartzite in Wisconsin is often deep red in colour. In Scotland. Schiehallion, Perthshire and the Paps of Jura form conspicuous conical mountains of quartzite in the Dalradian system of the highlands and Cambrian quartzites cap mountains in western Sutherland. The pure quartzites are a source of silica for metallurgical purposes and for the manufacture of silica brick. Quartzite is also quarried for paving blocks, riprap, road metal (crushed stone), railroad ballast and roofing granules. (F. J. P.; X.)

QUARTZ PORPHYRY, in petrology, a group of acidic igneous rocks that are porphyritic, that is, composed of larger crystals in a fine-grained groundmass. They contain visible crystals of quartz in a fine-grained matrix which is usually minutely crystalline in structure. In hand specimens the quartz appears as small, rounded, clear, grayish, vitreous blebs, which are crystals (double hexagonal pyramids) with their edges and corners rounded by resorption or corrosion. Under the microscope rounded enclosures of the groundmass or fluid cavities are often seen; these frequently have regular outlines resembling those of perfect quartz crystals and are known as negative crystals. Many of the quartz crystals contain liquid carbonic acid and a bubble of gas which may exhibit vibration under high magnifying powers. In addition to quartz there are usually prominent crystals (phenocrysts) of feldspar, mostly orthoclase, though a varying amount of plagioclase is often present. The feldspars are usually cloudy from the formation of secondary kaolin and muscovite throughout their substance; their crystals are larger than those of quartz and sometimes attain a length of two inches. It is not uncommon for scales of mica to be visible as hexagonal plates. Other porphyritic minerals are few, but hornblende (an amphibole), and augite and bronzite (pyroxenes) are sometimes found; the augite and hornblende are in most cases green, and are frequently decomposed into chlorite, but even then can usually be identified by their shape. A colourless rhombic pyroxene (enstatite or bronzite) occurs in a limited number of the rocks of this group and readily weathers to bastite. a variety of chlorite.

Apatite, magnetite and zircon, all in small but frequently perfect crystals, are almost universal minerals of the quartz porphyries.

Structure.—The groundmass is finely crystalline. To the unaided eye it usually appears dull, resembling common earthenware; it is gray, green. reddish or white. Often it is streaked or banded by fluxion during cooling but as a rule these rocks are not vesicular. Two main types may be recognized by means of the microscope—the felsitic and the microcrystalline. In the former the ingredients are so fine grained that even in the thinnest slices they cannot be identified under the microscope. Some of the rocks show perlitic or spherulitic structure; such were probably originally glassy (obsidians or pitchstones), but by lapse of time have slowly passed into a very finely crystalline state. This change is called devitrification; it is common in glasses, as these are essentially unstable. A large number of the finer quartz porphyries are also in some degree silicified or impregnated by quartz. chalcedony and opal. derived from the silica set free by decomposition (kaolinization) of the original feldspar. This redeposited silica forms veins and patches of indefinite shape or may bodily replace a considerable area of the rock by metasomatic substitution. The opal is amorphous, the chalcedony finely crystalline and often arranged in spherulitic growths which yield an excellent black cross in polarized light.

The microcrystalline groundmasses are those which can be resolved into their component minerals in thin slices by use of the microscope. They prove to consist essentially of quartz and feldspars, which are often in grains of quite irregular shape (microgranitic). In other cases these two minerals are in graphic intergrowth, often forming radiate growths of spherulites consisting of fibres of extreme slenderness; this type is known as granophyric. There is another group in which the matrix contains small rounded or shapeless patches of quartz in which many rectangular feldspars are embedded; this structure is called micropoikilitic (from the Greek for variegated or mottled), and though often primary is sometimes developed by secondary changes which involve the deposit of new quartz in the groundmass. As a whole those quartz porphyries which have microcrystalline groundmasses are rocks of intrusive origin.

Older Forms.—Many of the older quartz porphyries which occur in Paleozoic and Pre-Cambrian rocks have been affected by earth movements and have experienced crushing and shearing. In this way they become schistose, and from their feldspar minute plates of sericitic white mica are developed, giving the rock in some cases very much of the appearance of mica schists. If there have been no phenocrysts in the original rock, very perfect mica schists may be produced, which can hardly be distinguished from sedimentary schists, though chemically somewhat different on account of the larger amounts of alkalis which igneous rocks contain. When phenocrysts were present they often remain, though rounded and dragged apart while the matrix flows around them. The glassy or felsitic enclosures in the quartz are then very suggestive of an igneous origin for the rock. Such porphyry schists have been called porphyroids or porphyroid schists, and in North America the name aporhyolite has been used for them. They are well known in some parts of the Alps, Westphalia, Charnwood (England) and Pennsylvania. The *hälleflintas* of Sweden are also in part acid igneous rocks with a well-banded schistose or granulitic texture.

The quartz porphyries are distinguished from the rhyolites by being intrusive rocks.

QUASIMODO, SALVATORE (1901–), Italian poet who received the Nobel prize for literature in 1959. He was born at Modica Sicily, on Aug. 20, 1901, and had a technical education, which may explain the enthusiasm for technological progress of his later poems. After graduating in engineering at the Rome polytechnic. he spent ten years in different parts of Italy in the state engineering service's department of geometrical design, writing poetry in his spare time.

In 1935 he settled in Milan where he was appointed professor of Italian literature at the Conservatoire. Later he became dramatic critic for the Milan Tempo and a regular contributor to various reviews.

Quasirnodo published his first poems in the avant-garde review Solaria. In the 1930s he became a leader of the *ermetismo,* a school of poetry which derived from the French Symbolistes an experimental attitude to verse form and the theory that words should be used to convey unconscious associations of feeling and thought by being linked in unexpected arrangements. At first a disciple of G. Ungaretti and E. Montale (*qq.v.*), he soon developed a personal style with its own haunting music, introducing into the frigid and calculated skill of his technical innovations a human warmth and a consciousness of the mysterious power of man's ancestral hopes and fears. From Acque e terre ("Waters and Land," 1930) to La terra *impareggiabile* ("The Incomparable Earth," 1958) Quasimodo's poetry showed coherent development from a dry, sophisticated perfection of style to understanding of life and a commitment to contemporary struggles, expressed in his statement, "The ultimate conquest of poetry is reality." In his translations, notably Lirici Greci (1940), *Il fiore* delle Georgiche (1942) and La *Tempesta* (1952) he combined feeling for the original with modern taste and sensibility. (F. MI.)

QUASSIA, the generic name given by Linnaeus to a small tree of Surinam (Quassia amara), superseded for medical purposes in 1809 by the bitter wood or bitter ash of Jamaica, Picrasma excelsa, which has similar properties and can be obtained in larger pieces. Since that date this wood has continued in use in Great Britain under the name of quassia to the exclusion of the Surinam quassia, which, however, is still employed in France and Germany.

Picrasma excelsa is a tree 50 to 60 ft. in height, and resembles the common ash in appearance. It is found also in other West Indian islands. as Antigua and St. Vincent.

Quassia amara is a shrub or small tree belonging to the same family as *Picrasma,* namely, Simaroubaceae. but is readily distinguished by its large handsome red flowers arranged in terminal clusters. It is a native of Panamá, Venezuela, Guiana and northern Brazil.

Jamaica quassia is imported into England in logs several feet long and often nearly one foot thick. The wood is nearly white, has a pure bitter taste, and is without odour or aroma. It is usually met with as turnings or raspings, the former being obtained in the manufacture of the "bitter cups" which are made of this wood. The chief constituent is a bitter neutral principle known as quassin. It exists in the wood to the extent of about 0.1%. It forms crystalline needles soluble in alkalis, chloroform and 200 parts of water. There is also present a volatile oil. The wood contains no tannin, and for this reason quassia, like chiretta and calumba, may be prescribed with iron. The infusion is useful as a bitter tonic—a group of substances of which calumba is the type—and is also a very efficient anthelmintic for the threadworm (*Oxyuris vermicularis*). It is a substitute for hops.

QUATERNARY, in geology, is the latest chapter in the earth's history and comprises the time that has elapsed from the end of the Pliocene (*q.v.*) to the present day. It is the second division of the Cenozoic era (*q.v.*) as indicated in the accompanying geologic time chart but represents such a short time that some geologists hesitate to give it equal rank and regard it as merely a subdivision of the preceding Tertiary period. T o divisions of the Quaternary period are usually recognized: (1) the Pleistocene, the larger part; (2) and the Holocene or Recent, a short period following the Last Glaciation. For a brief history of the origin and application of the term *see* GEOLOGY: *Historical Geology: Paleontology and the Scale of Tzme.*

The Quaternary is characterized by wide climatic fluctuations. Compared with the Tertiary period. the climate was much colder: ice sheets developed in Scandinavia, on the higher mountain ranges of Europe and Asia and in North America. In the southern hemisphere the Antarctic ice, like that of Greenland, was larger and the Andes, Tasmania and New Zealand had important icecaps. Hence the term Ice Age or Glacial period is often used for the Pleistocene, though the Holocene, usually called "postglacial," may still be considered in the Ice Age.

The northern hemisphere probably had four separate ice advances; these ice advances comprise the major divisions of the Pleistocene. Elsewhere, Lower, Middle and Upper Pleistocene are paleontologically distinguished, though strict contemporaneity in different parts of the world has not been established. The Holocene is subdivided on the basis of its vegetational development (see *Vegetation,* below).

The beginning of the Quaternary is difficult to define since the transition from the last phase of the Tertiary (the Pliocene) was

Geologic Time Chart

System and Period	Series and Epoch	Distinctive Records of Liie	1,000 Yea:s
		CENOZOIC ERA	
Quaternary	Recent	Modern man	11
	Pleistocene	Early man	1,000
Tertiary	Pliocene	Large carnivores	
	Miocene	Whales, apes, grazing forms	
	Oligocene	Large browsing mammals	
	Eocene	Rise of flowering plants	
	Paleocene	First placental mammals	70,000
		MESOZOIC ERA	
Cretaceous		Extinction of dinosaurs	130,000
Jurassic		Dinosaurs' zenith, primitive birds, first small mammals	160,000
Triassic		Appearance of dinosaurs	200,000
		PALEOZOIC ERA	
Permian		Reptiles developed, conifers abundant	235,000
Carboniferous			
Upper (Pennsylvanian)		First reptiles, coal forests	260,000
Lower (Mississippian)		Sharks abundant	285,000
Devonian		Amphibians appeared, fishes abundant	320,000
Silurian		Earliest land plants and animals	350,000
Ordovician		First primitive fishes	400,000
Cambrian		Marine invertebrates	500,000
		PRE-CAMBRIAN TIME	
		Few fossils	3,500,000–4,000,000

in every respect gradual. Thus the gradation of animal life is imperceptible from the Late Pliocene into the Lower Pleistocene (Villafranchian). The onset of the First Glaciation is the event most widely accepted as marking the opening of the era.

This article deals with the stratigraphy and climate of the Pleistocene or glacial epoch of the Quaternary in Europe and Great Britain, the pluvial phases to the south of the glaciations and corresponding to them, the chronology, animal life and vegetation of the time up to the Recent or Holocene and briefly discusses the Quaternary as the age of man. For details of the glacial epoch in North America, its correlations with European and other regions and for a more detailed discussion of the extent and effects of glaciation, the glacial and interglacial ages and the life and climate of the epoch, *see* PLEISTOCENE EPOCH.

Stratigraphy.—A. Penck and E. Brückner in their classical work recognized four Alpine glaciations which they named in alphabetical and chronological order, Gunz, Mindel, Riss and Würm. The glaciations were separated by three mild interglacial epochs, Günz-Mindel, Mindel-Riss and Riss-Würm. Of these: the Mindel-Riss or Great Interglacial was the longest: it lasted almost half the total length of the Quaternary. Some geologists subdivide the glaciations: the first three into two and Würm into three phases, the phases being separated by minor mild phases called interstadials. While the interglacial epochs were warmer than the present—the Great Interglacial was warmer by about 2.5° C.—the interstadials remained cold.

A vast Scandinavian ice sheet radiated outward over the Netherlands, against the northern slopes of the Hartz and Sudeten mountains and over the plains of Russia to the Urals and down the valleys of the Don and Dnieper. In Germany three glaciations, Elster. Saale and R'eichsel, are recognized. A Warthe stage was intercalated between the Saale and Weichsel; whether it was a separate glaciation, a late phase of the Saale or an early phase of the Weichsel remains undecided. R'eichsel is equated with the Alpine Würm. Saale with the Riss and Elster with the Mindel. No northern European equivalent of the Alpine Gunz is definitely known, though Germany has indications of an Elbe or Baltic glaciation which preceded the Elster.

Britain was covered with ice as far south as the Bristol channel and the Thames valley; Ireland apparently was completely glaciated. In both countries the ice of the Last Glaciation (Newer drift) was much smaller in extent. The southern quarter of Ireland. parts of Wales, the Midlands, Derbyshire and Lincolnshire were also ice-free, though land ice in the North sea moved southward over Holderness to leave the Humber unobstructed. East Anglia, the classical region of the British Pleistocene, has the following succession: marine deposits called crags (see *Marine Animal Life,* below); North sea drift (Cromer till and Norwich brick earth); Great Chalky boulder clay; and Upper Chalky drift (with the Hunstanton boulder clay a product of the Warthe glaciation). The three intervening interglacial horizons are the Cromer forest bed; the Corton sands (Great Interglacial); Hoxne and other lake sites. Hoxne probably immediately preceded the Upper Chalky drift, though some writers place it in the Great Interglacial.

The North American ice sheet, unlike the ice masses of Europe, was mostly centred on low ground, namely, a Labrador centre east of and a Keewatin centre west of Hudson bay. Only in the west was the Cordilleran ice nurtured on high mountains. These coalescent ice sheets flowed northward to the Arctic ocean and southward across the Canadian boundary, extending as a group of vast lobes over the Great Lakes as far as St. Louis. As in Europe, four glaciations are usually distinguished, the Nebraskan. Kansan, Illinoian and Wisconsin. The Iowan, previously regarded as a separate glaciation or a late Illinoian phase, is now thought to have been the initial phase of the Wisconsin glaciation, corresponding perhaps to the European Warthe. The intervening interglacial~are the Aftonian, Yarmouth (Great Interglacial) and Sangamon.

The Alpine Würm, North European Weichsel and British Newer drift are almost certainly contemporaneous. The correlation of the earlier glaciations is less certain; they are usually bracketed as shown in the accompanying table (interglacials in italics).

Alps	North Germany	British Isles	North America
Würm	Weichsel	Newer drift	Wisconsin
Riss-Würm	*Eemian sea*	*Hoxne*	*Sangamon*
Riss	Saale	Great Chalky	Illinoian
Mindel-Riss	*Holstein sea*	*Corton sands*	*Yarmouth*
Mindel	Elster	North sea drift	Kansan
Günz-Mindel	*Mauer*	*Cromerian*	*Aftonian*
Günz	Elbe?	Later craes	Nebraskan

Climate. — At the beginning of the Quaternary, the climate of temperate Europe appears to have resembled that of the present day. Considerable cooling took place during the Early Glaciation, sufficient to exterminate many Pliocene types of mammals and to enable arctic species to spread southward. But on the whole, the effect of the first Quaternary Glaciation was slight and in the Antepenultimate Interglacial (that of the Cromer forest bed of East Anglia) decidedly temperate conditions prevailed again. The Antepenultimate Glaciation, however, was more intense and it caused a sharp break in animal life. In a broad zone surrounding the ice sheets (periglacial zone) the climate became cold and pronouncedly continental. Tundra and steppe prevailed; from northern France to southern Russia a broadening belt of loess (windblown dust) was deposited. Those Pliocene elements in the animal life that had survived into the Antepenultimate Interglacial died out. The following Penultimate or Great Interglacial was a prolonged period of temperate climate, at times apparently milder than the present (e g., *Rhododendron ponticum* in the Alps). The Penultimate Glaciation, being much the same size as the Antepenultimate, had similar effects on the environment. By this time, however, many animals had adapted themselves to the recurrent phases of rigid climate and they assumed a Pleistocene aspect, with ancestral mammoth, wooly rhinoceros, etc. Man had also adapted his economy to the cold and stayed in the periglacial zone. The Last Interglacial witnessed a repetition of the mild conditions of the Great Interglacial. Fossil soils, animal life and vegetation suggest higher summer temperatures and an absence of frost. The Last Glaciation, though smaller than the preceding two, appears to have had pronounced climatic effects. Its periglacial zone was slightly smaller than that of the two preceding glaciations, but many interglacial mammals which had survived into the Last Interglacial (*e.g.,* straight-tpsked elephant, Merck's rhinoceros) became extinct and a most characteristic arctic animal life reigned north of the Alps. A second break in animal life is thus observed in the Quaternary at the beginning of the Last Glaciation. Since the Last Glaciation the climate has returned to the temperate conditions of the present day, with fluctuations for which the vegetation provides evidence.

Pluvials.—In the countries around the Mediterranean basin, including north Africa from Morocco to Egypt, pluvial phases corresponded to the glaciations. The anticyclonic conditions reigning over northern Europe forced more cyclones onto a Mediterranean course than is now the case; lakes were deeper and more widespread; the higher mountains, *e.g.,* the Atlas, were clothed with ice; and the Mediterranean countries were covered with deciduous forests of the temperate type. Pluvial conditions occurred elsewhere on the polar side of the subtropical high pressure zones; e g., in North America (Great basin), Asia and in the southern hemisphere in the three southern continents. Pluvials and glaciations are generally thought to have been coeval.

Sea Level. — The formation of large ice sheets, especially in Europe and North America, resulted in the withdrawal of a large amount of water from the oceans. The sea level therefore was low during the glacial and high during the interglacial phases. These fluctuations of the sea level are called eustatic. Eviden'ce for low sea levels is provided by submerged terrestrial deposits (peats, etc.) and drowned river valleys; for high sea levels by traces of ancient shore lines (raised beaches) and terraces in the mouths of rivers. Raised beaches observed on coasts unaffected by tectonic movements or isostasy suggest two Pliocene phases: Calabrian and Sicilian, the latter about 80–100 m. above present sea level; and three interglacial phases: *Milazzian* (60 m.), Tyrrhenian (32 m.) and hlonastirian (18–7.5 m.). The fact that the order in time is one of successively lower levels shows that the eustatic fluctuations are superimposed on a general and persistent drop in sea level which continued from the Tertiary into the Quaternary.

The volume of the Scandinavian icecap of the Last Glaciation has been estimated at 5,000,000 cu.km.; that of the icecap of North America at 21,000.000 cu.km. These masses, by their weight, depressed the ground covered by them. When the ice disappeared and its load was removed, the earth's crust responded elastically by plastic deformation and subcrustal flow and the regions recovered from the depression. This phenomenon is called isostasy. The isostatic rise of Scandinavia was over 300 m. and because of isostatic lag is still taking place at a maximum rate of 1 m. per century. In North America, the uplift was about 1,000 ft. and is also still continuing and tipping the waters of the Great Lakes southward.

Chronology. — Quaternary chronology usually rests on the succession of climatic phases which provide convenient divisions: glaciations, pluviations and phases of high sea level are also used as outlined in the preceding paragraphs. In many parts of the world, however, paleoclimatic evidence is very incomplete and paleontological divisions based on mammals and marine mollusks are used instead. Where prehistoric implements are abundant, chronologies of a more or less local nature have been based on them.

Many attempts have been made to develop an absolute chronology of the Quaternary: several depend upon the time rates of erosion, sedimentation and soil formation. In the Alps, Penck arrived at 600.000 years for the Quaternary; other estimates extend the range to 1,000,000 or 2,000.000 years. A more elaborate time scale correlates the geologically established climatic phases with fluctuations of solar radiation caused by the perturbations of the earth's orbit. This method yields 600,000 years for the Quaternary, 190,000 for the Great Interglacial and 20.000 years for the interval since the Last Glaciation. This astronomical method, which may allow the dating of minor climatic phases, was conceived by J. Adhemar in 1842 and developed by the British scientists J. Croll and Sir Robert Ball in the second half of the 19th century. M. Milankovitch, from 1913 onward. undertook a recalculation of the astronomical tables. His theory, however. is not generally accepted and cannot be regarded as an explanation of the Ice Age as such.

Animal Life. — Terrestrial Animal Life. — The land animal assumed its modern character in the course of the Quaternary. This was due to three causes: (1) dying out of Tertiary elements; (2) appearance of new Pleistocene types; and (3) change of Pliocene forms into modern species by gradual evolution. It is noteworthy that in mammals, the lineages of which have been traced from the Villafranchian to the Holocene. the change in specific characters is slight; differences between Pliocene ancestors and Holocene descendants being no greater than differences between existing related species. In the Mollusca, which have been studied equally closely, these phylogenetic changes are even slighter and changes in the composition of the animals are chiefly the result of migration; *e.g.,* the fresh-water shell Corbicula in the Pleistocene of Britain, now from Egypt southward.

Characteristic mammals of the European Villafranchian are: monkeys (Macacus), a cheetah, sabre-tooth tiger, zebralike horses (Equus *stenonis*), Etruscan rhinoceros, tapir, primitive ox (*Leptobos*). mastodon, southern elephant; of the Lower Pleistocene: the same, except cheetah, tapir and Leptobos, but with red deer, elk (Alces), roe deer and a giant beaver (*Trogontherium*). Middle Pleistocene animal life is devoid of earlier exotic elements and new types appear which survive into the Upper Pleistocene. In the latter, the warm interglacial animal life and the cold glacial animal life have become more sharply separated. Interglacial species are the brown bear, beaver, Merck's rhinoceros, hippopotamus (west Europe), red deer, etc., straight-tusked elephant; glacial species are the arctic fox, varying hare, susliks (*Citellus*), lemmings, jerboa (loess steppe), true horses, wooly rhinoceros, reindeer, musk ox, mammoth, etc. Some of these became extinct before the Holocene began.

Marine Animal Life. — The marine animal life of the Quaternary shows slight evolution in the species, but there is evidence of much migration caused by climatic changes. The crags of East

Anglia, Lower Pleistocene beach deposits rich in shells, illustrate this point. In the Sicilian (Mediterranean deposits of the Günz glacial stage), temperate shells like *Cyprina islandica* and the common whelk extended to the Mediterranean. The Tyrrhenian and Monastirian animal life (collectively called Tyrrhenian by paleontologists) is generally warmer than the modern ones, with the west African *Strombus bubonius* in the Mediterranean and *Astralium rugosum* in the Channel Islands.

Vegetation. — The specific composition of the vegetation has changed much less than that of the animal life insofar as it is the result of phylogenetic evolution, though the shifting of vegetational zones in connection with climatic changes is a most characteristic phenomenon. With the growth of the ice sheets, the forest belts moved southward and tundra and cold steppe covered much of the periglacial zone. Each time the ice retreated, the vegetation belts moved northward again, producing a succession of plant associations which have been studied in peat deposits by means of pollen analysis, chiefly for the time since the Last Glaciation. The subdivisions of the Holocene make use of these changes in vegetation. Complicated divisions are now used in technical papers, but the classical scheme of Axel Blytt and R. Sernander may, with modifications; still serve in summarizing the major features: (a) Subarctic phase (to *c.* 8.000 B.C.), treeless, with *Dryas octopetala*, dwarf willows and birches, interrupted by the mild Allerod Oscillation, when Scotch pine and tree birches appeared temporarily; (b) Preboreal (8,000–7,000 B.C.), birch and pine immigrating; (c) Boreal (7,000–5.500 B.C.), with pine and birch dominating and alder, oak, lime and elm as subordinate, but increasing associates — later. hazel woods become prominent. climate continental; (d) Atlantic (5,500–2,000 B.C.), mixed oak forests culminate, hazel reduced to undergrowth, climate oceanic and in part warmer than at the present; (e) Subboreal (2.000–500 B.C.), climate begins to deteriorate, mixed oak forest retreats from the extreme limits reached, pine increases, but beech and hornbeam continue to spread north; (f) Subatlantic, mixed oak forest continues to retreat, beech culminates. present-day conditions.

Man. — The Quaternary is the age of man. Though it is now probable that man originated in the Tertiary, his skeletal and industrial remains are known from the Quaternary only. Pithecanthropus of Java and Sinanthropus of China are of Lower Pleistocene age. In the Middle Pleistocene, types like Smanscombe man (from the lower Thames) are regarded by some authorities as closer to modern *Homo sapiens* than Neanderthal man, who is characteristic of the lower division of the Upper Pleistocene. In Europe. *Homo sapiens* appears around the second phase of the Last Glaciation as an immigrant from the south and east.

The cultural evolution of man in Quaternary times is evidenced by his implements. mostly of stone. At the beginning of the Pleistocene, very primitive tools (the human origin oi which is debated) have been found in East Anglia. In the Antepenultimate Interglacial, the Chellian or Abbevillian hand-ax culture flourished and flake industries of the Clactonian variety appear. By Great Interglacial times. the Chellian had developed into the Acheulian which used the refined "wood technique" in manufacturing implements. The Clactonian persisted, but later the Levalloisian technique of making flakes from specially prepared cores marks another step forward in mental evolution. In the Last Interglacial, the Acheulian develops its final phase, the Micoquian; Levalloisian persists and from the fusion of these the Mousterian results, the culture of Neanderthal man par excellence. All these cultures are grouped together as Lower Palaeolithic. *Homo sapiens* brought with him the Upper Paleolithic culture of blade industries (Aurignacian, Gravettian. Solutrian. Magdalenian) which flourished during the Last Glaciation. When the Holocene began, man had reached the Mesolithic stage: many of his stone tools were now composite, being made up of numerous hafted, small microliths.

In temperate Europe, the Mesolithic was replaced by the Neolithic which introduced agriculture, about 5.000 B.C. *See* ARCHAEOLOGY; MAN, EVOLUTION OF; *see* also Index references under "Quaternary" in the Index volume.

QUATERNIONS, a linear algebra consisting of four-dimensional vectors nhose coordinates are any real numbers. The theory of this algebra was discovered by Sir William Rowan Hamilton in 1843 while he was trying, by analogy with the complex number representation of real two-dimensional vectors, to represent space vectors by the elements of a number system. For the definition of the algebra of quaternions and its place in the theory of algebras, *see* ALGEBRAS (LINEAR). Quaternions were intensively studied during the early part of the 20th century before the general theory of linear algebras came into being. Later, they were usually thought of as a special case of such algebras. Their early importance lay in applications to geometry and mathematical physics. These applications later became a part of vector theory. *See* also VECTOR *ANALYSIS*. (A. A. AT.)

QUATORZAIN, the term used in English literature. as opposed to "sonnet," for a poem in 14 rhymed iambic lines closing (as the Italian sonnet never does) with a couplet. The distinction was long neglected, because the English poets of the 16th century had failed to apprehend the true form of the sonnet. and called Petrarch's and other Italian poets' sonnets quatorzains, and their own incorrect quatorzains sonnets. Almost all the so-called sonnets of the Elizabethan cycles, including those of William Shakespeare, Sir Philip Sidney, Edmund Spenser and Samuel Daniel, are really quatorzains. They consist of three quatrains of alternate rhyme, not repeated in the successive quatrains. and the whole closes with a couplet. *See* SONNET. (G. W. A.)

QUATRAIN, sometimes spelled quartain, a piece of verse complete in four rhymed lines. The length or measure of the line is immaterial. This form has always been popular for use in the composition of epigrams, and may be considered as a modification of the Greek or Latin epigram. The commonest in English poetry is the ballad stanza, an outgrowth of the church hymn, in iambic metre rhyming *abcb*, with alternating four and three stresses to the line. Tennyson in "In Memoriam" used an iambic stanza rhyming *abba*. Though he did not invent it, it is often called the "In Memoriam" stanza. (G. W. A.)

QUAY, MATTHEW STANLEY (1833–1904), U.S. politician, was born in Dillsburg. Pa., on Sept. 30. 1833. His father was Anderson Beaton Quay, a Presbyterian minister. In 1850 Quay was graduated from Jefferson college, at Canonsburg, Pa., which later became Washington and Jefferson college. He was admitted to the bar in 1854. During the Civil War he served as colonel of the 134th Pennsylvania infantry, Aug.–Dec. 1862, and was Gov. Andrew G. Curtin's military secretary, 1863–65. Quay was awarded the congressional medal of honor for his war services.

Quay was a member of the state house of representatives, 1865–67, and was onner and editor of the *Beaver Radical,* 1867–72. He then became secretary of the commonwealth, holding that office until 1878. when he took the newly created position of recorder of Philadelphia. He nas also chairman of the Republican state committee. Resigning as recorder, he was again secretary of the commonwealth, 1879–82. After retiring from public office for a brief period. he served as state treasurer, 1886–87. In 1888. as chairman of the Republican national executive campaign committee, Quay managed the successful presidential campaign for Benjamin Harrison. Quay later broke with Harrison and did not actively participate in the campaign of 1892, in which Harrison was defeated by the Democratic candidate. Grover Cleveland. Quay was a United States senator from Pennsylvania, 1887–89 and 1901–04.

For nearly 20 years he dominated the government of Pennsylvania and also played a prominent part in national affairs. Quay died May *28,* 1904.

QUEBEC. The northeastern mainland province of Canada. bounded on the southwest and west by part of Ontario. James bay and Hudson bay, on the north by Hudson strait and Ungava bay. on the east by the coast of Labrador and the Gulf of St. Lawrence, on the south by the Bay of Chaleur, New Brunswick, Maine, New Hampshire. Vermont, New York and part of Ontario. Its greatest extent is from the U.S. border, about 45° N., to Cape Wolstenholme, about *62" 30'* N., and from Hudson bay, at a point about 79° *30'* W., to Anse Sablon, about *jj°* W. The total area is *594,860*sq mi., or about one-sixth the total area of Canada. The area includes 71,000 sq.mi. of fresh water.

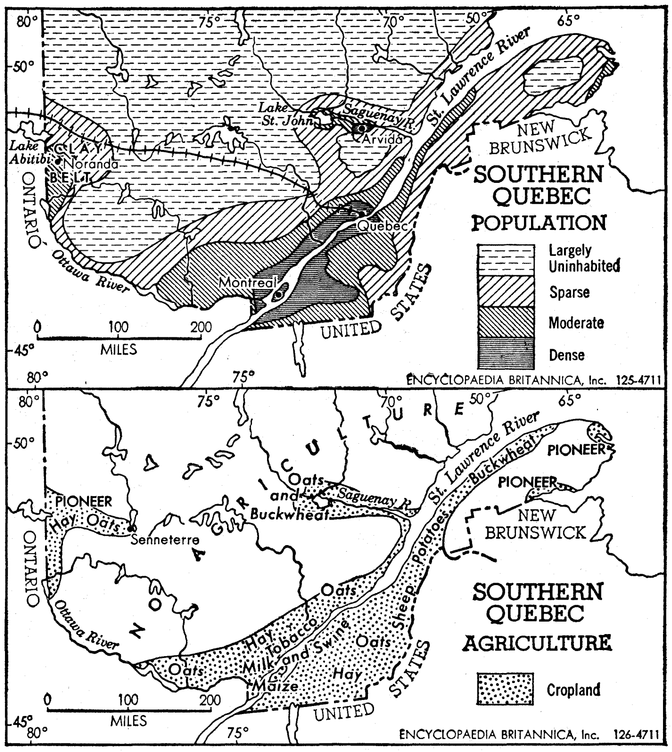
Climate. — The wide spread of latitude and the considerable distance from the Atlantic to the western parts of Quebec produce marked continental characteristics in the climate. In the centre of northern Quebec the range of temperature probably is as much as 70° F.; but along the St. Lawrence river near Montreal the range (between January and July) is about 57° F. (*i.e.,* from 13° to 70° F.). In July the isotherm of 57° F.—which determines the northern limit of the growth of crops—runs west-east through James bay. Hence it is the poor quality of the soils in southern Quebec rather than the temperatures which limits the northern extension of agriculture.

The outstanding feature of the climate is of course the constant passage of low-pressure eddies (cyclones) along the St. Lawrence. This results in an almost uniform type of rainfall in the southern part of the province, since these cyclones are the rain bringers in this part of the world. The weather, however, is quite variable, since the front of such a cyclone gives warm moist winds from the south, while the rear is accompanied by cold dry uinds from the north. The annual rainfall increases fairly regularly from 15 in. in the north to more than *40* in. on the southern boundary of the province.

The snowfall in the high plateau behind Quebec (in the vicinity of the Laurentides provincial park) is perhaps the highest in the continent. and usually exceeds *120* in. in winter. This in part accounts for the popularity of skiing in this part of Canada.

Physiography and Geology.—Physiographical studies divide the province into three main regions: Canadian shield, St. Lawrence and Appalachian. More than 90% of Quebec is built up of the Pre-Cambrian rocks of the shield. In general these consist of various forms of granite and gneiss, of which most perhaps belong to the Algoman formation. There are, however, large areas of altered sediments and of ancient lavas and ash beds; so that there is plenty of variety among the rocks of the shield. The shield exhibits an undulating surface or peneplain, possibly dating back to a period of 500,000,000 years ago. This peneplain surface is by no means near sea level, for large areas of it in Quebec province at the head of Moisie river are more than 2,000 ft. above the sea. It is clear that quite late elevation en masse affected a considerable area of the shield. One of the highest points reaches 3,900 ft. and is only about 50 mi. N.E. of the city of Quebec. Covering this extremely ancient peneplain surface is a layer of glacial till, spread in a haphazard fashion all over the shield. This deposit was only laid down in the last phases of the Ice Age, about *30,000*years ago. Hence we find in this part of Canada a curious association of an extremely old surface of rock covered by a thin veneer of the youngest deposit of all. So comparatively recent has been the deposition of the till that the rivers have not developed a regular drainage pattern. An infinite number of small lakes fills the hollows in the till, river divides are very low, and as a result the topography lends itself well to widespread canoe travel.

The most remarkable of the river valleys is that of the Saguenay which, after a swift descent from the Lake St. John reservoir, falls into a vast chasm running from west to east, in places almost 2,000 ft. above and *300* fathoms below sea level. Hundreds of rivers,



ABOVE: POPULATION. WITH TWO SMALL EXCEPTIONS. THE AREAS OF DENSE AND MODERATE SETTLEMENT ARE ALONG THE ST. LAWRENCE RIVER ON THE FLOOR OF THE FORMER CHAMPLAIN SEA. BELOW: AGRICULTURE. AREAS OF PRODUCTLON ARE CONCENTRATED IN THE ST. LAWRENCE LOWLAND AWAY FROM THE INFERTILE CANADIAN SHIELD

large and small! flow southward and northwestward ensuring to Quebec a huge potential water power which, with the forests covering the hills and valleys, preserving and preserved by this water supply, constitute an enormous reservoir of resources.

One subregion, Abitibi, on both sides of the Canadian National main line and reaching the Ontario border, is heavily mineralized; both Abitibi and the level region surrounding Lake St. John have soils suitable for cultivation, the former largely clay covered by other soils of varying nature, the latter also clay with a lighter topsoil. The rest of the area has a light moraine soil supporting both softwood and hardwood forests but not otherwise fertile.

The St. Lawrence region seems to be separated from the shield by a major fault and includes: *(1)* an area divided by the river, narrowing from about 60 mi. breadth at Montreal to about 20 mi. breadth at Quebec; *(2)* an area on the south side of the river only, stretching about *300* mi. N.E. from Quebec and *6* to 10 mi. in depth. This region has been divided into three subregions, the Montreal plain, the St. Lawrence valley between Montreal and Quebec and the south shore (Cote Sud) below Quebec. The Montreal plain is low, 250 ft. or less above sea level. The surface slopes evenly and very slowly down to the river on both sides and also downward from northeast to southwest; *i.e.,* against the direction of the river. The basement is of Ordovician rock broken near Montreal by the Monteregian hills, remnants of considerable volcanic mountains now almost completely eroded.

After the ice cap vanished, the sea temporarily invaded the lowlands forming the Champlain sea. The soil consists of clay and sand from the Champlain sea with more recent deposits: and is in most places good, although large parts have become sour. Considerable areas are covered by newly formed peat.s The St. Lawrence valley basement is likewise Ordovician rock; a mixed soil lies on a clay bed, much deeper on the south than on the north shore. The south shore is comparatively level, ba ed on Ordovician rock with many outcrops. The soil is mainly sandy, although there are considera'ble areas of black vegetable deposit, in one section already turned to peat, and is strewn with glacial boulders.

The rest of the province constitutes the Appalachian region, mainly Ordovician with lesser amounts of Cambrian and Devonian dotted with granite. and serpentine hills, well weathered and largely tree-clad, rising in the south of the region to about 3,000 ft. Logan's fault separates the folded rocks of the Appalachian region from the less disturbed area near the St. Lawrence. The Gaspé peninsula in the east has a central axis of Devonian rocks, and rises steeply from the north coast, ending in a high, narrow and precipitous promontory (Cape Gaspé). On the north side are the Shickshock mountains, much folded and faulted. On the south side is another range, with red sandstone and conglomerate along the western end of the Bay of Chaleur. At the east end of the south shore of the peninsula is a much eroded shore line of rocks filled with fossil shells from uhich a one-time peninsula, Perct! rock, has comparatively recently been cut.

History. — Prior to its cession to Britain most of the present province of Quebec and also a vast ill-defined area stretching from the far west to the Alleghenies and from the Great Lakes to the Gulf of Mexico. as well as the French territories on the North Atlantic, were subject to the crown of France under the name of New France; the district in the St. Lawrence and watershed area was called Canada. Government was held closely in the hands of the crown at Paris; the governor, advised by a "sovereign council," had some powers of initiative but he was called to task if he overstepped and was rivalled by the bishop. His chief financial adviser, the intendant, was responsible to Paris for economic control. Except for elections of churchwardens, very few official traces of democratic government existed. "Canada" was by 1750 the home of about 65,000 French Canadians, descendants of settlers who had been arriving during a century and a half. They had a quasi-manorial system of land tenure: seigneurs received grants of about six miles' frontage and generally greater depth on the St. Lawrence and like areas in the interior. These were parcelled out to habitants who paid annual dues, mostly in kind, to the seigneur as well as making special payments on transfers of property. Some traces of the system were still visible at mid-20th century. There were about 15,000 bourgeois in Quebec, Montreal and Trois-Rivières where the seigneurial system also existed There was a complete system of land registration and a notarial system for land transfers, marriage contracts, gifts, etc., which were unchanged at the cession and which, modernized, remained at mid-20th century. Births, marriages and deaths were recorded in the church of one or both of the persons concerned. These French Canadians who had become completely differentiated from the French (now mainly officials and soldiers), calling themselves "Canadiens" and not French. attributed vast importance to all theie customs, to the civil law and to their religion.

After the victory of James Wolfe at Quebec, a British military government carried on satisfactorily, making no important changes. By the treaty of Paris, Feb. 10, 1763, New France passed formally to Britain. This treaty followed in one respect the terms of the capitulation of Quebec in 1759, which had provided *inter alia* that the French Canadians were to retain their houses, goods, effects and privileges and that the Catholic Church was to be preserved. The treaty also provided for the maintenance of the Catholic Church but subject to the laws of Britain (under which Catholics were debarred from almost all offices). The "privileges" of the capitulation, taken as meaning French civil law and customs. were maintained, but English law was to be followed so far as compatible with them. This to most judges meant that the common law of Britain prevailed and as no French Canadians knew what that law was there was great confusion.

The province of Quebec as a governmental and geographical entity first appeared under the name of the Government of Quebec in a proclamation made by the crown of Great Britain (in virtue of the somewhat dubious royal prerogative right to legislate for newly conquered territory) on Oct. 7, 1763. This proclamation reached Quebec Aug. 10, 1764. The "Government" included the St. Lawrence valley, except for what is now the Ontario section, and the Ottawa valley, bounded on the north by a line from Lake Nipissing to Lake St John. The governor and captain general was authorized to. and did, set up a council to make laws and ordinances replacing the sovereign council. The governor in council was also authorized to. but did not, set up a popular assembly. The confusion as to law and religion resulting from the proclamation, as well as the wish of the British government to curb the American settlers to the south, brought about the Quebec act of 1774 which set up the "Province of Quebec" including most of the area now in the United States west of the Alleghenies. This act guaranteed the maintenance of French civil law and customs and freedom of worship. An executive and a legislative council, both nominated by the crown, were created and both continued in existence, although the executive council, under the same name. became a provincial cabinet.

The French Canadians were used to bureaucracy and were well enough pleased with the Quebec act to fight the invading Americans in 1775, and not at all concerned when the treaty of Paris in 1783 set the southern boundary west of the Quebec-Maine mountains back to the 45th parallel. In 1791, by the Constitutional act (enacted June 10, 1790), a government was set up for "Upper Canada" west of the Ottawa (except for a small triangle at the junction of the Ottawa and St. Lawrence) and "Lower Canada" extended by the act over the Magdalen Islands. Anticosti and Quebec Labrador. The act provided for Lower Canada an appointive legislative council (15) and an elective assembly (50).

The appointive council was at first all-powerful and there were many abuses of power, but there was little complaint until after the War of 1812, in which the French Canadians again fought and, in Lower Canada, defeated the Americans. The revolutionary ideas inspired liberals (French- and English-speaking) in the assembly; the struggle for responsible government and judges independent of the government which ensued culminated in the "rebellion" of the *patriotes* in 1837.

The Union act (July 23, 1840) became law on July 23, 1841, uniting Lower and Upper Canada as Canada East and Canada West, with one council and one assembly in which the two sections had equal numbers, the French language being for the first time recognized although only for debate.

After a conflict with the governor responsible government, in the modern sense, came into effect in 1841. The union nas never much more than nominal, since the practice was to require a majority of the representatives from each section to pass any act while many acts referred to one section alone. The powers of self-government vested in the colonial parliament gradually increased, judicial reform was obtained, the French language was accepted for all purposes in 1849. In 1867, at confederation, the province of Quebec reappeared with its own lieutenant governor, legislative council and assembly. French-Canadian control of Quebec was assured but the rights of the powerful and rich English-speaking minority were carefully safeguarded, particularly their control over their own education. At mid-20th century they constituted only about 15% of the population, but the growing French-Canadian majority had scrupulously regarded its obligations.

The boundary of Quebec on the north at confederation was the height of land north of the St. Lawrence valley. This was extended to the Eastmain and Hamilton rivers in 1898 and to Hudson strait in 1912. The boundary between Quebec and Labrador (as an adjunct of Newfoundland) was decided by the Labrador act (1825). The boundary was placed as a line due north from Anse Sablon, and for more than a century Newfoundland was presumed to have jurisdiction only over the coastal strip of Labrador, not over the interior (practically unknown). Exploration and the prospect of development raised dispute as to the boundary and in 1927 a decision of the privy council awarded to Newfoundland all of interior Labrador draining to the Atlantic (112,000 sq mi.). The period after confederation left the government of Quebec practically unchanged; parliamentary procedure and democratic practice follow British precedent even more than that of most other provinces, but the French-Canadian majority is quite firmly in the saddle. Quebec is a French-speaking island in North America owing allegiance to a queen who for it (and perhaps correctly) is queen of Canada, interpreting the Atlantic charter as confirming its right to its own religion, laws and language.

Population.- he 1961 census was 5,259.211, mostly French-

Canadians. English-speaking people were mainly centred in the larger cities, in Pontiac and Abitibi counties, where there were many new Canadians, the Saguenay'and St. Maurice industrial areas, Gaspe and the eastern townships north of the New Hampshire and Vermont border.

Government. — The queen is represented by the lieutenant governor: appointed for a renewable term of years by the governor general in council. The legislative council at mid-20th century had 24 members-, each sitting for a geographical district, appointed for life by the lieutenant governor in council (Quebec is the only peovihce with such a body). The legislative assembly had 95 members! each elected for a constituency. Rural constituencies are larger but far less populous than urban. The distribution of powers between the three'sections is identical with that between queen, lords and commons in Britain, the assembly having complete control of taxation and finance. Treasury bills issued under orders-in-council must be covered by appropriate votes. All private and some public bills are discussed in and reported by appropriate committee sessions at which persons affected may appear personally or by legal representative before passage. Otherwise the formalities duplicate those of the parliament at Westminster. The premier leads in the assembly, and a leader named by the government, generally also a minister without portfolio: in the council. The executive council is the provincial cabinet; its members must, as a rule! hold seats in the assembly, thus ensuring maintenance of the representative principle. Members are premier, provincial treasurer, provincial secretary, attorney general. ministers of roads. public works, colonization, agriculture, game and fisheries, lands and forests, trade and commerce, municipal affairs, health, labour, mines, social welfare and youth, each of whom has one or more deputies while the premier has a chef *du* cabinet ranking as a deputy minister. There are generally a number of ministers without portfolio, of whom the leader of the council is generally one. Elections are governed by the Provincial Elections act, substantially in accord with British practice. There are two parties, Liberal and National Union; a local organization of each usually selects a candidate prior to an election. Independents may run if nominated. Municipal government is carried on by 76 county municipalities and rural and urban municipalities generally under the Cities and Towns act and municipal code, although there are many special charters and acts which demand much parliamentary time for their enactment and revision.

Agriculture. — Main agricultural products of Quebec are wheat, oats, barley, rye, peas, beans, buckwheat, potatoes, turnips, hay, clover, alfalfa, fodder corn and sugar beets.

The main features of Quebec agriculture are: (1) Family farming: on most farms most of the work is done by the farmer and his family, eliminating most of farm labour costs. (2) Farm arts and crafts, mainly in the eastern section where most of the wool produced is woven locally. (3) Co-operation increasing rapidly. (4) Farm credits (under revised statutes of Quebec 194, chap. 113): a farmer whose debts exceed 65% of the value of his farm may borrow 75% thereof, provided his creditors accept this in full payment, A farmer establishing a new farm may borrow 75%. Interest is 3% per-annum, plus 2.714% amortizing loan in 25 years.

The department of agriculture comprises ten services: education, rural economics, extension, animal husbandry, horticulture, field husbandry, information and research, handicrafts and home economics, health of animals, rural engineering. There are also special provincial organizations of farm credit bureau, research council, rural electrification bureau, dairy industry commission. The province is divided into 20 districts, in each of which there is a district agronomist with a staff of one agronomist for each county and a number of assistant and special agronomists with demonstration farms, etc. The province assists agricultural colleges, holds county farm improvement contests, conducts drainage projects, maintains plant-breeding stations.

Environment and Settlement. — The people of Quebec, except for two districts, settled in the lands south of the shield. However, the accompanying population map shows that there is a notable number of settlers near Lake St. John at the head of the Saguenay river. As usual this can be explained in terms of the structure. A block of the earth's crust has sunk, forming a graben. In this depression clays and silts have accumulated, giving rise to much better soils than those which generally characterize the peneplain surface of the shield. Here also the waters of the lake rushing through gorges to the Saguenay have been harnessed by many power stations. Hence, there is a close industrial settlement around the towns of Arvida, Chicoutimi, etc., where large supplies of aluminum and other manufactured goods are produced. At the western margin of the shield there is a large area covered with the clays of the "clay belt." These are due to lake silts deposited in a bygone glacial lake and. as at Lake St. John, the soils are relatively fertile. From Senneterre to Abitibi lake there are many families of habitants who have developed a pioneer hay-oats-dairy economy, which is able to supply many of the needs of the flourishing mines around Noranda.

In the St. Lawrence valley there is extensive farming based in part on the good soils laid down in the temporary Champlain sea. In the warmest part of the province there is a large area devoted to tobacco. and also to maize. The latter is, however, fed green to animals. and the cobs do not generally ripen. In the same rich agricultural region is the densest dairy distribution and on the skim milk many swine are fed, as indicated in the map. Throughout the southern part of the province oats and hay are grown, while in the colder districts potatoes and buckwheat become relatively more important. In the rough foothills of the Appalachians, along the southeast border, is one of the main areas for sheep in eastern Canada.

Education. — Education in Quebec has three main branches: (1) formal school system; (2) college and university system; (3) technical and special schools. There is a growing system of adult education.

1. The formal system is under the control partly of government, partly of committees. Superintendent of education (appointed by the government) is chairman of a council of education which does not sit as such but is divided into a Catholic and a Protestant committee. each with its secretary (a deputy minister). The Catholic committee includes all Roman Catholic bishops, an equal number of laymen and some additional members. The Protestant committee has half the number of members and a number of associate members. In virtue of sec. 93 of the British North America act the Protestant committee has sole control of the curriculum in, and recommends all government grants to, Protestant schools. The Catholic committee deals likewise with Catholic schools. Under jurisdiction of the committees are: (a) Catholic-elementary, complementary, intermediate and high schools, colonization area schools and Catholic high schools; (b) Protestant elementary, intermediate and high schools. With the universities each committee controls normal schools. There are a few private schools (English-speaking). In school municipalities (erected and divided by the government), commissioners are elected by majority (Protestant or Catholic) and trustees by minority. In large cities there are two sets of commissioners. These finance schools and pay teachers.

2. The college and university system is independent of government control except where agreements exist There are a number of classical colleges (Roman Catholic) which give an eight-year arts and science course leading to a university baccalaureate. Convent schools train a large number of girls. Sir George Williams university (Y M C A). Montreal, gives a degree course. McGill university inon-sectarian), Montreal, Ste. Anne de Bellevue and St. Johns, have arts and science, professional and graduate faculties. Three Protestant theological colleges are affiliated. Bishop's university (Anglican) at Lennoxville, mainly residential. gives several degree courses. Laval university, Quebec. and the University of Montreal. with several affiliated schools, provide many branches of professional training.

3. The technical schools of Quebec are not concentrated under a department of education but are spread through the fabric of the government. For example, the department of agriculture is responsible for schools of veterinary medicine, dairy science, pot-

tery making. fisheries, forestry and domestic science; the department of youth and social welfare is responsible for schools of furniture making. papermaking and graphic arts. and in addition for schools teaching common trades and schools recognized as youth protection schools. Under the department of the provincial secretary there are several special schools affiliated to universities for standards and degrees, including the Montreal school of higher commercial studies, and the Montreal polytechnical school; and an institute of music and dramatic art, and a school of fine arts, which give instruction in Montreal and Quebec city.

4. Adult education is carried on in housekeeping schools. night schools and dressmaking schools. by McGill university in Montreal and rural areas, by the department of education and Canadian Legion educational services.

Forests. — Quebec forests are the most important asset of the province. The total forest area covered 356,059 sq.mi., of which 329,154 sq.mi. were still in the hands of the crown and 26,737 sq mi. were privately owned. Varieties are spruce, balsam fir, white pine, red pine, jack pine, hemlock, cedar (white and red), tamarack, birch, maple, basswood. elm, ash, white birch, aspen. poplar, oak (white, red, burr), butternut, cherry. beech, walnut, hickory. Control is by the department of lands and forests.

Mineral Production. — Mineral production at mid-century was characterized by rapid recent growth resulting from the rediscovery of copper (known to the Indians and described by them to Jacques Cartier in 1535) in Abitibi and the finding of gold in the same district. The region as known stretches about 120 mi. E. from the Ontario border about the northern line of the Canadian National railways and varies from 10 to 40 mi. in width. A considerable group of modern cities and towns (Rouyn. Noranda, Amos, Val d'Or, Duparquet, La Sarre, etc.) developed in consequence. As a world producer Quebec takes first place in one article only. asbestos of the serpentine type which exists throughout the Appalachian region. Gold is also mined.

Power and Manufactures. — The development of manufactures marched with that of hydroelectric power. The Shipshaw plant near Arvida on the Saguenay was the world's largest hydroelectric plant at mid-20th century. Main products were pulp and paper, nonferrous metals, women's factory clothing, cotton yarn and cloth, men's factory clothing and electrical apparatus.

Transportation and Communication. — The St. Lawrence seaway forms a section of the shortest route between Europe and the central U.S., furnishing deepwater communication to Quebec's main ports. Montreal is one of the most important rail-water-air connecting points in North America and Quebec manufactures are largely based on transportation facilities.

The province has railway lines of the Canadian National and Canadian Pacific railways, as well as pulp and paper company lines, together with about 50 mi. of New York Central feeder line into Montreal. In the 1950s a 360-mi. railway was built at Sept-Îles to run to the iron-ore deposits adjacent to the Labrador boundary. Montreal and Quebec city are major ocean ports used regularly by about a score of Canadian and foreign shipping lines.

QUEBEC, the oldest city of Canada and the capital of Quebec province, is situated on the north bank of the St. Lawrence river at its junction with the St. Charles, about 400 mi, from the Atlantic ocean and 180 mi. by river northeast of Montreal. It consists of an upper and a lower tomn. The upper town is built on the northern extremity of an elevated tableland which forms the left bank of the St. Lawrence for a distance of 8 mi. The highest part of the headland is Cape Diamond, 333 ft. above sea level, and crowned by the citadel; toward the St. Lawrence it presents a bold and precipitous front, while on the landward side and toward the St Charles the declivity is more gradual. The lower tomn is built all around the tableland, at the foot of the cliffs and in the basin of the St. Charles river, and expands on the Beauport coast. Steep, winding streets and an inclined elevator connect the two towns.

The climate of Quebec is severe but bracing, the mean temperature in winter being 12° and in summer 68° F. The city returns four members to the provincial house of assembly and three to the house of commons.

History. — The first known white man to visit Quebec was Jacques Cartier. the French navigator who, in 1535, found on the site a large Indian village called Stadacona. In July 1608, the present city nas founded and named by Samuel de Champlain. The origin of the name Quebec has been much disputed. but it is apparently the Algonkin word for a sudden narrowing, a strait, such as the case opposite Cape Diamond where the St. Lawrence narrons to 1,314 yd.

The most westward French settlement in America, Quebec mas captured in 1629 by the English under Sir David Kirke. They held it until the treaty of St Germain-en-Laye of 1632, when it mas restored to the French. When the colony of New France was made a royal province in 1663 Quebec became the capital and the centre of French operations in North America for a century. In 1690, Sir William Phips, governor of Massachusetts, attempted to reconquer it with a fleet and army fitted out by New England but was defeated by the French governor. the comte de Frontenac. In 1711 a great British expedition sent against Quebec under Sir Hovenden Walker was shipwrecked in the Gulf of St. Lanrence, and the French held possession until the Seven Years' War. In 1759, a young British general. James Wolfe (*q.v*), was given the command of an expedition against Quebec from the lower St. Lawrence. while Lord Jeffrey Amherst led a force from New England by Lake Champlain on Montreal. With 8.000 men convoyed by a powerful fleet, Wolfe tried unsuccessfully to disembark at Beauport and Montmorency below the city: seizing Point Lévis. he bombarded Quebec from there. Many weeks later he decided to land at the Foulon cove above Quebec, and move the main body of his troops to the top of the cliffs on the heights of Abraham. There he was able to fight and defeat the French army commanded by the marquis de Montcalm. Both Wolfe and Montcalm were killed. Quebec surrendered on Sept. 18, five days after the battle. New France was ceded to Great Britain by the treaty ending the French and Indian War in 1763.

In 1775 American forces under Richard Montgomery and Benedict Arnold attacked the city, but Montgomery was killed (Dec. 31, 1775) and Arnold was compelled to retreat in the following spring. Quebec was the capital of the province of Quebec (1763–91) as then existing; the capital of Lower Canada (1791–1841); the capital of the United Province of Canada. 1851–55 and again in 1859–67; and from 1867 the capital of the province of Quebec During World War II Pres. Franklin D. Roosevelt and Prime Minister Winston Churchill held a conference at the citadel in 1943, known as the Quebec conference, that prepared for the invasion of Europe by Allied forces.

Urban Characteristics.—The most notable feature of Quebec is the city within the walls, the only remaining enclosed city in North America. The present walls and the citadel that crowns Cape Diamond cover an area of about 40 ac.; they were built in 1823–32. Since then several of the gates have been destroyed and others rebuilt; among the most well-known are St. Jean and St. Louis gates. Between 1865 and 1871 three forts were built on the Lévis side of the river but were neither manned nor armed.

In the city. with its narrow and irregular streets, the visitor will discover the old world character of Quebec. Several houses built during the French regime are still occupied. Among the famous buildings located in this part of Quebec are the Chbteau Frontenac, a large hotel erected by the Canadian Pacific railway; the Anglican cathedral, built in 1804; the Roman Catholic basilica, founded in 1647, enlarged at various times. destroyed by fire in 1922 and rebuilt on the original site; the old Roman Catholic seminary, founded in 1663; Laval university; and the Ursulines convent. Th Dufferin terrace is a magnificent 1,400-ft, long promenade overlooking the St. Lawrence, 200 ft. above the level of the river. From the terrace one can see the Laurentian hills, Ile d'Orléans, the Lauzon-Lévis south shore communities. the ferry boats plying between the banks of the St. Lawrence, the traffic of ships on the river, and the lower town with the Louise basin and some of the port facilities such as the grain elevator. During the winter, the terrace is a favourite winter sport centre for skating and toboggan rides. The lower town (*basse-ville*) is a mixture of old buildings such as the Notre Dame des Victoires church (erected in 1688. but so named in memory of the defeats of Phips in 1690 and Walker in 1711), old houses and new warehouses and other commercial buildings. It is the financial and wholesale district of Quebec

In the upper town, beyond the walls, are the historic Plains of Abraham. a national battlefield park and site of the museum of the province of Quebec; the parliament buildings of French Renaissance style, built in 1878–92; and the Bois de Coulonge residence, seat of the lieutenant governor of the province.

Churches and Institutions.— The numerous spires and towers of buildings is another distinctive feature of Quebec. The city is 90% Roman Catholic and 92% French Canadian; many religious orders and congregations have established their mother houses there. Quebec is the seat of Laval university, named after the first bishop of Quebec, founded in 1852 by royal charter from Queen Victoria and in 1876 received a charter from Pope Pius IX. It includes faculties of theology, philosophy, law, medicine, sciences, arts, letters, forestry and commerce, a library, a museum and a picture gallery. In 1952 the university began its move to a new campus in the suburb of Ste. Foy. The principal benevolent institutions of Quebec are also administered by religious congregations. The Hôtel Dieu, one of the largest hospitals of the city, was founded in 1639 by the duchess of Aiguillon and has continuously served the public. Under the dual system of education in the province (French and English), there are two separate groups of primary and secondary schools and colleges. A number of government buildings are scattered over the city and in some of the suburbs.

Commerce, Industries and Transportation.— Quebec was long the chief port of Canada and one of the most important wooden shipbuilding and repair centres on the continent. With the deepening of the St. Lawrence channel upstream in the second half of the 19th century, Montreal became the great shipping port of Canada and Quebec suffered a serious economic setback. Later. with the construction of railway lines in all directions from the old capital, the building of new harbour facilities, the abundant services of hydroelectric power and the availability of skilled labour, an important industrial development followed. The chief industries are shipyards and shipbuilding, pulp and paper, shoe and leather, textiles, clothing, mechanical industries, gunpowder, ropes and food and beverages. Quebec is the main trade and commercial centre of the eastern part of the province. The principal commodities handled in the port are grain, coal, petroleum products, asbestos, steel. cement, pulp and paper, newsprint and general cargo. The port, formerly icebound between Christmas and the end of March, is now open to winter navigation. Quebec harbour is the seat of the regional administrator of the federal department of transport for marine operations, who is responsible for the maintenance of the St. Lawrence waterway from the ocean to Quebec From the Dufferin terrace one can see the Queen's wharf at the bottom. where arctic supply ships are loaded, buoys manufactured and repaired, maintenance barges and ships loaded or unloaded and icebreakers assigned to special duties in the winter.

To improve transportation of passengers and commodities between the municipalities on both shores of the St. Lawrence, the Quebec bridge, 7 mi. above the city, was completed in 1917, after ten years of work and two serious accidents to the structure (on both occasions one of the sections fell into the river). It is used by railway and vehicular traffic. Quebec is a major railroad centre, the terminal of the transcontinental line from Prince Rupert (British Columbia), the Lake St. John-Saguenay line and the North Shore line to Murray Bay (La Malbaie). These lines and the modern freight yard of Charny are operated by the Canadian National railway. Quebec is also the terminal of the Montreal-Quebec line of the Canadian Pacific railway and is linked with major Canadian and U.S cities by bus and truck transport service. The Quebec airport is located at Ancienne-Lorette. 10 mi. W. of the city. and is served by Trans-Canada air lines and Quebecair, with several daily flights to Montreal, Chicoutimi, the iron ore district of Sept Îles-Schefferville and other Canadian metropolitan districts

The Quebec metropolitan area has a population (1961) of 357.-568 (Quebec city proper. 171.979) and comprises 30 municipalities: several of these municipalities are located on the south shore. Lévis and Lauzon being the most important ones. Sainte-Foy and Sillery are two residential suburbs in the upper town. There is a Huron Indian reservation near Loretteville. See also references under "Quebec" in the Index volume.

QUEBEC ACT, the title usually given to a bill which received the royal assent on June 22, 1774. This act extended the boundaries of Quebec to include much of the country between the Ohio and the Mississippi. The French inhabitants of the province were granted the liberty to profess "the religion of the Church of Rome"; the French civil law was established, though in criminal law the English code was introduced. Government was vested in a governor and council, a representative assembly not being granted till the Constitutional act of 1791.

The granting of part of the western territory to Quebec, and the recognition of the Roman Catholic religion, greatly angered the American colonies. On the other hand, it did much to keep the French Canadians from joining the Americans in the coming struggle. The act is still regarded by the French in Canada as their great charter of liberty.

QUECHUAN LANGUAGES: see SOUTH AMERICAN LANGUAGES.

QUEDLINBURG, a town in the district of Halle, Ger.. on the Bode, near the northwest base of the Harz mountains, 12 mi. S E. by rail from Halberstadt. Pop. (1959 est.) 31,282. Quedlinburg was a fortress of Henry the Fowler about 922, its early name being Quitlingen. It joined the Hanseatic League. The abbey of Quedlinburg was founded by Otto the Great. and it owned, at one time. a territory about 40 sq.mi. in area. The abbesses ranked among the princes of the empire and had no ecclesiastical superior except the pope.

The town at first strove to maintain its independence of them, and to this end invoked the aid of the bishop of Halberstadt. In 1477. however, the abbess Hedwig compelled the bishop to withdraw. and for the next 200 years both town and abbey were under the protection of the elector of Saxony. In 1539 the townsmen accepted the reformed doctrines. and the abbey was converted into a Protestant sisterhood In 1697 the elector of Saxony sold his rights over Quedlinburg to the elector of Brandenburg. The abbesses, however, retained certain rights of jurisdiction, and disputes between them and the Prussian government were frequent until the secularization of the abbey in 1803.

QUEEN, the title of the consort or wife of a king (queen consort). or of a aoman who is herself the sovereign ruler of a kingdom (queen regnant); the widow of a former reigning sovereign is a queen donager, and, when the mother of the reigning sovereign, a queen mother. For the position of the queen consort in English constitutional law see CONSORT, and for her household see HOUSEHOLD, ROYAL.

QUEEN ANNE'S BOUNTY, the name applied to a perpetual fund of first-fruits and tenths granted by a charter of Queen Anne and confirmed by statute in 1703, for the augmentation of the livings of the poorer Anglican clergy. First-fruits (*annates*) and tenths (decimae) formed originally part of the revenue paid by the clergy to the papal exchequer. The former consist of the first whole year's profit of all spiritual preferments, the latter of one-tenth of their annual profits after the first year, but the First Fruits and Tenths Measure, 1926, made provision for the extinction of *annates* and *decimae* in most cases and for their redemption in the remaining cases. *See* TITHES.

QUEEN ANNE'S LACE: *see* WILD CARROT.

QUEENBOROUGH, a municipal borough in the Faversham parliamentary division of Kent, England, in the Isle of Sheppey near the junction of the Medway and Swale, 2 mi. S. of Sheerness. Pop. (1951) 3,137. Area 1.7 sq.mi. In 1339 the marshes were drained and the town's foundations laid. In 1361 Edward III replaced a nearby Saxon fortress by the castle, designed by William of Wykeham, which, from 1582 until demolished by Cromwell! was the official residence of the lord warden of the Cinque Ports. Edward III named the town *Regina Burgia* when he stayed there with his queen in 1366 and granted it a charter with markets and fairs and built the parish church. The guildhall contains valuable old regalia. Queenborough was a wool staple town in Tudor times and prospered still more when, in 1579. Matthias Falconer started manufacturing chemicals. This industry is still going on, and others include glass bottles, sanitary pottery and the importation and distribution of coal.

QUEEN CHARLOTTE ISLANDS, a compact group lying off the northern part of the coast of British Columbia, form part of that province of Canada. Pop. (1956) 3.082 (including 949 persons living on Indian reserves). Land area 3,970 sq.mi. The islands were named after his ship by Capt. George Dixon who, in 1787, sailed through Hecate strait, which separates them from the mainland. The islands contain resources of minerals (coal, gold, silver and copper) and softwood timber. The surrounding waters support prolific fisheries (chiefly salmon; halibut, herring, crabs and clams), but comparatively little settlement has occurred. The largest community, Queen Charlotte, had 283 inhabitants in 1956. Logging and fishing are the main occupations, most of the output going to processing plants on the mainland. There are scheduled air and marine transport connections with Prince Rupert but bad weather often disrupts the service, especially in winter: The native Haida Indians possessed one of the highest cultures and art forms found among aboriginal peoples of northwestern America. (A. L. FY.)

QUEENS, the largest of the five boroughs of the city of New York, U.S. Located on western Long Island, it extends across the island from the junction of the East river and Long Island sound to the Atlantic ocean; Queens county is conterminous with the borough. In the early colonial period the area was part of New Netherland and the first settlement was made by the Dutch in 1636 near Flushing bay. Gradually towns were organized, including Newtown in 1642, Far Rockaway in 1644, Flushing in 1645 and Jamaica in 1656. These settlements along with the rest of New Netherland came under English control in 1664 when Peter Stuyvesant surrendered to an English force acting for the duke of York. In 1683 the English established Queens county as one of the 12 counties of the province of New York. It was named for Catherine of Braganza, queen consort of Charles II.

During the American Revolution the residents of Queens county were divided in their allegiance; when the English captured Long Island in 1776 many of the patriots fled, and at the conclusion of the struggle a group of the Tories migrated to Newfoundland.

Throughout the 19th century Queens continued to be primarily a rural community with a few small trading centres. Some of the shore communities began to attract large numbers of summer vacationists and such popular resorts as the Rockaways became well known. In 1898 Queens borough was formed as a part of greater New York and at the same time assumed its present size (126.6 sq.mi.) when the three eastern towns of Hempstead, North Hempstead and Oyster Bay opposed joining New York city and were chartered as Nassau county. Pop. (1960) 1,809,578.

Queens experienced rapid development after the opening of the Queensboro bridge in 1909 and the Long Island Railroad tunnel the next year. This development continued and Queens became the fastest growing borough of the city, still retaining for the most part its residential character. *See* also LONG ISLAND; NEW YORK (CITY). (D. L. D.)

QUEEN'S BENCH, COURT OF, is descended from the court held *coram rege* ("before the monarch") when it was part of that undifferentiated *curia regis* which was still performing legislative and executive as well as judicial functions. It was a court to hear cases which concerned the sovereign, or cases affecting great persons privileged to be tried only before him. If he was absent abroad, such cases were heard *coram consilio nostro* ("before our council"). It was also a court to correct the errors and defaults of all other courts, and after the close of the civil wars of Henry III's reign was mainly occupied with the trial of criminal or quasi-criminal cases. In 1268 it obtained a chief justice of its own, but only very gradually did it become a separate court of common law. Thus it was not until a century after the court of common pleas (q *v.*) had become a distinct court of common law that the court of king's bench attained a similar position. It exercised a supreme and general jurisdiction. which comprised (1) criminal jurisdiction; (2) civil jurisdiction; and (3) jurisdiction over the errors of inferior courts including those of the court of common pleas, until by the act of 1830 the court of exchequer chamber became a court of appeal intermediate between the three common law courts and parliament. It also heard appeals from the court of king's bench in Ireland until 1783, and exercised jurisdiction over officials and others by means of the prerogative writs; *e.g.*, habeas corpus, certiorari, prohibition, mandamus, quo warranto and ne exeat regno.

By the Judicature act, 1873, the court was merged in the queen's bench division of the high court. It consists of a chief justice — now lord chief justice of England — and not less than 17 out of the total number of subordinate judges authorized by the High Court and County Court Judges act, 1950, as amended by the Restrictive Trade Practices act, 1956; there are 24 judges assigned to this division. Appeals from inferior courts come before a divisional court. composed of tno or three judges of the division. For appeals from the divisional court to the court of appeal *see* PRACTICE *AND* PROCEDURE. (H. H. L. B.; W. T. Ws.)

QUEENSBERRY, EARLS, MARQUESSES AND DUKES OF. The Queensberry title, one of many associated with the Scottish house of Douglas (*q.v.*), originated in the creation of SIR WILLIAM DOUGLAS (d. 1640) as earl of Queensberry in 1633. He was the eldest son of Sir James Douglas of Drumlanrig (d. 1616) and a direct descendant of Sir William Douglas, who obtained the barony of Drumlanrig in the 14th century.

His grandson WILLIAM, the 3rd earl (1637–1695), was created marquess of Queensberry in 1682 and duke of Queensberry in 1684; he held many high offices in Scotland under James II and VII until the earl of Perth contrived his dismissal.

His son JAMES DOUGLAS, the 2nd duke (1662–1711), was the royal commissioner to the Scottish parliament in 1700. Just after the accession of Anne in 1702 he was made one of the secretaries of state for Scotland and he was again commissioner to the parliaments of 1702 and 1703. In the latter part of 1703 he came under a temporary cloud through his connection with the Jacobite intriguer, Simon Fraser, Lord Lovat. Queensberry was deprived of his offices, but in 1706 he was once more commissioner to the Scottish parliament; in this capacity he showed great tact and ability in carrying through parliament the treaty for the union of the tno kingdoms. In 1708 he was created duke of Dover and marquess of Beverley in the peerage of Great Britain. In 1709 he was appointed third secretary of state.

CHARLES DOUGLAS. the 3rd duke (1698–1778), who had been created earl of Solway in 1706, was lord justice general from 1763 until his death in Oct. 1778. In 1720 he married Catherine, daughter of Henry Hyde, 4th earl of Clarendon, this lady, a famous beauty, although eccentric, was the friend of many of the wits and writers of her day, notably Gay, Swift and Walpole. Their two sons predeceased the duke, and when he died, his British titles became extinct, but the Scottish titles passed to his cousin, WILLIAM, 3rd earl of March (1724–1810).

This William Douglas, who now became the 4th duke of Queensberry, is best known by his sobriquet of "Old Q." On the turf he was one of the most prominent figures of his time, and his escapades and extravagances were notorious. From 1766 to 1776 he was vice-admiral of Scotland, and in 1760 he was made a lord of the bedchamber by George III; but later he mas an associate of the prince of Wales, being removed from his office in the royal household in 1789. He died unmarried, and the dukedom of Queensberry and some of his other titles, together with the Drumlanrig estates, passed to HENRY SCOTT, 3rd duke of Buccleuch, in whose family they still remain; but the marquessate of Queensberry and viscounty of Drumlanrig descended to SIR CHARLES DOUGLAS (1777–1837), the descendant of the first earl's second son, who became the 5th marquess. In his family the marquessate remains.

QUEENSLAND, a state of Australia occupying 670,500 sq.mi. in the northeast of the continent. A coastline of 3,000 mi.

— after that of Western Australia the longest of any individual state — bounds it on the north from the Gulf of Carpentaria and on the northeast and east from the Coral sea and the Pacific ocean respectively the 450-mi -long Cape York peninsula forming the only major irregularity in the coastal plan. In the west the boundary runs successively with that of Northern Territory along long. 138" E. and with that of South Australia along lat. 26° S and long. 141° E to the northwest corner of New South Wales In the south the boundary marches with that of New South Wales along lat 29" S , the Baruon-Macintyre-Dumaresq rivers and the crestlines of rhe Macpherson range to Point Danger.

The waters and islands of Torres strait nearly to New Guinea as well as the Great Barrier reef. are included within the political boundaries Maximum length (north-south) is 1,250 mi and maximum breadth (east-uest at lat 26° S) is 945 mi

Physical Features.—Queensland is characteristically an area of subdued relief Great plains occupy the heart of the state and, although they merge into higher country of sharper relief both to the easr and the northnest, there are relatively small tracts of country rhat are mountainous or where elevations exceed 3 000 ft

The Eastern Range, Plateau and Lowland Region.—This area occupies the eastern quarter of the state between the Main divide and the Pacific coast. It is underlain mainly by Palaeozoic rocks, folded into complex structures and invaded by widespread igneous intrusions between Devonian and Permian times. with a superposition of Mesozoic sediments in some central and southern basins and with Tertiary basalt-flow residuals capping'many of the higher areas. The two main components in the surface configuration pattern are the coastal ranges—a discontinuous and much-denuded series of low ranges and plateaus, often with cores of granitic rocks and flanks of metamorphics (considered by some to be the remnant of an early Tertiary watershed between east- and west-flowing streams)—and the present Main divide uhich follows generally the upwarped eastern rim of the Mesozoic rocks of the Great Artesian basin. Between these two structural swells is a series of extensive shallow interior basins and narrow near-coastal lowland corridors separated by ranges and plateaus, all with a marked north-northwest directional trend following the gram of the rocks.

The Main divide follows a course that is convex to the southwest so that the region has its greatest width (about 300 mi.) near the Tropic of Capricorn. In this central area, too, elevations are lowest. the great interior catchment basins of the Fitzroy and Burdekin river systems (occupying about 54,522 and 53,500 sq mi. respectively) with their markedly convergent tributary patterns being mostly undulating lowland westward oi the coastal ranges. The dominant structural feature of this central area is the huge Bowen syncline, a downwarp filled with sediments of Carboniferous to Triassic age including the most extensive bituminous coal measures in Queensland

Northnard and southward from the tropic the coastal and Main divide ranges become more conspicuous and continuous and converge to iorm the most striking ranges and highest plateaus in the state In the far north the Atherton tableland of about 12 000 sq mi everywhere exceeds 7,000 ft and rises irregularly southward to more than 3.000 ft. Pliocene basalt. weathering into rich red soils. covers much of its area and the Bellenden Ker range nith Queensland's highest peak. Mt Bartle Frere (5,225 ft) bounds it on the east In the far south. the rugged Macpherson range (Mt Barney 4 449 it) lies astride the state border inland from Tugun beach for 60 mi . merging thence into the highest part ot the Queensland Main divide (Mt Superbus 4 525 ft) which there presents a steep face to the edst but a lesser and more gentle descent westward toward the Darling downs The rivers in these mountainous arras have a more uniform flow than those of east-central Queensland The latter are classed as perennial. but considerable stretches of their courses dry out in winter.

Ihe Pacific coastline cuts transversely across the structural gram and is characterized by an alternation of rocky, north-facing promontories sheltering picturesque inlets and gently curving sandy beaches often backed by sdnd dunes and salt marsh The rivers generally How to the sea across deltaic plains those of the

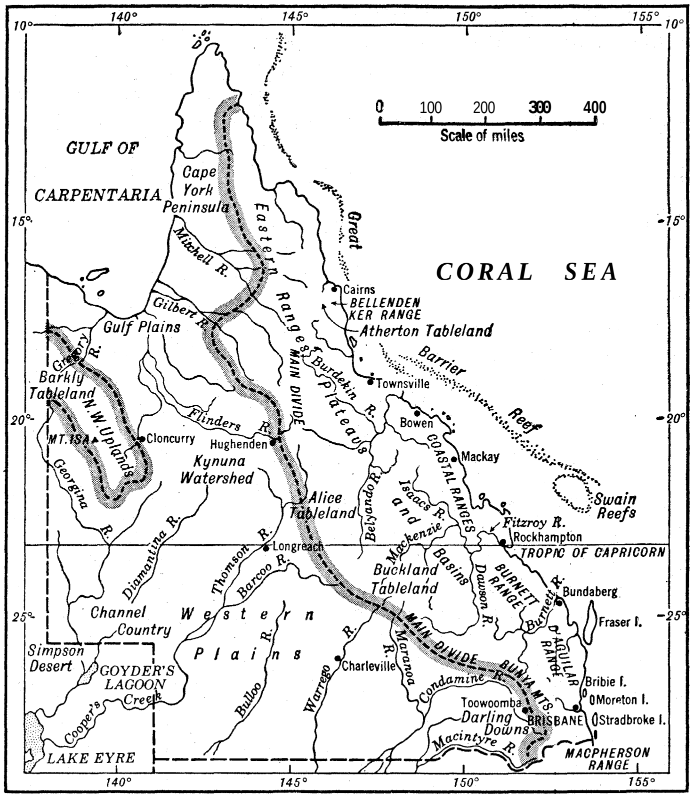

FIG. 1 —RELIEF AND DRAINAGE FEATURES OF QUEENSLAND. BROKEN LINES INDICATE THE LIMITS OF THE THREE PRINCIPAL PHYSIOGRAPHIC REGIONS

Burdekin and Fitzroy being of considerable size. The long, narrow islands close off the southern coast (Fraser, Bribie, Moreton and Stradbroke) are composed of sand dunes which are among the highest in the world The string of reefs and cays, collectively knonn as the Great Barrier reef that stretches for more than 1,100 mi from Torres strait to lat 24° S , lies along the seaward margin of the continental shelf (See BARRIER REEF) The Gulf coast oi Queensland is low-lying and mangrove-lined

The Western Plains—These plains occupy more than half the area of Queensland and form a great tract of lowland extending continuously from the Gulf coast to the southern border but constricted to a width of 280 mi in the low Kynuna watershed (lat 21° S) an upwarped structural and surface swell (600–1 200 ft , generally rising eastward) nith occasional low ridges. Northward and southward from this swell and westward from the hill country flanking the western side of the Main divide, there is a very gentle over-all slope northwestward toward the Gulf of Carpentaria and southwestward toward the Lake Eyre region, corresponding uith two great shallow sags in the thick Cretaceous sandstones and shales that underlie the plains These slopes are closely followed by the watercourses which form three systems converging respectively toward the Darling in the south the Lake Eyre flats of South Australia in the southwest and the Gulf of Carpentaria in the northwest Some of these watercourses are of considerable length but most flow only for short periods each year following the summer rains In floodtime, the Channel country of the far southwest is widely inundated. but nith the loss of water by evaporation and seepage the waters rarely reach Lake Eyre Of the western rivers, the Gregory alone has a perennial flow

West of the Channel country and astride the southnestern boundary of the state is a tract of fixed and partly vegetated sand dunes aligned generally along north-northnest axes

The extent of the western plains coincides fairly closely with that of the Queensland part of the Great Artesian basin with its underlying strata of water-bearing rocks

The *Northwest Uplands*—In the far northwest of Queensland is an outlier of the Pre-Cambrian rocks of the Australian shield trending north-northwest for 300 mi from near Selwyn and Dajarra to the state border west of Burketown. Especially in the south, the rocks are closely folded. intimately penetrated by igneous intrusions and locally mineralized. Dissected hill country with steep-sided rocky valleys following the north-south grain of the rocks characterizes this area. The Georgina plains west of Mt. Isa are floored by Cambrian limestones and rise gently northward to the Barkly tableland, the Queensland part of which is a watershed between the Georgina and Gregory river systems.

Climate.—Queensland is disposed with nearly equal proportions on either side of the Tropic of Capricorn and includes comparatively little high country, so that hot summers and mild winters are characteristic of the state.

The rainfall shows a well-marked summer maximum and varies widely. The heaviest falls occur in the northeast coastlands between Cooktown and Ingham and on the mountain slopes immediately to the westward (Tully 178.06 in.). The heaviest and most prolonged falls are from December to May. (R. H. G.; X.)

Vegetation and Animal Life.—Rain forest with strong Papuan floristic afhnities occurs in the higher rainfall districts, reaching its best development along the eastern coast in scattered areas. Inland it passes gradually into monsoon forest and disappears as a vegetation unit. The predominant vegetation type in a belt about 230 mi. wide along the eastern coast is eucalyptus forest. interspersed with extensive grasslands. The eucalyptus forests are the source of valuable hardwoods and the rain forests provide many important cabinet timbers. With increasing aridity the eucalyptus forests thin out. and the great pastoral areas such as the Mitchell and bluegrass downs, mulga and other scrubs, saltbush and bluebush stretch to the edge of the desert in the extreme west of the state. Extensive mangrove forests occur in the estuaries and on tidal mud flats.

Terrestrial mammals native to Queensland include 2 species of monotremes (echidna and platypus), 53 marsupials and 53 placental mammals. The echidna is common, and the platypus is more abundant in the southern part of the state than in the far north. Marsupials show the full present-day range in size from the great gray kangaroo (*Macropus* major) down to the two-inch pigmy mice (*Planigale ingrami*). Numbers of some species such as the koala have been greatly reduced as the result of settlement. Some, however, have adapted themselves to urban conditions, notably the brush-tailed opossum (*Trichosurus vulpecula*) and the short-nosed bandicoot (*Isoodon obesulus*). Two species of tree-climbing kangaroo (*Dendrolagus*) and two of the cuscus (*Phalanger*) in the north are examples of links with the marsupial fauna of New Guinea. Destructive carnivorous marsupials are few, but the native cat (*Dasyurus*), the largest of them. may cause considerable damage in poultry yards at night. Placental mammals include the dingo (*Canis* dingo), bats (including some destructive fruit-eating species, the Hying foxes) and rodents. Seals and dugongs are of species widely spread elsewhere. Of the snakes the largest authentic specimen is of *Python amethystinus*, 12½ ft. long, from north Queensland. Lizards are common, and among the turtles is included the edible green turtle. Emu, cassowary, four kinds of birds of paradise and four of bower birds are notable in the rich aviiauna. Marine fish species are numerous and of the freshwater species the lungfish (*Epiceratodus forsteri*) is of special interest. The corals and other marine life of the Great Barrier reef are of extraordinary richness, and a marine biological station was established at Heron Island. (D. A. Ht.)

HISTORY

By 1606 both the Dutch and Luis Vaez de Torres had found Cape York peninsula, but it was 1770 before Capt. James Cook discovered the east coast of Australia, the Torres strait itself, and removed the great south land from centuries of fireside speculation. At that time Cook noted signs that a great river might debouch on Moreton bay, which he named. Matthew Flinders, in 1799, denied it. hut in 1823 John Oxley, with the aid of castaways. discovered the Brisbane river and chose its neighhourhood as the new penal settlement that Sydney wished to establish in the remote north.

It was Allan Cunningham's discovery of the Darling downs (1827) that pointed the way to more flourishing settlement. This was already beginning overland from the south before the abolition of the penal colony in 1839 facilitated healthy development. The early squatters were followed in 1842 by the first free settlers and land sales. The main hindrances now became the remoteness of Moreton bay district, as it was called. the lack of understanding in Sydney, and the consequently tiny number of settlers, no more than 2,000 in the mid-1840s. The first emigrant ships from Britain did not reach Brisbane till the mid-19th century.

It was in 1859 that political separation from New Soufh Wales was achieved. when the population numbered 23,520, and before any industry had established itself. In the transition it was not always Brisbane that led the way. There was specific efforts to base the colony on Ipswich, and to make a main port of Cleveland, in Moreton bay. There was also an attempt (1846) to form a colony of north Australia, to be based on Gladstone ticket-of-leave men.

It might have been expected that the wide grazing lands would early tempt the sheep farmer, but it was 1840 before Patrick Leslie took the sheep to Warwick on the downs, and 1860 before there was any general migration westward. In that decade settlement was very rapid wherever there was water. The movement was encouraged in 1869 by act of parliament, which granted 21-year leases to those who had 25 sheep or 5 cattle to the square mile, Many of the early pastoralists failed. Wool had to be transported in drays by long trains of bullocks. the carriage of supplies to a station cost as much as the supplies themselves, markets were far away and uncertain. But by 1873 Victorian prosperity (in gold) began to be invested in Queensland and men of money came north. Studs were improved: fences replaced the shepherd. The first railways, from Ipswich to Dalby and Warwick, were operating by 1870. By 1900, 2.801 mi. of railway gave places like Longreach, Hughenden and Cunnamulla a link with the coast, and it was not till 1924 that the coastline from Brisbane to Cairns was completed.

In 1884 Dutton's act successfully encouraged the growth of a small squatting class. The great drought at the turn of the century when, between 1890 and 1902, 22.000.000 sheep were reduced to 7,250,000, made men turn energetically to the artesian boring that had been introduced in 1881 to open up land to sheep.

It looked at first as if the only impediments to cattle rearing were the distance from markets and the drought. The advent of refrigeration helped the first of these, though it did not change the trade and tradition of droving, bringing the cattle on the hoof from their pastures many hundreds of miles to the west. But in 1894 the cattle tick began to spread from northern Queensland, causing enormous losses, which with the drought of 1902 reduced the numbers from 7,000,000 to 3,500,000. Fluctuation continued, until World War II gave a fillip to prices and brought modern insecticides to combat the tick.

Apart from the Moravian missionaries at Nundah in the penal days, the first arable farmers were brought by John Dunmore Lang in the "Fortitude" in 1849. At once the farmer was resisted by the already settled graziers. Hewing out his farm by clearing the bush, attempting crops where none had been cultivated before, he won the contemptuous name of "cockatoo farmer." But, supporting himself, he advanced from maize and pumpkins to lucerne and sorghum, his livestock increased. and the plow, reaper and farmhouse supplanted hoe, scythe and sickle and bark hut. By the end of the century the government, spending over £1,000,000, had recovered much pastoral iand for the arable farmer; and by mid-20th century early pastoral settlement had become renowned for wheat or sugar cane.

After an early attempt, during the shortages of the American Civil War, to grow cotton (an attempt resumed in the 20th century), Queensland turned to sugar cane, introduced in the early 1860s by Louis Hope and now the state's largest product. The early growers, after the government's easy leases encouraged the industry, not only grew but manufactured the sugar in mills on their plantations. This system of many mills and few growers was later superseded by 8,000 small growers and by 32 central mills, encouraged by the government and often working as co-operative concerns. Cheap labour was scarce in Queensland, and the attempt to introduce Kanakas led to a prolonged political controversy, until in 1904 the federal government prohibited the traffic and ordered the deportation of those already in Australia.

Dairying did not flourish until there were sufficiently populous towns to give it encouragement. Up to 1888 Queensland imported much of its butter from the south, but in 1953 there were 100 factories producing butter and cheese, 20,000 dairy farms, and a production of £17,000,000 annually.

Although coal was discovered at Ipswich as early as 1827 and the first mine opened in 1846, it was the gold rush that really inaugurated Queensland's mining. From 1858 to 1873 the east and north of the state were invaded and opened up by diggers at Canoona, Peak downs, Gympie, Ravenswood, Charters Towers, Palmer river. Within a few months isolated spots in the bush became townships of 10,000 people. Here also the sensitive beginnings of the White Australia policy may be seen in the discrimination by act of parliament against Chinese and other Asian speculators (1877). Already by 1867 the population of the state had grown to 100,000. Even where the gold failed, as at Canoona, a town like Rockhampton could rise from the ruins; and a state with bank deposits in 1859 of only £287,000 became the possessor of mineral wealth that produced £222,420,264 in 1948. In 1882 came the discovery of a mountain of gold and copper, Mt. Morgan, and in the 1920s the process continued with the finding of the silver-lead-zinc deposits at Mt. Isa. But from 1880 the time of excitement was over, and it was replaced by the entry of capital, large-scale enterprise, road and railway, and the deepening of harbours.

Toward the end of the 19th century socialism began its advance in Queensland, and in 1899 the state had Australia's first Labour government, though a minority one. Labour's position, backed by strong trade unionism, became rapidly so powerful that after World War I it was almost continuously in office. In 1922 it abolished the upper house of parliament. but its early state enterprises largely reverted to private management, and its ardent socialism was modified by the practice of power. One of the most successful of its measures was the handling of agriculture through local co-operative boards of the producers themselves. (J. M. Cr.)

POPULATION AND ADMINISTRATION

Population. — At the 1961 census, the population of Queensland was 1,518,859 (excluding full-blooded aborigines, estimated at 9,579 in 1954). This represented 14.45% of the total for Australia, and an average density for the state of 1.96 persons per square mile. The vital statistics for Queensland compare favourably with those for other Australian states. The crude birth rate during the period 1956–60 was 24.17 per 1,000 of population per year. The crude death rate over the same period was 8.49 per 1,000 per year. The population of metropolitan Brisbane in 1961 was 620,121. The population (1961) in provincial cities, the largest of which are coastal or near-coastal in location, was: Rockhampton (44,102); Townsville (51,224); Toowoomba (50,107); Ipswich (48.668); Cairns (25,358); Bundaberg (22,791); Maryborough (19,136); Mackay (16,795). The greater part of the rural population is concentrated in the close hinterlands of these cities.

Education. — State education acts (1875 to 1948) established free and compulsory primary education to a leaving age of 14. In 1954 there were 1,522 primary schools (almost 1,100 of them one- and two-teacher schools) with an enrollment of 203.582 pupils. In 1951 there were 8,137 pupils in outlying parts of the state receiving education by correspondence. A pass in the scholarship examination entitles pupils to attend secondary schools (state or private) and to receive financial help. In 1954 there were 30 state high schools, 8 grammar schools and a system of private, denominational secondary schools. Teachers in state schools numbered 5,416 in 1954. Technical colleges provide apprentice training throughout the state together with a variety of other courses. There is a teachers' training college. Teachers for the state secondary service are trained at the university. The University of Queensland, established in 1911, now at St. Lucia, has faculties in arts, science, engineering, education, commerce, agriculture, law, dentistry, veterinary science, medicine and architecture. In 1954 its staff numbered 256 and its students 4,112 (of which about 1,406 were external students). (F. J. Sl.)

Administration. — The government consists of the governor. the executive council (*i.e.,* the governor and the ministers in office), and a legislative assembly of 75 members, elected by adult suffrage for a period of three years. There are four electoral zones, which are divided again into electoral districts as follows: 24 metropolitan districts of 10,795 electors each; 28 southeastern districts of 9,373 electors each; 13 northern districts of 7,696 electors each; 10 western districts of 4,613 electors each. Voting at elections is compulsory, as is electoral enrollment. The electorate consists of British subjects by birth or naturalization who have lived in Australia for six months, in Queensland for three and in an electoral district for one month.

Local authorities are classed as either city, town or shire councils, there being 12 cities of more than 7,000 persons, 10 towns and 112 shires. Councils are elected by adult suffrage and administer such services as public health and sanitation, roads, water, parks and amenities, and sometimes electricity and transport. (J. M. Cr.)

Social Services. — In 1954 there were 131 public hospitals. supplying free consultation and treatment, 110 public maternity hospitals, 205 maternal and child welfare centres, dental clinics and branches for free dental treatment. Advice is given to mothers in remote parts of the state.

The state department of health also administers a school health service and a scheme of mental hygiene and industrial hygiene. Maternity, child endowment and widows' pensions, which are financed by the commonwealth government, add to the social services available. (F. J. Sl.)

AGRICULTURE AND INDUSTRIES

Livestock Farming. — Pastoral industries have played a fundamental part in the economic development of Queensland, and the net value of pastoral production (£85,256.000 in 1951–52 including dairy products) was considerably greater than that of agriculture (£35,622.000) though less than that of manufacturing industries (£89,305.000). The relative importance of pastoral as compared with agricultural production is largely a reflection of the low and unreliable rainfall over a large part of the state and the concentration of rainfall mainly within four summer months. Bore water, indispensable for watering stock, is usually too highly mineralized for irrigating crops. Conditions on the savanna plains of western Queensland and on the less fertile ranges and basins of the east are thus most suited to extensive grazing.

Although sheep and cattle are run together on many properties, a belt of central Queensland extending from the southern border northward for 600 mi. through Charleville and Longreach to the Hughenden-Cloncurry downlands is mainly used for the raising of sheep and carries practically all the sheep grazed in Queensland. This corresponds with the plain country, receiving between about 10 and 20 in. of rainfall and lying south of latitude 20° S. Nearly all the animals (98.8%) are Australian merinos bred for their fine wool. Numbers fluctuate from year to year in relation to variations in rainfall and pasture growth. Stock losses through drought can be severe. Flocks totaled 16,163,518 (13.7% of Australian sheep) in 1952. The wool clip in the 1951–52 season was 138,-767,000 lb. (greasy), valued at £47.190.000 (12.9% of Australian production). Of the 4,504 properties carrying sheep in 1949–50, 1.811 (40.2%) were 10,000–50,000 ac. and 552 (12.3%) larger than 50,000 ac. In the far west, sheep stations up to 500 sq.mi. are not uncommon.

Queensland is the leading Australian beef-producing state, carrying half of the total herd and producing about 31% of the commonnealth's output of beef and veal. The raising of cattle for beef takes place under a wide variety of conditions and over a much greater total area of Queensland than sheep. About 40% are raised and fattened east of the Main divide where the higher total rainfall and the less meagre winter and spring fall create more

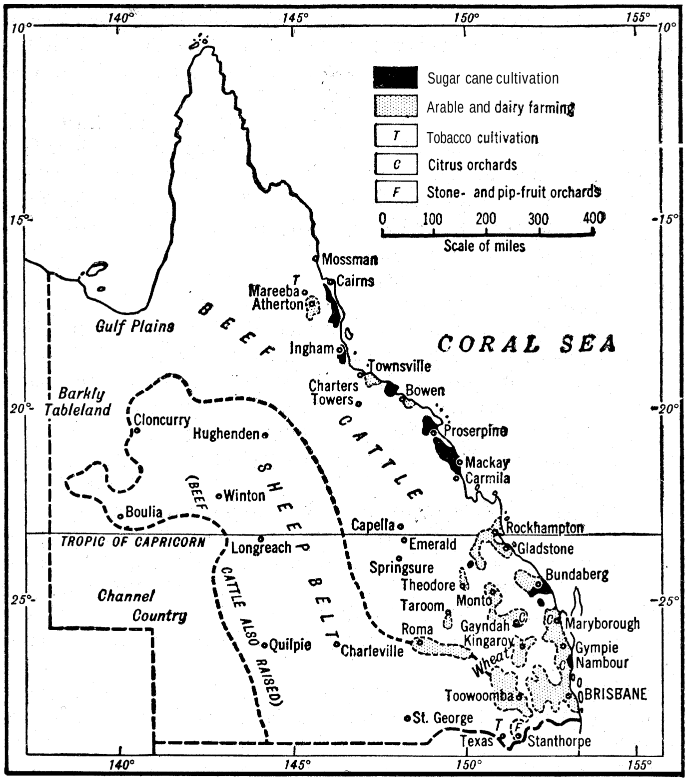

FIG. 2.— LAND USE IN QUEENSLAND

favourable year-round feeding conditions. About 20% are raised on the gulf plains and Barkly tableland. many of these being driven south to the Channel country where, together with the 5% that are raised in that area, they are fattened on the natural pastures that flourish for a short season after the late-summer floods. Most of the remaining 35% are reared on the broad belt of savanna country between the Main divide and the sheep belt. As with the sheep industry, drought and pests take serious toll of herds. Herds numbered 5,137,715 in 1952—49.8% of Australian beef cattle. Stations carrying cattle are generally larger than those carrying sheep, 44% of the stock being on stations of 100,000 ac. or more. Properties of 1,500 sq.mi. are not unusual in the remote north and west. The continued use of British breeds in a tropical environment is far from ideal. Zebu crossbreds. more tolerant of dry feed, water shortages and the cattle tick, were introduced experimentally on a number of stations.

Slaughtering and freezing works at the ports of Brisbane, Gladstone, Rockhampton, Bowen, Townsvilie and Cairns handle the bulk of the exported beef, the balance passing through New South Wales, Victorian and South Australian plants and the ports of Sydney, Melbourne and Adelaide. Production of beef and veal in the state in 1951–52 was 177,608 tons (30.5% of Australian production).

Dairy production is a major industry in three high-rainfall areas —the southeast coastlands as far north as Rockhampton, the Darling downs and the Atherton tableland. In 1951–52 the production of milk was 181,148,000 gal.; butter 28.211 tons (20.8% of Australian production); and cheese 4.700 tons (11.6%).

Pig raising is closely associated with dairy farming in the south; in 1952 there were 316,529 pigs (31%). Production of pork was 8,604 tons (24.6%) and bacon and ham 7,669 tons (20.9%).

Agriculture and Forestry.— The cultivation of crops is of major importance in the high-rainfall areas of the tropical east coast (sugar and fruit) and the Atherton tableland (maize), on the rich, moisture-holding soils of the Darling downs and south and central Burnett areas (wheat, lucerne, sorghum, maize and peanuts), and on the alluvial, volcanic and red-earth residua! soils of the southeast coastal region (maize, lucerne. fruit and vegetables). The total area under crops in 1951–52 was 2,022,400 ac.

Sugar cane is the leading crop in terms of value of production. In 1951–52, 5,005,172 tons (value £17,922,337) were cut, yielding 704,341 tons of raw sugar (94.5% of Australian production). Queensland's sugar industry was developed on a small scale during the second half of the 19th century with indentured Kanaka labour, but since 1906 has been operated exclusively by Australians of British or European descent, and its steady expansion under tariff protection has been the greatest single iactor in the peopling and development of tropical Queensland, 78.5% of the crop being, grown north of Carmila (lat. 22° S.). Cultivation is concentrated in areas with a combination of high rainfall and rich soil. Refineries at Brisbane and Bundaberg meet the needs of Queensland consumers, sugar being exported—both to other states and overseas—mainly in its less perishable raw state.

In respect of acreage under cultivation, wheat is Queensland's leading crop (454,543 ac. in 1951–52) though the value of the crop (£5,395,520 in 1951–52) is much less than that oi sugar cane. Production of wheat has increased markedly. In some measure this has been achieved by the more widespread use of drought-rcsistant varieties giving higher yields, but it has also been accompanied by a significant increase in area of cultivation. Production is concentrated mainly on the black soils of the Darling downs (Toowoomba-Dalby) and the chocolate soils of the South Burnett (Kingaroy) region. Cultivation and harvesting are highly mechanized and the size of holdings ranges up to 2,000 ac.

Maize is grown on many of the mixed farms of southeast Queensland to provide supplementary feed for stock. It is also the main crop of the Atherton tableland, a considerable surplus being shipped from Cairns to southern states and overseas. Total maize production in 1951–52 was 2,438,871 bu.

Peanuts are an important crop in the S. Burnett region and are becoming established on the Atherton tableland. Production of other oil crops such as linseed and sunflowers mas steadily increasing. but cotton growing declined aiter 1944 as a result of uniavourable seasons (dry farming methods are used), labour shortages and comparatively low profit margins. Tobacco growing has also undergone many vicissitudes.

A variety of tropical and subtropical fruits and vegetables is grown on smallholdings and mixed farms in coastal and near-coastal areas, the hulk of the production being within 100 mi. of Brisbane. Pineapples superseded bananas as the chief fruit crop, the gross value of the 1951 pineapple crop being £1,586,537, exceeded only by sugar cane, wheat and maize. 4 substantial proportion of this crop is canned for sale in southern and overseas markets. Papaws and mangoes are grown in coastal areas: citrus fruits are concentrated mainly in the Gayndah, Maryborough and Nambour areas of the southeast. The elevated "granite belt" around Stanthorpe, near the New South Wales border, is the only part of the state where apples, peaches and plums are grown commercially, and this is also the chief grape-producing area.

Queensland forests fall into three main types, the tropical rain forest (locally known as scrub or jungle) of the northeast coastlands and ranges, the rain forests of the southeast and the open forest covering most of the remainder of the eastern half of the state. Considerable areas of the tropical rain forest have been cleared for farming, but valuable reserves of silky oak, red cedar, Queensland maple and Queensland walnut remain. The southeastern forests provide a higher proportion of native pinewood, especially hoop and bunya pine, but natural reserves of these softwoods are becoming depleted, and the state government is steadily increasing the area of afforested country by the planting of exotic pines (especially North and Central American species such as Caribbean and Mexican pine) and the native hoop pine. The open forest of eucalypt hardwoods constitutes by far the greatest proportion of timber country despite ring-barking and clearing in many areas, and most of the state's building and constructional timber is obtained from ii. In 1951–52, 261,521,000 super.ft. of sawn timber, valued at £10,946,504, were produced by 650 sawmills. In addition, 110,028,000 sq.ft. of plywood and 47,139,000 sq.ft. of veneers were cut (£2,759,821 and £283,594 respectively).

Mining and Manufacturing Industries.— The metalliferous areas of Queensland are concentrated in the metamorphosed zones of the Pre-Cambrian rocks of the northwest and the Palaeozoic rocks of the northeast and southeast. With the gold rushes of the 1860s and 1880s, gold production rose steadily irom 2,738 fine oz. (worth £12,000) in 1860 to 676,027 fine oz. (£2,872,000) in 1900, but subsequent production declined. Production in 1952 was 84,642 fine oz., mainly from Mt. Morgan and Cracow, the total value (£1,375,465) being considerably less than that of lead (£6,564,910) and zinc (£4,471,637) production. The state's most extensive mineral workings are at Mt. Isa (in the far northwest) and Mt. Morgan (26 mi. southwest of Rockhampton). The Mt. Morgan cpencut is the state's main source of copper (j.650 tons, 90.6%), the smelters producing auriferous blister copper, A recent development is the extraction of zircon, ilmenite, rutile and monazite from south coast beach sands. Coal production was 2,742,236 tons in 1952 (a record figure). About half came from the 60 collieries of the West Moreton fields near Ipswich. The Big seam at Blair Athol is 70–80 ft. thick with only a thin (25–135 ft.) overburden—measured reserves of this seam alone amount to 112,500,-000 tons. The Callide open-cuts were developed extensively aiter 1950, most of the output being trucked or railed to Gladstone (80 mi.) for shipment to Victoria.

Manufacturing industries mere expanded considerably, the number of factories being increased from 2.882 in 1945–46 to 4,858 in 1951–52, and the net value of production from £29,105,442 to £89,304,791. The two major groups of factory industries are metal working-engineering and food processing. A little more than half (52.6%) of the total production was from factories in metropolitan Brisbane. Brisbane's industries range from shipbuilding (naval craft and cargo ships up to 10,000 tons), motor-vehicle assembly and furniture manufacture to sugar refinin , fruit canning and brewing. Developments after World War II included a cotton spinning mill and a tire factory. Two provincial cities are primarily industrial in function: Ipswich, with railway engineering shops and woollen mills, and Maryhorough, with railway engineering, sugar-mill and mining-machinery works and a small shipyard. Railway workshops are also maintained at Rockhampton and Townsville, and Toowoomba and Dalby manufacture agricultural machinery and implements. The generation and supply of electric power has also become a major industry.

External Trade.—External trade was valued at £325,243,000 in 1951–52. Of this. £142,867,000 related to trade with other Australian states and £182,376,000 to overseas trade. Total exports were valued at £144,233,000 and imports at £181,010,000, most of the balance being absorbed by invisible trade items. The chief items of oversea exports (1951–52 values) were: wool (£53,752,557), canned meat (£6,759,172), suear (£6,521,516), lead and silver-lead bullion (£5,672,224), zinc (£4,461,554) and frozen beef and veal (£4,045,763). The total value of pastoral-industry exports overseas mas £65,590,502, agricultural and dairy products £13,804,232 and mineral £12,005,113. Imports from overseas consist largely of manufactured goods, the main items being machinery and appliances (£14,481,826), hardware and metal manufactures (£11,775,123), textile? (£11,621,854), motor vehicles and parts (£9,257,070) and oil (£8,853,519).

TRANSPORT AND COMMUNICATIONS

With a comparatively small population dispersed over a wide area and with a large volume of primary commodities needing transport over great distances the provision of adequate public transport facilities—rail, road and air—has involved a high capital outlay in relation to returns. Standardization of the 3 ft. 6 in. gauge by the State Railway department was primarily a device to enable maximum railway mileage to be constructed and operated at minimum cost, and by 1924, when the Brisbane-Cairns coastal line was completed (1,043 mi.), the present system was substantially in operation, though the 69 mi. of standard gauge (4 ft. 8½ in.) line from Brisbane to Kyogle providing through running to Sydney was not completed until 1930. In 1953 rail mileage was 6,560. Five main lines, each having branching lines, serve interior districts. Air-conditioned trains with diesel power were introduced in 1953 on the Brisbane-Cairns ("Sunlander") and Townsville-Mt. Isa ("Inlander") lines. In 1951–52, 18,421,466 train-miles were run and 34,840,109 passengers carried.

A network of interstate and internal air services by the commonwealth government's Trans-Australia-Airlines, by Australian National Airways Pty., Ltd., and by several smaller concerns was established. Regular services are operated to New Guinea and New Caledonia and connections with other overseas air routes are made via Sydney and Darwin. Flying doctor aircraft are based at Charleville, Cloncurry and Charters Towers.

There are 133,987 mi. of roads in the state, of which 20,890 mi. are maintained by the Main Roads commission. Creek and river crossings form the main obstacle to road transport in country districts during the summer rains as it is uneconomic to build high-level bridges on lightly trafficked roads. An inland highway linking Brisbane and Townsville via Eidsvold, Emerald and Charters Towers provides an all-weather route from north to south. Passenger and cargo ships maintain regular services along the Queensland coast and to southern states, Thursday Island and New Guinea, and overseas shipping lines serve Queensland ports. (R. H. G.)

QUEENSLAND NUT, Australian nut and *Macadamia* are names applied to the edible fruits of two closely related trees of the silk-oak family (Proteaceae) native to Queensland and New South Wales. *Macadamia ternifolia* has stiff oblong-lanceolate leaves four to eight inches in length, with coarsely serrate margins; M. *integrifolia* has similar leaves, but with smooth margins. Under favourable conditions of growth (a climate about like that for the orange) and rather moist rich soil, the trees ultimately attain a height up to 60 ft. and are highly ornamental in appearance.

Hard-shelled, shiny round nuts, covered by thick husks and following the small white flowers, are abundantly produced on racemes six to eight inches long. The husks split open and release the nuts when the latter are fully ripe. The kernels are rich in oil and of unusually delicate flavour, which accounts for their popularity and the high prices they bring in food-specialty markets. They are used almost exclusively as a dessert nut.

Propagation is commonly by seed, but superior varieties (of which a number have been established in Hawaii and Australia) must be propagated vegetatively. Grafting is commercially feasible but rather difficult. Because of their eventual large size, trees in orchards are planted 35 to 40 ft. apart. There are numerous small commercial orchards in Hawaii and Australia, many trees in California and Florida and occasional ones in other tropical and subtropical regions. (W. Po.)

QUEENSTOWN, a town in the province of Cape of Good Hope. Republic of South Africa, in the upper valley of the Great Kei river, 154 mi. N.W. of East London by rail. 31° 53' S., 26° 52' E.; altitude 3,544 ft. Pop. (1960) 33.126, including 9,658 Europeans, 20.449 natives, 2,896 "Coloured" and 123 Asiatics. The town is the centre of a good wheat- and wool-producing area.

QUENTAL, ANTHER0 DE (1842–1891), Portuguese poet, was born in the Azores and studied at the University of Coimbra. After the publication of one volume of verse, he joined the revolt of the young men which dethroned Castilho, the chief living poet of the elder generation, from his place as dictator over modern Portuguese literature. He adopted socialist opinions, worked as a compositor in Paris though he had independent means, visited the United States and then returned to Lisbon where he worked actively for socialism.

Quental found his way through a series of disappointments to the mild pessimism, a kind of western Buddhism, which animates his later productions. His melancholy was increased by a spinal disease which, after several years of retirement, eventually drove him to suicide on his native island. Quental seldom attempted any form of composition other than the sonnet but few poets who have chiefly devoted themselves to this form have produced so large a proportion of really exquisite work. The comparatively few pieces in which he either forgets his doubts in inward conflicts or succeeds in giving them an objective form are among the most beautiful in any literature.

His friend, Oliveira Martins, edited the sonnets (1886), supplying an introductory essay; and an interesting collection of studies on the poet by the leading Portuguese writers appeared in a volume entitled *Anthero de Quental, In Memorianz* (1896). The sonnets have been turned into most European languages. They were translated into English by Edgar Prestage (*Anthero de Quental, Sixty-four Sonnets*, 1894) together with a striking autobiographical letter addressed by Quental to his German translator, Dr. Storck.

QUERCIA, JACOPO DELLA (*c.* 1374–1438), one of the most original Italian sculptors of the early 15th century, was born, probably at Siena, between 1370 and 1374. In *c.* 1406 he carved the tomb of Ilaria del Carretto in the cathedral of Lucca, a town with which his father, the goldsmith and sculptor Pietro d'Angelo, had long been associated. The effigy and sarcophagus from this tomb alone survive. In 1408 Quercia was employed at Ferrara on a statue of the Virgin and Child which still exists in the Museo dell' Opera del Duomo, and a year later he received the commission for the celebrated Fonte Gaia in the Campo at Siena (now replaced by a copy, original in the loggia of the Palazzo Pubblico). The scheme of this highly individual fountain was repeatedly modified, and effective work upon it seems to have been confined to the years 1414–19. Concurrently with the Fonte Gaia, Quercia was engaged on commissions at Lucca which included a statue of an apostle for the exterior of the cathedral (1413), the tomb slabs of Lorenzo Trenta and his wife in S.

Frediano (1416) and the Trenta altar in the same church (1416–22). These are strongly northern in character. In 1417 Quercia agreed to undertake two gilt bronze reliefs for the baptismal font in S. Giovanni in Siena; the contract for one of these was later transferred to Donatello, but the second, "Zacharias in the Temple." was completed in 1430 and is still on the font. Between 1427 and 1430 he also designed the hexagonal tabernacle in the centre of the font and carved the reliefs of prophets in the niches with which five sides of it are filled. In 1425 he had signed a contract for the central doorway of S. Petronio at Bologna: work on this occupied him until his death on Oct. 20, 1438. In its present form the doorway consists of ten scenes from Genesis set in the pilasters at the sides, five scenes from the early life of Christ across the architrave and a lunette surrounded by reliefs of prophets containing statues of the Virgin and Child and SS. Petronius and Ambrose (the latter an addition by Domenico da Varignana). The Genesis scenes are Quercia's most inspired and expressive works. In 1435 Quercia was appointed superintending architect of Siena cathedral for which he was employed on the decoration (unfinished) of the Cappella Casini. To the same late phase belongs the Vari-Bentivoglio monument in S. Giacomo Maggiore. Bologna (after 1433). Quercia also carved in wood, notably an Annunciation group in the Collegiata at San Gimignano (1421). Though his work is exceptionally fully documented, Quercia is a mysterious artist and his ambivalent style fits less easily than that of his more conventional contemporary Ghiberti into the context of Tuscan early Renaissance sculpture.

"THE VIRGIN AND INFANT JESUS" BY JACOPO DELLA QUERCIA. IN THE LOUVRE, PARIS

BIBLIOGRAPHY.—P. Bacci, *Jacopo della Quercia. Nuovi documenti e commenti* (1929) ; G. Nicco, *Jacopo della Quercia* (1934) ; L. Biagi, *Jacopo della Quercia* (1946). (J. W. P.-H.)

QUERCITRON BARK is the inner bark of *Quercus velutina*, the black oak, a native of the middle and southern United States. The exterior bark is removed from the tree by shaving and the inner portion, which contains the colouring matter, is detached and ground. The colouring matter of quercitron bark is quercitrin, $C_{21}H_{22}O_{12},H_2O$, a glycoside which by hydrolysis with acid yields quercetin, $C_{15}H_{10}O_7$, and the sugar rhamnose, $C_6H_{12}O_5$. When quercitron bark is exhausted with hot water under pressure, the extract deposits a crude quercitrin which is known commercially as yellow flavine. A second variety known as red flavine, prepared by digesting an extract of the bark at the boil with dilute acid, is in reality a crude quercetin. These products dye wool mordanted with aluminum and tin bright yellow and orange shades; they were at one time used with cochineal for obtaining especially vivid scarlets. (A. G. P.)

QUERCY, a former county of France which derived its name from the Gallic tribe of the Cadurci and corresponds to most of the present *départements* of Lot and Tarn-et-Garonne. In the middle ages it was divided into Upper or Black Quercy and Lower or White Quercy, the capital of the former being Cahors and that of the latter Montauban. Its two other chief towns were Figeac and Moissac.

Early in the 6th century Quercy passed under the authority of the Franks and in the 9th century it was part of the Frankish kingdom of Aquitaine. At the end of the 10th century its rulers were the counts of Toulouse and it fell to the French crown with the inheritance of Alphonse de Poitiers (1271). In the 13th and 14th centuries it was in dispute between the kings of England and France. In 1259 some rights over Lower Quercy were ceded to England; in 1360 the treaty of Brétigny assigned the whole county to Edaard III but in 1440 the English were finally expelled. In the 16th century Quercy vas a Protestant stronghold and the scene of savage warfare. During the reign of Louis XIII, Montauban was again the centre of activity.

QUERÉTARO, a central plateau state of Mexico. Pop. (1950) 286,238; (1956 est.) 314,034; area 4,432 sqmi. On the semiarid mesa and traversed at the north by a spur of the Sierra Madre known as the Sierra Gorda, Querétaro is about evenly divided between mountainous mineralized areas and the rolling plains and fertile valleys of the south which form part of Mexico's granary or *bajío*. The state has good air connections and is traversed in a southeasterly direction by the trunk highway from Nogales to Mexico City and the National Railways of Mexico. The climate is generally dry and temperate except in the northwest portion which is hot. Rainfall is moderate and frosts are few and light.

With soil 10 to 15 ft. deep in the southern lowlands, the state produces a large variety of crops. fruits, grain, medicinal plants and a notable sweet potato or camote. Though deposits of gold, copper, lead, tin and other metals occur, the chief products are opals and mercury especially in a compound (sulphoselenide of mercury) known as onofrite, from Cerro San Onofre. The breeding of fighting bulls is also an important activity.

The area was inhabited by the Otomi-Chichimec Indians who were conquered by the Spaniards in 1531. Colonization took place in the 1550s and Querétaro was administered with Guanajuato before it became a state in 1824. (J. A. Cw.)

QUERÉTARO, a city of Mexico and the capital of the state of Querétaro, is 167 mi. by rail and 162 mi. by highway N.W. of Mexico city, and located at the foot of the Cerro de las Campanas. Elevation 6,168 ft., pop. (1950) 49,209; (1958 est.) 53,114. Querétaro is considered an excellent example of a Spanish colonial city. It was founded by the Otomie Indians and was incorporated into the Aztec empire in 1446 and henceforth served as an outpost against the warlike tribes to the north until it was brought under Spanish control in 1531. Throughout most of the colonial period Querétaro was important primarily as a way station and supply centre serving the rich mining districts of Guanajuato and Zacatecas. Colonial buildings include the cathedral (restored several times), the federal palace and the churches of Santa Rosa, Santa Clara and San Augustin. Water is brought to the city by an aqueduct (built 1726–1738) approximately 5 mi. long, vith 74 arches, 50 ft. high and upborne by piers 46 ft. thick. The main products are textiles, pottery and agricultural produce. The city has one of the largest and oldest cotton factories in Mexico.

Querétaro has witnessed many fundamental changes in the evolution of modern Mexico. In 1810 it was the scene of a plot against Spain ahich led to the uprising headed by Miguel Hidalgo y Costillo in September of that year. In 1848 the treaty of Guadalupe Hidalgo terminating the U.S.-Mexican War was signed there. The forces of Benito Juárez defeated those of Emperor Jlaximilian at Querétaro in 1867; and on a nearby hill Maximilian and his generals Miguel Miramón and Tomás Mejía faced the firing squads. The Mexican constitution of 1917 nas written in Querétaro which was also the birthplace of the National Revolutionary party of Mexico (1929). the dominant political force in the republic. (J. J. J.)

QUESNAY, FRANÇOIS (1694–1774). French economist and leader of the first systematic school of political economy (see PHYSIOCRATIC SCHOOL), was born. perhaps at Méré, near Paris, on June 4, 1694. He studied surgery, graduated as a doctor of medicine (1744) and eventually became consulting physician to Louis XV. He did not publish anything on economics until the age of 60 and then mainly anonymous articles. But at Versailles, where he enjoyed the support of Mme. de Pompadour. there gathered around him and Jean C. M. V. de Gournay (1712–59) the secte des *économistes,* notably Victor Riqueti de Mirabeau, Nicolas Baudeau, P. P. le Jlercier de la Riviere. G. F. le Trosne and P. S. du Pont de Nemours, who looked to Quesnay as their leader and enthusiastically propagated his doctrines, A. R. J. Turgot was partly associated with the group; Adam Smith got to know

Quesnay and had a great respect for his ideas. Quesnay died at Versailles on Dec. 16, 1774.

Quesnay's peculiarities of expression and his extreme emphasis on agriculture as the sole economically productive activity-yielding a *produit net,* as contrasted with the "sterility" of industry and commerce, should not be allowed to conceal the great importance of his contributions to economic thought. He contributed, above all, to that systematization of economic analysis which introduced the classical period in Britain and France; only Richard Cantillon preceded him in this. Quesnay's system is summed up in his *Tableau économique* (1758), which displays diagrammatically the interdependence of the different economic classes and sectors and the flow of payments between them. In his *Tableau* Quesnay develops the assumption of a state of stationary economic equilibrium! a fundamental simplifying concept from which so much subsequent economic analysis departed. The general equilibrium analysis of Léon Walras and the input-output analysis of modern economics developed by W. W. Leontief are descendants of Quesnay's *Tableau.* Especially important was his analysis of capital as *avances,* or a stock of wealth which had to be accumulated in advance of production, and his classification of these *avances* in a manner which developed the distinction between fixed and circulating capital. Quesnay's analysis of savings as possibly harmful, in that if they are not invested but hoarded they may disturb the equilibrium of the flow of payments. is closely similar to that of J. M. Keynes. However, Quesnay's ideas on saving represent a line of thought which was to be supplanted immediately in orthodox economic thought for a century or more by the theory of Turgot and Smith, according to which saving is unconditionally beneficial.

The methodology of Quesnay's system and his principles of policy start from an extreme form of the doctrine of natural law which led him to proclaim that laissez-faire in economics—plus the single tax on net income from land—represented the divinely appointed economic order. Quesnay, in fact, is one of the originators of 19th-century doctrines of the harmony of class interests and of the related doctrine that the maximum social satisfaction occurs under free competition. He also developed the *a priori* method, often employed subsequently, of attempting to demonstrate these doctrines. In their day his principles of policy represented an active campaign against monopolies and privilege, requiring a strong government based, as Quesnay advocated, on a powerful monarchy.

Quesnay's *Oeuvres économiques et philosophiques* were edited by A. Oncken (1888).

See M. Beer, *An Inquiry Into Physiocracy* (1939) ; J. A. Schumpeter, *History of Economic Analysis,* pp. 223–243 (1954). (T. W. H.)

QUESNEL, PASQUIER (1634–1719), French Jansenist theologian and author of the *Réflexions morales,* was born in Paris on July 14, 1634, and joined the French Oratory in 1657. His Jansenist sympathies led to his banishment from Paris in 1681, and three years later he was expelled from the Oratory. Fearing further measures of persecution, he fled to Brussels where he lived with Xntoine Arnauld. In 1703 he was arrested, but soon escaped to Amsterdam, where he lived until his death on Dec. 2, 1719.

After Xrnauld's death in 1694 Quesnel was generally regarded as leader of the Jansenist party *(see* JANSENISM). His *Le Nouveau Testament en français avec des réflexions morales* (1692) played almost as large a part in its literature as Jansen's *Augustinus.* The bull *Unigenitus* (1713) condemned 101 sentences from the *Réflexions morales.* Quesnel, who had never admitted that his opinions were heretical, received the last sacrament on his deathbed.

See A. Le Roy's edition of Quesnel's correspondence, 2 vol. (1900) ; A. Vacant, *Dictionnaire* de *théologie catholique,* vol. xiii, col. 1460–1535 (1937). (N. J. A.)

QUÉTELET, (LAMBERT) ADOLPHE (JACQUES) (1796–1874), Belgian mathematician, astronomer and statistician, was born on Feb. 22, 1796, in Ghent and educated there in the lyceum and new university. He later studied astronomy at the Paris observatory and the probability theory under Pierre Simon Laplace. He lectured at the Brussels athenaeum, military college and museum; became head and founder in 1828 of the Royal observatory; and perpetual secretary (1834–74) of the Royal academy. He made important contributions to the study of meteoric showers.

Quételet was a prime mover in the development of methods for simultaneous observations of astronomical, meteorological and geodetic phenomena at scattered points throughout Europe. His outstanding contributions to statistical organization and practice included many aspects of governmental statistics, notably census taking; organization of the first international statistical conference; the development of uniformity and comparability in international statistics; and the application of probability theory to anthropology and sociology. His *Sur l'homme* (1835) developed the concept of the "average man" as the central value about which measurements of a human trait are grouped according to the normal probability curve. His studies of the numerical constancy of such voluntary acts as crimes stimulated extensive studies in "moral statistics" and wide discussion of free will versus social determinism in human behaviour. He died on Feb. 17, 1874, in Brussels. *See* also MEDICINE, HISTORY OF: *Beginning of Vital Statistics.* *(F.* H. Hs.)

QUETTA, a city in West Pakistan. which was formerly capital of Baluchistan, is the headquarters of the Quetta district and also of the division of the same name. The population (1951) was 83,892 including 28,094 in the cantonment area. It rose to prominence in 1976 when Sir Robert Sandeman founded a residency there. The name Quetta (Kawatah) is a variation of the word *kwat-kot,* signifying a fortress, and the place is still locally known as Shal or Shal Kot. Quetta is the southernmost point in the line of frontier posts and in the system of railways on the northwest frontier of West Pakistan, 536 mi. N. of Karachi. The cantonment and civil station of Quetta stand in an open plain about 5,500 ft. above sea level, within a ring of mountains. North of Quetta is the open plain leading to Pishin. During the last quarter of the 19th century Quetta grew into a strong fortress and an army station. A trade mart for western Afghanistan, eastern Iran and much of central Asia, Quetta's population had grown to 84,343 by 1951, despite a disastrous earthquake which practically destroyed the city in June 1935. Its importance as a summer resort increased after the establishment of Pakistan.

QUETTA DISTRICT has an area of 5,310 sq.mi. Pop. (1951) 212,885. The actual line of valley which contains Quetta and the Bolan pass was originally rented from the Khan of Kalat. This perpetual leasehold was afterward extended so as to include Nushki and give the British government the command of the trade route to Seistan. (K. S. AD.)

QUEVEDO Y VILLEGAS, FRANCISCO GÓMEZ DE (1580–1645), one of the greatest Spanish poets and prose writers. Born in Madrid on Sept. 17. 1580, he studied arts and theology at the universities of Alcalá and Valladolid from 1596 to 1606. In 1613 he became a counselor of the duke of Osuna, viceroy of Sicily and later of Naples, who entrusted him with diplomatic missions in Italy and Spain. Accused by the Venetian government of being one of the ringleaders of the conspiracy of 1618, he is said to have escaped from the city disguised as a beggar. Compromised by the fall of Osuna, Quevedo was imprisoned in 1620 but released in the following year. After refusing the post of ambassador in Genoa, he was given the honorary title of king's secretary in 1632. In 1639 he was arrested and confined in the monastery of San Marcos at León. This downfall has been traditionally attributed to a poem denouncing the political conduct of affairs, which was placed upon the king's table, but the incident may be apocryphal and Quevedo's authorship of the poem is not certain.

He was released from the monastery in 1643 and died at Villanueva de los Infantes on Sept. 8, 1645.

Quevedo is an outstanding figure in the European literature of his age. Of brilliant intellect and strong passions, he reveals his complex personality in the extreme variety of tone in his life and work. His learning and wide culture impelled him to write works of high moral seriousness; but he shows familiarity with low life and he kept a mistress by whom he had several children. The enormous range of his work, from the obscene to the devout, shows a capacity to live intensely on every level of experience but not to unify its extremes. The tension underlying his work reveals pent-up bitterness. traceable to sincere self-reproach. His humour is never far from the'sardonic. By itself much of his satire would seem splenetic, but in association with his serious poetry and prose treatises it discloses anguish at his failure to reconcile the defects of the world and of himself within it with the standards set by his own intelligence and conscience.

As a poet, Quevedo is supreme. His large output ranges from verse in the cant of the underworld through lampoons and parodies to meditative poems on time and death. His love poetry includes both poems showing an obsession akin to disgust with the crudely physical, and sonnets that transform the conventional Petrarchan tradition by their intensity of feeling. The keynote is his feeling that the divine calls the mind to a love which is torture to the body, that passion shows the light of life while consuming itself in darkness. There is no sensuous prettiness or emotional softness in Quevedo's poetry: his intense feeling is conveyed with dignity of expression and intellectual strength.

Though an opponent of the Latinizing innovations introduced by Luis de Góngora, whom he parodied unmercifully, Quevedo was adept in the new Baroque style. The greatest exponent of *conceptismo (see* SPANISH LITERATURE), he shows as masterly a use of the metaphysical conceit as does John Donne. In his satires his linguistic ingenuity and audacity are unbounded, and as a virtuoso of language he is unequaled in Spanish literature. The *Sueños* (1627), mostly visions of hell written at intervals from 1606 to 1622, show his development in the technique of satire: the conceits grow from mere puns into scintillating images that transpose the identities of objects and invert their functions. This culminates in his masterpiece, *La hora de todos* (written 1635–36). Here transposition and inversion produce a picture of a world where commercialism, imperialism, racialism, slavery and international politics have turned values inside out. No less masterly is the picaresque novel, *La vida del Buscón* (1626). Its verbal wit and often grotesque exaggeration have tended to obscure the acuteness of its psychological insight: the son of disreputable parents, the protagonist carries a burden of shame and guilt from which he seeks escape in illusory fantasies that lead to a life of roguery and deception.

In his nonsatirical work, Quevedo's *conceptismo* produces a terse and dignified style. His precision in the association of disparate concepts gives, in such works as *La política de Dios (I,* 1626; II, written 1634–35) and *La providencia de Dios* (written 1641), an original and powerful expression to a thought that is mainly conservative and traditional. His *Marco Bruto* (1644) is an interesting defense of monarchy against democracy. For Quevedo social and political issues resolve themselves into questions of personal morality. This made him promulgate in Spain the Stoic doctrines which Justus Lipsius had popularized throughout Europe. He translated Phocylides. Epictetus and Seneca and wrote Stoic treatises of his own of which the chief are *La cuna* y *la sepultura* (1634) and *Virtud militante* (written 1634–36). Their originality consists in presenting the subject in terms of the 17th-century preoccupation with the paradoxes of human nature and life. Quevedo's Stoicism is neither priggishness nor indifference, but a concern for one's own integrity that does not exclude compassion for one's neighbour, but does exclude the desire to judge, rebuke and punish him.

QUEZAL, QUETZAL or QUESAL, one of the most beautiful of birds, an inhabitant of the mountains of Central America. This bird, *Pharomacrus mocinno,* is one of the trogons (*q.v.*), and in body is about the size of a turtledove. The plumes of the tail, which may measure 33 ft., are golden green and before the Spanish conquest could be worn only by chiefs. The rest of the plumage is green above and scarlet below. In the female the tail is short. The eggs are a pale bluish green.

QUEZALTENANGO is a department in western Guatemala. Its surface elevations range from near sea level to more than 12,000 ft. at the peak of the volcano Santa Maria; its mountain valleys lie at altitudes of about 8,000 ft. It has some industry and a diversified agricultural production which includes grains, coffee, bananas and livestock. Area 753 sq.mi. Pop. (1957 est.) 222,498, chiefly Indian or mestizo descendants of preconquest Quiché stock.

The capital city Quezaltenango, pop. (1957 est.) 33.726, the second city of the republic, is connected with Guatemala city by paved highway and air transportation. It stands at the foot of the volcano Santa Maria near the site of the battle in which the Spaniards under Pedro de Alvarado and their Indian allies from Mexico decisively defeated the native Quiches in 1524. Before the conquest it had been the capital of a Quiché kingdom known as Xelajú. It is a marketing and processing centre important for textile factories, mills and breweries, and the seat of two university faculties.

An electrified railway, built in 1930 to connect with the coastal line, ceased operation in 1933 after extensive flood damage, but the Santa Maria hydroelectric plant continued to operate and in the early 1960s was capable of supplying power in excess of demand.

The name Quezaltenango means "palace of the quetzal," a native bird which had great symbolic importance among the Mayas and is now the national symbol of Guatemala. (W. J. G.)

QUEZON, MANUEL LUIS (1878–1944), Philippine statesman, was born at Baler on the island of Luzon, and studied law at Santo Tomas university in Manila. He joined the insurrectionist movement of Aguinaldo, but later swore allegiance to the territorial administrators and became a provincial prosecutor. He was a member of the Philippine assembly 1907–09, resident commissioner to the U.S. congress 1909–16, and president of the Philippine senate 1916–35. He was elected first president of the Commonwealth of the Philippines Sept. 17, 1935. He died Aug. 1, 1944, at Saranac, N.Y.

QUEZON, a long narrow coastal province of Luzon Island, Philippines, is 270 mi. long and varies from 5 to 35 mi. in width. Area 4,616 sq.mi. Formerly called Tayabas, the name was changed in 1946 in memory of Pres. Manuel Luis Quezon. The northern two-thirds of the province is mountainous and sparsely inhabited but excellent cabinet and plywood timber is produced near Infanta and Baler. Southern Quezon contains some of the largest coconut plantations in the world. Provincial population (1960) 656,892. Lucena, on Tayabas bay. is the capital and major copra centre; Tayabas, 8 mi. N. of Lucena, is also a trading and copra centre. (R. E. HE.)

QUEZON, CITY OF, capital city of the Republic of the Philippines named for Pres. Manuel Luis Quezon, is located immediately east of Maniia on Luzon. Area 28 sq.mi. Pop. (1960) 397,374. Much of the city lies at an elevation about 100 ft. above downtown Manila, which is slightly above sea level. Temperatures are lower than in Manila; because Quezon is further from the bay,'humidity is lower.

The city of Quezon officially replaced Manila as the Philippine capital in 1948 and in the second half of the 20th century construction of government buildings was underway. Most functions of the national government however remained in Manila. The University of the Philippines is located in Quezon as well as Ateneo de Manila and a veterans' hospital. The city is bisected by the Circumferential highway along which light industry began to develop.

San Francisco del Monte and Kamuning are first-class residential sections, while the Cubao section is an important transportation junction and bazaar area. (R. E. HE.)

QUIBERON, CAMPAIGN AND BATTLE OF. Several plans were made for the invasion of the British Isles by the French during the Seven Years' War, and in 1759 an army was assembled at Vannes in Brittany, with its transports lying in the Morbihan, the landlocked waters inside Quiberon bay. To protect this force while undertaking the invasion, the French planned to unite their fleets at Toulon and Brest; but these ports were blockaded by Adm. Edward Boscawen and Adm. Sir Edward Hawke respectively. During July 1759, Boscawen was compelled to take his squadron to Gibraltar for provisions and refitting, and Adm. de la Clue led the Toulon fleet through the straits of Gibraltar with the idea of reaching Brest. But he was pursued from Gibraltar by Boscawen, and in the running fight which finished in Lagos bay his force was completely disorganized and defeated.

Meanwhile Hawke continued the blockade of Brest with the utmost pertinacity, but on Nov. 9, 1759, he was forced to run into Torbay by lack of stores and exceptionally bad weather. Adm. Conflans took the Brest fleet to sea on the same day that Hawke left Torbay (Nov. 14), and headed south. Hawke also headed south. On the morning of Nov. 20 both fleets were about 30 mi. off Belle-Ile. Conflans, seeing a few English ships under Commodore Duff watching Quiberon bay, stood in close to capture them, but on sighting Hawke's fleet to the northwest, he changed his mind and determined to run into the bay itself.

On sighting the French, Hawke signaled "line abreast" in order to concentrate his force, and followed this up by "general chase" and "line of battle ahead." Hawke's leading ships soon began to overhaul the French. At 2:30 p.m., just as Conflans was rounding Belle-Ile, his rearmost ships began to be attacked and soon afterward both fleets swept into the bay. There were 21 of the line in each fleet, but the French had a great advantage in carrying pilots who knew the coast. Two French ships were sunk and another was captured before Hawke made the signal to anchor. Next morning, Nov. 21, the French fleet scattered; seven ships ran up the Vilaine river and nine ran out to sea for Rochefort, one sinking on the way. Conflans' flagship, the "Soleil Royal," ran herself ashore on Nov. 21 and was burned by her own crew. An attempt to burn the ships in the Vilaine by a boat attack was abandoned, because of bad weather and the strong defenses of the river mouth. Nevertheless, the French Brest fleet was now quite useless as a tactical combination, and "had we had but two hours more daylight," wrote Hawke, "the whole had been totally destroyed or taken; for we were almost up with their van when night overtook us." With both their fleets defeated, the French were now compelled to abandon their invasion project, and cease all major naval operations for the rest of the war.

(G.A. R.C.; W. C.B.T.)

QUICHÉ, the most important Indian nation in Guatemala at the time of the Spanish conquest. Today the Quiché tongue, a Mayan dialect, is spoken by about 275,000 pure-blooded natives throughout the departments of Quiché, Quezaltenango, Totonicapán, Retalhuleu and Sacatepéquez.

Quiché history and tradition are preserved in a book known as the *Popol Vuh* written by a native shortly after the conquest. It relates four attempts to create a satisfactory world and people it. On the last attempt the gods made four men: Balam-Quitze, Balam-Agab, Mahucutah and Igi-Balam: of these the first three became the ancestors of the Quiché. As first constructed these men had too many divine attributes to suit the gods, so their wits were dulled, but in compensation they were given wives. At this time the other Indian tribes were created and they all went to Tulan Zuiva to receive their household gods. The Quiché god, Tohil, then made the first fire by striking it from his sandal, while the other Indians learned the art from the Quiché. To gain this end, with one exception, they were tricked into giving human hearts in sacrifice. All then started to migrate to Guatemala and when they arrived the first sunrise took place. Then the four leaders withdrew to the woods and after the Quiché had successfully fought a war, these holy men died. They were succeeded by their sons who immediatelv departed on a mystic journey to the east where they received fhe insignia of temporal power at the hands of the great king, Nacxit, who also taught them the secret of writing.

Upon the return of their leaders the Quiché settled in stone wrought cities and from this point the *Popol Vuh* assumes a definitely historical character. It describes the reigns of many kings and pictures in detail their wars with neighbouring nations. The apogee of Quiché power was reached under Kicab who made tributary all his neighbours, but these conquests were never consolidated into a kingdom. Fighting continued with varying fortunes until the arrival of the Spaniards.

In 1524 Pedro de Alvarado, the lieutenant of Cortés, entered Guatemala. The Quiché had received warning of his coming and of the strength of the Spanish arms from the Aztec emperor Montezuma. They had hastily made peace with warring neighbours but were unable to unite them in a common defence. Their preparations to repel Alvarado were impeded by the death of their king, Tanub. His successor, Tecum Umam, met the Spaniards with a huge army upon the plains of Zelahuh near the modern Quezaltenango. There followed a series of desperate actions in which the Indians failed to withstand the Spanish cavalry and artillery, backed by a force of native allies. Finally Tecum Umam personally attacked Alvarado and after unhorsing him was slain. Then the Quiché retreated to their capital, Gumacaah, leaving innumerable dead along the banks of a stream to this day known as Xiquiguel, the river of blood. However, the Quiché were not yet conquered and the new king, Chignauivcelut, endeavoured to entice Alvarado into his capital so that he might burn the houses over the Spaniards' heads while his men cut off their retreat over the narrow causeway by which the city was entered. Alvarado discovered this plan, captured the Quiché by stratagem and hanged the king: thus the opposition was broken.

At the time of the conquest a king ruled the Quiché in regal style. He was surrounded by 24 councilors who gave the ruler their advice and acted as judges and revenue collectors. The principal touns were governed by appointed lieutenants who, however, had no jurisdiction over the nobility. Each governor had his council organized in the same fashion as the king's. All these officials and others down to the rank of doorkeeper of the council were drawn from the nobility who took great care to preserve the purity of their blood.

Today the Quiché live in small villages in the highlands of Guatemala, for the most part on various coffee plantations where the Indians are held in a state of peonage. Some of the towns, however, particularly Chiquinula, Nahualá and Chichicastenango, have maintained a semi-independence and run their affairs with little interference from the central government. Chichicastenango is of peculiar interest because its inhabitants claim descent from the Quiché nobility and recognize one of their number, Manuel Ajanel, as king.

QUICHERAT, JULES ETIENNE JOSEPH (1814–1882), French historian and archaeologist, was born in Paris on Oct. 13, 1814, the son of a working cabinetmaker from Paray-le-Monial. He was educated at the college of Ste. Barbe and at the École des Chartes. Inspired by Jules Michelet's pages on Joan of Arc in the *Histoire de France,* he published the text of the two trials of Joan, adding much contemporary evidence on her heroism in his *Procès de condamnation et de réhabilitation de Jeanne d'Arc* (5 vol., 1841–49), as well as half a volume of *Aperçus nouveaux sur l'histoire de Jeanne d'Arc* (1850).

He published, in the *Bibliothèque de l'École des Chartes,* a full biography (1840) of Jean Castel, an obscure chronicler of the reign of Louis XI, and another (1842) of Thomas Basin, bishop of Lisieux, whose writings he also edited (4 vol., 1855–59). In 1849 he was appointed professor of diplomatics at the École des Chartes. He died at Paris on April 8, 1882.

BIBLIOGRAPHY.—After his death his unpublished papers were printed as *Mélanges d'archdologie et d'histoire,* vol. i, *Antiquités celtiques, romaines, gallo-romaines,* ed. by A. Giry and A. Castan, with a biographical notice of the author by R. de Lasteyrie (1885); and vol. ii, *Archdologie du moyen âge,* ed. by R. de Lasteyrie (1886). Quicherat's *Histoire de la laine,* on which he was occupied for many years, was missing from his papers, and only the introductory chapters (up to the 11th century) of his lectures on archaeology were found. Among

his lectures published in contemporary reviews are *La Formation française des anciens noms de lieu* (1867); *De l'ogive et de l'arckitecture dite ogivale* (1850); *L'Age de la cathédrale de Laon* (1874); and *Histoire du costume en France* (1875; 2nd ed., 1877) a popular work. *See* also J. Berthelé, *Jules Quicherat, sa vie et son oeuvre* (1884).

QUICKSAND, a state in which saturated sand loses its supporting capacity and acquires the character of a liquid. Once considered, especially by construction men, to be a special type of sand, quicksand is now recognized as a condition that may be assumed by any sand if its effective weight is temporarily or permanently carried by interstitial water. Some natural sands are in a condition so loose that minor disturbances caused by a footstep may collapse the loose structure and produce a "quick" condition. Under these circumstances a person may become engulfed as in a fluid, but since the density of the sand-water suspension exceeds that of the human body, the body cannot sink. Struggling may lead to loss of balance and drowning. This possibility has no doubt led to the superstition. prevalent in literature. that quicksand has the ability to draw a person to his death. (R. B. P.)

QUICKSWOOD, HUGH RICHARD HEATHCOTE GASCOYNE-CECIL, Baron (1869–1956), English Conservative politician, prominent layman in the affairs of the church assembly and youngest son of Robert Cecil. 3rd marquess of Salisbury and prime minister, was born in London on Oct. 14, 1869. He was educated at Eton and at University college. Oxford. becoming a fellow of Hertford college in 1891. His interests turned to politics and he became assistant private secretary to his father. Cecil sat in the house of commons as Conservative member, first for Greenwich (1895-1906) and later for Oxford university (1910–37). He took a vigorous part in the stormy debates on the Balfour education bill (1902), opposed tariff reform and resisted the parliament act of 1911.

During World War I he served in the Royal Flying Corps (1915–18) and afterward took a less active part in politics but generally supported his brother, Lord Robert Cecil (afterward Lord Cecil of Chelwood), in adopting an independent attitude toward David Lloyd George's coalition government. With him, too. he supported the enabling bill (1919). and he became a prominent member of the church assembly set up in accordance with its provisions. In the conflict which arose over the revision of the prayer book in 1928 he gave energetic if unsuccessful support to the new proposals in the house of commons and in the assembly. He also had a long dispute with the bishop of Liverpool in 1933-34 over permitting Unitarians to preach in Anglican churches.

Cecil's political career never fulfilled its early promise. In the early 20th century his independence and ability temporarily attracted a group of young and able Conservatives, but it was perhaps this very independence which kept him out of the cabinet. His reputation as an orator, gained early in his career, rarely persuaded, although it was impressive and often witty. He was created a privy councilor in 1918 and made a baron in 1941. He was also. from 1936 to his retirement in 1944. provost of Eton. a position which necessitated his withdrawal from the house of commons in 1937. He died at Bournemouth on Dec. 10, 1956,

QUIDDE, LUDWIG (1858–1941), German historian, politician and pacifist! was born in Bremen on March 23, 1858. During 1889–96 he was editor of the *Deutsche Zeitschrift fur Geschichtswissenschaft* and in 1890 became professor and secretary of the Prussian Historical institute in Rome. In 1892 he returned to Munich and joined the German Peace society. In 1894 he wrote a satire, *Caligula,* against William II, which brought him three months' imprisonment for lese majesty. During 1907–19 Quidde was a liberal member of the Bavarian diet and member of the Interparliamentary union. From 1914–29 he was chairman of the German Peace society. During World War I he urged peace without annexations. In 1919 he joined the Democratic party and was a member of the national assembly, where he fought for a proportional electoral system and against the treaty of Versailles. In 1920 the party did not send him into the *Reichstng,* but he remained a member until 1932. He was chairman of the German peace cartel, 1921–29, representing the right wing of pacifism. He believed in securing peace "from above." rejected the war resistance movement, compromised on war guilt and fought against such radical pacifists as F. W. Foerster. Quidde was arrested in 1924 in Munich after writing in *Welt am Montag* against illegal military training. In 1927 he received the Nobel peace prize. Defeated by the left, he resigned in 1931. In 1933 he emigrated to Geneva, where he died on March 5, 1941. His books include *Studien zur Geschichte des rheinishcn Landfriedensbundes von 1254* (1885), *Der Fortschritt der Rechtsidee der Kulturentwicklung* (1911) and *Die Schuldfrage* (1921). (H. Jr.)

QUIDOR, JOHN (1801–1881), U.S. painter, was born at Tappan, K.Y., on Jan. 26, 1801. A pupil of the portraitist John Wesley Jarvis, he enjoyed limited success as a painter in New York city from about 1828 to 1868, subsisting mainly by commercial work. In 1868 he retired to a daughter's home in Jersey City. N.J., where he died, Dec. 13. 1881. His animated grotesque paintings. chiefly based on Washington Irving's tales of Dutch New York, were rediscovered in the 20th century and highly praised for their style and emotional intensity.

See John I. H. Baur, *John Quidor* (1942). (D. H. W.)

QUIETISM, a complicated religious movement that swept through France, Italy and Spain during the 17th century. Its chief apostles were Miguel de Molinos; a Spaniard resident in Rome, Fénelon, the famous French archbishop and his countrywoman. Jeanne Marie Guyon. Quietism was essentially a reaction against the bureaucratic ecclesiasticism always latent within the church of Rome. though it had come more especially to the front during the struggles of the Counter Reformation carried through by the Jesuits. Like their contemporaries the French Jansenists and the Quakers and Anabaptists of northern Europe, the Quietists fell back on a doctrine of immediate inspiration of the individual conscience. To the many God spoke only in general terms through the church; but to the few He made His will directly known. But how did He do so? How distinguish the voice of God from the vagaries of our own imagination? Quietism offered an easy test: The less "sense of proprietorship" a man had in his own good actions—the more they came from a source outside himself—the surer might he be that they were divine. If, on the other hand, they were the fruit of his deliberate thought and will, that was enough to show that they did not come from God. but from his sinful self. Hence the first duty of the Quietist was to be "passive."

The Spanish monk, Juan Falconi. who is generally reckoned as the father of Quietism, died in the odour of sanctity in 1632; about 30 years later his fellow countryman, Molinos, transported his doctrines to Rome, where they gained unbounded popularity with bishops and cardinals and even with Pope Innocent XI. In 1675 Molinos published the *Guida Spirituale,* the great textbook of his school. But his success soon aroused the suspicion of the Jesuits, the great champions of militant ecclesiasticism. "Passivity" accorded ill with a zealous frequentation of the confessional, their chief centre of influence. Failing to turn public opinion against Molinos in Rome, they brought pressure to bear on Louis XIV through his confessor. Père La Chaise. At the instance of the French ambassador Molinos was arrested (1685); his papers were seized, and his chief disciples examined by the Inquisition. Two years later he was convicted of heresy and sentenced to imprisonment for life.

The later stages of the Quietist drama were played out in France. There Quietist ideas had long been spreading under the leadership of enthusiasts like François Malaval (1627–1719), a blind layman of Marseilles. A more romantic figure was Jeanne Marie Guyon (1648–1717), a widow of good family and remarkable personal charm, who devoted her life to missionary journeys on behalf of "passivity." In 1688 fate brought her to the French court, where she made a great impression on Mme. de Maintenon and other persons of quality. But her most illustrious convert was Fénelon, then tutor to the duke of Burgundy, eldest son of the dauphin. Mme. Guyon and Fénelon made Quietism famous.

In 1697 Jacques Benigne Bossuet was at work on an *Instruction sur les états d'oraison,* which was intended to distinguish once for all what was true in Quietism from what was false. Fénelon, feeling sure that Bossuet would do the Quietists less than justice, determined to be beforehand with him. While Bossuet's book was still in the press, he suddenly brought out an *Explication des maximes des saints*. The little volume raised a violent storm. For two years Fénelon was at feud with Bossuet; he was banished from Versailles; finally, he was censured by the pope (1699), although in very measured terms. This condemnation, and Fenelon's bitter controversies with Bossuet, proved the deathblow to official Quietism.

BIBLIOGRAPHY.—H. Heppe, *Geschichte der quietistischen Mystik* (1875), covers the whole subject. On the place of Quietism in the history of religious thought *see* W. R. Inge, *Christian Mysticism* (1899); on its psychology *see* H Delacroix, *Etudes sur le mysticisme* (1908); J. Denis, *Mémoires de l'Académie de Caen (1894)*; W. James, *The Varieties of Religious Experience* (1902).

QUILLER-COUCH, SIR ARTHUR THOMAS (1863–1944), English writer (pseudonym "Q"), born in Cornwall on Nov. 21, 1863. He was educated at Clifton college and Trinity college, Oxford, where he was afterward appointed lecturer in classics (1886–87). While he was at Oxford, he published (1887) his *Dead Man's Rock* (a romance in the vein of R. L. Stevenson's *Treasure Island).* following it up with *Troy Town* (1888) and *The Splendid Spur* (1889). Gaining some journalistic experience in London, mainly as a contributor to the *Speaker,* in 1891 he settled at Fowey in Cornwall and wrote several Cornish tales, including *The Blue Pavilions* (1891), *The Ship of Stars* (1899), *Hetty Wesley* (1903), *The Shining Ferry* (1905). He published several volumes of critical articles, *Adventures in Criticism* (1896), *On the Art of Writing* (1916), *Studzes in Literature* (1918; 2nd series, 1927; 3d series. 1929) and *Shakespeare's Workmanship* (Bristol, 1918). In 1898 he completed Stevenson's *St. Ives*. From his Oxford days he was known as a writer of excellent verse; most of his poetical work is contained in *Poems and Ballads* (1896). In 1895 he published a delightful anthology from the 16th and 17th century lyrists, *The Golden Pomp;* the invaluable *Oxford Book of English Verse 1250–1900* (1900); the *Oxford Book of Ballads* (1910); the *Oxford Book of Victorian Verse* (1912); the *Oxford Book of English Prose* (1925); *Poems* (1929); *The Poet as Citizen and Other Papers* (1934); *Q's Mystery Stories* (1937); *Victors of Peace: Florence Nightingale, Pasteur, Father Damien* (1937). In 1910 Quiller-Couch was knighted. In 1912 he was appointed King Edward VII professor of English literature at Cambridge, and was elected fellow of Jesus college, Cambridge. He died in Fowey, Cornwall, May 12, 1944.

QUILMES, Argentine city and suburb of greater Buenos Aires, 12 mi. S.E. of the federal district on the estuary of the Rio de la Plata. Pop. (1960) 318,144. The Indians who gave the city its name were subdued and settled in the area by the Spanish in 1666. During the early 19th century it was twice the scene of hostilities: in 1806 when the first English invasion landed on its shores, and in 1827 when Argentine forces defeated the Brazilian fleet in the estuary. Quilmes is one of the important industrial centres of Buenos Aires and the location of large breweries and distilleries. (Js. R. S.)

QUILON, a seaport on the Malabar coast, in Kerala state, India. Pop. (1951) 66,126. The palace of the maharaja of Travancore stands on the bank of Quilon lake.

QUIMBY, PHINEAS PARKHURST (1802–1866), U.S. pioneer in the field of mental healing and generally regarded as the father of the New Thought movement, was born in Lebanon, N H., on Feb. 16, 1802. His active career was spent largely in Belfast and Portland, Me., and he died at Belfast on Jan. 16, 1866.

Professionally interested in hypnosis (*q.v.*), Quimby employed it for a time as a means of healing, but later discovered that he was quite as able to heal by suggestion. He came to believe that illness resulted from the patient's mistaken beliefs, and that its cure lay in discovering the truth. Not primarily religious in the orthodox sense, he believed that he had rediscovered the secret of Jesus' healing ministry. He wrote down his philosophy in the so-called Quimby manuscripts. Quimby became a controversial figure because Mary Baker Eddy (*q.v.*), who sought healing at his hands, and was at first a disciple and warm admirer, later denied, as it was thought by many, that she had been influenced by him. It is the official belief that her discovery of Christian Science (*q.v.*), a divine revelation, depended in no sense on Quimby.

The best source is *The Quimby Manuscripts,* ed. by H. W. Dresser (1921), the first edition of which contains a number of letters of Mrs. Eddy to Quimby and others not found in later editions. (C. S. B.)

QUIMPER, formerly Quimper-Corentin, a town of France, capital of the *département* of Finistère. 158 mi. N.W. of Nantes. Pop. (1954) 15,629. Quimper, or at least its suburb Locmaria on the Odet, was occupied in Roman times. Later Quimper became the capital of Cornouailles and the residence of its kings. It is said to have been Grallon Meur who brought the name of Cornouailles from Great Britain and founded the bishopric, first held by St. Corentin about 495. Hoel, count of Cornouailles, united the countship with the duchy of Brittany. Quimper suffered in the local wars of succession. In 1344 it was sacked by Charles of Blois. Monfort failed to take the town in 1345, but it opened its gates to his son John IV in 1364 after the victory at Auray. The cathedral of St. Corentin (13th to 16th centuries), with a fine façade (*c.* 1425), is a splendid example of the Gothic style in granite. Breton pottery is made there.

QUIN, JAMES (1693–1766), a leading English actor of his day, was born in London on Feb. 24, 1693. He made his first stage appearance at the Smock Alley theatre, Dublin, as Abel in Sir Robert Howard's *The Committee* in 1712. Engaged at Drury Lane theatre for small parts, his remarkable memory enabled him to deputize at short notice as Bajazet in *Tamerlane* with great success. Quin then went to Lincoln's Inn theatre and remained there for 14 years. A noted swordsman, he was convicted of manslaughter for killing another actor in a duel, and at Lincoln's Inn he defended the stage with his sword against rioters. He went to Covent Garden theatre in 1732 and became a leader of the stage, returning to Drury Lane from 1734 to 1741. His style was declamatory, very slow but impressive, and he always wore the same costume. In 1746 his supremacy was challenged by David Garrick (*q.v.*), the exponent of a new type of acting, and when the two played together in *The Fair Penitent* at Covent Garden, Garrick triumphed. Quin bore him no ill will; they became friends and acted together at Drury Lane. Quin was one of the finest Falstaffs the stage ever knew. He retired to Bath in 1757 and died there on Jan. 21, 1766, being buried in the abbey church with an epitaph by Garrick.

Although of poor education. Quin had great wit and warm-hearted generosity. He was also a great epicure, his appetite being as prodigious as his memory.

See *Life of Mr. Janzes Quin, Comedian,* anon., 2nd ed. (1887). (W. J. M.-P.)

QUINAULT, PHILIPPE (1635–1688), French dramatist and one of the collaborators with Lully in the creation of French opera, was born in Paris, where he was baptized on June 5, 1635. By 1666 he had written 16 comedies, tragedies and tragi-comedies. He later wrote librettos for Lully, creating with him the form of the *tragédie-lyrique* which became the model for French opera. Their first work in this form was *Cadmus* (1673) followed. between 1674 and 1683, by *These'e, Atys, Isis, Prosperpine, Persée* and *Phaéton* He was particularly successful in his later romantic works, *Amadis* (1684). *Roland* (1685) and *Armide* (1686). His librettos long survived him and were used by Gluck. J. C. Bach and others. Though his reputation later suffered by comparison with Racine, his plays were popular, providing a theatrical counterpart of the polite novel, and presenting an ideal world, less heroic than that of Corneille and less harrowing than that of Racine. He died in Paris on Nov. 26, 1688.

BIBLIOGRAPHY.—The best edition of his works is *Théâtre,* 5 vol. (1739). *See* also E. Gros, *Philippe Quinault* (1926); J. B. A. Buijtendorp, *Philippe Quinault* (1928); A. Adam, *Histoire de la littérature française au 17e siècle,* vol. ii (1951).

QUINCE, a fruit tree concerning which botanists differ as to whether or not it is entitled to take rank as a distinct genus, *Cydorzia,* or as a section of the genus *Pyrus* (family Rosaceae, *q.v.*). The name *Cydonia oblonga* is to be preferred to *Pyrus cydonia.*

Bailey gives five varieties of *C. oblonga,* namely. varieties *lusitanica, maliformis, pyriformis, marmorata* and *pyramidalis.* The quinces are much-branched shrubs or small trees with entire leaves. small stipules, large solitary white or pink flowers like those of the pear or apple. but with leafy calyx lobes and a many-celled ovary, in each cell of which are numerous horizontal ovules. The fruits may be round and flattened or somewhat pear-shaped, with large leafy calyx persisting on the mature fruit.

ROCHE
QUINCE (CYDONIA OBLONGA) BLOSSOMS

The common quince is a native of Iran and Anatolia, and perhaps also of Greece and the Crimea. By Franchet and Savatier *C. oblonga* is given as a native of Japan, with the native name "maroumerou." It is certain that the Greeks knew a common variety upon which they grafted scions of a better variety from Cydon in Crete. whence it was obtained and from which the later names have been derived. The fragrance and astringency of the fruit of the quince are well known, and the seeds formerly were used medicinally for the sake of the mucilage they yield when soaked in water. The quince is but little cultivated in Great Britain; in Scotland it seldom approaches maturity, unless favoured by a wall. The fruit has a strong aroma and in the raw state is astringent; but it makes an excellent preserve. and is often used to give flavour and sharpness to stewed or baked apples.

The Japanese quince. formerly considered in the genus *Cydoniu* but now known as *Chaenomeles lagenaria,* has been widely used as an ornamental plant in gardens as a shrub, particularly because of the beauty of its flowers that appear on the stems before the leaves open fully in late winter and early spring months. Some of the small shrubs bear large green fragrant fruits that are quite inedible in the fresh state but have been used in making preserves.

The quince was formerly grown in home fruit gardens and commercial plantings in the northeastern United States but later became the least esteemed of all tree fruits for orchards in that area. The fruit is almost inedible in the uncooked state. and other fruits are preferred in the fresh state for the diet. It thrives under the same systems of cultivation as do apples and pears and does fairly well along fence rows, where it may be given little care. The quince is susceptible to a bacterial disease called fire blight, which is also a serious hazard to pear growing in the United States. Trees that are not forced into strong vegetative growth by pruning and fertilization are less susceptible to the fire blight disease. The trees are subject to the same scale insects that attack apples and pears and should receive the same dormant spray treatment for the control of these pests. The fruits are golden yellow in colour and the flesh takes on a pink colour when cooked, giving an attractive colour to jellies and conserves made from this fruit. Orange and Champion are the more commonly grown varieties. Quince stocks are used on which to graft the pear to dwarf the tree and hasten early bearihg. The Angers variety, imported from France, is the most important stock used for dwarfing pears. (F. P. C.)

QUINCY, JOSIAH (1744–1775), American patriot, son of Josiah Quincy (1709–84), was born in Boston on Feb. 23, 1744. Between 1767 and 1770, he contributed several papers to the *Boston Gazette* that were flaming tirades against British oppression. After the Boston massacre he and John Adams defended Captain Preston and the accused soldiers and secured their acquittal. From this time on he wrote repeated letters to the *Boston Gazette* and published several books in which he urged opposition to England. In Sept. 1774 he left for England where he consulted with leading Whigs as to the political situation in America; on March 16, 1775 he started back, but he died on April 26 in sight of land. (B. B. K.)

QUINCY, a city of Illinois. U.S., on the Mississippi river, 110 mi. N.W. of St. Louis. First settled in 1822. it became the seat of Adams county, March 4. 1825, the day Pres. John Quincy Adams was inaugurated, and was named in his honour. Incorporated as a village in 1834 and chartered as a city in 1839, Quincy had a population of about 7,000 and was second in size to Chicago when the sixth Lincoln-Douglas debate was held there in John's square (non Washington park), Oct. 13. 1858. A prosperous river town, Quincy declined with the passing of the steamboat era in the latter part of the 19th century but after 1920, with the development of industry, population again increased. Among the manufactures are agricultural and industrial machinery, automotive parts, clothing and footaear, food products, chemicals, office supplies, paper products and heating equipment.

Most of the city occupies the upland about 150 ft. above the valley floor where the blississippi river flows against its steep left bank. A navigational dam and lock impound the water in Quincy bay. Riverview, Sunset and Gardner parks north of the business section and Indian Mounds and South parks to the south line the river bluffs. Quincy. a Roman Catholic coeducational college established in 1860. is in the residential part of the city Illinois Soldiers and Sailors home (founded 1887) occupies more than 200 ac. at the northern city limits. For comparative population figures *see* table in ILLINOIS: *Population.* (J. H GD.)

QUINCY, a city of Norfolk county, Mass., U.S., located on Boston harbour, about 8 mi. S.E of Boston (*q.v.*). A part of the Boston standard metropolitan statistical area, it is a manufacturing city and a centre of retail trade. Pop. (1960) 87,409. (For comparative figures *see* table in MASSACHUSETTS. *Population.*) Manufacturing is diversified (gears. confections, dairy products, detergents, electronic tubes and machinery for riveting, packaging and materials handling) but it is dominated by shipbuilding. The Fore River shipyards are among the most important in the country. The city was formerly famed for its granite quarries, which supplied granite for King's chapel and the Bunker Hill monument in Boston. Retail sales per capita are substantially above the average for the Boston metropolitan area and for the state, with sales of lumber. building materials, hardaare and farm equipment constituting nearly 10% of the total. Quincy's residents are distinguished by the high proportion with origins in Scotland, Sweden and Finland and by the predominance of craftsmen, foremen and clerical workers in the labour force. Prior to 1792, when Quincy was incorporated as a town, the area was part of the town of Braintree. It became a city in 1888. The birthplaces of two presidents, John Adams and John Quincy Adams, are preserved in Quincy. The two buildings. the Quincy homestead (built about 1636) and the Adams National Historic site, are open to visitors except in the winter season. (E. E. M.)

QUINET, EDGAR (1803–1875), French historian. philosopher and poet, a supporter and theorist of the republican movement. Born at Bourg-en-Bresse (Ain), Feb. 17. 1803, of a Protestant mother and a soldier in the army of the Rhine, he was greatly affected in his youth by Napoleon's defeat which he later recalled in his poems *Ahasvérus* (1833) and *Napoléon* (1836). After studying law in Paris he published a satirical work, *Tablettes du juif errant* (1823), but he first won recognition by his translation of J. G. Herder's *Philosophie der Geschichte (Ide'es sur la Philosophie,* 1827) which was admired by Goethe. Victor Cousin and Jules Michelet, with whom he formed a lifelong friendship. In 1829 he visited Morea on a government mission and on his return published *La Grèce moderne* (1830). Though attracted to German philosophy. he was critical of German political ambitions, which he denounced as "Teutomania," in his pamphlets *L'Allemagne et la Révolution* and *Le Système politique de l'Allemagne* (1831). Later he traveled in Germany nhere in 1834 he married Mina Moré. In 1838 he was appointed professor of foreign literature at Lyons and in 1842 became professor of literature at the Collège de France. There his views on the Jesuits and papal supremacy antagonized the clergy and in 1846 his lectures were banned by Guizot.

Quinet took part in the revolution of 1848, and was returned for Ain to the legislative assembly, where he supported the extreme radical party. An opponent of Bonapartism, he was banished after the coup *d'état* of 1862 and settled in Brussels where, after the death of his first wife, he married Hermione Asaki, daughter of the Rumanian poet. Georges Asaki. During the first years of his exile he wrote Philosophie de *l'histoire* de France (1855), *Révolution* religieuse *du 19e siècle* (1857) and *Histoire* de mes iddes (1858). In 1858 he moved to Veytaux in Switzerland where he wrote historical, political and philosophical works including La Rkvolution (186j), La Morte de la conscience *humaine* (1867) and La *Création* (1870), which was inspired by Charles Darwin. After the fall of the Second Empire in 1870 he returned to his professorship at the Collège de France. In the following year he was elected to the national assembly and opposed the peace terms after the Franco-German war of 1871. His last work, *L'Esprit* nouveau (1874) is a summary of his theories. He died at Versailles, March 27, 1875.

Quinet's complete works were published in 30 vol. (1877–81). His Lettres *d'exil* were published in 4 vol. (1885).

BIBLIOGRAPHY.—Mme. Edgar Quinet, *Memoires d'exil* (1868–70), *Edgar Quinet avant l'exil* (1887), *Edgar Quinet depuis l'exil* (1889) and *Cinquante ans d'amitid: Michelet et Quinet* (1899); Henri Monin, "Étude critique sur le texte des *Lettres d'Exil*" in *Revue d'histoire littdraire de la France* (1907–08, 1910); P. Gautier, *Un prophdte, Edgar Quinet* (1917); H. Tronchon, *Le Jeune Quinet ou l'aventure d'un enthousiaste* (1937).

QUININE is the most important alkaloid of cinchona bark; its chief use is in the treatment of malaria. In the 300 years between its introduction into western medicine and World War I, quinine was the only effective remedy for malaria. As a specific for this disease, quinine benefited more people than any drug ever used for the treatment of infectious diseases. The treatment of malaria with quinine marked the first successful use of a chemical compound in combating an infectious disease.

Like the other cinchona alkaloids, quinine is a large and complex molecule, and its total laboratory synthesis by Woodward and Doering in 1945 is one of the classical achievements of synthetic organic chemistry. However, commercial synthesis of quinine is not economically feasible.

Quinine acts by interfering with the growth and reproduction of the malarial parasites inhabiting the red cells of the blood, probably by preventing them from oxidizing glucose, their chief source of energy. Administration of quinine dramatically improves the condition of a person suffering from malaria; the parasites promptly disappear frorn the blood, and the symptoms of the disease are quickly alleviated. However, when quinine treatment is terminated, many recovered patients suffer another attack of malaria several weeks later. This is because quinine does not kill the malarial parasites iiving in cells of the body other than the red blood cells. These parasites persist and, after a time, reinvade the red blood cells and precipitate the second malarial attack, or relapse.

Because quinine fails to produce a complete cure in malaria, better antimalarial drugs were long sought for. At the beginning of World War II, two new synthetic antimalarial drugs, pamaquine naphthoate (Plasmochin) and quinacrine hydrochloride (Atabrine), had already been developed in Germany. They were definitely effective but not clearly superior to quinine. When the Allies' supply of East Indian quinine was cut off by the entrance of Japan into World War II, the search for new and more effective antimalarial drugs was greatly intensified. Although Atabrine remained the mainstay of Allied forces throughout the war, wartime research produced a number of antimalarial drugs that later almost completely replaced quinine. Some of them, such as chloroquine and paludrine, are more effective than quinine in suppressing the growth of the blood forms of the malaria parasite; while others, such as primaquine and daraprim, act upon both the blood and tissue stages of the parasite, thus producing complete cures and preventing relapses. All! the newer antimalarials, unlike quinine, may be completely synthesized in the chemical laboratory on a commercial scale.

In addition to its specific use in malaria, quinine is sometimes used as a nonspecific remedy for fever and pain. It probably reduces fever by dilating the small blood vessels of the skin, while its analgesic effect may result from depression of certain centres in the central nervous system.

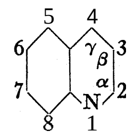
Prolonged administration of quinine may produce toxic symptoms such as deafness, disturbances in vision, skin rashes and digestive upsets. See also CINCHONA; CINCHONA BARK, ALKALOIDS OF; MALARIA. (J. W. MR.)

QUINNAT (Oncorhynchus tschawytscha), most important salmon (*q.v.*) of North American Pacific coast, frequently weighing upward of 50 lb. It has been naturalized in New Zealand.

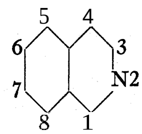
QUINOA (Ckenopodium quinoa), a small annual herb of the goosefoot family (Chenopodiaceae). very similar to the common lamb's quarters (*q.v.*), native to Bolivia, Chile and Peru, where it has long been cultivated as a food plant by the native peoples of the Andean plateau. The plant produces a great profusion of very small seeds, which are ground intq meal and made into cakes or gruel or boiled like rice; the green parts are used as a pot herb like spinach.

See CHENOPODIUM.

QUINOLINE is an organic compound of formula C_9H_7N which in general chemical behaviour resembles pyridine (*q.v.*) very closely. It is, in fact, a benzopyridine, bearing the same relation to pyridine as naphthalene does to benzene. The benzene and pyridine rings are fused together in the 2,3 position, the other possibility, fusion in the 3,4 position, giving isoquinoline which is discussed below.



Quinoline



Isoquinoline

The positions of substituents in derivatives of the two compounds are indicated by numbers as shown above. The prefixes N, α, β and γ were also used formerly for the pyridine ring of quinoline.

Quinoline itself was first isolated from coal tar by F. F. Runge in 1834. The modern commercial product is obtained from that source or is made synthetically. It also occurs in bone oil. C. F. Gerhardt in 1842 obtained quinoline by heating the alkaloid cinchonine with potassium hydroxide and this was the first evidence of the occurrence of the quinoline nucleus in certain of the natural alkaloids; quinine similarly heated gives 6-methoxyquinoline.

The first synthesis of quinoline was achieved by W. Koenigs in 1879 by passing the vapour of allylaniline over hot lead oxide. A large number of further synthetical methods are available for the preparation of quinoline and its derivatives. Of these, the best known is probably the Skraup reaction (1880), which is of exceedingly wide application; it is employed for the formation of quinoline itself and for that of the derivatives substituted in the benzene ring. A primary aromatic amine is heated with glycerol, sulfuric acid and a mild oxidizing agent, nitrobenzene or arsenic acid being often used. Aniline is converted into quinoline in good yield by this method which can also be applied to practically all aromatic amines.

As was mentioned above, the natural alkaloid, quinine, contains the quinoline nucleus. Several synthetic antimalarial drugs, which are like quinine in being derivatives of 4-aminoquinoline, have also been prepared; of these, quinacrine (Atabrine) has found the widest use. (See MALARIA.)

Quinoline is a colourless, highly refractive oil boiling at 239° C. and with a characteristic smell. It is almost insoluble in water but miscible with organic solvents, and it behaves as a weak monoacidic base. Its salts are readily soluble in water except the bichromate which is sparingly soluble in the cold and can be used for the purification of quinoline. Since the pyridine ring is deactivated by the presence of the nitrogen atom, a substituting reagent such as nitric acid attacks the benzene ring and gives a mixture of the 5- and 8-substituted compounds. Further nitration gives the 5,7- and 6,8-dinitro derivatives. These nitro compounds can be reduced to amines which behave as true aromatic amines and can be diazotized and converted into other derivatives. Anionoid substituting reagents, such as sodamide, react with the pyridine nucleus in the 2 and 4 positions, and 2-aminoquinoline can be obtained directly by the action of sodamide.

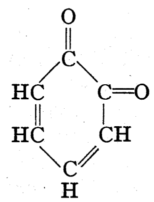
Quinoline and its homologues are tertiary bases and thus react with alkyl halides to give quaternary ammonium salts which show the normal behaviour of strong electrolytes. The quaternary hydroxides derived from these salts are not stable and tend to pass more or less completely into un-ionized forms, as with many other cyclic bases. The reactivity of these compounds is the basis for the preparation of dyestuffs of the cyanine class (isocyanines, pseudocyanines and carbocyanines) which are of great value as sensitizers of the photographic emulsion to wave lengths in the red and infrared,

Isoquinoline is found in coal tar and crude quinoline from that source contains about 4% of isoquinoline. It is a solid melting at 24° C. and boiling at 240° C. and with a smell quite different from that of quinoline. It is more strongly basic than the latter, since the nitrogen atom is not directly attached to the benzene ring, and its sulfate is not very soluble in cold water; separation from quinoline is based on these facts.

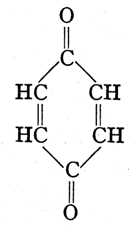
The isoquinoline nucleus is found in a number of important alkaloids; *e.g.*, papaverine, berberine, hydrastine and narcotine. A valuable reaction for synthesizing this nucleus is that of A. Bischler and B. Napieralski (1893). Acyl derivatives of β-phenylethylamines when heated with powerful dehydrating agents in boiling xylene or tetralin give 3,4-dihydroisoquinolines which can be dehydrogenated to isoquinolines with permanganate or catalytically with palladium. Many of the isoquinoline alkaloids have been synthesized by means of this reaction. (T. W. J. T.)

QUINONES, a group of coloured cyclic organic compounds containing two carbonyl groups, C = O (see ALDEHYDES AND KETONES) either adjacent (orthoquinone, I) or separated by a vinyl group, C = C, (paraquinone, II) in a usually six-membered unsaturated ring. All quinones have these features except a few in which the carbonyl groups are located in different rings: *e.g.* amphinaphthoquinone, III. The term quinone usually refers to the specific compound, parabenzoquinone (p-benzoquinone), II, but may also apply to some other compound having the required structural features.

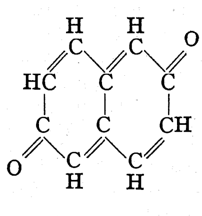
A similar ambiguity exists also for the terms hydroquinone and quinhydrone (see below). The general reactions of quinones are entirely analogous to the specific reactions of p-benzoquinone.



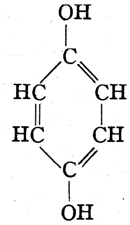
I



II



III



IV

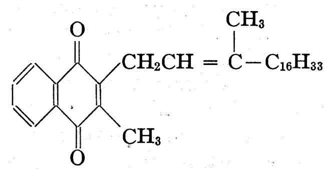
By a variety of reducing agents, p-benzoquinone is easily and quantitatively reduced to its corresponding hydroquinone IV. This change is readily reversed by oxidizing agents.

$$\underset{p\text{-Benzoquinone}}{C_6H_4O_2} + 2H^+ + 2e \rightleftharpoons \underset{p\text{-Benzohydroquinone}}{C_6H_6O_2} \text{ where } e \text{ is an electron.}$$

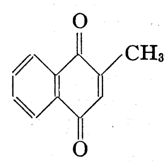
If a platinum electrode is put into a solution which contains equivalent amounts of some quinone and its hydroquinone, and which is saturated with respect to the addition compound of the two (the so-called quinhydrone), an electric potential is produced which is dependent on the hydrogen-ion concentration. By making connection through a suitable conducting solution with a reference half cell, this potential can be measured. A device, the quinhydrone electrode was developed to make use of the above principle in measuring the hydrogen-ion concentration of an unknown solution.

The ring of atoms in a quinone is said still to have a quinonoid (or quinoid) character if one of the sets of doubly bonded carbon and oxygen atoms is replaced by another doubly bonded atom pair, or even if both of those sets are so replaced. Quinonoid structures are important in theories concerning the relationship of chemical constitution to colour. Many quinones, among which one of the most important is anthraquinone (see ANTHRAQUINONE), are used as dyestuff intermediates. All vat dyes have quinonoid structures. An important feature in the use of vat dyes is the fact that the dye is placed on the cloth while in the hydroquinone state, and the oxidation to the quinone state takes place on exposure to air.

Many quinones occur in natural products. One of the most important of these is vitamin K_1, which possesses the structure V and is the antihaemorrhagic agent found in certain green plants. (See VITAMINS: Vitamin K.) Synthetic quinones, in particular 2-methyl-1,4-naphthoquinone, VI, have similar properties and are used in medical practice.



V



VI

A number of interesting naturally occurring quinones are described in Organic Chemistry by L. F. Fieser and M. A. P. Fieser, pp. 722–31 (1956). (M. S. N.; X.)

QUINSY, a common term for an abscess which develops around the tonsil, usually following acute tonsillitis (*q.v.*).

QUINTAIN, an instrument used in the age of chivalry in practising for the tournament (O. Fr. *quintaine,* from Lat. *quintana,* a street betaeen the fifth and sixth maniples of a camp, where warlike exercises took place), An early form consisted of the wooden figure of a Saracen armed with shield and sword: the object being to strike the figure on the forehead between the eyes.

As late as the 18th century running at the quintain survived in English rural districts.

QUINTANA, MANUEL JOSÉ (1772–1857) Spanish patriot and poet. was born in Madrid, April 11, 1772. A typical Spanish neoclassic, he wrote tragedies (El Pelayo), eloquent organ-voiced odes on large humanitarian themes, dared comparison with Plutarch—Vidas de *españoles célebres* (1807–33)—and wrote the best literary criticism of the century in his anthologies *Colección* de *poesías* castellanas and *Musa épica*. The national respect he earned for his clarion calls for unity against the French invaders never waned (Queen Isabel crowned him national poet in 1855), though his liberalism excluded romanticism and his pen was silent for half a century before his death in Madrid, March 11, 1857. (R. F. B.)

QUINTANA ROO, a federal territory of Mexico on the eastern side of the Yucatán peninsula, bounded by British Honduras and Guatemala. Pop. (1950) 26,967; (1956 est.) 33.434; area, 19,630 sq.mi. formed in 1902 from parts of the states of Yucatan and Campeche. The territory is hot, humid and heavily forested, with 50 to 60 in. of rain annually. Like the rest of the peninsula, Quintana Roo is a level, porous limestone plain through which water percolates to form underground grottos, caverns and wells.

The area is populated chiefly by descendants of Maya Indians who in 1847 rebeled in Yucatán and were eventually driven into these fastnesses by continuous military campaigns. Distrustful of Yucatecan Mexicans, they carry on sporadic trade in chicle nith British Honduras. Their main contacts with the outside world lie along the narrow-gauge railway that connects Felipe Carrillo Puerto (Santa Cruz de Bravo), to Vigía Chico on Ascension bay. Another penetration from the coast inland is by a rail line in the northern section from Leona Vicario (Santa Maria) to Puerto Morelos. Air strips at various points. and regular service to Belize, Brit.Hond., and Merida lessened some of the characteristic isolation of the territory, which for many years was used as a dumping ground for political prisoners.

Chicle and a small amount of copra, produced on the coast near Cozumel Island, are the main products. There are valuable stands of mahogany and other hardwoods which are largely unexploited. Sponge and turtle fishing is significant along the coast. The small Mayan hamlets are nearly self-sufficient.

The capital is Chetumal. The territory contains numerous important archaeological remains of the earlier pre-Spanish Mayan empire, notably those at Tulum.

In 1517, the first Spanish landing in Mexico was made at Cape Catoche. Hernán Cortés in 1519 landed first on the island of Cozumel alongside Quintana Roo. An airline links the island, now a tourist resort, with Merida. (J. A. Cw.)

QUINTESSENCE, according to some Renaissance philosophers (Paracelsus, Agrippa von Nettesheim, Rudolf Goclen), was the purest and most intimate nature of created things. Earlier the Latin term *quinta* essentia, "fifth essence" (equivalent to the Greek *pempte* ousia, which occurs in John Philoponus), was used to denote the thinnest and most divine material element surrounding the world of the four Empedoclean elements (fire, air, water and earth); the Pythagorean Philolaus (*q.v.*) spoke of a *pempton* soma or "fifth body"; and Aristotle described the ether as a primary substance distinct from the other four. (L. M.-Po.)

QUINTILIAN (MARCUS FABIUS QUINTILIANUS) (*c.* A.D. 35–*c.* 100), Roman writer whose work on rhetoric is one of the most valuable contributions of the ancient world to educational theory and to literary criticism, was born at Calagurris in Spain (the modern Calahorra in the Logroño province). He received at least part of his education in Rome; the orator Domitius Afer had a share in his training. He went back to Spain (not before A.D. 57). then returned to Rome in the retinue of Galba (68). There he taught rhetoric and was subsequently (c. 71?) appointed a public professor of that subject by Vespasian. The younger Pliny was among his pupils. At the same time he was a successful pleader in the law courts. After 20 years spent in these activities he retired (c. go) and devoted himself to writing; it took two years to compose his great work, the Institutio oratoria ("The Training of an Orator"), which was published *c.* 95. He achieved fame and wealth; ultimately Domitian made him tutor of his two grandnephews, prospective heirs to the throne, and awarded him the consular insignia. The preface to book vi of the Institutio expresses in tenderest terms his grief for the loss of his young wife (when she was 19) and of both his very young sons.

The Institutio oratoria was written at a time when, political life being no longer free, eloquence had lost its former power. But it had not lost its prestige. Rhetoric dominated education—in the form essentially of a training in liberal culture. The *Institutio,* in 12 books, provides a comprehensive course of instruction taking the student from infancy to the time when he has become a complete orator. Book i deals with the training prior to the study of rhetoric, book ii with the first rhetorical exercises and with declamation, and also with the nature and end of oratory. These two books contain the best Roman thought on education, much of it of enduring value for its practical good sense, sympathetic personal quality and insight into human nature. "Grammar" is considered in its two departments, the art of speaking correctly and the interpretation of literature. Books iii–xi are concerned with the five departments of rhetoric: books iii–vi with "invention" (iii discusses also the origin of rhetoric, and its kinds—of these the judicial receives most attention in the Institutio as a whole; in iv–vi invention is applied to the formal parts of a discourse; and vi includes a lively chapter on the arousing of laughter); book vii with arrangement; books viii–x with style (in viii and ix the elements of a good style are treated, and in x various practical methods of assuring command over them).

Book x contains the much-praised survey of Greek and Latin authors recommended to the orator for study. with neat summaries of their outstanding qualities. Often Quintilian gives us the established opinions of his time, but sometimes again he is independent, especially with respect to Roman writers; and his exposition is felicitous and interesting. He reproves certain stylistic abuses of his day (and the influence of Seneca) and would effect a return to the classical tradition of the Golden Age (his greatest admiration is for Cicero), but with concessions to the demands of changed conditions. The subjects of book xi are memory and delivery.

Quintilian's aim was to mold the character as well as to train the intellect (iv, preface, 3); and book xii delineates the ideal orator—taking the elder Cato's definition, "a good man skilled in speaking"—and offers advice for the employment of his gifts in public life. Since eloquence serves the public welfare, it must be fused with virtue; and philosophy is a component part of the rhetorical training. The moral power of this book makes it especially impressive and induces one to overlook the author's occasional lapses, as when he asserts with worldly wisdom that "Sometimes the public interest requires that the speaker defend what is not true" (ii, 17, 36) or accords fulsome praise to Domitian (iv, preface, 3–5).

Quintilian reviews and studies the principles of rhetoric in their fullest scope and variety, preserving what is valuable in the Greek and Roman tradition, but without slavish adherence to any one school; he applies discriminating judgment where the doctrines of his predecessors are contradictory, rejects them when they are absurd. He scorns superstitious conformity to rules as though they were immutable laws and particularly to such as are laid down without experience of actual battle in the courts. The work is everywhere marked by learning, wisdom and taste; and the engaging personality of the author, combining kindliness, sincerity and high principle, shines through it.

Quintilian's style exhibits some of the characteristics of the silver Latin, such as point, the use of rare and poetic words, and occasional looseness of structure, but no writer of his time departs less widely from the best models of the late republican period. The language is on the whole clear, unlaboured, energetic and dignified.

The Institutio exerted its greatest influence during the Renaissance and Reformation, after the discovery of a complete text by Poggio at St. Gall in 1416.

For the text of the *Institutio* oratoria see the edition by L. Radermacher, 2 vol. (1907–35); for the text with Eng. trans., that by H. E. Butler in the "Loeb Series," 4 vol. (1921–22). For commentary see Jean Cousin, *Études* sur *Quintilien* (1936) and the separate editions of book i by F. H. Colson (1924), of book x by W. Peterson (1891; new ed., 1903) and of book xii by R. G. Austin (1948). The text of Declamationes *majores* is ed. by G. Lehnert (1905), that of Declamationes minores by C. Ritter (1884).

Quintilian published one other rhetorical work, De *causis corruptae* eloquentiae, which has not survived; it probably dealt with the technical and educational aspects of the decline of oratory rather than the political and social. Of his speeches he published only one (now also lost), in defense of Naevius Arpinianus, accused of killing his wife. The other speeches that once circulated under his name he repudiated as having been corrupted by careless stenographers bent on profit (vii, 2, 24). He disowned also two books on rhetoric which kindly intentioned pupils had published from lecture notes without his authorization (i, preface, 7). Neither of the two extant collections of declamations ascribed to him (Declamationes *majores,* 19 in number; and Declamationes minores, 145 from a collection originally numbering 388) is regarded as genuine; both are of uncertain date. (HY. CN.)

QUINTUS SMYRNAEUS, Greek epic poet. probably flourished in the latter part of the 4th century A.D. He is sometimes called Quintus Calaber, because the only manuscript of his poem was discovered at Otranto in Calabria by Cardinal Bessarion in 1450. According to his own account (xii, 310), he tried his hand at poetry in his early youth, while tending sheep at Smyrna. His epic in 14 books, known as Ta meth *Homeron,* or *Posthomerica,* takes up the tale of Troy at the point where Homer's Iliad breaks off (the death of Hector), and carries it down to the capture of the city by the Greeks, their departure and dispersal in the storm. The poet has no originality; in conception and style his work is closely modeled on Homer.

See F. A. Paley, *Quintus Smyrnaeus* and the "Homer" of the Tragic Poets (1879); G. W. Paschal, *A* Study of *Quintus Smyrnaeus* (1904).

QUIPU, a knotted cord used by the Incas of ancient Peru and other Indians of the central Andes as a mnemonic aid and a recording device. The Inca type consisted of a heavy, central cord from which 1 to 100 variously coloured strings were suspended. A single knot or loop in a pendant string represented a number from one to nine, depending on the distance of the loop from the central cord. There also were positions for tens, hundreds. thousands and ten thousands. The quipus were used to record statistical information, in recording and reciting genealogies, in narrating legends and for recalling the proper order of complex ceremonial events. Apparently the quipu was not a calculating device. In the Guianas, knotted strings were used as timekeepers for ceremonial events.

QUIRINO, ELPPDIO (1890–1956), second president of the Republic of the Philippines, was born Nov. 16, 1690, in Vigan, in Ilocos Sur province. on the island of Luzon. He attended high school in Manila and took his law degree at the University of the Philippines. Quirino served in the Philippine house of representatives (1919–25) and in the senate (1925–31). He was a member of the Philippine independence mission which helped to obtain the passage in the U.S. congress in 1934 of the Tydings-McDuffie act under which the Philippines achieved independence on July 4, 1946. Also in 1934 he was elected to the constitutional convention. Thereafter he served as secretary of finance and later as secretary of the interior in the commonwealth government (1935–38). He was elected to the senate in 1941 and stayed in the Philippines during the Japanese occupation. After the war, Quirino again became secretary of finance in May 1916. As the candidate of the newly formed Liberal party, he became vice-president and secretary of foreign affairs of the new republic in July 1946. He succeeded to the presidency on the death of Pres. Manuel Roxas in 1948 and was elected president in 1919. During his term of office an intensive program of economic development was initiated with the assistance of the United States, the treaty of peace was signed with Japan and a new mutual defense treaty was concluded with the United States in 1951. The Hukbalahaps, or social dissidents in Luzon. were pacified primarily because of the efforts of his secretary of defense. Ramón Magsaysay. After being defeated for re-election in 1953 by Magsaysay he retired to private life and died on Feb. 28, 1956. See also PHILIPPINES: History. (C. A. B.)

QUIRINUS, a major Roman deity ranking close to Jupiter and Mars (*qq.v.*). Their *flamines* constituted the three major priests at Rome. His name is in adjectival form and would seem to mean "he of the *quirium,*" a word generally taken to signify the very ancient Sabine settlement which united with the Palatine community to form the original Rome. It has also been derived. however, from *covirium,* meaning "assembly of men." That the Quirinal, traditional site of Sabine settlement. was the seat of his cult there is no doubt. and the Sabine origin of the god is reilected in Ovid (Fasti II. 475). In spite of his importance rather little is known about Quirinus. He bears a similarity to Mars, and some believe that he is only another form of that deity. By the late republic he is identified completely with Romulus (*q.v.*), a confusion perhaps originally suggested by Quirites (*q.v.*). He had a festival. the Quirinalia. on Feb. 17; his temple on the Quirinal was one of the oldest in Rome. A cult partner Hora is spoken of, also minor deities, the Virites Quirini, of whom nothing else is known. Janus (*q.v.*) appears with the epithet Quirinus, but the relationship between the two is a matter of conjecture.

(R. B. LD.)

QUIRITES, earliest name of the burgesses of Rome (*see* QUIRINUS). In the phrase "*populus Romanus Quirites*" (or *Quiritium*), it denoted the individual citizen as contrasted with the community. Hence *ius Quiritium* in Roman law denotes full Roman citizenship. Whether the word ever had military associations is a point much debated, but if so it lost them at an early date and came to designate Roman citizens in their civil, as distinct from their military, capacity, and referred solely to Romans concerned in domestic affairs. Thus Caesar is said to have quelled a mutiny among his legionaries by the device of addressing them as "Quirites" (citizens). See ROMAN LAW.

QUIROGA, HORACIO (1878–1937), Uruguayan, short-story writer, became famous for his ability to portray man's futile struggle against the tropical jungle in Argentine territory of Misiones. Born Dec. 31, 1878, in Salto, he spent a good part of his life in Argentina, taking frequent trips from Buenos Aires to San Ignacio in the jungle province of Misiones. This primitive environment as well as his many personal experiences in the jungle furnished material for most of his *cuentos.*

His early period of literary apprenticeship. marked by his tendency to emulate the modernistic fashion, Los arrecifes de coral (1901). soon led him to realize that his talent was better suited to short stories. Some of his finest compositions. *Cuentos* de la selva (1918), El salvaje (1920), Anaconda (1921), El desierto (1924). Los desterrados (1926) and others, belong to this genre. *Más allá* (1935) reflects the depressed mood of his later years when he suffered from ill health and other misfortunes.

Quiroga took his own life in a charity hospital in Buenos Aires, Feb. 19, 1937. (H. Co.)

QUISLING, VIDKUN ABRAHAM LAURITZ JONSSON (1887–1945), Norwegian fascist, whose name became synonymous with "traitor." An army officer: he served as military attaché in Petrograd (later Leningrad) and Helsinki and later assisted Fridtjof Nansen in Russian relief. From 1927 to 1929 he represented British interests at the Norwegian legation in Moscow. He became Norwegian minister of defense in the Agrarian government, 1931–33. Resigning, he founded the fascist Nasjonal Samling (National Union) party. but never won a seat in the *storting.* Friendly to the Nazis, he visited Hitler in Dec. 1939 and collaborated in the German invasion of Norway in April 1940. The new regime proclaimed by him so incensed the Norwegians that it collapsed within a week, but he continued to lead Nasjonal Samling, the only party permitted by the Germans. On Feb. 1, 1912, Reichskommissar Joseph Terboven named him "minister president." Quisling's attempts to nazify the Norwegian church, schools and youth aroused bitter opposition. He persecuted the Jews, sending almost 1.000 to death in concentration camps. Despite difficulties with his party and the Germans, he held office until Norway was liberated in May 1945. Arrested, tried and found guilty of treason and other crimes, he was executed on Oct. 24. 1945. (HD. LN.)

QUITO, the capital of Ecuador and of the province of Pichincha. is situated about 114 mi. from the Pacific in a narrow Andean valley. Pop. (1950) 209.932. It was already an ancient city when the Spaniards arrived there in the 16th century. Before them there were the Incas, to whose empire it had belonged since 1487. Between that date and the year 1000 it was ruled by the Shyris, sovereigns of the Caras who are said to have come "by way of the sea." Prior to the Caras, it was the seat of the kingdom of the Quitus, the largest unit of an Indian tribal confederation that left no recorded history. Sebastibn de Benalcbzar, one of Pizarro's lieutenants, occupied it on Dec. 5, 1531. In the presence of his soldiers and 206 native inhabitants, he set up a municipal council (cabildo) and declared it in operation. He planned Quito as a typical Spanish city with streets running north and south, east and west from the central square or *plaza mayor.*

Quito lies on the lower slopes of the Pichincha (15,700 ft.) a volcano that last erupted in 1666. The central plaza, bounded by the cathedral, the palaces of the president and the archbishop and the municipal building, is only 15 mi. south of the equator, but because of its altitude of 9,350 ft. Quito enjoys a stimulating climate, the mean temperature at noon being 70°. Carved by two ravines spanned by masonry bridges, the city, oldest of all South American capitals, preserves much of its ancient atmosphere. The towers of numerous churches outlined against a circle of volcanoes, peaceful squares, fountains, balconied houses, steep streets, iron-grilled doorways and secluded gardens mark it as a place of charm.

Quito of the Spaniards was not a year old when the Franciscans established an art school, the first of its kind in South America. Thus began a celebrated religious art movement that flourished throughout the colonial period, leaving a wealth of polychrome sculpture in wood, and paintings without equal in the new world. Indian artists made of the churches, cloisters and old mansions of Quito veritable museums. The names of the sculptor Manuel Chili (Caspicara), and the painters Adrián Sánchez Galque, Miguel de Santiago and Gorivar González, among others, are noteworthy. Among the most admired Quiteiio churches and convents are La Compañía (Jesuit), whose baroque columns, ceilings and massive altars are covered with gold leaf; San Francisco, with its magnificent cloister; Carmen Alto, where the native Saint Mariana de Jesús lived and died; San Agustin, famous for carved ceilings, and Santo Domingo notea for a handsome façade; the Sagrario, where Ecuadorean independence was declared in 1809; and the 17th century cathedral, burial place of the hero of independence Antonio José de Sucre. Also worth mentioning is the church of the Merced convent, decorated in the Quiteiio style by the contemporary Ecuadorean artist Victor Mideros.

Although the city's convents and monasteries and its museum of colonial art indicate the deeply religious and contemplative character of its life, Quito is no longer an isolated capital, as in the past. There is a modern and busy airport meeting all international standards, including a 9,000-ft. runway required at that altitude. Quito has several daily newspapers and broadcasting stations, new housing projects for workers and athletic fields. Factories produce everything from textiles and soap to matches, shoes, hats, soft drinks, cosmetics, ready-to-wear apparel and pharmaceutical products. There are two institutions of higher learning, Central university founded in 1787 and the new Catholic university, offering facilities for the study of all the liberal and technical professions; also a technological institute, national library, astronomical observatory and conservatory of music. The city has several hospitals and a nursing school, two schools of social work, an American grade and high school, many modern residential developments and good public utilities.

Ecuadoreans are proud of the Casa de la Cultura, a cultural centre created in 1943 and financed with a share of the export duties. It acts as publisher and distributor of the works of Ecuadorean writers and organizes concerts, lectures, art exhibits and theatrical performances. In addition, it awards prizes for scientific research, literary and artistic excellence.

Among the characteristic sights of Quito are several outdoor markets or fairs operating once a week in different quarters of the city. Each one has a specialty—Santo Domingo, held on Saturday, is known for furniture and San Blas, for flowers, fruits and fowl. Only on Tuesdays, in the "24th of May" market, can one buy everything.

Equally typical are the countless diminutive shops where native craftsmen make silver jewelry, religious figurines, rugs, shoes, men's suits, furniture and other items. Although Quito is predominantly Roman Catholic there are a number of Protestant churches and a Jewish synagogue. (C. R. J.)

QUIXOTE, DON (in Spanish Don Quijote), the hero of Cervantes' (*q.v.*) romance (part 1, 1605; part 2. 161S), which was originally conceived as a satire of farcical incident directed against the romances of chivalry. (See SPANISH LITERATURE.) He has given his name in all European languages to a type of character which misses practical success by supposing that common humanity is governed by ideals as exalted or as imaginative as its own.

QUM, a district and city in the Central or Teheran *ostan* of Iran. The district produces abundant grain and cotton. Qum, the administrative headquarters, has a population (1956) of 96,463. It is a stronghold of the Shi'ite faith and has many tombs of saints and pious persons including the shrine of Fatima, sister of the imam Riza. Besides Fatima, at least ten kings and about 400 saints are interred in Qum and its precincts. Shah Abbas II, whose piety won him high favour with the ecclesiastical authorities, is buried in the shrine in a special mausoleum which is furnished with a set of 14 remarkably fine silk rugs, dated 1666. On the south side of the city is a group of five superb mausoleums (four of them of the 14th century) all distinguished by quite remarkable polychrome stucco ornament. The chief industries are glass, pottery and shoemaking.

QUOIN, in architecture, originally any vertical external corner of a building; more generally applied to large cut stones used either to form an accurate corner in a wall of rough rubble or brick or else to furnish a decorative termination to a wall surface of any material. Projecting stone quoins, frequently rusticated, or with the edges slightly recessed or beveled, are common decorative features in high Renaissance work in Italy, early 17th-century work in France and the Palladian style in England. In these styles they are used not only at the corners of a building, but also often at the edges of windows and doors. In much 18th-century work in Scandinavia. England and America, projecting quoin shapes are formed with brick.

In printing the term is applied to an expandable device used to tighten a form in its chase. See PRINTING.

QUOITS: see HORSESHOE PITCHING.

QUORUM, in its general sense, a term denoting the number of members of any body of persons whose presence is requisite in order that business may be validly transacted by the body or its acts be legal. The term is derived from the wording of the commission appointing justices of the peace which appoints them all. jointly and severally, to keep the peace in the county named, It also runs—"We have also assigned you, and every two or more of you (of whom [quorum], any one of you the aforesaid A. B, C, D, etc., we will shall be one) our justices to inquire the truth more fully," whence the justices so named were usually called justices of the *quorum*. The term was afterward applied to all justices, and subsequently, by transference, to the number of members of a body necessary for the transaction of its business.

QUOTA. Quotas, on imports or exports, are one type of quantitative or direct trade restriction. Quantitative controls are measures which directly limit the quantity—in exceptional cases the value—of goods (or services) that may be exported or imported. The opposite to quantitative controls are controls which operate by making imports or exports more expensive without fixing a limit on the quantity; of these, tariffs, which put a special tax on exports or imports, are the main type.

The principal quantitative trade controls are the quota, payments restrictions (exchange controls), licensing and monopoly systems. Under the monopoly system a governmental agency has an exclusive monopoly for the import or export of the restricted commodities. The distinction between the quota, exchange control and licensing system is riot so clear-cut. By exchange control is meant the complex of measures controlling and regulating international payments which enable a country to maintain the international value of its currency at a higher level than it would have in the absence of these controls. One of the most important of this complex of measures is the quantitative restrictions of imports by quotas and licences. There is a tendency to speak of quotas when the quantities are determined in advance and the rules for the distribution of the quota among countries of origin and traders are more or less clearly formulated; and of a licence system when the granting of import licences is left to the discretion of the administrative organs. This article refers chiefly to quotas, but much of what is said holds of exchange control and licensing and monopoly systems as well.

Quotas are fixed either by zutonomous action of a country or in agreement with other countries (autonomous v. contractual quotas). Another distinction is between import and tariff quotas. By a tariff quota is meant a regulation which permits the import of a certain quantity (quota) of a commodity duty free (or at a specially low duty), while quantities exceeding the quota are subjected to a (higher) duty. An absolute or import quota restricts imports absolutely.

Another type is milling or mixing quotas; this is a rule which requires that imports of, say, barley must be milled or mixed in a certain proportion with home-grown grain. In the following, reference will be made chiefly to absolute import quotas.

Throughout the last quarter of the 19th century and up to 1914 the predominant method of trade control was the tariff. In the 20th century quantitative restrictions on trade were first imposed on a large scale during and immediately after World War I. During 1914 to 1918 such controls were an integral part of mar economics. After the Armistice quotas were fairly rapidly abolished, except in central and eastern Europe. There the dislocations produced by the war were much more serious than elsewhere. Trade was resumed first on the basis of intergovernmental barter and then on that of general prohibitions modified by licences. During the 1920s quotas were progressively abolished and replaced by tariff protection. The next great wave of quota protection of trade came with the great depression in the early 1930s. Especially after 1931 one country after another introduced quantitative restrictions, first on cereals and certain other foodstuffs and then on a great variety of agricultural and industrial products. France was the first large country to introduce a comprehensive quota system (1931), but it was followed by practically all European countries. In 1935 to 1936 there was a slight relaxation, but this movement toward somewhat freer trade soon came to an end. Everywhere economies were being geared for the approaching war; and a tightly controlled trade is an integral part of a war economy. The United States was the only important country that made very little use of quotas during the 1930s. The only important U.S. quota was on sugar.

After the end of World War II quotas and other quantitative import restrictions were widely used to maintain equilibrium in the balance of payments. In the U.S. they were used more than before the war for the purpose of restricting imports of agricultural products, especially those supported by the agricultural parity price program. The draft charter for the proposed International Trade organization (ITO) contained extensive provisions on quotas which were incorporated into the General Agreement on Tariffs and Trade (G.A.T.T.).

Why did quotas become so popular and how does quota protection differ from tarifi protection? The increasing use made of quantitative trade controls is a phase in the trend toward autarky and protection observable irom about 1870. Tariffs went higher and higher, the last free-trade countries (Great Britain, the Netherlands, Denmark) introduced protective measures and eventually quantitative restrictions were piled on top of tariffs. But quotas are a much more effective device for restricting trade than tariffs and much more disturbing to the international trade mechanism. Under the tariff system volume and value of trade, although restricted, are still flexible. The flow of goods changes according to changes in demand and supply at home and abroad. Despite an import duty imports can rise, if cost of production and prices fall abroad and rise at home. Thus the effect of a tariff can be offset by a depreciation of the foreign currency or an export subsidy, while a quota constitutes a rigid bar to imports. This is one of the main reasons why during the great depression of the 1930s one country after the other switched from tariffs to quotas. Tariffs were no longer regarded a sufficient protection in the face of violently changing prices, unstable currencies and extensive utilization of export subsidies. Another related reason was that tariffs could in many cases not be increased at short notice without violating international treaties, while such treaties did not mention, and therefore were thought not to prohibit, the imposition of quotas. Quotas are a more poweriul weapon of discrimination between individual countries and traders. This makes them popular with economic nationalists and protectionists in all countries. In fact, it has been found practically impossible to find a method of quota allocation which could be called nondiscriminatory and in accordance with the most-favoured-nation principle, while under the tariff system nondiscrimination has a precise, generally accepted meaning. During the post-World War II period the principal motive for the use of quotas and other quantitative import restrictions was the balance of payments difficulties (dollar shortage) experienced by many countries. These problems stemmed irom inflation and overvaluation of currencies.

An important characteristic of the mode of operation of quotas differentiates them sharply from tariffs. If a quota is effective, *i.e.*, if it is smaller than the quantity which mould he imported in the absence of the quota, it creates a price differential between the importing and exporting country which is not covered by transportation cost plus duty. Under the tariff system, too, the price of the taxed commodity mill be higher in the importing than in the exporting country, hut (except if the tariff becomes prohibitive and imports cease altogether) the price difference tends to be equal to transportation cost plus duty; if it were greater, imports would increase; if it were smaller, imports would fall until the price differential was again equal to transportation cost plus tax. Under the quota system this mechanism is eliminated. It follows that the importation of the quota-restricted commodities becomes a very lucrative business. Under the tariff system the price difference flows into the coffers of the treasury; under the quota system it flows into private pockets, and in all countries with extensive quota systems fortunes have been made by importers. The consequence is that the government is forced to distribute the quota among individual traders. When quotas were first introduced in 1931, many countries made the mistake of fixing only global quotas and of letting everybody import until the quota was exhausted. Naturally every trader tried to import at once as much as possible, and the quota was exhausted within the first few days of the period (usually a month or a quarter of a year) for which it was fixed. Distribution of the licences to import within the quota must be made according to some principle. It should be remembered that the granting of an import licence under the quota system is equivalent to the granting of an unearned income. While under'the tariff system the selection of the actual importers is left to the automatic mechanism of the market and is no concern of the government, under the quota system the authorities have to decide how much each trader is allowed to import. The import function ceases to be a business activity where success depends on commercial efficiency and imagination, but becomes a sinecure handed out by government agencies. In the 1930s, the usual procedure was to distribute quotas among countries of origin and individual traders (usually importers but sometimes also foreign exporters) in proportion to the imports from the respective countries effected by the individual traders in some base period which was considered as "normal." It is easy to see that this is not a satisfactory solution and that it becomes less and less satisfactory as time goes on and the underlying situation changes. But the fact that quotas give rise to large profits made in connection with imports and exports has made the system popular with importers and exporters. This popularity is enhanced by the fact that quota restriction, much more than tariffs, facilitates monopolistic price policies by domestic producers.

All these unavoidable abuses, inefficiencies and inconveniences made it unlikely and undesirable that the quota system would replace the tariff system.

QUO WARRANTO, in English law, the name given to an ancient prerogative writ calling upon any person usurping any office, franchise, liberty or privilege belonging to the crown, to show "by what warrant" he maintained his claim, the onus being on the defendant. It lay also for nonuser or misuser of an office, etc. If the crown succeeded, judgment of forfeiture or ouster le main was given against the defendant. The procedure was regulated by statute as early as 1290 (the statute of *Quo Warranto),* which was superseded by the modern form of an information in the nature of a quo warranto. exhibited on behalf of the crown or a private person called the relator. The information will not be issued except by leave of the court on proper cause being shown. It lies where the office is of a public nature and created by statute, even though it is not an encroachment upon the prerogative of the crown. Where the usurpation is of a municipal office the information is regulated by 9 Anne ch. 25 (1711). Such an information must, in the case of boroughs within the Municipal Corporations act, 1882, be brought within 12 months after disqualification (s. 225); in the case of other boroughs, within 6 years after the defendant first took upon himself the office. Though nominally a criminal it has long been really a civil proceeding, and has recently been declared to be so.

In the United States, quo warranto is the proper remedy under the statutes of the various states to ascertain the right of a person to an office of a public nature or one in a corporation. It also is used to test the validity of a franchise held by a municipality or a public service corporation. Some states have substituted by statute information in the nature of quo warranto and other remedies, and where such substitution has been made, quo warranto is improper.

R THE letter corresponding to modern R in the ancient Semitic alphabet was 4 (resh), perhaps deriving from an earlier sign representing a head. Greek rho is found in a form practically unchanged in the early inscriptions from the island of Thera. The same form also occurs in early inscriptions from Attica and Corinth and in the Chalcidic alphabet. The most usual Greek form was rounded P; this is the form in which the letter occurs in the Lydian alphabet. A form D in which the loop is extended to the bottom of the vertical stroke also occurs in both the eastern and western alphabets. This was the form of the letter in the Umbrian and Oscan alphabets of Italy, while Etruscan had a form in which the loop reached nearly to the bottom. In the Chalcidic alphabet a form R with an additional oblique stroke occurred, and this must be the ultimate source of the Latin form, in which the oblique stroke was exaggerated.

The minuscule form has been subject to many variations. In cursive Latin of the 6th century occurred a form √ in which the loop has disappeared, the three right-hand oblique strokes, or the loop and oblique stroke. being reduced to a single stroke. The Irish form in the 7th century was ɼ in which a similar process had taken place, but the remnants of the loop and oblique stroke had become extended in a horizontal direction. On the basis of this was formed the Carolingian r, in which the vertical stroke was not extended below the line. The Carolingian form is the minuscule r of modern printing, but in handwriting it still contends with the form 𝓇, resembling the Latin cursive tradition.

The sound represented by the letter has been in general the liquid formed by contact between the tip of the tongue and the palate, but its precise quality differs considerably from one language or dialect to another. The trilled *r* produced by rolling the tip of the tongue, is found not only in several continental languages but in certain dialects of English as well. The back or uvular *r* is characteristic of standard French and is current in many parts of Germany. In southern England and the eastern United States the *r* is feebly pronounced and in final position is often dropped altogether. The spelling with initial *rh* is practically limited to words of Greek origin (*e.g.*, rhetoric), where it represents the classical Creek writing of *rho* with a rough breathing (῾) to indicate an unvoiced pronunciation. It has intruded itself incorrectly in "rhyme" (for "rime") and in "Rhegium," "Rhaetic." (B. F. C. A.; J. W. P.)

DEVELOPMENT OF LETTER "R" FROM EARLIEST TIMES TO THE PRESENT

RA, the Egyptian solar god, one of the most important figures in the Pantheon. See EGYPT: Ancient Religion: The Pantheon.

RABAH ZOBEIR (d. 1900), the conqueror of Bornu (an ancient sultanate on the western shores of Lake Chad, included since 1890 in British Nigeria), was a half-Arab. half-Negro chieftain. He was originally a slave or follower of Zobeir Pasha (see ZOBEIR RAHAMA), and is said to have formed one of the party which served as escort to Alexandrine Tinne in her journeys in the Bahr-el-Ghazal in 1862–64. In 1879, Zobeir being in Egypt, his son Suleiman and Rabah were in command of Zobeir's forces in the Bahr-el-Ghazal. They persisted in slave raiding. and denied the khedive's authority, and Gordon sent against them Romolo Gessi Pasha. Gessi captured Suleiman and routed Rabah, who in July 1879 fled westward with some 700 Bazingirs (black slave soldiers).

He made himself master of Kreich and Dar Banda, countries to the south and southwest of Wadai. He finally established himself in Bagirmi, a state southeast of Lake Chad. In 1893 Rabah overthrew the sultan of Bornu. In his administration of the country he showed considerable ability and a sense of public needs. To the British. represented by the Royal Niger company, Rabah gave comparatively little trouble. Early in 1897 he began an advance in the direction of Kano, the most important city in the Fula empire. The news of the crushing defeat by Sir George Goldie of the Fula at Bida, induced Rabah to return to Bornu. He now turned his attention to the French. Émile Gentil had in this same year (1897) reached Lake Chad, via the Congo and Bagirmi, and had installed a French resident with the sultan of Bagirmi. As soon as Gentil had withdrawn, Rabah again fell upon Bagirmi. and forced sultan and resident to flee. In 1899 the French sent an expedition to reconquer the country, but it was only after a third encounter (April 22. 1900) that Rabah was slain and his host defeated. The chieftain's head nas cut off and taken to the French camp In this battle Major Lamy, the French commandant. also lost his life.

The French continued the campaign against Rabah's sons, two of whom were killed. Rabah had left instructions that if his army was finally defeated by the French. his successor should return to Bornu and make friends nith the British Rabah's third son, Fader-Allah. accordingly threw himself entirely upon British protection. But, in the later part of 1901 Fader-Allah, who had 2,500 riflemen, again made aggressive movements against the French. In retaliation, Captain Dangeville pursued him into British territory. A battle was fought at Gujba, Fader-Allah being defeated. He fled mortally mounded and died the same night.

RABAT, the capital of the kingdom of Morocco. North Africa, lies on the Atlantic coast, at the mouth of the Bou Regreg, 57 mi. N.E. of Casablanca and 174 mi. S.W. of Tangier Rabat. on the south bank. is separated by the Bou Regreg from the town of Salé opposite. Until March 2, 1956, when France relinquished its possessions in Morocco. Rabat was the capital of the protectorate and the seat of the French resident general. Pop. (1960) 227,445; (1952) 156,209. of whom 105.223 are Moslem, 10.239

Jewish and 40.747 non-Moroccan.

The old town, still surrounded by ramparts, lies near the coast, from which it is separated by a hill covered with extensive cemeteries. Within the ramparts are the medina, or Moslem town. and the *mellah*, or Jewish quarter. To the north stands an ancient fortress, the Kasba des Oudaya, on a cliff above the mouth of the Bou Regreg; it is entered by a splendid 12th-century gateway built during the dynasty of the Almohads (*q.v.*). Close to the Kasba is a charming Andalusian garden and in the adjoining medersa (college) there is a museum of Moroccan art. At .the southern edge of the old town, dominating the valley, is the 12th-century Hassan tower, a magnificent minaret of the Almohade period, at the foot of which are the ruins of the mosque of Al-Mansur. Intended to be the biggest in the world, it was never completed.

The European town of Rabat is partly enclosed within a great fortified wall which still stands along the greater part of its perimeter. As well as modern European quarters, the fortifications surround the Dar-el-Makhzen, or Sultan's palace, in front of which is the *Mechouar*, an immense walled courtyard, once bare, but laid out at the end of the 19th century with lawns. It was there that the sovereign received homage from his subjects. Various administrative buildings, among them the supreme court of justice, are in this part of the town, and nearby is Bab-er-Rouah, or the gate of the winds, a beautiful Almohade gateway.

Most of the government buildings are situated on the slopes of a hill around the former residency general, which is now the French embassy. The residential districts of Orangers and Aguedal, consisting of villas surrounded by gardens, extend far beyond the Almohade walls.

The harbour has never been busy because its approach is made difficult by the sand bar outside and by the constant silting up of the canal. The harbour has been abandoned and a bridge, completed in 1957, links Rabat with Salk, making it impossible for any merchant ships to enter the harbour.

History. — The town's history is inseparable from that of Salé. The first settlement was the Roman town of Sala Colonia, the remains of which were excavated in 1930 near Chella to the south of the city. These ruins adjoin the tombs of the Merinid (Beni Merin) dynasty (14th century). The present town of Salé was established on the north bank of the Bou Regreg between the 10th and 11th centuries and was founded by the Zenata Berbers, who were orthodox Moslems. to house the heretical Berghouata Berbers, whose domain stretched from the Bou Regreg west to the Oum-er-Rebia during the 10th and 11th centuries. The Kasba, later called "des Oudaya," was in the first place a bridgehead on the south bank for the occupants of Salk, and was for a long time called Salé-le-Neuf.

In the 12th century the first Almohade sultan, 'Abd al-Mumin, built a *ribāt* (camp), where he concentrated troops for his religious war in Spain. His second successor, Yakub al-Mansur, called it *Rībāt-el-Fath*, "the camp of victory," from which the town of Rabat takes its name. He erected the great fortified wall, within which the modern town has developed, as well as the tower of Hassan. In the 17th century numbers of Moors driven from Spain (the *Hornacheros*) settled in Rabat, which became with Salé a Corsair republic. (See BARBARY PIRATES.)

The Alaouite sultans, who stopped in Rabat on their way from Fez to Marrakesh, had a palace built there. Under the French protectorate (1912), Rabat mas made the capital of the country.

See Rabat et sa *région*, 4 vol. (Paris, 1918–20); H. Terrasse, *Villes impériales* du *Maroc* (Grenoble, 1937); J. Caillé, La *ville de* Rabat *jusqu'au* Protectorat *français*, 3 vol. (Paris, 1949). (A. AM.)

RABAUT, PAUL (1718–1794), French pastor of "the Church of the Desert" (see HUGUENOTS), was born at Bédarieux, near Montpellier, on Jan. 29. 1718. In 1738 he was admitted as a preacher, and after a year's study (1740–41) at the Lausanne seminary, received charge of the church of Nimes. In 1744 he was vice-president of the general synod. During the persecution of 1745–1752 Rabaut went into hiding, and in 1753 a price was put on his head. During the years that followed he sought, with Antoine Court and others, to place French Protestantism on a solid basis and to improve their legal position. In 1785, when he was visited by General La Fayette, it was arranged that Rabaut's son, Rabaut Saint-Btienne, should go to Paris on behalf of the Reformed Church. In Nov. 1787 Louis XVI's edict of toleration was signed, though it was not registered until Jan. 29, 1788. Two years later liberty of conscience was proclaimed by the national assembly, of which Rabaut Saint-Étienne was chosen vice-president, and it was declared that non-Catholics might be admitted to all positions. After the fall of the Girondists, however, in which Rabaut Saint-Btienne was involved, Paul Rabaut, who had refused to renounce his title of pastor, was arrested, dragged to the citadel of Nimes, and kept in prison seven weeks (1794). He died Sept. 25, 1794, soon after his release.

RABBI (Hebrew "my master" or "my teacher"), RABBAN or RABBENU ("our master" or "our teacher") and RAB. ("master" or "teacher") are titles applied to Jewish scholars or teachers. The title rabbi first came into general use toward the end of the 1st century A.D., although the heads of the Sanhedrin (*q* v.) had borne the title rabban since the time of Gamaliel I. Scholars who received their ordination in Palestine were called rabbi, while the Babylonian scholars who were not ordained in Palestine were called rab.

The title rabbenu was applied to Judah the Prince, the codifier of the Mishnah (2nd–3rd century AD.), and since then it has been a title designating the outstanding scholars of every generation.

There is no sharp distinction in religious status between the rabbi and the layman in Judaism. The rabbi is simply a layman specially learned in the Scriptures and the Talmud. To be recognized as a rabbi, however, a talmudic student has to be ordained. The custom of ordination is very old.

Joshua was ordained by Moses, the ceremony being as follows: Moses placed Joshua before Eleazar and the congregation and laid his hands upon him while giving him instructions. Symbolically. a portion of the spirit of Moses was transferred to Joshua through Moses' hands.

Moses also ordained the 70 elders who assisted him in governing the people. According to tradition the elders'ordained their successors, who in turn ordained others. so that there existed an unbroken chain of ordination down to the time of the Second Temple.

The practice of ordination in its Mosaic form ceased in Palestine in the second half of the 4th century when the Judaean academies were closed. (In the 16th century an attempt was made in Palestine to revive the ancient ordination, as well as the Sanhedrin. with all the power and authority that it possessed, but this attempt resulted in failure.) Down to the end of the 14th century, rabbinic ordination was purely a verbal ceremony. Later a new procedure was introduced whereby ordination was conferred upon a candidate in the form of a written statement awarded by a well-known and recognized scholar. Traditionally, the authority to act as a rabbi may be conferred by any other rabbi, but it is usual for students in theological academies to receive this authority from their teachers. In America the best-known rabbinical schools that ordain graduates are: the Hebrew Theological college, Skokie, Ill. (Orthodox); the Hebrew Union College-Jewish Institute of Religion. Cincinnati-New York city (Reform); the Jewish Theological Seminary of America, New York city (Conservative); and the Rabbi Elchanan Theological seminary, New York city (Orthodox). The main associations of U.S. rabbis are the Central Conference of American Rabbis (Reform), the Rabbinical Assembly of America (Conservative) and the Rabbinical Council of America (Orthodox).

In the middle ages there was strong opposition toward the chief rabbis, who usually were government appointees rather than persons chosen by the Jewish communities. The office of the chief rabbi exists today in some western European countries and in Israel. In England the chief rabbi of the United Hebrew Congregations of the British Commonwealth of Nations is elected by representatives of the congregations in Great Britain and the British dominions. He is thus recognized as the spiritual head of the majority of Jews in the British Commonwealth. The first chief rabbi of England was Rabbi David Tebele Schiff

(1765–92).

In France the office of the chief rabbi goes back to the Napoleonic consistorial system of 1808.

In Israel the chief rabbinate is based on the Religious Community ordinance of 1926, which conferred religious authority upon the rabbinical council headed by two chief rabbis, one belonging to the Sephardic, the other to the Ashkenazic section of the Jewish community.

See Louis Finkelstein, ***The*** *Beliefs* and *Practices of Judaism,* rev. ed. (1952). **(J. M.** RL.)

RABBIT, a well-known rodent, formerly called cony, The rabbit, *Oryctolagus cuniculus,* is a member of the family Leporidae *(see* RODENTIA). From the hare (*q.v.*) the rabbit is distinguished by its smaller size, shorter ears and feet, absence of black on the ears and gray colour; by the facts that the young are born naked and blind and that it lives in burrows in the ground. It breeds from four to eight times a year, a litter comprising three to eight young. It begins to breed at the age of six months and lives seven or eight years.

Originally inhabiting the western half of the Mediterranean basin, the rabbit spread, partly by the agency of man, throughout temperate Europe, and it is still extending its range. Introduced into New Zealand and Australia, where natural enemies were few. it increased beyond bounds until it became an unmitigated nuisance. The name rabbit is loosely used to include many members of the family Leporidae, especially in North America *(see* HARE).

The rabbit has long been domesticated, and the variations produced are greater than in any other mammal except the dog (*q.v.*). For not only has the weight been quadrupled and the structure of the skeleton modified, but the proportionate size of the brain has been reduced (cf. the domestic duck) and the colour and texture of the fur remarkably altered. The old English lop-eared breed may have ears 23 in. from tip to tip and 6 in. in width. The hardy and prolific Belgian hare resembles the true hare in colour and form. while a similar but larger variety is the (so-called) Patagonian rabbit. The Angora rabbit has very long fur, which is of commercial value; the most valued variety is the albino. The Dutch breed is small and particoloured, being dark posteriorly and white anteriorly. The silver gray is esteemed for its skin, while the Flemish giant is the biggest of all breeds.

Modern dressing and dyeing methods have developed rabbit fur (known to the fur trade as "coney") into the most satisfactory of low priced furs for wearing qualities. Because it lends itself readily to dyeing, it is used in great quantities in imitation of such furs as squirrel, seal, beaver, nutria, chinchilla, muskrat, ermine. leopard and still others.

Various tame varieties of rabbits, which are heavier and have a fur stronger and less liable to shed. are raised especially in Belgium and France, to supply the demand. Because of the excellent felting properties of rabbit fur it now forms the largest proportion of fur going into the manufacture of felt hats. Forty to fifty rabbit skins furnish material for a dozen hats. Rabbit fur is also in demand for upholstery purposes. The supply of rabbits for the hat industry comes chiefly from Australia (which for some years averaged 70,000,000 skins annually), New Zealand, Belgium, France and England.

RABBŪLĀ, a distinguished bishop of the Syrian church early in the 5th century. He was a native of Kenneshrin, a town some few miles south of Aleppo and the seat of a bishopric. He resided for some time in a monastery, and then passed to a life of greater hardship as a solitary hermit. On the death of Diogenes, bishop of Edessa, in the year 411–412, Rabbiila was-chosen his successor. On one occasion he visited Constantinople and there preached before Theodosius II. (who was then favourable to Nestorius) and a great congregation a sermon in denunciation of Nestorian doctrine, of which a portion survives in the Syriac version. He became the friend of Cyril of Alexandria, with whom he corresponded, and whose treatise *De recta fide* he translated into Syriac. The version survives in a British Museum ms.; ***see*** Wright's *Catalogue* p. 719. He died in August 435.

RABELAIS, FRANÇOIS (*c.* 1495–1553), French author, was born at Chinon on the Vienne in the province of Touraine The date of his birth is uncertain: it has been put by tradition and by authorities lonq subsequent to his death. as 1483. 1490 and 1495. It is said that he had four brothers and no sisters, that his father had a country property called La Devinière. and was either an apothecary or a tavern keeper. An indistinct allusion of his own has been taken to mean that he was tonsured in childhood at seven or nine years; and tradition says that he was sent to the convent of Seuilly. From Seuilly at an unknown date tradition takes him to the convent school of La Baumette near Angers. where he is supposed to have been at school with the brothers Du Bellay, with Geoffroy d'Estissac and others. He certainly entered the Franciscan monastery of Fontenay le Comte some time before April 5, 1519, by which date he held a position sufficiently senior to sign deeds for the community. Rabelais in all probability became disgusted with the cloister—indeed his great work shows this beyond doubt. In 1524 his friend Geoffroy d'Estissac procured from Clement VII an indult, licensing a change of order and of abode for Rabelais. From a Franciscan he became a Benedictine. and from Fontenay he moved to Maillezais, of which Geoffroy d'Estissac was bishop. But even this learned and hospitable retreat did not apparently satisfy Rabelais. In or before 1530 he left Maillezais, abandoned his Benedictine gdrb for that of a secular priest. For a time the Du Bellays provided him with an abode near their own château of Langey, but on Sept. 17, 1530. he entered the faculty of medicine at the University of Montpellier. becoming bachelor on Nov. 1, a remarkably short interval, which shows what was thought of his acquirements. Early in 1531 he lectured publicly on Galen and Hippocrates, and his stay at Montpellier, which lasted rather more than a year at first, was renewed at intervals for several years.

In 1532 he had moved to Lyons. He was appointed before the beginning of November physician to the Hôtel Dieu and lectured on anatomy with demonstrations from the human subject. He edited for Sebastian Gryphius, in 1532, the medical *Epistles* of Giovanni Manardi. the *Aphorisms* of Hippocrates, with the *Arr Parva* of Galen. and an edition of two supposed Latin documents, which happened to be forgeries.

At this time Lyons was the centre of an unusually enlightened society, and indirectly it is clear that Rabelais became intimate with this society. At this time probably appeared the beginnings of the work which was to make Rabelais immortal. The earliest known and dated edition of *Pantagruel* is of 1533, of *Gargantua* 1535. Besides this, 1533 saw the publication of an almanac, the first of a long series which exists only in titles and fragments, and of the amusing *Prognostication Pantagrueline.* Both this and *Pantagruel* itself were published under the anagrammatic pseudonym of "Alcofribas Nasier," shortened to the first word only in the case of the *Prognostication.*

On Oct. 23, 1533, *Pantagruel* was condemned by the Sorbonne. and in Jan. 1534 Jean du Bellay. passing through Lyons on an embassy to Rome, engaged Rabelais as physician. The visit did not last very long, but it left literary results in an edition of a description of Rome by Marliani, which Rabelais published in Sept. 1534.

In the spring of 1535 the authorities of the Lyons hospital. considering that Rabelais had twice absented himself without leave. elected Pierre de Castel in his place; but the documents do not imply any blame and the appointment of his successor was once definitely postponed in case he should return. In the summer of 1535 Rabelais once more accompanied Jean du Bellay, now a cardinal, to Rome, and stayed there till April in the next year To this period belong letters to Geoffroy d'Estissac and the bull of absolution which freed Rabelais from ecclesiastical censure, gave him the right to return to the order of St. Benedict when he chose. and to practise medicine. He took advantage of this bull and became a canon of St. Maur. In 1537 he took his doctor's degree at Montpellier and lectured on the Greek text of Hippocrates, and in July 1538 he was present in the capacity of *maître des requites* at the conference between Francis I and Charles V at Aigues-Mortes. In 1540 he was for the third time in Italy in the service of Guillaume du Bellay-Langey, elder brother of Jean, who was governor of Piedmont; and according to the letters of Pellicier, bishop of Montpellier and ambassador to Venice, Rabelais was then employed by him to collect manuscripts for the king's library. In Dec. 1540 he was compelled to return to France to clear himself of a charge of having revealed diplomatic secrets, but he rejoined Guillaume du Bellay at Turin in the following spring, and remained in hi5 service until he died on Jan. 9, 1543. Rabelais wrote a panegyrical memoir of Guillaume, which is lost. and the year before saw the publication of an edition of *Gargantua* and *Pantagruel,* book i, together (both had been repeatedly reprinted separately), in which some dangerous expressions were cut away. Nothing at all is known of his life, whereabouts, or occupations till the publication of the third book, which appeared in 1546, *avec privilège du roi,* which had been given in Sept. 1545.

Up to this time Rabelais, despite the condemnation of the Sorbonne referred to above, had experienced nothing like persecution or difficulty. Even the action of Dolet, who in 1542 reprinted the earlier form of the books which Rabelais had just slightly modified, seems to have done him no harm. But the storm of persecution which towards the end of the reign of Francis I was fatal to Dolet himself and to Des Périers, while it exiled and virtually killed Marot, threatened him. It is certain that he passed nearly the whole of 1546 and part of 1547 at Metz in Lorraine as physician to the town at the salary of 120 livres, and Sturm speaks of him in a contemporary letter as having been "cast out of France by the times," and says that he himself in another letter gives a doleful account of his pecuniary affairs and asks for assistance. At Francis's death on March 31. 1547, Du Bellay went to Rome, and at some time not certain Rabelais joined him. In 1549 a monk of Fontevrault, Gabriel du Puits-Herbault, made in a book called *Theotimus* the first of the many attacks on Rabelais. It is, however, as vague as it is violent, and it does not seem to have had any effect. Rabelais had indeed again made for himself protectors whom no clerical or Sorbonnist jealousy could touch. Rabelais was able to return to France, and in 1550 was presented to the livings of Meudon and St. Christophe du Jambet. There is very little ground for believing that the "curé of Meudon" ever officiated or resided there. He certainly held the living for less than three years, resigning it in Jan. 1553 with his other benefice, and at the episcopal visitation of 1551 he was not present.

Some chapters of Rabelais's fourth book had been published in 1548, but the whole did not appear till 1552. The Sorbonne censured it and the *parlement* suspended the sale, taking advantage of the king's absence from Paris. But it was soon relieved of the suspension. He died, it is said, on April 9. 1553, but actual history is quite silent save on the point that he was not alive in May of the next year, and the legends about his deathbed utterances—"La farce est jouée," "Je vais chercher un grand peut-être," etc.—are altogether apocryphal.

Ten years after the publication of the fourth book and nine after the supposed date of the author's death there appeared at Lyons 16 chapters entitled *l'Île sonnante par maistre François Rabelais,* and two years later the entire fifth book was printed as such. In 1567 it took place with the others and has ever since appeared with them although from the beginning of the 17th century its authenticity has been disputed.

Gargantua and **Pantagruel.**—Rabelais's works are so little read that some sketch of their contents is necessary. The first book, *Gargantua,* describes the birth of that hero (a giant. the son of gigantic parents), whose nativity is ushered in by the account of a tremendous feast. In this the burlesque exaggeration of the pleasures of eating and drinking, which is one of the chief exterior notes of the whole work. is pushed to an extreme. Early. however. the author becomes serious in contrasting the early education of his hero—a satire on the degraded schools of the middle ages—with its subsequent and reformed stage, in the account of which all the best and noblest ideas of the humanist Renaissance in reference to pedagogy are put with exceptional force. Gargantua is recalled from Paris, whither he had been sent to finish his education, because of a war between his father, Grandgosier, and the neighbouring king, Picrochole. This war is described at great length, the chief hero of it being the monk Friar John, an unclerical cleric in whom Rabelais greatly delights. Picrochole defeated and peace made. Gargantua establishes the abbey of Thelema in another of Rabelais's most elaborate literary passages, where all the points most obnoxious to him in monastic life are indicated by the assignment of their exact opposites to this model convent. The second book introduces the principal hero of the whole, Pantagruel, Gargantua's son, who goes through something like a second edition of the educational experiences of his father. Like him, he goes to Paris, and there meets with Panurge, the principal triumph of Rabelaisian character drawing, and the most original as well as puzzling figure of the book. Panurge has almost all intellectual accomplishments but is totally devoid of morality. This book, like the other, has a war in its latter part; Gargantua scarcely appears in it and Friar John not at all. It is not till the opening of the third book that the most important action begins. This arises from Panurge's determination to marry—a determination, however, which is halfhearted and which leads him to consult a vast number of authorities, each giving occasion for satire of a more or less complicated kind. At last it is determined that Pantagruel and his followers (Friar John has reappeared in the suite of the prince) shall set sail to consult the oracle of the *Dive Bouteille.* The book ends with the most obscure passage of the whole, an elaborate eulogy of the "herb pantagruelion," which appears to be. if it is anything, hemp. Only two probable explanations of this have been offered, the one seeing in it an anticipation of Joseph de Maistre's glorification of the executioner. the other a eulogy of work, hemp being on the whole the most serviceable of vegetable products for that purpose. The fourth and fifth books are entirely taken up with a description of the voyage. Many strange places with stranger names are visited, some of them offering obvious satire on human institutions, others, except by the most farfetched explanations, resolvable into nothing but sheer extravaganza. At last the Land of Lanterns, borrowed from Lucian, is reached, and the oracle of the bottle is consulted. This yields the single word "Trinq," which the attendant priestess declares to be the most gracious and intelligible she has ever heard from it. Panurge takes this as a sanction of his marriage, and the book ends abruptly. This singular romance includes the most bewildering abundance of digression, burlesque amplification, covert satire on things political, social and religious, miscellaneous erudition of the literary and scientific kind. Everywhere the author lays stress on the excellence of "Pantagruelism," and the reader who is himself a Pantagruelist (it is perfectly idle for any other to attempt the book) soon discovers what this means. It is, in plain English, humour, which may be said to consist in the extension of a wide sympathy to all human affairs, together with a comprehension of their vanity.

Moroseness and dogmatism are as far from the Pantagruelism of Rabelais as maudlin sentimentality or dilettantism. Perhaps the chief things lacking in his attitude are, in the first place,.reverence, of which, however, from a iew passages, it is clear he mas by no means totally devoid and, secondly, an appreciation of passion and poetry.

Interpretation and Criticism—In interpreting and criticizing Rabelais's works three questions must be discussed: What is the general drift and purpose of *Gargantua* and *Pantagruel,* supposing there to be any? What defense can be offered, if any is needed, for the extraordinary licence of language and imagery which the author has permitted himself? What mas his attitude toward the great questions of religion, philosophy and politics?

According to some expositors. Rabelais is a sober reformer, an apostle of sound education, of rational if not dogmatic religion, who wraps up his morals in a farcical envelope partly to make them go down with the vulgar and partly to shield himself from the consequences of his reforming zeal. According to others, Rabelais is all this but with a difference. He is not religious at all; he is more or less antireligious and his book is more or less oi a general protest against any attempt to explain supernaturally the riddle of the earth. According to a third class, the Rabelaisian legend does not so much err in principle as it invents in fact. Rabelais is the incarnation of the "esprit Gaulois," a jovial, careless soul. not destitute of common sense or even acute intellectual power, hut first of all a good fellow, rather preferring a broad jest to a fine-pointed one and rollicking through life like a good-natured undergraduate. But it is impossible to think that any unbiased judge reading Rabelais can hold the grave-philosonher view or the reckless-goodfellom view without modifications and aliowances which practically deprive either of any value Those who identify Rabelais with Pantagruel strive in vain to account for the vast ocean of pure or impure laughter and foolery which surrounds the few solid islets of sense and reason and devotion. Those who identify Rabelais with Panurge can never explain the education scheme, the solemn apparition of Gargantua among the farcical and fantastic variations on Panurge's wedding and many other passages; while, on the other hand, those who insist on a definite propaganda of any kind must justify themselves by their own power of seeing things invisible to plain men.

In only two points can Rabelais he said to be definitely polemic. He hated the monkish system as it existed in his time; he as certainly hated the brutish ignorance into which the earlier systems of education had suffered too many of their teachers and scholars to drop. At these two things he was never tired of striking, but elsewhere, even in the grim satire of the *Chats fourrés*, he is the satirist proper rather than the reformer. It is in the very absence of any cramping or limiting purpose that the great merit and value of the book consist. It holds up an almost perfectly level and spotless mirror to the temper of the earlier Renaissance. The author has no universal medicine of his own (except Pantagruelism) to offer, nor has he anybody else's universal medicine to attack. It is not indeed possible to deny that in the oracle of the bottle, besides its merely jocular and fantastic sense, there is a certain "echo," as it has been called, "of the conclusion of the preacher," a certain acknowledgment of the vanity of things; but it is little more than a suggestion, and is not strengthened by anything in the body of the work. Rabelais is, in short, if he be read without prejudice, a humorist pure and simple, feeling often in earnest, thinking almost always in jest.

If this general view is correct it will probably condition to some extent the answer to be given to the two minor questions stated above. The first is connected with the great blemish of *Gargantua* and *Pantagruel*—their extreme coarseness of language and imagery. Rabelais's errors in this way are of course, looked at from an absolute standard, unpardonable. But judged relatively there are several, we shall not say excuses, but explanations of them. In the first place, his comparative indecency has been much exaggerated by persons unfamiliar mith early French literature. The form of his book was above all things popular, and the popular French literature of the middle ages as distinguished from the courtly and literary literature, which was singularly pure, can hardly be exceeded in point of coarseness. Moreover, Rabelais's coarseness, disgusting as it is, has nothing of the corruption of refined voluptuousness about it, and nothing of the sniggering indecency which disgraces men like Pope, like Voltaire, and like Sterne. The general taste having been considerably refined since, Rabelais has in parts become nearly unreadable—the worst and most appropriate punishment for his faults. As for those who have tried to make his indecency an argument for his laxity in religious principle, that argument hardly needs discussion. It is notoriously false as a matter of experience.

This brings us to the last point—what his religious opinions were. He has been claimed as a freethinker of all shades, from undogmatic theism to atheism, and as a concealed Protestant. The last of these claims has now been very generally given up, but the accusation of freethinking, if not of directly anti-Christian thinking, has always been more common. Those who hold this opinion, however, never give chapter and verse for it, and it may be said confidently that chapter and verse cannot be given. The sayings attributed to Rabelais which colour the idea are purely apocryphal. Even a jest at the Sorhonne couched in the Pauline phrase about "the evidence of things not seen," was removed by the author from the later editions. It must be remembered that the later middle age, which in many respects Rabelais represents almost more than he does the Renaissance, was, with all its unquestioning faith, singularly reckless and, to our fancy, irreverent in its use of the sacred words and images. On the other hand, there are in the book expressions which either signify a sincere and unfeigned piety of a simple kind or else are inventions of the most detestable hypocrisy. For these passages are not, like many to be found from the Renaissance to the end of the 18th century, obvious flags of truce to cover attacks—mere bowings in the house of Rimmon to prevent evil consequences. They are always written in the author's highest style, a style perfectly eloquent and unaffected; they can only be interpreted (on the freethinking hypothesis) as allegorical with the greatest difficulty and obscurity, and it is pretty certain that no one reading the book without a thesis to prove mould dream of taking them in a nonnatural sense. There is absolutely nothing within the covers of Rabelais's works incompatible mith an orthodoxy which would he recognized as sufficient by Christendom at large, leaving out of the question those points of doctrine and practice on which Christians differ. Beyond this no wise man will go, and short of it hardly any unprejudiced man mill stop.

BIBLIOGRAPHY.—The first complete edition of Rabelais was published by Jean Martin (1567). By 1600 about 60 editions had been published (P. P. Plan, *Biblio. rabelaisienne,* 1532–1711, 1904). The first important critical edition mas that of Le Duchat (1711). Eloi Johanneau published an elaborate edition in nine volumes (1823–26). Later editions and commentaries have been numerous.

Monographs on Rabelais include those by E. Noel (1850); A. Mayrargues (1868); J. Fleury (1876); P. Stapfer (1889); H. Hatzfeld (1923);.Jean Plattard, *La vie de François Rabelais* (1929), Eng. trans. by Louis Roche (1930); L. Sainéan, *La langue de Rabelais,* 2 vol. (1922–23), *L'influence et la reputation de Rabelais* (1930); P. Villey, *Les grands écrivains du XVI siècle, Rabelais et Marot* (1923); J. Boulenger, *Rabelais à travers les ages,* with bibliography (1925); W. Nicati, *Rabelais notre maître; son oeuvre, sa doctrine, le Pantagruelisme* (1926); G. Lote, *La vie et l'oeuvre de François Rabelais* (1938); and P. Jourda, *La Gargantua de Rabelais* (1948). *See* also *Revue des études rabelaisiennes* (1903–12), continued after 1913 as *Revue du seizième siècle.*

Sir Thomas Urquhart translated the first two volumes of Rabelais into English in 1653; his work reproduced the spirit of the original with remarkable felicity, and was recognized by many as a masterpiece of translation. In 1693 Pierre Motteux republished the two volumes with a long commentary and added the third volume which Urquhart had not completed. Later Motteux translated the last two volumes of Rabelais. W. F. Smith made a new translation of the five books and minor writings in 1893; a second edition of this work appeared in 1934. Other English translations were made by Samuel Putnam, 3 vol. (1929) and by Jacques Le Clercq, 5 vol. (1942).

Wilson, *Francis Rabelais; the Man and His Work* (1929); H. Brown, *Rabelais in English Literature* (1934); J. C. Powys, *Rabelais, His Life* (1948); and Mary P. Willcocks, *Laughing Philosopher* (1951).

RABI, ISIDOR ISAAC (1898–), U.S. physicist, invented in 1937 the atomic and molecular beam magnetic resonance method for observing spectra in the radio-frequency range. Subsequent development of several spectroscopic methods over a wide frequency range depended greatly on Rabi's pioneering work, for which he was awarded the Nobel prize in 1944. The importance of the work lies in the fact that a number of fixed mechanical and magnetic properties and the shape of a nucleus in an atom or molecule may be deduced from the observations of radio-frequency spectroscopy (*q.v.*). The observations also yield detailed information about the structure of atoms and molecules.

Born in Rymanow, Aus., on July 29. 1898, and raised in the United States. Rabi received a Ph.D. degree from Columbia university in 1927, joined its faculty in 1929 and became professor of physics in 1937. After he spent the year 1928 in Germany in the 'laboratory of Otto Stern, who had done important work with atomic beams, Rabi's continuing work in this field brought refinements in experimental technique and increasing insights into atomic phenomena. After 1940 he was active in research administration. and dealt with the relationships of scientific inquiry and its technological consequences to national and international affairs. From 1940 to 1945 he was associate director of the Radiation laboratory of the Massachusetts Institute of Technology, Cambridge, Mass., for the development of microwave radar. After World War II Rabi served on various government scientific committees, including the general advisory committee of the U.S. Atomic Energy commission. He was also a U.S. representative to UNESCO and was instrumental in arranging the 1955 Geneva conference on the peaceful uses of atomic energy, of which he was a vice president. (P. KH.)

RABIES (HYDROPHOBIA) is an acute, ordinarily fatal, infectious disease of the central nervous system caused by a virus and is, as a rule, propagated in domestic dogs and wild carnivorous animals such as the wolf, jackal, coyote, fox, mongoose and skunk. Rabies is propagated by vampire bats and insectivorous bats in some regions. Man and all warm-blooded animals are susceptible to infection with rabies.

History.—Rabies has been known in Europe and Asia since ancient times. The period of summer reckoned by the heliacal rising of the dog star, Sirius, has since antiquity been referred to as "dog days," when dogs are supposed to be especially liable to spells of madness. The people of ancient Egypt, Greece and Rome ascribed rabies to evil spirits because ordinarily docile and friendly animals developing this disease became suddenly vicious and aggressive without evident cause and, after a period of maniacal behaviour, developed paralysis and died. Aristotle (d. 322 B.C.) recognized the relationship of hydrophobia in man to rabies in animals and recommended cauterization of wounds produced by rabid dogs.

The transmission of rabies from a rabid dog to a normal dog by the inoculation of saliva was accomplished by Zinke (1804), by Griiner and by Salm-Reifferscheidt (1813). These experimental studies showed that the disease was infectious, and on the basis of this evidence it was assumed that destruction of stray ownerless dogs and quarantine of other domestic dogs would eliminate the disease. Sanitary measures including these provisions were adopted in Norway, Sweden and Denmark, and by 1826 these countries were free from rabies and remained so. Rabies was eliminated from some urban centres in continental Europe during the 19th century, but after a few years these areas frequently became reinfected, since rabies was established among the wild animals.

Nature of the Disease.—The disease often begins with such symptoms of excitation of the central nervous system as irritability and viciousness. During the early stages of the disease a rabid animal is most dangerous because it appears to be healthy and may seem friendly but will bite at the slightest provocation. Wild animals which appear to be tame and approach man or human habitation in daytime should be suspected of having rabies. The virus is often present in the salivary glands of rabid animals and is excreted in the saliva, so that the bite of the infected animal introduces the virus into a fresh wound. Under favourable conditions, the virus becomes established in the central nervous system by propagation along nerve tissue from the wound to the brain. When infection occurs, the disease develops most often between four and six weeks after exposure, but the incubation period may vary from ten days to at least eight months.

Bat Rabies.—A variety of rabies propagated by the vampire bat. Desmodus *rotundus murinus* Wagner, is known as paralytic rabies, paresian rabies, *mal* de *caderas* and derriengue. Although the disease symptoms produced by this virus differ from those of rabies contracted from dog bite, they are varieties of the same disease. One vaccine will protect against all types of rabies. In the vampire bat the rabies infection sometimes is limited to the salivary glands so that the animal can transmit rabies by bite for a period of several months without exhibiting symptoms of illness. This animal lives on blood alone and feeds by biting and lapping up the blood after inflicting a craterlike wound with its sharp incisor teeth. Therefore it does not need to become vicious in order to transmit rabies. Vampire bats are found only in Mexico, Central America and South America. The occurrence of epizootics of cattle rabies in Brazil, Trinidad and Mexico, in regions where dog rabies was rare or unknown, stimulated research on rabies during the period 1931–44 which resulted in the discovery that rabies exists as an enzootic disease of vampire bats in these countries. Rabies is found also in fruit-eating and insect-eating bats. Bats found flying in daytime or which try to attack and bite are likely to be infected with rabies.

Dog Rabies.—Dog rabies is commonly classified as furious rabies or dumb rabies, depending on the signs shown by the animal. In the former type the excitation phase is prolonged. while in the latter the paralytic phase is present from the beginning or develops early. Most infected dogs show some manifestations of each type. that is, a short excitation phase characterized by restlessness, nervousness, irritability and viciousness, followed by depression and paralysis. Sudden death from rabies, without recognizable signs of illness, is not uncommon. Dogs that develop the predominantly excited type of rabies invariably die of the infection, usually within three to five days after the onset of symptoms. Dogs developing the paralytic type of rabies without any evidence of excitation or viciousness may in rare instances recover from the infection. The symptom of hydrophobia or fear of water does not occur in dogs, but difficulty in swallowing is a common symptom of dog rabies. The paralysis of the muscles of phonation in rabid dogs often produces a characteristic change in the bark. There is no characteristic seasonal incidence of dog rabies.

Hydrophobia or Human Rabies.—Rabies in man is similar to the disease in animals. The excitation phase may continue until death occurs during a convulsive seizure. More often, symptoms of depression of the central nervous system develop before death. The hydrophobia symptom consists of repeated episodes of painful contraction of the muscles of the throat on attempting to swallow. This symptom may be elicited by the sight of water because of the association of water with the act of swallowing, hence the fear of water or hydrophobia. Rabies in man is uniformly fatal when associated with excitation of the nervous system and the hydrophobia symptom. Death ordinarily occurs within three to five days after the onset of symptoms. Abnormal sensations about the site of exposure are a common early symptom of rabies. Sometimes the disease is characterized by paralysis without any evidence of excitation of the nervous system. In such cases the disease may be prolonged to a week or more and recovery does occur on rare occasions. Human rabies contracted from the bite of vampire bats is uniformly of the paralytic type and the hydrophobia symptom does not occur. Rabies virus is often present in the saliva in human rabies and saliva specimens are examined for rabies virus by the mouse inoculation test.

Diagnosis.—Inclusion bodies, first described by A. Negri (1903), are found in the nerve cells of the brain of animals that die of rabies. They are not always present but a prompt diagnosis of rabies can be made in about 90% of the cases of furious rabies in dogs by demonstration of Negri bodies in the brain tissue after the animal dies. Negri bodies are found more frequently in those animals that show symptoms of viciousness for several days before they die of rabies. They are a specific reaction product and not a visible form or conglomerate of virus particles. Negri bodies are not found in the brains of animals infected with fixed varieties of rabies virus (see below).

The mouse test for rabies virus consists of intracerebral inoculation of mice with aqueous extracts prepared from brain tissue, salivary gland tissue or diluted saliva from cases of suspected rabies. Mice are uniformly susceptible to infection with rabies virus when thus inoculated and ordinarily sicken and die about one week after inoculation. The diagnosis of rabies is confirmed by demonstration of Negri bodies in the brain tissue.

Treatment.—Investigation by *Pasteur*.—The discovery by Louis Pasteur (1881) that the infective agent of rabies could be recovered in a relatively pure state from the brain of an animal that died of the disease opened the way for an extensive study of rabies. Since the infective agent as obtained from brains of rabid animals could not be identified by microscopic examination and could not be cultivated in nutrient mediums used for the growth of ordinary bacteria, it was called virus, from the Latin word for poison. The ultramicroscopic nature of some disease-producing organisms was first postulated by Pasteur. He was also the first to modify the pathogenicity of a virus for its natural host by serial intracerebral passage in another host. In an attempt to develop a variety of rabies virus which could be used safely for vaccination, he passaged the virus of rabies intracerebrally in rabbits. This resulted in the development of an infection characterized by a short, fixed incubation period; this modified virus was called fixed, to distinguish it from the natural, or so-called street virus. After 100 passages in rabbits, the fixed virus had little capacity to infect dogs when given by subcutaneous inoculation. By means of a series of ten daily subcutaneous injections of fixed virus, graded from no infectivity to maximum infectivity by drying infected rabbit spinal cord tissue at room temperature for various time periods, dogs were made resistant to experimental infection with the natural street virus. During 1885, a peasant boy who had been severely bitten by a rabid dog was taken to Pasteur, and, in view of the serious nature of the exposure and the plea that something be done, the boy was vaccinated in a manner similar to that used for immunization of dogs, the theory being that, if dogs could be immunized in a two-week period so that they would resist infection with the natural virus, the long incubation period of rabies in human beings would allow the development of a high grade of immunity before the potential onset of the disease. The treatment appeared to be without ill effect and the boy remained well, This became known and other persons were taken to Pasteur for treatment; soon the vaccine treatment for rabies was adopted as a routine procedure in medical centres throughout the world. The mortality from rabies was reduced from about 9% for all types of bites by rabid dogs to less than 0.5%. In rare instances the vaccine treatment will not prevent the onset of rabies, because the virus produces the disease before an adequate immunity is achieved by vaccination.

Vaccine Treatment (Active Immunization).—There have been many modifications of the Pasteur method of vaccination with live fixed virus vaccine. C. Fermi (1908) was the first to use chemical treatment—with phenol—of the fixed virus in the preparation of the vaccine. Later D. Semple (1919) showed that by incubation of the phenol-treated fixed virus at 37° C. it could be killed and still retain its capacity to immunize. A variety of chemical and physical methods have been used for inactivating fixed virus for the preparation of rabies vaccine. The commonly employed vaccines are the live fixed virus (Pasteur strain), the killed-virus vaccines of the Semple type and the U.V. (ultraviolet light treated) type. The vaccine treatment consists of 7 or 14 daily injections, depending on the severity of the exposure to rabies.

Serum Treatment (Passive Immunization).—V. Babès and Lepp (1889) introduced the serum treatment whereby animals are immunized with fixed rabies virus and the blood serum of these animals is injected into exposed persons to give them temporary immunity to rabies. This treatment is most effective if given within 24 hours after exposure. It has little value, if any. when given three or more days after exposure to rabies. A combination of serum and vaccine treatment is given in cases of severe exposure to rabies. Immediate treatment of animal bite wounds by cleansing with soap and water is important because much, if not all, of the virus can be removed thus. Chemical treatment is to be avoided before the wound is seen by a physician.

Control of Dog Rabies.—Dog rabies can be eliminated by enforcement of quarantine regulations for dogs, except in those regions where rabies is present in wild animals. Rabies has been kept out of Australia, Great Britain, Denmark, Norway, Sweden and the Hawaiian Islands by enforcement of quarantine regulations for imported dogs. The fact that dogs have developed rabies while under quarantine in these countries, and the development of rabies in dogs eight months after their arrival in Great Britain, makes it certain that the virus can remain latent in an exposed dog for at least this period of time. The eradication of rabies from Great Britain (1903) was accomplished with great difficulty and with much opposition from the dog-owning public because the quarantine regulations for dogs had to be maintained for several years before the disease disappeared. The vaccination of dogs, when combined with the collection of ownerless dogs, will eliminate dog rabies. The single-dose vaccination for dogs with Semple-type vaccine combines in one dose the amount of killed fixed virus ordinarily given in a complete course of vaccine treatment for persons bitten by rabid animals. The avianized live virus vaccine (Flury strain) is a fixed virus modified by serial intracerebral passage in one-day-old chickens and by prolonged cultivation in chicken embryos. This live virus vaccine is used for immunization of dogs and a single injection of the vaccine will produce good immunity for at least three years following vaccination.

RACAN, HONORÉ DE BUEIL, MARQUIS DE (1589–1670), French poet, became page at the court of Henry IV. and then entered the army, seeing some active service. In 162j he published his most important work, Bergeries, a dramatic pastoral. Racan was a follower of Malherbe, and was one of the original members of the French Academy. He died in February 1670.

His Oeuvres *complètes* which include versions of the Psalms and sacred odes, were edited *by* Tenant de Latour in 1857, and the edition includes a biographical notice. See Sainte-Beuve, Causeries *du lundi.*

RACCOON, the typical representative of a family (Procyonidae) of American arboreal Carnivora (see CARNIVORE) The raccoon has a curious habit of washing its food in water before rating it The typical raccoon (Procyon *lotor*) is a thickly built animal about 3 ft. long, of which the tail is 10 in., with a coat of long coarse grayish-brown hairs, short ears and a bushy black-and-white-ringed tail. It extends over the whole of the United States and reaches northward to southern Canada and southward into Mexico where it attains its maximum size. The following are from C. Hart Merriam's The Mammals of the Adirondacks:

> Raccoons are omnivorous beasts and feed upon mice, small birds, birds' eggs, turtles and their eggs, frogs, fish, cray fish, molluscs, insects, nuts, fruits, maize, and sometimes poultry. Excepting alone the bats and flying-squirrels, they are the most strictly nocturnal of all our mammals. . . . They haunt the hanks of ponds and streams, and find much of their food in these places, such as crayfish, mussels, and fish, although they are unable to dive and pursue the latter under water. . . . They are good swimmers. . . . The raccoon hibernates during the severest part of the minter. . . . It makes its home high up in the hollow of some large tree, preferring a dead limb to the trunk itself. . . . From four to six young are . . . born at a time. . . . The young remain with the mother about a year.

The South-American species, P. *cancrivorus,* the crab-eating raccoon, differs by its shorter fur, larger size, more powerful teeth, and other minor characters. It extends over most of South America, as far south as northern Argentina.

RACE RELATIONS: see INTERRACIAL RELATIONS.

RACES OF MANKIND. The study of the varieties of the human race has occupied the attention of thinkers from early times. Two entirely different forms of classification have been employed, one based on the study of the skull, the second, and more generally used method, on superficial characters, such as skin and hair, which may be observed on the living man. To some extent these two methods have been combined in modern times.

Cranial Form.—Apart from Sergi, who elaborated a method of classification based on cranial *form,* the shape being estimated by viewing the skull from on top, most anthropologists have preferred to take measurements, especial importance being attached to the cephalic index—the percentage ratio of the length to the breadth—but numerous other measurements have been made, mostly of little value for classification. W. L. H. Duckworth suggested the combination of three characters on the skull, the cranial capacity, the cephalic index and the degree of prognathism (measured by taking the angle which the most projecting part of the jaw makes with the forehead). On the basis of the possible combinations of these criteria Duckworth divided mankind into seven groups.

Colour Groups.—The oldest grouping of mankind, still in popular use, is that of skin colour. It has been suggested that the degrees in pigmentation of the human skin are due to the effects of environment, either to sunlight or humidity or a combination of both, the evolutionary changes which took place at an earlier date having become part of the heritage of the races we know to-day. Although the darkest skins are to be found in the tropics, whereas the fairest occur in the temperate climate of western Europe, attempts to correlate skin colour and environment break down when specific cases are considered. Some exceptions can be explained by recent immigration, others again, especially in the individual, by racial admixture, for where races are mixed we may find members of the same family who are very ditferently pigmented. On the whole the average value of the skin colour in various groups is correlated with other criteria, which appear to be good bases for classification.

One of the most important of these is the cephalic index. Taking the length as 100, the proportion of the breadth seldom falls below 70 or over 90, and it is usual to describe those peoples with an index below 75 as *dolichocephalic* (long-headed), those above 80 as brachycephalic (short-headed), the intermediate group being *mesocephalic.* Taken by itself, either in the individual or the race, the cephalic index is by no means a certain guide. We find brachycephalic, mesocephalic and dolichocephalic groups in all the greater divisions of mankind.

Hair Form.—On the basis of the form of the hair, mankind may be divided into straight-haired (*leiotrichous*), woolly-haired (*ulotrichous*) and an intermediate group of wavy or curly-haired (cymotrichous). Certain types are difficult to define, but usually the distinction is clear-cut. All types of hair may occur in the same population, where racial admixture has taken place, but normally the variation is slight in the same group.

Straight-haired Groups.—The straight-haired peoples correspond to a large extent to the races called by some writers Mongol or Mongoloid, or "the Yellow-Brown Race." All these peoples possess cheek-bones of a greater or lesser degree of prominence. In most cases the face is flattened, often markedly so. The skin is usually yellow, shading into a coppery yellow or brown on one side, and on the other, especially in women, a pale almost white yellow tinge. In Asia the cephalic index tends to vary between mesocephaly and brachycephaly, with some marked cases of the latter form. In America the Eskimo are dolichocephalic and a wide range of mesocephaly and brachycephaly occurs among the other tribes.

Asiatic Groups.—There are three groups in Asia, a northern or Arctic group, a central group, the Pareoeans (the Dwellers beside the Dawn) and a southern or Proto-Malay, it being possible that the two latter groups, formerly included under the term Southern Mongoloid, should be classed together.

The northern group is rather indeterminate, and includes a number of tribes living in the circumpolar regions of Asia and extending even as far west as northern Scandinavia, where they are represented by the Lapps. Most of these peoples have mixed with other races, to which fact their diversity is due, but they certainly include a mesocephalic and a round-headed subdivision. In eastern Asia at least there is a more northerly group, living in the most easterly ,extension of the continent and a more southerly group, but the difference is probably due to racial admixture, consequent on the intrusion of the peoples who brought in the Turko-Mongol culture from the west and thus divided the northern and central groups of the straight-haired peoples.

In Korea there is a narrow belt which forms a connecting link between the northern and the Pareoean peoples. The latter differ most strikingly from their northern neighbours in having less prominent cheek-bones and a broadish nose. In the north of China they are often tall; in the south, where the type is found in greater purity, they are short and more stockily built. The Japanese represent a special variety of this type; they have mixed considerably with the Ainu, and this, at least in some cases, has altered their physical type.

The southern extension of these peoples, the Proto-Malays, are widely spread in south-eastem Asia and in the islands. They have been mixed with the various other peoples of this region and it is often difficult to distinguish them except by their broader heads.

The straight-haired peoples also extend into Central Asia, where they are known as Turks and Mongols. These terms are cultural and linguistic, and cannot be used in a racial sense. Great racial admixture has undoubtedly taken place in this region and much of the population is closely connected with the peoples of the west, but types occur with straight hair and other characters which show affinities with the Arctic group.

Most remote from the straight-haired peoples and showing certain relationships to them are the Polynesians, who live on the islands of the Pacific from Samoa to Easter I. and Hawaii to New Zealand. They probably represent an old mixture between the Proto-Malays and a group of the curly-haired people called Nesiots (islanders, see below), but other admixture has taken place and their position is difficult exactly to determine.

The *Amerinds*.—As regards the American aborigines, for whom the term *Amerind* has become conventionalised, it has been disputed whether they should be considered to belong to one race or not. The Eskimo, who to-day inhabit the Arctic coast of America, with a western extension into Asia, and an eastern into Greenland, once lived as far south as the coast of Massachusetts, and survived near Quebec till comparatively recent times. They differ from the other inhabitants of America in many respects notably in having extremely long skulls (the western Eskimo differ somewhat in this respect), which are compressed laterally and are very high-pitched. They have broad faces, an unusual feature in people with a long skull, and very narrow noses. The jaws are exceptionally well-developed and the individual teeth are very large, possibly owing to the nature of their food.

The Amerinds themselves vary considerably in most of those characters usually considered to be of racial significance. Hrdlicka, however, believes that they all belong to the same race. Verneau has recently affirmed the concurrence of types akin to the Melanesians, a view previously held by others also. Haddon suggests with every degree of probability that side by side with the straight-haired peoples there is a cymotrichous type, which he has called Palaeo-Amerinds.

The peoples of the north-west coast are most closely allied to the inhabitants of Asia, and are distinguished from the other Amerinds by their lighter skin colour. East of the Rockies and extending over the great plains and into the woodland area there is a group of tall tribes with mesocephalic heads, of whom the Sioux are a typical example. On the east coast in ancient times there was a different type with longer, narrower heads. On the American plateau and extending into central and southern America there is a round-headed type, of short stature and with straight noses, to whom the Maya of ancient times were akin. The Aztecs were more long-headed and their relationship with the more northerly peoples can be traced through some of the inhabitants of northern Mexico to-day.

The ethnology of South America is as yet not fully established, but several types can be distinguished, one akin to the Maya peoples and a different type, with a round head and tall stature, in Patagonia, of whom the Fuegians are a branch. Side by side with these straight-haired peoples there exist traces of a curly-haired race, both in ancient deposits and also among some modem tribes. With the exception of the Palaeo-Amerinds the distribution of the straight-haired peoples is continuous, the Bering Strait dividing the Asiatic and American branches.

Woolly-haired Groups.—The woolly-haired people have an extremely discontinuous distribution, namely, an eastern habitat which stretches from the continent of Asia to Fiji, and a western, the greater part of Africa. Attempts have been made to bridge this gap. Husing believes that in ancient times short dark curly-haired peoples occurred on the Persian Gulf in localities where negroes are still found. These negroes are, however, the descendants of imported slaves, and there is no information of a definite character to support Hüsing's contention.

In addition to woolly hair all these peoples have the following characters in common: dark skins sometimes almost black, broad noses, usually a rather small brain in relation to their size, especially among the taller members of the group, with forearms and shins proportionately long. In the skeleton there is a smoothness of contour which even in adults often recalls the bony form of a child, and among some members of the group the forehead has that prominent and smooth form which is so characteristic of the infant of our own race. In both eastern and western groups there is a division which includes some very small or pygmy peoples and another of medium or tall-statured tribes.

Eastern Group.—The eastern group may be divided on this basis into the pygmy Negritos and the taller Papuans and Melanesians. The former are all dark-skinned and have heads which are slightly rounded, the cephalic index varying from just under 80 to about 83. There are slight local differences due to the extreme isolation to which these peoples have been subjected. Four separate geographical groups occur, one in the Andaman Islands (the Andamanese), one in the central regions of the Malay Peninsula and eastern Sumatra (the Semang), a third in various parts of the Philippine Is., usually called after a well-known tribe, the Aeta and a fourth group called after a tribe in the western mountains of Dutch New Guinea, the Tapiro, who have left traces in other parts of New Guinea and probably also in parts of Melanesia. All these groups are isolated from one another and occupy as it were almost the circumference of a circle. The Andamanese occupy a very special position, both racially and geographically; they have been isolated for a long period and until recently were not in contact with any other race.

The Papuans and Melanesians are distinguished from the Negritos by their greater stature and narrower heads; the former probably represent the original stock. At one time they had a wide distribution throughout all Melanesia, probably to Australia, and the extinct Tasmanian aborigines seem to have been a variety of this stock. To-day Papuans are found in New Guinea and in some of the most easterly of the Indian Archipelago islands. They may be distinguished from their kinsfolk by their retreating forehead, prominent brow-ridges and the form of their noses, which are often prominent and rounded, with a down-turned tip.

The Melanesians are extremely variable and include a variety of racial elements, though the basis of the stock is Papuan. The racial mixing which has taken place will account for the fact that, although they are usually woolly-haired, all varieties of hair are found. Stature is equally variable, although the average height is under 5 ft. 3 inches. The prominent brow-ridges so characteristic of the Papuans is not common and the nose is usually smaller than in these peoples. The Melanesians have a wide distribution from the coastal regions of New Guinea and the neighbouring islands to the Pacific from New Caledonia to the Admiralty Is., and as far eastwards as Fiji; formerly they seem to have extended over most of the Pacific.

The Bushmen. — The Bushmen, who belong to the second group of the woolly-haired peoples, are also short, though not of pygmy stature; they differ from the other Ulotrichi in having yellowish skins. Now restricted to the Kalahari desert, they formerly ranged over the whole of south Africa and possibly over a much wider area. Their hair is short and curls into little tufts like pepper-corns, giving the appearance of bald patches. The head is small and low and there is little or no forward projection of the jaw. The most distinctive character of the Bushmen is a great development of the buttocks (*steatopygia*); this feature is specially developed in the women. The Hottentots are closely allied to the Bushmen and possess most of the characters already described. They represent a cross between the latter and other negroid stocks.

True Negroes. — The true negroes inhabit the Guinea Coast, but their original range seems to have been over most of tropical Africa. They are tall with black or dark brown skins, long narrow heads and retreating foreheads and prominent jaws. The lips are thickened and everted and the nose is very broad. They have mixed with other elements and have produced hybrid stocks. In the upper Nile valley numerous tribes, called Nilotes, are to be found; they are characterised by a very tall stature, a slender build and extremely narrow heads. There is also a more round-headed strain, due probably to an early admixture with some curly-haired people. Most, if not all, of the Nilotes have been considerably altered by contact with other non-negro peoples.

The Pygmies — In the equatorial forests certain pygmy tribes live. These Negrillos differ from the tall negroes not only in their stature but also in the lighter colour of their skin, which is often yellowish and covered by a light down, and in the more rounded form of the head; the nose is broader even than that of the negro.

Curly-haired Groups. — The third great division of the human race, the curly-haired or Cymotrichous, occupies in many ways an intermediate position between the other two groups. Its distribution is world-wide, and it includes both undifferentiated and highly differentiated groups of mankind. The white races belong to this class. The centre of dispersion of the group was probably somewhere in Asia, but the precise limits of this cradle land have not yet been determined.

The hair varies from wavy to curly, and, whereas in other races it is, with but few exceptions, black or dark brown, in this group every shade occurs from a dead black to a fair straw colour; the brown, however, predominates. The skin colour is equally variable.

Every degree of cephalic index is found, and this still remains the most convenient method of simple classification. The race, however, contains certain sub-races which appear to be more primitive than others and the division into primitive and more advanced groups brings out certain points which may otherwise be overlooked. The primitive which survive are the Proto-Nordics, the Proto-Indics and the Australian aborigines. The Palaeo-Amerinds also probably belong to this class. The more advanced peoples include a dolichocephalic group, a mesocephalic and a brachycephalic group.

Proto-Nordics. — The Proto-Nordics appear at one time to have had a wide distribution over northern Asia. Some of the present inhabitants of the Turkoman steppes present this type in an undifferentiated form, namely the Ainu, who have within comparatively recent times been driven out of the main islands of Japan, and who still inhabit the northern island (Hokkaido) Saghalien, and to the south the Ryukyu islands. This curious people are of medium stature, very stockily built, with large heads and a marked bar across the forehead. They have an abundance of hair on the head and body and long, wavy beards. Their eyes are straight as in Europeans and their general appearance contrasts very strongly with the Japanese who to-day live amongst them.

Proto-Indics.—The Proto-Indics may be classed geographically into three, possibly four, divisions: first, the jungle tribes of southern India (some of the more primitive tribes of northern India also have affinities with this stock); secondly, the Vedda, the most primitive of the inhabitants of Ceylon; and thirdly, some of the more primitive peoples of the southern part of the Malay Peninsula, of whom the best-known are the Sakai and Senoi. In Sumatra and Celebes and possibly elsewhere in the Malay Archipelago there survive tribes who may be considered as a fourth division of the Proto-Indics, but here they have for the most part been mixed with other stocks. In much of south-eastern Asia there is a racial background of Proto-Indics who have been overlaid by other invaders, but the stock has survived in a relatively pure state in the places enumerated above. The Proto-Indics have curly hair, very dark and often nearly dead black skins, a short stature and extremely broad noses.

The Australian Aboriginal. — The Australian aborigines almost certainly belong to the same stock, but they possess some special characteristics which may be due to the length of time they have been isolated from the parent stem. The skin is usually of a dark chocolate brown, the hair, which is somewhat variable but usually curly, is frequently very abundant on the face and body. The stature is medium, the nose very broad, and their most distinctive feature is the great bony development of the skull, including a great massing of bone over the eyes and a big development of the jaws and teeth. Whereas the Proto-Indics, notably the Veddas, have extremely small skulls, those of the Australians, though often containing an extremely small brain-case, are always massively built, and the beetling brows, low forehead and projecting lower part of the face give the males a very characteristic appearance.

Eastern Groups. —The most easterly representatives of these stocks in Asia are the Nesiots, who are found mixed with the straight-haired, round-headed Proto-Malays in the Malay Archipelago, in the Philippines, sporadically in southeastern Asia and in the interior of southern China; the exact extension of these peoples is not yet fully known. In southern India a large proportion of the population belongs to a second group, Chersiots (mainlanders, as opposed to Nesiots, islanders). They are here much mixed with Proto-Indics and round-heads. In the northern part of India the proportion of the round-heads is much greater, and in the northwest the round-headed element predominates. In Rajputana and in the Punjab there is another group of long-heads, to be distinguished from the Chersiots by their taller stature, fairer skins and narrower noses. These Haddon terms Indo-Afghans.

Western Groups. — Further west, in the horn of Africa and the desert between the Nile and the Red Sea, this stock is dominant in the population, though frequently mixed with negroes. These tribes represent the modern descendants of the Proto-Egyptian population. Among the groups of this stock with a white complexion severai varieties may be distinguished: one, the ***Eur-african,*** seems only to occur in isolated spots in north Africa and western Europe, including part of the British Isles, another is met with among the Bedouin Arabs, while the third or Mediterranean race forms the fringing population of the Mediterranean sea and the western Atlantic seaboard of Europe. In the eastern Mediterranean it is inextricably mixed with the Armenoid peoples.

Among the Mesocephals Haddon includes three groups; two, however, the Pyrenean and the Atlanto-Mediterranean are probably hybrids. The third, the Nordic, is more clearly marked and is characterised by fair skin and hair, blue eyes and a tall stature. To-day they form one element in the population of the British

Isles and northern France, Belgium and Holland, and northern Germany. They predominate in Scandinavia.

The Round-headed Group.—The great round-headed branch of the Cymotrichi is conveniently called Eurasiatic. It extends all along the great mountain chain from the central plateau of France on the west to the Himalayas on the east. The Alpine branch of the family is distributed along the central massif of Europe into central and even Eastern Asia, the Armenoid or Illprio-Anatolian has a more limited range in south-eastern Europe and western Asia. They may be distinguished by the extreme flatness and height of the head. In the Pamirs, in Persia, and extensively in central Asia and in India, a separate branch of this race, the Pamiri, is found, while locally in western Europe isolated examples of two early groups, the Prospectatores and the "Beaker Folk" still survive. They probably resulted from early crossing of round-heads with Mediterranean and Nordic man respectively.

All these peoples are marked by the roundness of their heads, their brown, auburn or black hair and somewhat sallow or olive skins. The eyes vary from brown to hazel, but blue eyes are found.

Most of the migratory movements which resulted in the present distribution of mankind took place to? far back in history for us to estimate their exact course, but in all probability human stocks were evolved near the places where we first find them recorded in historic times. Some migrations belong to the domain of ancient history, but it is very doubtful how far these movements have actually affected the physical type. In all probability ethnological history has consisted chiefly of the gradual extension of dominant types. (L. H. D. B.)

RACHEL, MLLE. (ÉLISA FÉLIX) (1820–1858), the great French classical tragedienne, was born at Mumpf, Switz., Feb. 28, 1820, the child of wandering peddlers. She sang on the streets of Lyons and Paris, where her acting ability was quickly discovered by Isidore Samson, who taught her all the technique he had learned from Talma. Rachel studied classical statuary for posture, practised vocal intonations and gestures, performed in many academy plays and at 17 made her debut at the Comédie Française as Camille in Corneille's *Horace.* Press and public acclaimed the new star, who although thin and less than five feet tall dominated the stage with her regal bearing, fiery glances and intense concentration.

Rachel was admired for her pantomime, the feverish excitement she brought to climactic scenes and the evil fascination of some of her characterizations. For 17 years she dictated the policy and program of the Comédie Française, bending its facilities and personnel to her will. Knowing that her genius and drawing power lay in classical plays, Rachel appeared in five by Corneille and seven by Racine, finding her greatest triumph in Racine's *Phèdre.* She was persuaded to join the popular romantic movement and appeared in plays by Hugo, Dumas *père* and De Musset, but of these only *Adrienne Lecouvreur* by Scribe and Legouvé was successfully received.

Rachel toured the provinces regularly and traveled to England, Austria. Russia, Italy, Germany and Belgium. Her United States trip in 1855 failed. Weakened from the constant struggle to maintain her artistic and social eminence, the strenuous touring and the vicissitudes of her notorious private life. Rachel died of tuberculosis on Jan. 3, 1858, and was buried at Pbre Lachaise in Paris.

RACHMANINOFF, SERGEI VASSILIEVITCH (1873–1943), Russian composer and pianist, was born on his father's estate Oneg, near Ilmen Lake. Government of Novgorod, on April 2, 1873. At nine he became a pupil of Demjansky's at the St. Petersburg conservatoire, going three years later to the Moscow conservatoire, where he studied piano under his cousin, Siloti. and composition under Taneiev and Arensky. In 1892 he won a gold medal with his opera *Aleko,* which was favourably received when produced at Moscow, 1893. Concert tours in Russia and elsewhere followed.

In 1899 Rachmaninoff appeared in London as pianist, conductor and composer, and in 1902 he had great success in Vienna. In 1903 he went back to Moscow where he remained for three years as piano professor at the Maryinsky institute, also conducting at the Imperial opera. Subsequently he lived for several years in Dresden where he devoted himself mainly to composition, varied by occasional concert tours.

In 1909 he paid his first visit to the United States, and in 1912–13 he conducted the Moscow Philharmonic Symphony orchestra. After the Russian revolution he escaped to Sweden, with his family, and in 1918 took up his permanent residence in the United States.

Among Rachmaninoff's many compositions, particularly notable are the Second Symphony in E minor, his piano concertos, op. 1, 18 and 30, *Rhapsody on* a *Theme by Paganini,* and *Etudes Tableaux.* His *Recollections,* dictated to his editor, Oskar von Riesmann, was published in 1934.

Rachmaninoff was internationally known for his creative ability as a composer, and for his technique and interpretation as a pianist.

He died in Beverly Hills, Calif., March 28, 1943.

RACINE, JEAN (1639–1699), French tragic dramatist, was born at La Ferté-Milon (Aisne), and was christened on Dec. 22, 1639. His father was a solicitor, and held the office of *contrôleur au grenier à sel* at La Ferté. Racine's mother died when he was little more than a year old and his father married again but himself died soon afterwards, whereupon the child went to his grandparents, who had strong Jansenist leanings. He was sent to the grammar school at Beauvais, and in Oct. 1655 was transferred to the school which the "Solitaires" had established at Port Royal. He was a diligent student, and wrote verse both in Latin and French, his Port Royal odes being far from despicable. In 1658 he was entered at the Collège d'Harcourt, and it is clear from his correspondence, which, as we have it, begins in 1660, that he was not at all of an austere disposition at this time, and that he was already given up irrevocably to literature. The marriage of Louis XIV. was the occasion of an ambitious ode, La *nymphe de la Seine,* which earned 600 livres, and in 1660 Racine finished one piece, *Amasie,* and undertook another, *Les Amours d'Ovide,* for the theatre. The first, however, was rejected by the actors of the Marais, and it is not certain that the other was ever finished. Racine's letters show that he was intimate with more than one actress at this time; he also made acquaintance with La Fontaine, and the foundations of the legendary "society of four" (Boileau, La Fontaine, Molibre and Racine) were thus laid. In Nov. 1661 he went to Uzbs in Languedoc to live with his uncle the Pbre Sconin, vicar-general of that diocese, whose attempts to secure a benefice for him were, however, in vain. Racine was back in Paris before the end of 1663, and an ode on the recovery of Louis XIV. from a slight illness secured him another grant of 600 livres in the summer of 1664. The ode in which he thanked the king for his presents, *La Renommée,* is said to have introduced him to Boileau, to whose censorship he was deeply indebted. Unfortunately there is a break in his correspondence after Nov. 1663, and from this time forward the gossip of the period, and the *Life* by his son Louis, who was only six years old when his father died, are our main sources.

The first but the least characteristic of the dramas by which Racine is known, *La Thébaide,* was played by Molière's company at the Palais Royal theatre on June 20, 1664. In Feb. 1665 the greater part of his second acted play, *Alexandre le Grand,* was read before a distinguished audience at the Hôtel de Nevers, and Molière's company played it on Dec. 4. But a fortnight afterwards *Alexandre* was played, "de complot avec hi. Racine," says La Grange, by the rival actors at the Hôtel de Bourgogne, and Racine's friendship with Molière ended in consequence. If, however, *Alexandre* was the occasion of showing the defects of Racine's character as a man, it raised him vastly in public estimation as a poet. He was now for the first time proposed as a serious rival to Corneille, and the contrast between the two was accurately apprehended and put by Saint Evremond in his masterly *Dissertation sur l'Alexandre,* still the best criticism of the faults of Racine, though not of the merits, which had not yet been fully seen. It may be added that in the preface of the printed play the poet showed the extreme sensitiveness to criticism which often accompanies a tendency to criticize others. These defects of character showed themselves still more fully in another matter. The Port Royalists detested the theatre, and in Jan. 1666 Nicole, their chief writer, spoke of dramatic poets as "empoisonneurs publics." Kacine immediately published a letter to the author, which, though very smartly written, is full of savage personalities. He had written a second pamphlet and was about to publish it when fortunately Boileau, who had been absent from Paris, returned and protested against the publication. It remained accordingly unprinted till after the author's death, and in later years he expressed bitter regret for having published the first.

After this disagreeable episode Racine's life, for ten years and more, becomes simply the history of his plays, if we except his liaisons with the actresses Mademoiselle du Parc and Mademoiselle de Champmeslé, and his election to the Academy on July 17, 1673. The series of his unquestioned dramatic triumphs began with *Andromaque* (Nov. 1667), and this play may perhaps dispute with *Phèdre* and *Athalie* the title of his masterpiece. It is much more uniformly good than *Phddre,* and the character of Hermione is the most personally interesting on the French tragic stage. Whatever may be thought of the *tragédie pathétique* (a less favourable criticism might call it the "sentimental tragedy"), it could hardly be better exemplified than in this admirable play, which owes its success to the application of the most delicate art to the conception of really tragic passion. *Andromaque* was succeeded, at the distance of not more than a year, by the charming comedietta of *Les Plaideurs* (printed on Dec. 5, 1668). At first it was a complete failure, though Molière is reported to have said on leaving the house, "Que ceux qui semoquoient de cette pièce meritoient qu'on se moquoient d'eux"; but the piece was suddenly played at court a month later; the king laughed, and its fortunes were restored. It was followed by a very different work, *Brttannicus,* which appeared on Dec. 13, 1669. This was much less successful than *Andromaque,* and seems to have held its own but a very few nights. Afteraards it became very popular, and even from the first the exquisite versification was not denied. But the complete nullity of Britannicus himself and of Junie, and the insufficient attempt to display the complex and dangerous character of Nero are not redeemed by Agrippina, who is really good, and Burrhus, who is solidly painted as a secondary character. Voltaire calls it "la piece des connaisseurs," a double-edged compliment. The next play of Racine has, except *Phèdre,* the most curious history of all. Henrietta of Orleans proposed the subject of *Bérénice* to Corneille and Racine at the same time, and both plays, but especially Racine's, were successful. *Bajazet,* first played on Jan. 4, 1672, has great technical merit, but it is impossible to imagine anything less oriental than the atmosphere of the piece, which is scarcely saved by its ingenious scenario and admirable style. This charge is equally applicable with the same reservations to *Mithridate,* which appears to have been produced on Jan.. 13, 1673, and was extremely popular. Racine's next attempt, *Iphigénie,* was a long step backwards and upwards in the direction of *Andrornaque.* Greek tragedy gave examples which prevented him from flying in the face of the propriety of character as he had done in *Bérénice, Bajazet,* and *Mithridate.* The date of its appearance is very uncertain. It was acted at court on hug. 18, 1674, but it does not seem to have been given to the public till the early spring of 1675.

The last and finest of the series of tragedies proper was the most unlucky. *Phèdre* was represented for the first time on New Year's Day 1677, at the Hôtel de Bourgogne. Within a week the opposition company launched an opposition *Phèdre* by Nicolas Pradon, who had been employed to write it by the duchess of Bouillon and other influential enemies of Racine. So well had their measures been taken that the finest tragedy of the French classical school was all but driven from the stage, while Pradon's was a positive success. The unjust cabal against his piece no doubt made a deep impression on Racine. But it is impossible to decide exactly how much influence this had on the subsequent change in his life. For 13 years he had been constantly employed on a series of brilliant dramas. He now broke off his dramatic work entirely and in the remaining 20 years of his life wrote but two more plays, and those under special circumstances and of quite a different kind. He had been during his early manhood a libertine in morals and religion; he now became irreproachably domestic and almost ostentatiously devout. No authentic account of this change exists; what is certain is that Racine reconciled himself with Port Royal, accepted their doctrine of the incompatibility of the stage and the Christian life. and on June 1 married Catherine de Romanet and definitely settled down to a quiet domestic life, alternated with the duties of a courtier. His wife had money, and he had possessed for some time the post of treasurer of France at Moulins. His annual "gratification" had been increased from 800 to 2,000 livres, and in the year of his marriage he and Boileau were made historiographers-royal with a salary of 2,000 crowns. Racine's labours brought him, in addition to his other gains, frequent special presents from the king, and in 1690 he further received the office of "gentilhomme ordinaire du roi," which afterwards passed to his son. He had two sons and five daughters.

The almost complete silence which Racine imposed on himself after the comparative failure of *Phèdre* tvas broken once or twice even before the appearance of his two last exquisite tragedies. The most honourable of these was the reception of Thomas Corneille on Jan. 2, 1685, at the Academy in the room of his brother. The discourse which Racine then pronounced turned almost entirely on his great rival, of whom he spoke even more than becomingly. But it was an odd conjunction of the two reigning passions of the latter part of his life—devoutness and obsequiousness to the court—which made him once more a dramatist. Madame de Maintenon had established an institution at Saint Cyr for the education of poor girls of noble family; the tradition of including acting in education was not obsolete, and the favourite asked Racine for *a* new play suited to the circumstances. The result was the masterpiece of *Esther,* with music by Moreau, the court composer and organist of Saint-Cyr. The beauty of the chorus, the perfection of the characters and the wonderful art of the whole piece need no praise. Almost immediately the poet was at work on another and a still finer piece of the same kind, and he had probably finished *Athalie* before the end of 1690. The fate of the play, however, was very different from that of *Esther.* The public cared very little for it, but the just judgment of posterity has ranked *Athalie,* if not as Racine's best work (and there are good grounds for considering it to be this), at any rate as equal to his best. Thenceforward Racine was practically silent, except for a brilliant *Histoire abrégée de Port Royal* and four *cantiques spirituels,* in the style and with much of the merit of the choruses of *Esther* and *Athalze.* The general literary sentiment was against him, and his weakness for spiteful epigrams cost him many friends. At last even the king withdrew his favour. He died April 21, 1699, and was buried at Port Royal.

Racine may be considered from two very different points of view,—(I) as a playwright and poetical artificer, and (2) as a dramatist and a poet. From the first point of view there is hardly any praise too high for him. Every advantage of which the Senecan trdgedy adapted to modern times was capable he gave it. He perfected its versification; he subordinated its scheme entirely to the one motive which could have free play in it,—the display of a conventionally intense passion, hampered by this or that obstacle; he set himself to produce in verse a kind of Ciceronian correctness. The grammar-criticisms of Vaugelas and the taste-criticisms of Boileau produced in him no feeling of revolt, but only a determination to play the game according to these new rules with triumphant accuracy. The result is that such plays as *Phèdre* and *Andromaque* are supreme in their own way But his greatest achievements in pure passion — the foiled desires of Hermione and the jealous frenzy of Phèdre — are cold, not merely beside the crossed love of Ophelia and the remorse of Lady Macbeth, but beside the sincerer if less perfectly expressed passion of Corneille's Cléopâtre and Camille. He had cut away from himself, by the adoption of the Senecan model, all the opportunities which would have been offered to his varied talent on a freer stage, though the admirable success of *Les Plaideurs* makes us regret that he did not experiment further in comedy.

BIBLIOGRAPHY.—The first collected edition of Racine's works appeared in 1675–76; the last appeared in the poet's lifetime (1697), perhaps revised by him. Among posthumous editions the most important is that of P. Mesnard in the *Grands écrivains* series, 8 vol. (1865–73). Louis Racine's *Life* was first published in 1747. Among English imitations are the *Distressed Mother* of Ambrose Philips (1712) and the *Phaedra and Hippolytus* of Edmund Smith (acted in 1707); and a complete verse translation by R. B. Boswell (1889–91). *See* Sainte-Beuve, *Portraits Littdraires*, vol. i, and for criticism the studies by G. Larroumet (1898) and J. Lemaitre (1908), and the *Life* by Mary Duclaux (1925). The case for and against Racine has been concisely stated by G. Lytton Strachey in *Books and Characters* (1922) and J. C. Bailey in *The Claims of French Poetry* (1907).

RACINE, LOUIS (1692–1763), French poet, second son and seventh child of Jean Racine, was born in Paris on Nov. 6, 1692. *La Grace* (1720) and *Religion* (1742), his most important work, are inspired by a sincere piety, and are written in verse of uniform clearness and excellence. His other works include epistles, odes, among which the *Ode sur l'harmonie* (1736) should be mentioned, *Mkmoires* (1747) of Jean Racine, and a prose translation of *Paradise Lost* (1755). Louis Racine died on Jan. 29, 1763.

His *Oeuvres complètes* were collected (6 vol.) in 1808. The *Lettres inédites de Jean Racine et de Louis Racine,* containing a notice on Louis Racine by the Abbé A. de La Rogue, were published in 1862.

RACINE, a city of southeastern Wisconsin, U.S., situated on Lake Michigan at the mouth of the Root river, 25 mi. S. of Milwaukee and 65 mi. N. of Chicago. It was founded in 1834 by a lake captain, Gilbert Knapp, and quickly obtained settlers in the first important American population movement into southeastern Wisconsin in the late 1830s. At first it was called Port Gilbert after its founder but in 1837 it adopted the French name of the river on which it stands and in 1848 it was incorporated as a city. Pop. (1960) city 89,144, of which about 10% mas foreign-born white (mainly from Denmark, Germany, Czechoslovakia, Italy, Russia. Poland and Lithuania); standard metropolitan statistical area (Racine county) 141,781. (For comparative population figures *see* table in WISCONSIN: *Population.*) Industry began to develop shortly before the American Civil War and Racine became an important centre for farm machinery at an early date. Its industrial development received a considerable impetus from World War II and was exceedingly diversified. Among its more important industrial products are tractors and farm machinery, automobile accessories, power tools, iron and, steel castings, electrical products, floor wax. malted milk, leather goods and furniture. The city is served by the Racine extension division of the University of Wisconsin, nhich provides two years of accredited college work. Racine possesses an extensive park system including recreational areas and Zoo park. (RE. H.)

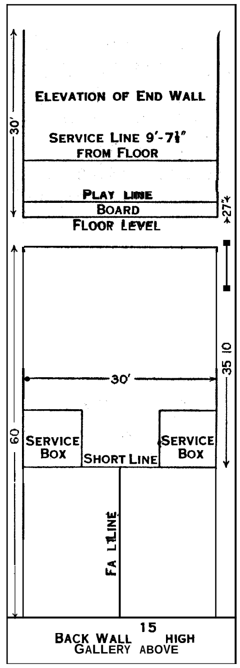
RACKETS (RACQUETS), a game played in an enclosed court with a ball and an implement called a racket, with which the ball is struck. The racket is about $2\frac{1}{2}$ ft. long and the head is tightly strung with catgut. No specific, standard dimensions are laid down. In the earliest days of the game, the head of the racket was inclined like a tennis racket; later it was pear-shaped. In modern days it is nearly circular and some seven or eight inches in diameter. The average weight of a racket is about nine ounces, and it is made of ash. Experiments have been made with metal frames but with no practical success. The balls are one inch in diameter and weigh one ounce. They are made of strips of cloth tightly wound over each other and then bound with twine, with a sewn covering of smooth white leather.

In England the floor of the rackets court is black or red in colour and the walls black. In India and some other places in the far east, where the floor and walls of the court are painted white, black balls are used.

The Court.—No standard size has been established for a rackets court, but the majority of courts are about 60 ft. long by 30 ft. wide. Both the single and the double or four-handed game are played in courts of this' size. Formerly there were several courts as large as 80 ft. by 40 ft. built specially for the double game.

Modern rackets courts have four walls and a roof, but in India some courts are left unroofed for the sake of coolness.

The floor, which must be perfectly level and smooth, is made of cement. The floor cannot be too hard since the faster the ball travels the better the game; similarly the walls, which should be built of masonry faced with cement and most carefully smoothed, cannot be too hard and fast The front and side walls are about 30 ft. high, the back wall being about half that height with a gallery for spectators (containing the marker's box) above it. The court is entered by a door in the centre of the back wall which, when shut. must be perfectly flush with that wall with no projecting handle. The court is lighted from the roof. The divisions and the markings of the court are shown in the figure. On the front wall is fixed a wooden board, the upper edge of which, 27 in. from the floor, constitutes the play line. and which usually fills the whole space from that height to the floor. At a height from the floor of 9 ft. $7\frac{1}{2}$ in. is a second line called the cut line or service line, usually painted red or green. At a distance of 35 ft. 10 in. (in a court 60 ft. by 30 ft.) from the front wall and parallel to it a line is painted on the floor from wall to wall called the short line. From the centre of the short line to the centre of the back wall is the fault line, dividing the space between the back wall and the short line into two equal rectangles. These lines again are usually red or green in colour.



PLAN AND ELEVATION OF

The rectangles are the service courts, called the right-hand and left-hand court respectively. Against the side walls outside these courts. but so that one side in each case is formed by the short line, are squares called the service boxes.

The Game. — Rackets is usually played by two persons (singles) or four persons playing two against two (doubles). The general idea of the game is the same as in lawn tennis and fives (*qq.v.*), the object of the player in all these games being to score a point by striking the ball either before it reaches the ground or on its first bound, in accordance with the rules of the game and in such a way that his adversary may fail to make a valid stroke in return. In the four-handed game one of each set of partners takes the right-hand court and his partner the left. The game consists of 15 points called aces. Aces can be scored only by the hand-in (the player, or side, having the service) and the hand-out must therefore win a stroke or strokes to obtain service before he or they can score an ace. In doubles each of the partners serves in turn; both must therefore be ousted before hand-out obtains the service; but the first hand of each game affords an exception to this rule (*see* below).

The right to serve first is determined by the spin of a racket, and the service must be made in the following manner. The server, standing with at least one foot inside one of the service boxes, must toss the ball from his hand and while it is in the air he must hit it with his racket so that it strikes the front wall above the service line and falls to the floor nithin the service court on the opposite side. After striking the front wall the ball may, but need not, strike the side wall, back wall or both; it may do so before or after touching the floor. The serve is a fault if the ball (1) strikes the front wall above the board but on or below the service line, in which case it is called a cut; or (2) touches the floor on the first bound, outside the proper service court, when it is called short or fault according to the position of its pitch (see below). If the hand-out player to whom the fault is served takes it (*i.e.*, if he plays at it), the fault is condoned and the play proceeds as if the serve had been good. If, however, the fault is not taken, the server must serve again from the same box; if he serves a second fault he loses his hand or innings and his partner or opponent, as the case may be, takes his place. Two consecutive faults thus have the same result as the loss of a stroke in the rally by the hand-in. In the United States only one serve is permitted and the server is retired by one fault. A serve that makes the ball strike the board, or the floor before reaching the front wall, or that sends it out of court (*i.e.*, into the gallery or roof of the court). counts the same as two consecutive faults: it costs the server his innings.

Skill in service is a most important part of proficiency in rackets; a player can seldom become first-rate unless he possesses a strong service. A great deal of cut may be imparted to the ball by the stroke of the racket which makes the ball in its rebound from the wall behave like a billiard ball carrying side when striking a cushion. When this cut is combined with great pace in the bound of the ball off the side wall, the back wall and the floor, at varying angles which the server has to a great degree under his control, it becomes exceedingly difficult for hand-out to get up the service (*i.e.*, to hit it on the first bound, sending it above the play line on the back wall) and still more so to make a good stroke which will render it difficult for his adversary to get up the ball and thus continue the rally. Rackets courts vary much in pace and conditions; in some. service is much easier to return than in others, but it not infrequently happens that a long sequence of aces. sometimes the whole 15 aces of a game, are scored consecutively by service that hand-out is unable to returri. To obtain first service is therefore an initial advantage, although in doubles it is limited by the rule that only one partner shall have a hand in the opening service.

The server may begin in either of the service boxes. When he has started, however, the service must proceed from the two boxes alternately until the close of the innings of the side, whether singles or doubles. When the other side obtains the innings they may also begin in either box nithout regard to where the last service of their opponents was delivered. In singles. harid-out changes sides in the court after each serve, answering to the change over of the server; in doubles the serve is taken alternately by the two hand-out players who permanently occupy the right- and left-hand courts, being allowed to change the order in which they receive the service at the end of any game or rubber. Except in the case of left-handed players, most of the play in the left half of the court, including the taking of service on that side, is backhanded; therefore the strongest partner in backhand play usually takes the left-hand court

The best position in the court lor the hand-out taking the serve depends entirely on the nature of the service; he has to use his judgment the instant the ball leaves the server's racket in order to determine where it will strike the floor and at what precise point in its course it will be best for him to attempt to take it. A strong fast service. heavily cut, that sends the hall darting around the corner of the court, leaving the back mall at an extremely acute angle or dropping almost dead off it, can only be got up by standing near the back wall a long way across the court and taking the ball by a wrist stroke at the last instant before it falls to the ground a second time On the other hand, nhen the server avoids the side wall altogether and strikes the hack wall direct and hard, whether he achieves a nick serve (*i* e., the ball striking precisely in the angle betneen the back wall and the floor) or hits the nall high up. hand-out will have little time to spare in changing position to get nithin reach of the ball Many good players make a practice uherever possible, especially in the case of heavily cut service. of taking the service on the volley (*i e.*, beiore the ball reaches the ground). sometimes taking the ball after it leaves the side mall and before it reaches the back wall. In returning the service or in playing any stroke during the rally, the ball may strike any of the other walls beiore the front mall. This boasted stroke is quite legitimate, often most valuable and sometimes indispensable

Good play consists for the most part in hard low hitting, especially as close as possible along the side walls into tho corners of the back wal?. One of the most effective and beautiful but difficuit, strokes in rackets is the drop that occurs when the ball is hit so that it just reaches the front wall and drops close to It. The half-volley, in nhich the ball is struck at the moment of its contact with the floor and before it has had time to rise. is employed with great effect especially in hard play, it makes the return much quicker than when the ball is allowed to rise to the full length of the bound and requires corresponding quickness on the part of the adversary

If hand-out succeeds in returning the serve, the rally proceeds until one side or the other fails to make a good return A good return mesns (1) that the ball is struck by the racket beiore its second bound on the floor, snd without its having touched any part of the clothes or person of the striker or his partner; (2) that it is hit against the front wall above the board without first touching the floor or going out of court; and (3) that it returns off the front wall into play (*i.e* , to the floor of the court or to an adversary's racket) nithout gomg out of court. If hand-in is the one to fail in making a good return. he loses his hand, and (in singles) hand-out goes in dnd proceeds to serve, in doubles one of the hand-in partners loses his hand and the second partner goes in to serve until he in turn similarly loses his hand, except that in the case of the opening service in the game there is (as already mentioned) only one hand in any event.

If hand-out fails to make a good return to the serve or to any stroke in the rally, hand-in scores an ace and the side that first scores 15 aces wins the game. When, however. the score reaches 13-all (*i.e.*, when each side has scored 13 aces), hand-out may, before the next serve is delivered, declare that he elects to set the game either to 5 or 3, whichever he prefers; and similarly when the score stands'at 14-all. hand-out may set the game to 3. He makes this declaration by calling "set-5!" or "set-3!" It means that 5 or 3 aces, as the case may be, shall be required to win the game.

It is the player's first duty to give the opponent full room for his stroke. but in the ccnfined space of a rackets court it is not always easy and sometimes, especially in doubles, absolutely impossible not to obstruct him. The rules. thereiore. carefully provide for lets (an old English word for "impediment" or "hindrance"). When in matches a let is claimed by any one of the players and allowed by the referee, or the referee and two umpires, the service or rally counts for nothing and the server serves again frorn the same service box.

In ordinary garnes, the marker makes the decision as to a let. It is the duty of the marker who occupies a box in the gallery to "call the game." As soon as the server serves the ball the marker calls "Play!" At the end of every rally he calls the state of the game, always naming the score of hand-in first: "One-love" (love being the term for zero) meaning that hand-in has scored one ace and hand-out nothing, "Two-love," "Five-all," "Five-ten," "Fourteen-eleven."

When the player reaches 14 it is customary for the marker to call "game-bail"; *e.g.*, "14–11 game-ball." When one side has scored 15, the marker calls "Game!"

The server in possession at the end of the game continues to serve in the new game, subject as before to the rule limiting the first innings of the game to a single hand. The usual number of games in matches is five for singles and seven for doubles. In matches where there are umpires and a referee, there is an appeal to them from the marker's decision except as regards those questions relating to the service, on which the marker's decision is final.

History. — Attempts have been made to trace rackets, like tennis, to an ancient origin; but although it is doubtless true that the striking of a ball with the hand or some primitive form of bat is one of the oldest forms of pastimes and that rackets evolved from such an origin. the game as now known can hardly be said to have existed before the 19th century. The first school that took to rackets was Harrow in the 1820s. It was about the middle of the century that closed courts of the modern pattern began to be built and the founding of Prince's club in 1853 increased the popularity and standing of the game in England. In modern times, largely because of the expense of the game, there is not so much play as previously, except at the British public schools. A number of courts went out of use in the 1930s, several being converted into squash rackets courts.

Rackets was first played on the North American continent in Canada, being well established in favour in the second quarter of the 19th century. The first court of which anything is known definitely was built in Montreal in 1836. One of the players there. Edward LaMontagne, took up residence in New York city and interested friends in playing the game shortly before the end of the first half of the century. He found that rackets already was known in New York and that there was a court in use just off the Bowery.

The first U.S. court of which there is a definite record was built in New York in 1850. The game was played in a few clubs in a half-dozen cities of the United States. The Racquet and Tennis club of New York was the game's main stronghold. The number of courts and players dwindled however, because of the expense.

See E. B. Noel and C. N. Bruce, *First Steps to Rackets (1925).*

(E. B. N.; A. DA.)

RACKHAM, ARTHUR (1867–1939), English illustrator, was born Sept. 19, 1867, in London. He studied at the Lambeth School of Art, London. Works he illustrated included *Rip van Winkle* (1905), *Peter Pan* (1906), *Alice in Wonderland* and the *Ingoldsby Legends* (1907). He won gold medals at Milan (1906) and Barcelona (1911). He was elected associate of the Société Nationale des Beaux-Arts in 1912 and in 1919 became master of the Art Workers' guild.

Rackham died Sept. 6, 1939, in Surrey.

Later illustrations include those to *Undine*, Grimm's *Fairy Tales*, Aesop's *Fables*, Dickens' *Christmas Carol, Comus, The Tempest, The Compleat Angler*, Poe's *Tales of Mystery and Imagination, The Rubaíyát* and *Peer Gynt*.

RADAR is an electronic device which provides man with the ability to detect and locate objects of a certain sort at distances and under conditions of lighting or obscuration which would render the unaided eye quite useless. Further, radar affords a means for extremely precise measurement of the range, or distance, to each of the objects it detects and locates—or "sees." It can also measure the speed of such an object toward or away from the observing station in a simple and natural way.

Radar is superior to the eye because it can "see" regardless of visibility conditions and because it affords an easy and accurate means for measuring target range and its rate of change. Radar is greatly inferior to the eye in the detailed definition of the picture offered. Largely because of the lack of detail in radar vision, the class of objects usefully seen by radar is smaller than the class distinguishable by the eye. Radar deals best with isolated targets in a relatively featureless background: aircraft in flight, ships on the open sea, islands and coast lines, and the like.

This article is divided as follows:

I. INTRODUCTION

How **Radar** Works. — Radar is a coined word, an acronym, derived from the initial letters of the phrase "radio detecting and ranging." Radio waves sent out from the powerful radar transmitter are reflected by objects within range of the set. A tiny fraction of the outgoing energy returns as an echo to the radar receiver, which is usually located, for convenience, at the same place as the transmitter. The properties of the received echo are used to form a picture or to determine certain properties of the object which caused the echo. As we shall see later on, there are several different forms of radar systems, making use of different properties of the received echo and involving different sorts of radio transmissions from the radar transmitter. The form employed in the majority of the sets is pulse radar. U'hen the word "radar" is used without qualification in this article, pulse radar will be meant.

Pulse radar is so called because the transmitter is keyed to send out short, very intense bursts or pulses of energy with a relatively long interval between pulses. The receiver is active during this interval. It receives echoes from the nearest objects soon after the transmission of the pulse, from objects at intermediate range later on and from the most distant objects near the end of the interpulse interval. When sufficient time has elapsed to permit the reception of echoes from the most distant objects of interest, the transmitter sends another short pulse. and the cycle repeats.

The delay between the transmission of the pulse and the reception of the echo is due to the fact that the radio waves used travel with the great but finite speed of light. In the units convenient in radar, the speed of light (about 186,000 miles per second, or 3×10^{10} cm./sec.) is 328 yd.[1] per millionth of a second, or microsecond. Since the radio energy from the radar transmitter must travel the distance from the radar to the target twice, once out and once back as an echo, each microsecond of delay between the transmission of a pulse and the reception of an echo corresponds to 164 yd. of range between radar set and target. If the delay corresponding to target range R is called T„ it will be given by

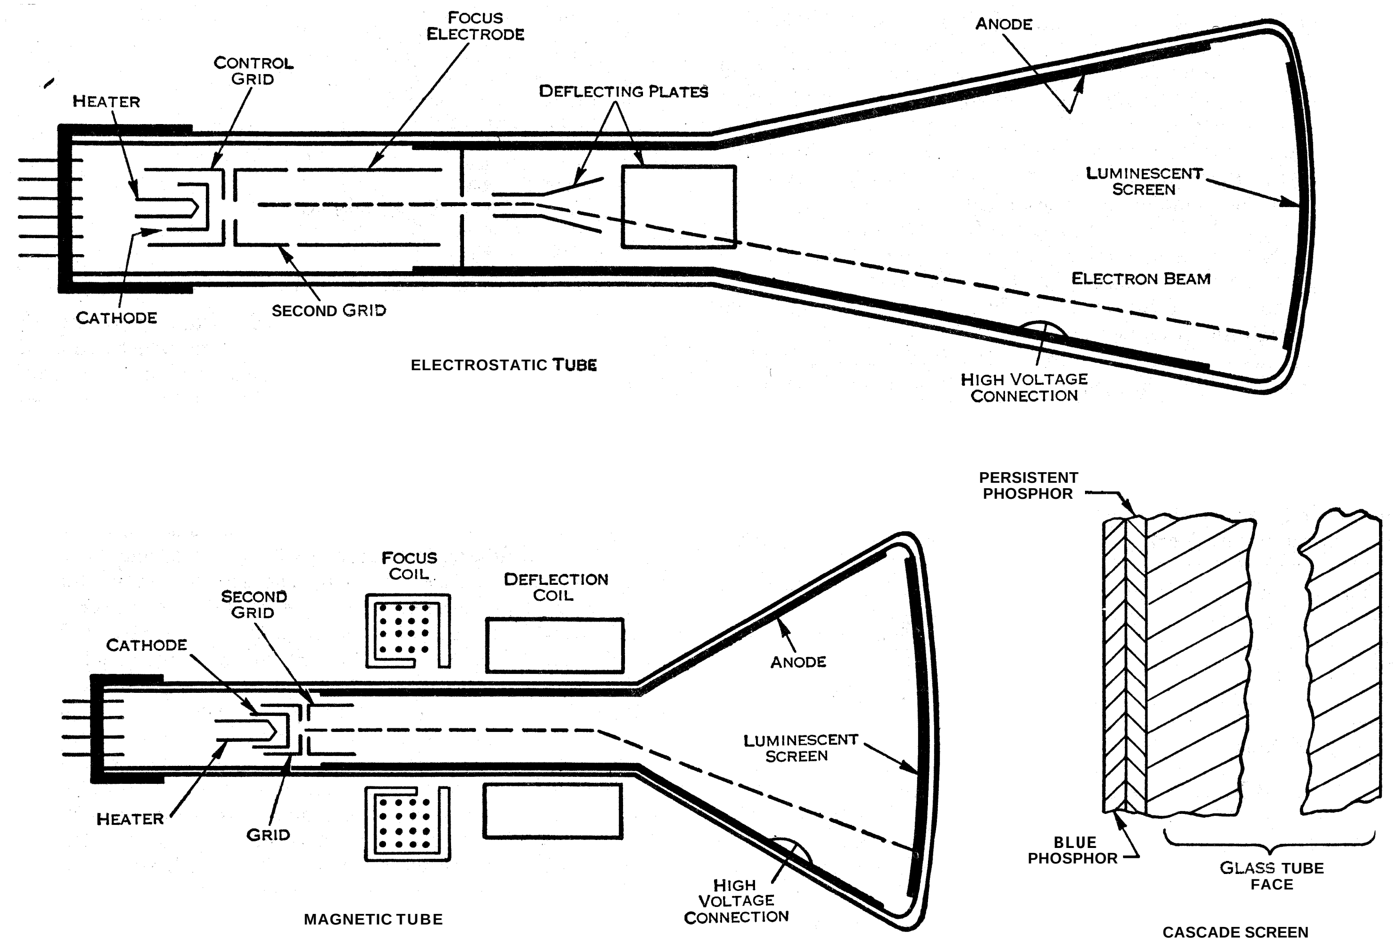
$$T_R = \frac{2R}{c}, \tag{1}$$

where c is the velocity of light.

This is the clue to the accuracy with which range can be measured by radar. Range measurement is reduced to the measurement of time, which can be performed more accurately than the measurement of any other basic quantity of physics. Very short intervals must be timed to get absolute precision in range, of course; if an error in range of only five yards can be tolerated, time intervals must be measured with an accuracy of one-thirtieth of a microsecond. Electronic timing and display techniques developed during World War II enabled such measurements to be made with great ease and convenience.

In 1945, for example, a serious map error was discovered by the use of bombing radar. This equipment enabled a bombing plane to find its position accurately by measuring the ranges to two fixed ground stations at which radar beacons (*see* below) were located. One beacon station was on the island of Corsica. A miss of about 1,000 yd., nearly 50 times the error expected, was scored on the first bombing mission carried out in Italy with this system. After an investigation of all possible sources of error, it was suggested that the reputed position of Corsica might be

[1]This is about 1,000 **ft.** (984) in one microsecond.



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC

FIG. 1.— ELEMENTS OF A CATHODE-RAY TUBE

wrong A correction of about 1.000 yd in the position of the island was used on the next bombing run The results, and those of later missions that used the corrected position of the island, were indistinguishabie from those of optical bombing.

A cathode-ray tube (CRT) is almost always used for the display of radar signals This device, shonn schematically in fig 1, has an ' electron gun" at the base of its glass envelope, deflection plates or coils in the neck of the tube and a luminescent screen on the inside of the large, nearly flat face of the tube. The electron gun produces a narrow, accurately focused beam of electrons which is aimed toward the centre of the screen. This pencil of electrons can be deflected in its flight from gun to screen either by electric fields produced by voltages applied to deflection plates, or by magnetic fields produced by electric currents passing through deflection coils.

Means are almost always provided for producing two independent deflections of the beam at right angles to one another. When the beam of electrons strikes the screen covering the inner face of the tube, the impact of the electrons excites the luminescent material there and causes it to emit light.

Thus the CRT screen instantaneously displays a single small spot of light whose position depends on the deflecting voltages or currents effective at that instant. Because of the very small mass of an electron and the consequent small inertia of the electron beam the spot can be deflected at very great rates of speed "Writing speeds" (that is, speeds of CRT spot motion) of as much as 200 in per microsecond were used in laboratory test equipment during World War II. Writing speeds of 1/10 in. per microsecond were common in service radar equipment. Not only the position of the spot but also its intensity can be conttolled electrically

The voltage applied to a "control grid" in the electron gun determines the electron beam current to which the light intensity produced at the screen is proportional.

A simple way to display radar signals is in the form of a "one-dimensional" display. The signal beam of the CRT is swept across the face of the tube from left to right at a uniform rate of speed, beginning at the instant a pulse is sent out from the radar transmitter. Thus the distance the beam has traveled to the right from its initial position is a measure of the time that has elapsed after the transmission of the pulse, and the distance of an echo signal from the left end of the sweep is proportional to the range of the target causing the echo. The output signals of the radar receiver are applied to deflect the beam vertically, so that an echo appears as an upward deflection of the trace. To make sure that the weakest signals that are detectable at all are not missed, the over-all amplification of the receiver is great enough so that random electrical disturbances, called "noise," originating in the receiver, can be seen on the display. For example, in successful attempts to receive a radar echo from the moon, time exposures were taken of the CRT screen. The photograph showed the entire path traced by the spot of light on the CRT face, in this case, in $2\frac{1}{2}$ sec.

On the left could be seen the "tail" of the transmitted pulse leaking into the receiver. and, on the right, the echo signals from the target. The distance of the echo signals from the left side of the CRT screen gave the distance of the target, the moon, as about 250,000 mi.

The type of indicator just described has come to be called an A-scope. Besides being simple, it affords an easy and straightforward way of measuring range. It makes no use of alterations in the intensity of the CRT spot.

In addition to finding target range, it is usually necessary to determine also the direction in which each target lies as viewed from the radar station. This could be done, in principle, by triangulation, using two or more simultaneous range readings on the same target as seen from separate radar stations. From the standpoint of simplicity, it is far preferable to measure both range and direction from a single radar station.

This is possible if the radio energy sent out from the radar can be confined to a narrow beam, like that of a searchlight. Echoes will then be received only from targets which lie in the direction in which the beam is pointing. If the radar beam is swept or scanned around the horizon, the strongest echo will be received from each target when the beam is pointing directly toward it, weaker echoes when the beam points a little to one side or the other of the target and no echo at all when the beam points in other directions. The bearing of a target can thus be determined by noting the direction in which the radar beam must be pointed to give the strongest signals from that target.

This can be done in several ways, some of which are highly precise. None is more graphic than the radar display called PPI, for plan position indicator. The PPI shows the range and angular disposition of all targets seen by a radar set which is scanning the horizon. In the PPI, the radar echo signals from the receiver are applied to the control grid of the CRT indicator tube in such a way that the screen will be dark in the absence of a signal, and a bright spot will appear when a signal is received.

The electron beam executes a sweep of uniform speed beginning at the instant each pulse is transmitted. just as in the A-scope, but in the PPI each of these sweeps commences at the centre of the tube and goes radially outward. Target bearing is indicated on the PPI by making the direction of each radial sweep on the indicator correspond to the geographical direction in which the antenna (and hence the radar beam) is pointing at that moment. North can be chosen to be at the top of the tube, for example; when the radar beam is pointing north, the radial sweep is executed from the centre upward. When the antenna has swung around to point east, the sweep on the PPI will take place from the centre to the right, and so on. The result is a map, on which the direction of each luminous spot marking a radar echo, measured from the centre of the tube, shows the bearing of the target causing the echo, and the distance of the spot from the centre of the tube face shows the target range.

In addition to the A-scope and the PPI, many other forms of radar indicator have been devised for special purposes; some of these will be referred to later.

The Basic Radar Set.—A radar set is shown schematically in fig. 2, separated into the major components fundamental to its action. The operation of these components is as follows.

A cycle of operation is begun by the modulator, which spplies a high-power, high-voltage pulse to the magnetron, a type of transmitting tube developed specifically for radar use. For the brief duration of the modulator pulse, which may typically be one microsecond, the magnetron oscillates at a frequency of several thousand megacycles per second[1], usually abbreviated simply as mc., transforming the D.C. power applied to it by the niodulator into R.F. (radio frequency) power with an efficiency usually larger than 50%. The R.F. pulse thus produced travels down the R.F. transmission line shown by double lines in fig. 2, and passes through the two switches marked TR and ATR. These are gas-discharge devices in which the discharge is initiated and maintained by the high-power R.F. pulse produced by the magnetron. During this time, the TR (transmit-receive) switch connects the transmitter R.F. line to the antenna, and disconnects the mixer and the rest of the receiver, in order to prevent damage to these sensitive circuits by the high outgoing power. The ATR (anti-TR) switch, when operated, simply permits the R.F. pulse from the magnetron to pass through it with negligible loss. Between pulses, when these gas-discharge switches are in a quiescent state, the TR switch connects the mixer to the antenna, and the ATR disconnects the magnetron to prevent any of the feeble received signals from being lost.

The R.F. pulse, after passing through these two switches, travels down the R.F. line to the antenna, where it is radiated. As is usual in radar. a single antenna is indicated in fig. 2 as being used both for transmitting and receiving; this requirement gives rise to the need for the duplexing arrangements involving the TR and ATR switches. The antenna design depends on the shape of radar beam required to meet the functional demands placed on the radar. It is almost always mounted on a scanner arranged to sweep the beam through space in the manner desired, simple azimuth rotation is indicated in fig. 2.

After the pulse has been transmitted, the discharges in the TR and ATR switches cease and the system is ready to receive echoes. These are picked up by the antenna and sent down the R.F. line to the mixer. The mixer shown is identical with the usual mixer of a superheterodyne radio receiver; it is a nonlinear device which, in addition to receiving the signals from the antenna, receives power from a CW (continuous-wave) local oscillator operating at a frequency only a few tens of megacycles away from the frequency of the radar transmitter. The difference frequency that results from mixing the echoes with the local oscillator signals contains the same intelligence as did the original echoes, but it is at a sufficiently low frequency (typically 30 mc) to be amplified by more or less conventional techniques in the intermediate frequency (I.F.) amplifier shown. Output signals from the I.F. amplifier are demodulated by a detector, and the resulting unipolar signals, still containing the echo intelligence, are further amplified by a video-frequency amplifier similar to those familiar in television receiver technique.

Output video signals are passed to the indicator for display. The indicator shown is a PPI which must, in addition to receiving echo signals from the indicator, receive a timing pulse from the modulator to indicate the instant for the start of each sweep. It must also receive information from the scanner on the direction in which the antenna is pointing, in order that the radial range sweep be executed in the proper direction from the centre of the tube. The necessary connections are indicated in fig. 2.

Each of the components shown in fig. 2 presented a series of difficult new problems of design during the period of radar development in the years 1935–45. Broad problems of component design are treated later in this article.

II. THE DEVELOPMENT OF RADAR

1. Early History.— Radar was developed independently and nearly at the same time in the United States, England, Germany and France during the 1930s under various names, such as radio detection or radio location. In 1942 the U.S. Navy coined the term radar which became universal in all later applications.

The independent occurrence of almost simultaneous and very similar radar developments in all these countries should not be surprising. The ideas basic to radar principles had been repeatedly presented for many years preceding the development of radar. It is perhaps more surprising that practical radar systems were not evolved at an earlier date.

Of the two ideas basic to pulse radar. the echo principle and the pulse principle, the former dates from the pioneer work of Heinrich R. Hertz in electromagnetic waves. This German physicist in the 1880s. seeking demonstrable proof of theories on the nature of light and radiation that the English mathematician James C. Maxwell had published in the 1870s, produced radio waves in the laboratory. Hertz also demonstrated that these radiations could be reflected by metallic objects, as light is reflected by a mirror.

While Marchesc Guglielmo Marconi and others at once pursued the radio communications possibilities that Hertz had opened up. a German engineer, Christian Hiilsmeyer, developed a simple form of radar. or radio echo device, to prevent ship collisions He even obtained patents in 1904 in several countries. But therr was little interest in such a device at that time.

Meanwhile, the radio echo or reflection phenomenon was repeatedly observed, and comments were often made regarding its possible uses. Nikola Tesla wrote in Century *Magazine* (June 1900, lx, p. 208) that by means of radio a moving object such as a ship at sea might be detected and located. Marconi, speaking in New York city at a meeting of the Institute of Radio Engineers in 1922, elaborated upon this same application.

[1]The electromagnetic waves used in radar, like light and radio wales, can be characterized either by their wave length, λ, or by their trequency, ν These two quantities are related, since their product is the velocity of propagation of light, c,

$$\lambda\nu = c$$

Numerically, a wave length of 10 cm. corresponds to a frequency of about 3×10^9 cycles per second, or 3,000 mc. per second.

By the mid-1920s radio researchers were seeking to measure the height of the ionosphere, a layer of ionized gas near the top of the atmosphere that reflects high-frequency radio waves, making possible long-range radio transmission around the curve of the earth. In England, under the auspices of the British Radio Research board, Edward V. Appleton and Miles A. F. Barnett employed CW radiations in original experiments beginning in 1924 to determine the altitude of this reflecting layer. The method they used involved observation of the interference effect between the waves reflected from the ionized layer and the direct (or ground) waves radiated by the transmitter.

The second idea basic to radar is the pulse principle, which was developed in 1925 by Gregory Breit and Merle A. Tuve of the Carnegie institution, Washington. D.C., in ionospheric work. Their pulse-ranging method was soon adopted by ionospheric investigators all over the world.

2. Development Before World War 11.—In the 1930s radio detection research began to receive earnest attention in a number of countries. largely under military supervision and in secret, because of the urgent need to detect and locate enemy warplanes at night or in cloud.

Germany.—German scientists, having begun development of a ship detector for the navy as early as 1933, soon concentrated their efforts on aircraft detectors. By Sept. 1939 a German ground set, the Freya, for early warning of approaching airplanes, was in production. The ship detector Seetakt went into production soon after. An especially excellent radar, the Wurzburg, its medium-length waves of 50 cm. (at 600 mc.) giving sufficient accuracy to direct effective antiaircraft fire against unseen planes, began to be employed in mid-1940 before any comparable precision position finder or gun layer (GL) radar had been developed by the Allies.

France.—The French, who had developed a simple obstacle warning set (an iceberg detector) for use aboard the ocean liner "Normandie" in the mid-1930s, also devised an aircraft warning system just before World War II. This was an interference-type radar using long waves (at 30 mc.) and requiring wide separation of the transmitter and receiver. The system was developed by Pierre David, chief engineer of the National Radio laboratories, who worked in great secrecy with army officers and civilian technicians. Not until about the time of an exchange of radar information with the British in 1939 did the French begin serious work on high-power pulse radar.

L'nrted States.—Scientists under A. Hoyt Taylor and Leo C. Young in the Naval Research laboratory and under Col. William R. Blair in the Army's Signal Corps laboratories made early progress in radio detection. Navy workers had devised an interference type of radio detector by 1930. Army scientists first worked on microwave radar types in the early 1930s, but the sets were failures militarily because they could not attain sufficient range. The output power of microwave oscillator tubes at that time was too weak.

Success came by 1936 when both the army and navy developed pulse radars on longer wave lengths generated by special high-power tubes. The signal corps demonstrated a model of the army's first radar, a searchlight control (SLC) set. in May 1937. This set was developed for the coast artillery corps to locate in darkness any airplane within searchlight range so that gun crews could trap the plane in searchlight beams and direct visual fire upon it.

The army air corps at once put in a priority request for a long-range aircraft detector for early warning (EW). This led to the development of a mobile set capable of detecting and locating aircraft well over 100 mi. distant. The signal corps completed development of both this set and a fixed version by the end of 1939, and contracts for their production were let by 1940. Both ,were in military use before the Pearl Harbor attack. U.S. navy radars

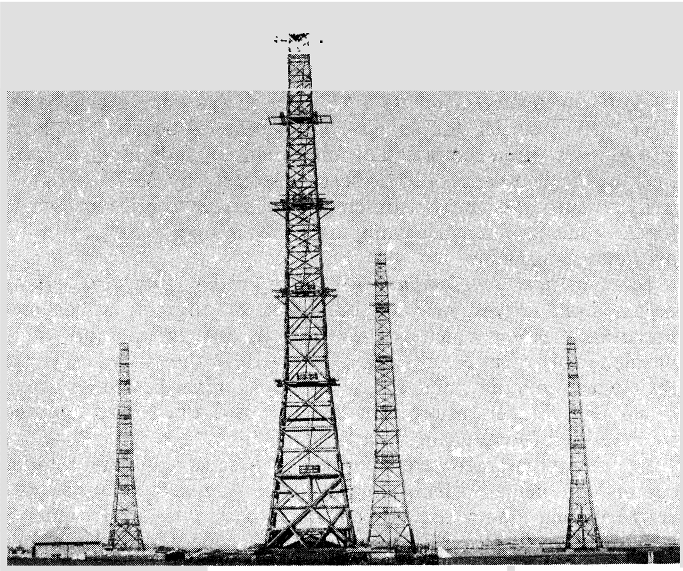
FIG. 2.—BLOCK DIAGRAM SHOWING COMPONENTS OF A SIMPLE RADAR SET

were also in production and use by then, following successful ship-board tests in early 1939.

Great Britain.—British radar grew from the efforts of a committee that the air ministry set up in 1934 for the scientific survey of air defense. This committee received, among other suggestions, a carefully uorked out plan for the radio pulse-echo detection of aircraft. This was tested on Feb. 26, 1935, by a physicist then heading the radio department of the National Physical laboratory, Robert Watson-Watt.

The first experimental system of the type proposed by Watson-Watt was set up in the late spring of 1935 on the east coast of England. By that autumn the main features of a chain of warning stations to protect England had been worked out. By early 1338 the first five chain home (CH) stations, which protected the Thames estuary, were completed and in operation under Royal Air Force personnel. A chain of similar stations was erected around the borders of Great Britain in succeeding years.



WOODEN RECEIVING-ANTEYNA MASTS OF THE EARLIEST BRITISH RADAR, THE CH. THESE SETS WERE USED THROUGHOUT WORLD WAR II, HAVING BEEN USED IN 1944–45 TO DETECT GERMAN V.2 ROCKETS DIRECTED AT LONDON SET SHOWN IS AT SWINGATE, DOVER, FACING ACROSS THE ENGLISH CHANNEL TOWARD FRANCE

Development emphasis then shifted to air-borne radar equipment. Two types were designed: (1) a set for the detection of surface vessels or surfaced submarines by patrol aircraft (called ASV, for air-to-surface vessel), and (2) an equipment to enable night fighters to home on enemy aircraft (called AI, for aircraft interception).

An experimental ASV system was successfully demonstrated during British fleet maneuvers in Sept. 1938. Experimental AI equipment was demonstrated to the chief of R.A.F. fighter command in Aug. 1939.

The focusing of radar energy into sharp beams is especially important in the case of air-bcrne radar; for energy reflected when the radar beam strikes the ground or sea beneath the plane can mask entirely the much weaker echoes of the targets sought. Sharp beams can be obtained by the use of either very large antennas or very short radio wave lengths. Since large antennas cannot be carried in aircraft, short wave iengths are essential. The early British interest in military air-borne radar led to an intensive search for a type of radio transmitter which could give very high-power pulses at wave lengths of a few centimetres.

By early 1940, British researchers succeeded in developing just such a transmitting tube, the revolutionary multicavity magnetron, which gave about ten kilowatts of pulse power. The invention of this tube made microwave radar practical for the first time, and the history of modern radar can be said to date from the introduction of this device.

3. World War II Radar Development. — By the end of 1940 U S. and British radar work was being carried out on a basis of full mutual exchange of information. A British technical mission, headed by Sir Henry T. Tizard, visited the U.S. In September and October of 1940, bringing complete information on British radar developments and samples of the cavity magnetron. Arrangements were made for continuing exchange of technical information and for co-ordinating the development work of both nations.

In discussions with the microwave committee of the C.S. National Defense Research committee (NDRC), which had been set up a few months before, members of the British mission proposed that the U.S. undertake two specific microwave developments: a microwave AI radar and a microwave position finder or gun layer (GL), for antiaircraft fire control. To implement these proposals; the microwave committee arranged to create a radar development laboratory staffed principally by university physicists in a pattern originated by the British several years earlier.

United States.—The Radiation laboratory, as the new NDRC establishment was .. opened its doors at the Massachusetts Institute of Technology, Cambridge, Mass., early in Nov. 1940 Its director throughout its 62 months of life was Lee A. DuBridge, on leave from t University of Rochester, later president f California Institute of Technology, Pasadena, Calif. The U.S. army and navy looked to the new Radiation laboratory for tl development of microwave radar. Their own development agencies were already fully occupied with tl many problems connected with getting the long-wave ra ., already developed, through manufacture and into service use. At the end of 1940, the usefulness of microwave radar seemed highly speculative, and the army and navy laboratories quite properly felt it more important to on trate their effort on radar techniques which had already been worked

During 1941, though not a single microwave rad unit was delivered for service use, development work a the Radiation laboratory broadened far beyond the two specific e which had been s t l by the British mission. Microwave i ment was showing great promise f many different wartime uses, and a considerable amount oi army and navy interest was developing.

The t nendous expansion f the radar development program during the war years can e measured by tl personnel figures of the various t The t t personnel of tl Radiation laboratory was about 40 at the beginning of 1941; by the middle of 1945 it had risen to its peak of nearly 4,000. The radar section of the Naval Research laboratory increased its personnel to about 600 in the same period. The radar section of the Signal Corps laboratories grew into the Evans Signal laboratory, with a peak personnel of more than 3.000. A similar growth took place at the Aircraft Radio laboratory at Wright field, Dayton, Ohio.

Great Britain. — British research and production experience during World War II set a precedent for wartime radar development in the U.S. The Telecommunications Research establishment (TRE), located during the last years of the war at Malvern college, Eng., pioneered the path followed by the Radiation laboratory in the U.S. TRE originated five years earlier than its American counterpart, having begun with a nucleus of dedicated physicists and technicians who built the first CH station on the shore of the North sea in 1935.

By 1915 TRE personnel grew to number about 3,000. Throughout these years British government and military officials co-operated closely with university scientists and industrial engineers, providing funds and facilities while permitting great latitude and free play of imaginaiion to the end that complex but workable equipment might be devised and quickly brought to combat use. A new pattern of military-civilian co-operation and a spirited partnership of civilian scientists and military users was created with marked success, first in England and then in the U S., bringing revolutionary concepts and weapons to bear upon the enemy with devastating effectiveness and crucial timeliness. Experimental radar devices, hand-built at the laboratories, were often used in combat missions, the equipment being installed and maintained by civilian technicians who sometimes operated it as well.

The British and U.S. radar efforts together brought against the enemy increasing quantities of superior microwave radar. Notable examples were the precision position finders or GL sets that, by 1944. surpassed the German Wurzburg radars. Such too were the efficient air-borne microwave radars whose shorter wave lengths permitted use of smaller antennas and gave greater detail (higher resolution) of target reflections. The first of these was the British H_2S (wave length 9 to 10 cm.), used in 1943 in such effective raids as those on Hamburg. Next was the improved H_2X which employed still shorter waves (about 3 cm. long).

Increasing use of these and other microwave radars replacing long-wave sets such as the enemy continued to employ (for want of efficient microwave generators like the cavity magnetron) gave the Allies through the last two years of the war an overwhelming radar superiority. In particular, the Allies developed jamming devices that blinded all German radars, both ground and air-borne types, that were operating on medium or long waves. Meanwhile, the Allies freely employed their superior microwave sets (unaffected by medium- or long-wave jamming) to direct attacks upon enemy targets at sea, on land and in the air.

Germany.—German radar development during the war was much retarded, as compared with the Allied effort, by over-confidence at first and throughout by poor management and defective co-operation between the military services and civilian scientists. Particularly harmful was a cutback in research that Hitler ordered in 1940. But as Allied air attacks increased, German radar production was stepped up.

More than 2,000 Freyas were built during the war and thousands of other sets as well. Improved Wiirzburgs and other types were developed and organized into effective systems of early warning, target tracking. and fire control or gun laying. An effective AI set, the Lichtenstein, was hastily devised and placed in night fighters. All these efforts enabled the Germans to take an increasing toll of Allied aircraft over western Europe until a turning point in the radar war came in mid-1943.

When in Feb. 1943 the Germans salvaged an H_2S radar and its magnetron from a plane wreck near Rotterdam, they first learned that the Allies had developed microwave sets. (By the end of 1943 they learned of the still better 3-cm. radar when an H_2X set was recovered from a U.S. bomber that also crashed in Holland.) Desperately, the Germans hastened to set up the Rotterdam commission to develop cavity magnetrons and microwave radars, but only toward the very end of the war did they begin to produce the Berlin series of microwave sets, and these were too late to be of any help.

Japan. — Such radar as the Japanese had developed before World War II was of the continuous-wave type, utilizing interference or Doppler techniques. Not until 1940 did work begin on pulse-type radar.

Some types were strongly influenced by foreign radar design. For example, a Japanese version of the Wurzburg was developed by 1945, based on plans the Germans had sent via submarine. The army's Taichi-6 resembled a U.S. army set, and a type of naval ground-based radar for antiaircraft fire control, the S-3, was based upon another U.S. set, a number of which had been captured in the Philippines in 1942. More than a thousand sets of an ASV type, the Taki-1, were produced. Using waves a metre and a half long, at 200 mc.. the set was mounted in Japanese bombers that carried the necessarily large antennas mounted on the exteriors of their fuselages.

The Japanese also developed a 10-cm. magnetron. One of their best shipboard radars employed this type of tube. They did not, however, develop in World War II any radar comparable to the Allied microwave SCR-584 or the MEW (microwave early warning) radar set.

4. Use of Radar in World War 11.—The brilliant success of the early British chain home stations in countering the threat of the Luftwaffe demonstrated the usefulness of radar in its original military role — the detection and location of aircraft at ranges and under conditions of visibility that precluded locating planes in any other way. As the war continued. many other uses for radar were developed. The most important are described below.

Aircraft Warning. — The earliest sets used were 'those of the British home chain. These large installations used radio waves about ten metres in length, and gave their display on an A-scope. Target bearing was found by comparing the intensity of the target signal received on one fixed receiving array with the intensity of the echo from the same target received on another fixed array aimed in a different direction; the elevation angle of a target, and thus its altitude, was measured in a similar way. These CH radar stations, as they were called, remained the principal reliance of the British radar defense throughout the war, and were used in 1944 and 1945 for the detection of German V-2 rockets aimed at England.

Later aircraft warning sets used shorter radio wave lengths, usually about 1.5 to 3 metres. At this wave length, a relatively narrow beam can be produced by an antenna array small enough for installation on shipboard, or for use in a transportable ground equipment. At the same time, the use of a radar beam requires continuous scanning in azimuth in order to cover all directions from the station.

In early 1944, there was introduced a microwave early-warning radar, operating on a wave length of 10 cm., which was highly successful. The radar beam produced by this set was only 1° wide in azimuth; in consequence, the ability of the set to resolve closely spaced targets on its PPI display was very much better than that of earlier equipment having broader beams. In large R.A.F. raids, often comprised of more than 500 individual aircraft, most of the bombers could be seen separately by MEW radar.

In situations of heavy air traffic, or under conditions where precise control of aircraft is important, such high radar resolution is extremely valuable.

Identification *Equipment.*—When a radar indicator shows echoes from dozens, or even hundreds, of aircraft, it becomes important to know which of these aircraft are friendly and which hostile. This requirement was recognized by the British early in their work on radar, and they devised an identification system, called IFF (identification as friend or foe), which was adopted by the Allied forces during World War II.

All friendly aircraft were equipped with a transponder — a radar beacon (see below) which gave a coded response when the aircraft carrying it was in the beam of a radar set. Arrangements were made to display this response on a scope which was either that used by the challenging radar set, or a special scope associated with the radar. Aircraft showing an IFF response were taken to be definitely friendly; aircraft not showing such a response were doubtful. Either they were hostile, or they were friendly planes whose transponders were out of order or not turned on.

While IFF was extremely useful in the early days of the war when aircraft density was still low, it failed operationally in the enormously high aircraft densities of the latter years of the war. A means for rapid and secure identification was, therefore, one of the unsolved operational problems of radar at the end of World War II.

IFF equipment of the standard type was also used by Allied naval vessels in order to identify friendly ships both to aircraft and to other surface vessels. In this use, of course, the problem of high density seldom arose, and maintenance of transponders was easier than it was in aircraft. IFF in ships was, therefore, considerably more reliable than it was in aircraft.

Control of *Aircraft* Interception. — The observation was early made by the British that, since both a hostile plane and a friendly fighter can be seen on the indicator of a single radar, it might be possible for a ground controller, viewing the radar scope, to coach the fighter into position to make an interception. The development of the plan position indicator greatly facilitated such ground control of interception.

Special radar equipment, called GCI, was designed for this purpose in the earliest days of the war, and proved to be quite successful.

When the Germans abandoned daytime attacks on England at the end of 1940, the technique of ground control became much more exacting. It was no longer sufficient to bring the defensive fighters into the general vicinity of the enemy aircraft and then to rely on the pilot's vision to complete the interception. A skilful ground controller could, under favourable circumstances, bring a fighter close enough to his target to enable a visual contact to be made even at night; but this was so difficult that further radar aids to the interception were clearly needed.

AI Radar. — It was this reasoning which led to the development of radar for aircraft interception. Night fighters were provided with air-borne radar sets with a range of a few miles against other aircraft. The ground controller coached the night fighter into a position a mile or two behind the hostile plane, a little below and on the same course. He then instructed the radar observer in the night fighter to turn on his AI equipment. If the early phases of the interception had been successfully carried out, the hostile aircraft gave a signal on the AI radar, and the combat was joined on the basis of homing information made available by the night fighter's own radar.

By the time reliable microwave AI equipment had been developed by the Allies in World War II, they enjoyed such thorough air superiority that it did not play a major tactical role. The early British 1.5 metre AI equipment used in 1940 and 1941 had many drawbacks, but it was sufficiently effective to enable the R.A.F. to master the night-bombing campaign of the *Luftwaffe.*

Antiaircraft Position *Finders* or Gun Layers (*GL*).—The earliest radar set developed by the U.S. army signal corps was the searchlight control set, mentioned above, for determining azimuth, elevation and range of aircraft targets at night in order to direct searchlight beams upon them. These sets also were employed for control and direction of gunfire under conditions preventing visual tracking — at night or in cloud — although the set had not been designed for GL use. Such use of radar for fire control became a most important application in World War II, but neither early British nor U.S. sets, working at wave lengths of a metre or more: had sufficient accuracy to direct very effective blind gunfire.

The introduction of microwave sets, however, enabled the design of radar position finders whose accuracy was good enough to permit blind fire that was as effective as visually controlled fire. The most successful of all Allied types of such equipment was the SCR-584. This C.S. radar measured the azimuth and elevation angles of a target with an error of less than one-twentieth degree, and range with an error less than 25 yd. It was the first radar equipment which incorporabed automatic tracking; when the SCR-584 was pointed at a target, it could be "locked on" in such a way that servomechanisms actuated by the radar kept its antenna pointing continuously at that target.

Naval antiaircraft fire was controlled by radar of a similar sort, although no navy, Allied or Axis, had equipment for the purpose that was as effective or as satisfactory as the U.S. army's SCR-584.

Close Control of Aircraft.——The GCI techniques which were referred to above had as their aim the location of a friendly fighter in such a position that he could attack a hostile bomber, usually with the help of an AI radar carried by the night fighter. Minor errors in positioning the friendly plane were usually relatively unimportant, and the target with respect to which the friendly plane was being positioned was an aircraft moving with a speed comparable with that of the plane under radar control. Both these facts simplified the GCI problem.

As the position-finding precision of radar grew, it began to be clear that a ground controller could direct aircraft accurately into a desired position with relation to ground targets. Two principal problems presented themselves during the war, one of which is important in peacetime air operations.

First, the tactical air commands that accompanied the U.S. armies on the continent of Europe were composed, for the most part. of fighter bombers. These single-seat aircraft were much too small to carry radar equipment, and the pilot of such a plane was much too busy to interpret its readings even if he had had radar. Nevertheless, the TAC aircraft had to operate often in conditions of greatly restricted visibility. Controllers located at ground radar sets had considerable success in guiding TAC fighter bombers to their targets by radiotelephone instructions. Even entirely blind bombing was done by such aircraft, altogether on the basis of course and release-time instructions received from a controller at a ground radar. The SCR-584, suitably modified, was used for this work.

The second application of close aircraft control from the ground is that of coaching a plane in to a landing under poor visibility conditions. A special high-precision radar set, called GCA (ground controlled approach), was designed at the Radiation laboratory for this purpose. Though it emerged from production rather late in World War II, it was used quite successfully both in Europe and in the Facific. Its use had become common by the 1960s in both civil and military air operations.

Surface Search and Fire Control. — In addition to locating aircraft and directing fire against them, radar was used during the war to locate and direct fire against surface vessels, both from other ships and from coastal defense stations. As will be seen in the next section, microwaves enjoy a great superiority in search for targets near the surface of the sea, so that it often happened that the same radar was used for search and for fire control against surface vessels.

Such radar could also locate precisely the splashes caused by the fall of shot, thus permitting the spot correction of unseen fire. In naval engagements in the Pacific, on several occasions, ships of the U.S. fleet engaged and sank Japanese vessels without ever seeing them visually.

ASV Radar. —Of the several types of air-borne radar equipment used in the war, that employed by patrol aircraft for searching out and attacking surface vessels was one of the most common. A ship on the open sea is an ideal radar target, and even quite primitive equipment suffices to home on such an object. As the art of radar design advanced, ASV equipment developed from a heavy, bulky installation to a compact and effective unit.

ASV radar was most effective in the antisubmarine campaign. During much of 1943. German submarines were sunk at a rate not far from one per day, two-thirds of them by aircraft attack. Almost all of the aircraft attacks developed from radar sightings.

Means were also developed for bombing ship targets accurately on the basis of the radar display. In a single month, a single squadron of the U.S. 14th air force sank 110.000 tons of Japanese shipping in the China sea, entirely at night and entirely by radar.

Air-borne Radar for Navigation and Bombing. — During trials of AI and ASV radar, it was found that microwave equipment, with its narrow beams, could give a sufficiently good picture of the terrain beneath an aircraft to enable navigation by pilotage. Cities and built-up areas returned much stronger signals than open country, and hills, rivers and coast lines were especially well defined.

The British R.A.F. bomber command pioneered in using such radar to guide its pathfinder aircraft. These planes, manned by specially chosen personnel, dropped flares on the target at which the main force aimed by ordinary optical means. The U.S. strategic air forces, committed to daytime bombing, found by experience that target visibility was often so poor that in order to maintain full operation they also needed such radar aids.

Even on occasions when target visibility was good, the radar was useful in permitting the bombers to line up correctly on their approach to the bombing run. A medium-sized city is visible for about 50 miles on radar of wartime performance; it can rarely be seen as far as this with the eye. Of the 400,000 tons of bombs dropped by the 8th air force after Nov. 1943, when this equipment (called "Mickey" or "H_2S") was introduced, more than half was aimed entirely by radar.

Beacon *Bombing* Systems.-Mention has already been made of the use of radar beacons for identification. Since these beacons give an immediate response to a radar challenge, they provide an excellent means for measuring the range to a point whose nature is known. Two such measurements based on a single point enable the exact position of such a point to be found by triangulation. Since range can be measured so conveniently and so accurately by pulse-timing methods, every precise position can be determined.

Two different bombing systems were based on this principle during World War II. In one of them, called "Oboe," the aircraft carried a radar beacon. The beacon was challenged by two ground stations, and the range of the aircraft from each station measured. Signals were sent to the plane by radio to keep it on a circular course of constant range from one station, called the "cat." The other station, called the "mouse," sent signals to the aircraft indicating the exact moment of bomb release necessary to hit the previously chosen target.

The Oboe system was highly accurate; with good ground and air crews the operational errors were less than 250 yd. from an altitude of 30,000 ft. Its limitations were that. since it depended on the ability of ground stations to see the signals from a beacon in the bombing aircraft, it would not work over the optical horizon (about 250 mi, for an altitude of 30,000 ft.); and that it demanded a high degree of co-ordination between two widely separated ground stations. Even with this co-ordination, it could handle only one aircraft at a time.

Despite the limitations of the Oboe system, the British used it quite successfully to guide the pathfinder aircraft of R A.F. bomber command. The devastation of the Ruhr, which was just within Oboe range from the United Kingdom, was carried out almost entirely with the help of Oboe.

In the other type of beacon bombing system, called "H" by the British, beacons were placed on the ground at accurately located spots, and the interrogation and display equipment was carried in the bombing aircraft. A U.S. system based on this principle, called Shoran (for short range navigation), was highly successful during World War II.

Although Shoran was subject to the same horizon limitation as that affecting Oboe, it did not suffer from as severe a limitation in traffic-handling capacity. Each aircraft could challenge the ground beacons independently of all the other planes that might be doing so at the same time. It was with Shoran that the error in the map position of Corsica, already mentioned, was discovered.

Electronic Navigation *Systems.*—The beacon bombing systems and the air-borne radar for navigation that have just been described will be recognized as navigational equipment. They were rather specialized in nature, being designed for the exacting use of leading a bomber to its target. No such accuracy is needed to facilitate the ordinary navigation of aircraft from base to base. Radio-beam navigational aids to such navigation had been in use for years, but the development of pulse-timing methods for radar led to the development of navigational aids based on the pulse-ranging principle. Among the more important systems of this sort are the British Gee and the U.S. Loran.

Air-borne *Range-finding* and Gun-laying Radar. — The vigorous opposition of German fighters to Allied bombing in the early days of World War II led to the U.S. development of light, compact radar to aid in air-to-air gunnery, intended principally to contribute to bomber defense. One type was an automatic radar range finder for optically aimed fire by daylight. Another provided complete position-finding to protect bombers against night fighters under conditions precluding optical sighting. Both of these radars became available during World War II, but at such a late date that their operational usefulness was small. In the Korean War, however, they and successor equipment proved indispensable aids to air-to-air gunnery in jet aircraft combat.

Radar *Countermeasures.*—Use of radar by the Germans and the Japanese led to a considerable Allied effort in the field of countermeasures designed to mislead enemy radar or to render it ineffective. A similar effort was mounted by the Germans and the Japanese. These countermeasures took two forms: they consisted either of electronic "jamming" or "spoofing" of enemy radar by the transmission of suitably timed signals on the appropriate frequency; or, alternatively, they involved the dispersal of material which gave confusing radar reflections and thus hid attacking aircraft.

The second type of radar countermeasure was the most important single means of confusing enemy radar. Aluminum foil, cut into strips about a half wave length long at the enemy radar frequency, was the most commonly used form of material dispersed from aircraft to give false echoes. Such material was called "window" by the British, "chaff" by the U.S. army air force, and *Dueppel* by the Germans. Long-wave radar, with its broad beams, was the most readily confused by this means. The appearance on the scope of an Allied 10-cm. radar of "window" cut to confuse the German 60-cm. radar showed false echoes which were prominent but not hopelessly confusing. German radar, however, could see the aircraft targets under these conditions only with the greatest difficulty.

For about 18 months, both the Germans and the British refrained from using this deceptive trick, on the theory that the other side was ignorant of the possibility of doing it. Once it was introduced. however, the R.A.F. bomber command dispensed in the form of window, on each full-scale raid, a weight of aluminum sufficient to construct three heavy bombers. Loss figures showed that the protection afforded by this amount of window saved, on the average, seven bombers per raid.

5. Radar Development After World War II.—At the close of World War II the main outlines of radar system design had been reasonably well defined, and many of the operational applications had been completed. In the following years radar development included improvements of components and circuitry, electronic processing of received data, increasing use of solid-state transistors and masers. introduction of genuinely new components such as ferrite duplexers and new scanning methods, both mentioned below, and many new applications.

In civil uses commercial aviation and marine vessels increasingly employed radar aids to navigation. Highway police used a simple form of CW for the detection of speeding vehicles, the Doppler shift of the reflections from moving cars enabling instant and direct measurement of their speed. Astronomers and space researchers found that radar could help map the moon and could yield usable echoes from the sun and planets.

In U.S. military uses, remarkable attainments in transmitters of ever higher power and in receivers of greater sensitivity led to extremely long-range radars for early warning of ballistic missiles. Pulse-Doppler (PD) methods, utilizing such refinements as data processing and "memory" circuits, enabled the development of supersensitive radars for use in ground surveillance and personnel detection.

Military Developments. — Military radar equipment, as such, underwent little improvement in the period between the end of World War II and the beginning of hostilities in Korea in 1950. The Korean conflict made greatly increased military budgets available, but even then only detailed improvements in radar performance took place, resulting mainly from the development of improved components. This is well illustrated by the fact that radar sets differing only slightly from the SCR-584 (development of which was undertaken in 1941 with field use beginning in early 1944) were built for equipping the NATO military forces in the mid-1950s.

The most prominent postwar trend in the design of military radar systems was toward the elimination of human beings as links between a radar indicator and the controls of a weapon system. This general development was forced on military technologists by the astounding increase in aircraft performance, the development of nuclear weapons, the appearance of successful guided missiles and by the growth of commercial aviation.

In the years following World War II. the development of jet engines tripled the speeds of relatively conventional aircraft, thus putting unprecedented demands on air warning and control organizations and on air defense generally. The leisurely human plotting-and-telling organizations of World War II clearly had to be replaced by something faster and less fallible. If antiaircraft guns were to be useful at all, they would clearly have to be controlled entirely automatically to engage such high-speed targets. The performance of fighter interceptors had increased to the point where the reflexes of a human pilot were barely adequate to control an attack; a high degree of automatic control extending from the AI radar to the final weapon—gun or rocket — was clearly required for the best results.

In the case of guided missiles, the situation was even plainer.

An interceptor missile is a fighter aircraft without a human pilot. There can be no debate about the requirement for automatic control. The same is true of long-range missiles intended for a strategic bombing role, and indeed for missiles in general. In all these cases. radar is an important part of the system as a whole.

In addition, the development of nuclear weapons, to the point at which a single well-executed air raid might utterly destroy the capability of a great country to wage war, made it imperative to have an air-defense system that would be continuously alert and effective against a single unexpected raid. At the same time, the vast growth of civil aviation translated this requirement into the need for developing a system which could keep current track of thousands of aircraft, so that potentially hostile aircraft could be distinguished and investigated (counterattacked, if necessary) before they had an opportunity to attack. Any such system obviously would require a degree of automatic operation not dreamed of during World War II.

Fortunately, the development of high-speed digital computers. begun in the late years of the war, provided the basic techniques which made it possible to mechanize the use of radar data. The most ambitious undertaking of this sort in the 1950s was the development of the semiautomatic ground environment (Sage) system, designed to control weapons defending the continental United States against air raids.

In the Sage system, high-performance ground radar sets were placed in the U.S. and Canada at locations that gave reasonably continuous coverage of aircraft, except those at very low altitude. Signals from these radars were transmitted to central control stations, each equipped with a vast computer capable of establishing and maintaining aircraft flight paths from the intermittent radar data, performing partial identification of aircraft from flight-plan information filed by friendly aircraft before take-off, assisting in the assignment of defensive fighters to investigate unknown aircraft, and doing the GCI job for fighters and interceptor missiles ordered to the attack. In addition, such defense organizations as naval units and the antiaircraft missile batteries guarding important targets could be alerted and given information on the tracks of incoming hostile aircraft.

To increase the time available to ready defenses, long-range radar installations (the distant-early-warning. or DEW, line of radars) were constructed in the far north of the North American continent. Man-made islands (Texas towers) were built on the eastern continental shelf as far out as 200 mi, into the Atlantic. Ultra-long-range aircraft equipped with high-performance radar were flown as air-borne pickets as far out as 1.000 mi. at sea.

The DEW line was designed to detect and locate aircraft while they were yet a considerable flight time distant, even at supersonic speeds. But against much swifter long-range ballistic missiles, which began to present a threat by the mid-1950s, another radar system had to be developed. Called the ballistic missile early warning system. or BMEWS, this comprised two stations in North America and one in northern England.

The first BMEWS station! which began operation in Oct. 1960 at Thule, Greenland, under U.S. air force direction, cost nearly $500~000,000. Four antenna arrays, each standing 165 ft. high and 400 ft. long. were designed to emit the highest power radiations employed up to that time in military radar. The immensely powerful transmitters, generating several million watts at peak pulse, projected two fanlike beams over the north pole and far beyond. capable of detecting a missile 3,000 mi. distant when it attained an altitude of 600 mi. Two sets of echo data. which would be received as the missile passed first through the lower beam and then through the upper one, would enable electronic calculators at Thule to predict within moments the missile's course and impact area. Thus about 15 or 20 minutes could be provided for warning and countermissile action.

During the late 1950s there were many military applications of radar besides the advanced warning and interception efforts described above. Marked progress was made in radar range and accuracy. A variety of new applications appeared. Unprecedented demands for both offense and defense uses arose from the needs of military technology in support of radically new concepts of modern armed forces in the atomic and missile era. The needs and the applications involved navigation. meteorology, bombing, mapping, missile tracking and guidance, reconnaissance and surveillance.

Combat surveillance. to illustrate only one application, resulted in U.S army requirements for radar able to detect and locate such moving targets as a creeping soldier at short ranges and moving vehicles and troops at longer distances. The need for such "intrusion detectors" led to radar systems that combined certain characteristics of both pulse and CW techniques. The consequence became a type of radar system called pulse-Doppler. or PD, discussed near the end of this article,

Several types of PD radar, for detection and location of moving targets only, were developed for sensory and surveillance uses by ground troops. A small portable set called the "silent sentry," which used transistors instead of electron tubes and could therefore be readily powered by batteries, was able to detect moving tanks, trucks or troops up to 3 mi. distant, converting the pulse-Doppler echoes into audible sounds in the earphones of the radar operator. Differences in the sound made it possible to distinguish a walking from a running man up to a half mile away. Target location could be determined with an error of less than 25 yd.

A larger medium-range system indicated moving echoes, both audibly in headphones and visually on an oscilloscope, with a sensitivity so great that the audible signals differed recognizably for tanks. trucks or troops up to 10 mi. distant, and for a creeping man up to 2 mi. away.

Military needs for detailed surveillance of large areas of enemy terrain under conditions of cloud or night (preventing normal photography) and at considerable distances from one side (safely within friendly territory) led to a remarkable air and ground radar system developed by University of Michigan scientists and the US. army signal corps. The echo signals of the air-borne radar are recorded on film during the surveillance flight. This film is developed after the plane lands and is then processed by an analogue computer. The process yields a detailed presentation of the scanned area, which appears as if it had been viewed directly beneath the airplane, although actually it lay miles to one side. The entire system thus departs radically in its signal storage and delayed output aspects from radars that give an instant visual or aural indication of targets. The system also embodies a major innovation in its unique antenna treatment. Fine radar focusing and resolution, revealing great detail at long distances as well as in the foreground. would ordinarily require an immensely wide antenna, obviously impossible to mount in an airplane.

Yet the superior effects of such a huge antenna array are attained with a 5-ft. antenna (the size that is actually employed) by coupling its action to the forward flight of the plane. The forward motion. combined with the recorded reception of echo pulses and subsequent treatment in a computer. permits a scanning and focusing effect as though the short antenna were extended many times the length of the airplane. This circumstance requires exact navigation and automatic correction of inevitable flight aberrations. Therefore, a flight navigation system, including an automatic pilot, is included in the system design. As a result the radar is kept in accurate focus throughout the surveillance flight and is focused simultaneously at all ranges. The printed product turned out by the computer resembles a photographic map with better detail at greater ranges than previously possible—revealing, for example, the individual poles of a telephone line seen almost lengthwise many miles away.

Civil Developments.—Immediately after World War II several manufacturers in Great Britain and the U.S. offered simple radar equipment suitable for coastwise navigation. Ship-borne sets generally employ microwaves in the X band (3 cm.) in order to keep the antenna size small. The rotating antenna presents upon a PPI scope the echoes from the coast lines, obstacles and other ships. Shipboard radars steadily increased in number, coming into use even in small fishing and pleasure craft.

In some ports large radar surveillance sets have been installed ashore overlooking the harbour and approach waters in order to assist shipping when visibility is bad. The radar operator observing ship movements in the confined waters advises pilots of harbour traffic conditions from moment to moment by means of radiotelephone. A notable system at Liverpool, Eng., installed in 1948, guided ships through the narrow approach waters under adverse conditions of visibility. The system utilized six PPI scopes to cover in detail (discriminating within 40 yd.) the 14 mi. of the Mersey river channel and harbour front that are kept under constant surveillance.

Proposals were also made soon after World War II for the installation of radar navigational equipment in commercial airliners and for the establishment of ground radar stations along commercial airways and at airports. The U.S. Civil Aeronautics administration, which became the Federal Aviation agency (FAA) in 1958, promoted installation at major airports of GCA radar systems by means of which traffic controllers could observe airliners approaching in bad visibility or at night, guide them by means of radiotelephone and "talk" the pilots safely down to the field. GCA had not been provided at all airports in the early 1960s, partly because pilots preferred the instrument landing system, or ILS, a radio navigation and landing aid that has long been standard equipment at many airports over the world.

GCA in this application requires two types of radar. Airport surveillance radar (ASR) scans a circle 30 mi. or more in radius around the field and displays upon a PPI scope in the control tower all aircraft within range up to within about 5 mi. Within this smaller inner circle a precision approach radar (PAR) takes over, using a limited-angle PPI or B-scope and a range-height indicator. Airport surveillance sets employ pulse modulation, and all recent types also include MTI so that operators can switch to the MTI technique if necessary in order to distinguish moving echoes (airplanes) from fixed reflections in the area being scanned.

More GCA radar of an improved type was coming into use by the early 1960s as the FAA carried out a program of installing sets with longer range and greater refinement. A high-definition radar, known as airport surface detection equipment (ASDE), that gives almost photographic clarity (using very short 1-cm. waves) in distinguishing planes and motor trucks on the field, began to be used in 1960. The first two installations were made at the Idlewild, N.Y., and Newark, N.J., airports.

Meanwhile, air-borne radars, using wave lengths of about 5 cm., were being installed in increasing numbers of large modern air transports, primarily for storm detection, enabling pilots to fly evasive courses around dangerous turbulence. Frequencies corresponding to the wave lengths of about 5 cm. were found to be best for echo reflection from storm clouds.

Radar astronomy, the study (by means of radio reflection) of the moon and other bodies in the solar system, became possible with increased transmitter power, greater receiver sensitivity and the uses of electronic computers to discriminate the extremely weak echo signals from the stronger interfering signals of inevitable noise. The radar technique enables more accurate measurement of distance than optical methods permit, and it enables study of surface structure of bodies in the solar system. Radar astronomy is closely related to radio astronomy (*q.v.*), since the supersensitive radar receiver can be used alone to listen to the many active emitters of radio waves, such as those from heat and gaseous sources within the solar system and from innumerable other sources both in our galaxy and beyond it.

The first radar contact with the moon, about 250,000 mi. away, was made by the U.S. army signal corps in Jan. 1946, using a modified SCR-271 radar. This initial success was followed in 1958 with radar reflections from Venus, some 28,000,000 mi. distant, and in 1959 by radar contact with the sun, nearly four times as far.

Both the Venus contacts (by the Lincoln laboratory of the Massachusetts Institute of Technology) and the echoes from the sun (accomplished by researchers at Stanford university) required computer techniques for study of the echo patterns. The echoes, returning minutes after the transmission because of the enormous distances involved, were so weak that they could not be immediately distinguished from the radio noises, both those received from without and those generated within the receiver circuits. But by recording the received signals and processing them with an electronic computer, researchers were able to separate out the echo pattern. From it they could determine something of the nature and characteristics of the reflecting body. With improved equipment and techniques radar astronomers expected to be able to map the planets in considerable detail.

III. FACTORS AFFECTING RADAR PERFORMANCE

1. The Free-space Radar Equation.—A radar set must detect the weak signal returned from a distant reflecting object. The radar equation is important because it connects the various quantities that govern the strength of the signal so received. This relation will not serve to determine the maximum range at which the radar can detect a target unless the minimum power which gives a detectable radar signal, $S_{\min}$, is known. The value of this latter important quantity will be found to depend on many factors. not all of which are accessible to measurement.

In discussing the radar equation, we first assume the very simple case of free-space propagation of the radio waves used in radar. This corresponds to a situation in which (1) no large obstacles intervene between the radar antenna and the target, along the optical line of sight; (2) no alternate transmission path, via a reflecting surface, exists for the radio energy; (3) the intervening atmosphere which must be traversed by the radio energy is homogeneous with respect to index of refraction at the frequency used; and (4) no appreciable absorption occurs in the atmosphere.

These conditions restrict our attention to radar targets within the optical horizon, and in fact to targets high enough above the horizon to avoid important effects (see below) which arise from the reflection of an appreciable amount of energy from the surface of the land or sea. If the conditions of free-space propagation apply. the transmitted radio wave has spherical wave fronts (limited in extent by the directional properties of the antenna) which spread out in such a way that the intensity of the radio wave changes with the inverse square of the distance from the radar antenna.

If the transmitting antenna radiated energy uniformly in all directions, the power flow through unit area at a distance R from the antenna would be the transmitted power, P, divided by $4\pi R^2$. Most radar antennas are directive, however, and concentrate the energy in certain directions. so that the power flow observed at some distant point will differ by a factor G from that which would be produced by an antenna radiating uniformly the same total power. The quantity G is called the gain of the antenna in the direction in question. Its average taken over a complete sphere surrounding the antenna must clearly be unity. As radar antennas are ordinarily highly directive. we shall usually be interested in the maximum value of G, which we call G_o. When the radiating system, or antenna, can be regarded as an aperture of large area (measured in square wave lengths), over which a substantially plane wave is excited, we can write a useful expression for the maximum antenna gain. G_o. The maximum antenna gain is related to the antenna area A and the wave length λ by the following relation:

$$G_o = \frac{4\pi A d}{\lambda^2} \tag{2}$$

For actual antennas, the dimensionless factor d is usually about 0.6.

A second important property of an antenna is its effective receiving cross section. This quantity, whose dimensions are those of area. yields the total signal power available at the terminals of an antenna when an incident plane wave of unit power per unit area falls upon it. Effective receiving cross section is related to antenna gain as follows:

$$A_r = \frac{G\lambda^2}{4\pi} \tag{3}$$

In this equation. G has been written instead of G_o to emphasize that the applicability of eq. (3) is not limited to the direction of maximum gain or to beams of special shape. Once the gain of an antenna in a particular direction has been specified, its effective receiving cross section for plane waves incident from that direction is fixed.

To obtain a measure of the amount of power reflected by the target, we define the radar cross section of the target. σ, as follows: σ is to be 4π times the ratio of the power per unit solid angle scattered back toward the transmitter, to the power per unit area in the wave falling on the target. In other words, if the power falling on an area a located at the target position were to be scattered uniformly in all directions, the power received at the radar would be just the same as it is in the case of the actual target. Ordinarily, σ must be inferred by measurements on actual targets, since it depends in a complicated way on the wave length and on the angle at which a target is viewed.

We are now ready to formulate the radar equation. If S is the signal power received, P the transmitted power. G the antenna gain. λ the wave length, σ the radar cross section of the target, and R the range, or distance between radar and target,

$$S = \left(\frac{PG}{4\pi R^2}\right)\left(\frac{\sigma}{4\pi R^2}\right)\left(\frac{G\lambda^2}{4\pi}\right) \quad (4)$$

The quantity in the first parentheses gives the power density at the target; when we multiply by the second parentheses we obtain the power which returns to the radar antenna; the last factor is the receiving cross section of the antenna. Rearranging,

$$S = P\frac{G^2\lambda^2\sigma}{(4\pi)^3R^4} \quad (5)$$

This equation contains G, not G_o, and is thus valid for any direction. Usually we are interested in the return signal when the target lies somewhere along the direction the radar beam is pointing; G should then be replaced by G_o. If we then write G_o in terms of A, according to Eq. (2), we obtain

$$S = \frac{P\sigma A^2d^2}{4\pi R^4\lambda^2} \quad (6)$$

The received signal power is proportional to the power of the transmitted signals, to the radar cross section of the target and to the square of the antenna area. It is inversely proportional to the wave length squared. and to the fourth power of the range. If the minimum signal power required for detection, $S_{\min}$, is known. we can rearrange Eq. (6) to give the maximum range of detection, $R_{\max}$, for a target of given cross section, σ:

$$R_{\max} = \sqrt[4]{\frac{P\sigma A^2d^2}{4\pi S_{\min}\lambda^2}} \quad (7)$$

To help fix ideas. it will be useful to give a numerical example of the use of this equation, with values for the quantities involved which were not unusual in wartime pulse radar practice. Let $\lambda = 0.10$ ft. ($=3.0$ cm.), P $= 10^5$ watts, A $= 10$ ft.^{2}, d $= 0.6$, a $= 100$ ft.^{2} (the radar cross section of a small aircraft) and $S_{\min} = 5 \times 10^{-12}$ watts. We then obtain $R_{\max} = 155{,}000$ ft. or 29 statute miles.

A sixteenfold increase in transmitted power is required to double the maximum range. It would appear that $R_{\max}$ could be doubled by doubling the linear dimensions of the antenna. However. this change cannot be discussed so simply, as the decrease in radar beam width resulting from making the antenna larger indirectly affects $S_{\min}$. A change in wave length is also difficult to discuss, since it produces changes in $S_{\min}$, P and possibly σ as well.

2. The Minimum Detectable Signal.—The reason that $S_{\min}$ has a finite value. and cannot be made indefinitely small, is that an amplifier intended to increase the power of a feeble electrical signal always produces random electrical fluctuations, called "noise." As the true signal entering any receiver is made weaker and weaker. it subsides eventually into the fluctuating background of noise and is no longer discernible.

The limit of sensitivity of an ordinary low-frequency radio receiver is set, not by internal noise, but by similar random disturbances which originate outside the receiver. These disturbances enter the receiver by means of the antenna, so that the effectiveness of a desired signal in competition with such interference is the ratio of signal to the interference power at the antenna terminals. The absolute level of interference power throughout the conventional radio bands (down to a few metres wave length) is so high that internal noise in a reasonably well-designed radio receiver is negligible by comparison.

The situation is different in the microwave region, where external noise interference is almost wholly negligible. Great effort has. therefore, been put on reducing the inherent noise of microwave receivers.

Quite general theoretical considerations give the result that the mean square noise voltage unavoidably generated in a receiver is proportional to the width of the band of frequencies amplified by the receiver. This band width will be denoted by B. The excellence of a receiver in respect to its noise output is usually specified in terms of an over-all noise figure. N. This quantity is more or less arbitrarily defined as the ratio to the quantity kTB of the signal power at the antenna necessary to make the output signal power equal to the mean noise power. In this definition, k is Boltzmann's constant (1.38×10^{-23} joules/degree), and the temperature T is taken as 291" K.

Over-all noise figures of 10 were not uncommon for the best post ar microwave receivers. A noise figure of 10, at a bandwidth of 3 mc.. means that an input signal of 1.2×10^{-13} watts is sufficient to increase the receiver output by an amount equal to the average noise output.

When a receiver is designed to detect pulses of duration τ seconds. there will be a best choice for the band width B. As already remarked, the average noise power increases in proportion to B. However, this does not mean that B should be made as small as possible, for when B becomes much less than $1/\tau$, the output signal power resulting from each pulse will be proportional to B^2. Experiment has shown that the best value of B is about $B = 1.2/\tau$, but it can be changed by small amounts from this best value without serious effect on performance. In the mid-1950s, a value of B near $2/\tau$ was typical of pulse radar practice.

What has just been said does not yet constitute a specification for $S_{\min}$, the minimum detectable signal. The noise with which a signal must compete for recognition is statistical in character: that is. while the likelihood of large noise peaks is small, such large peaks do occur. For example, in the output of a receiver whose band width is 2 mc., there is better than an even chance that one noise peak having more than 20 times the power of the average will be seen in an hour's observation. About 100 noise peaks greater than 10 times the average will be observed each second. This random character of the magnitude of noise peaks makes signal detection largely a game of chance. It is a game of chance in which several factors favour an actual signal, however, A true radar echo is repeated at the same point on the indicator for each successive sweep. while noise peaks occur at random locations. This important difference between a signal and noise can either be used by the indicator directly—if the indicator screen shows a stronger signal for repeated excitation in the same place—or by the eye and mind of the observer. The latter means is astonishingly effective, as has been shown by experiment. The practical effect of this phenomenon of integration. whether it occurs in the indicator or in the mind of the observer, is to make $S_{\min}$ depend upon the pulse repetition frequency, n, of a radar approximately in proportion to $1/\sqrt{n}$.

The problem of actual signal detectability is much more complicated than has been indicated here. It should be noted. however. that the very strong dependence of signal power on range shown by eq. (6) illustrates the fact that most signals which are at all detectable will be very strong.

3. Propagation of Short Radio Waves.—We shall now examine the principal ways in which propagation conditions near the surface of the earth and through the atmosphere introduce effects which are not included in the free-space radar equation, Eq. (6). This is a vast subject, and only a few of the basic considerations can be mentioned here.

Effect of a Reflecting *Surface.*—If the transmission path between radar and target lies near a reflecting surface. energy may be able to reach the target (and scattered energy to return to the radar) by way of reflection from the surface, as well as directly ifig. 3). In the case of a flat, perfectly reflecting surface, the ratio. W, between the actual power at the point B of fig. 3 and the power which would have been observed at B for free-space conditions, can be readily computed. It depends on (among other things) the phase change produced in the reflected wave by the process of reflection. This phase change depends on the angle of incidence, θ, on the state of polarization of the incident wave and on the electrical properties of the reflecting surface. In radar. only grazing angles of incidence are practically important, and only the surface of the sea is sufficiently smooth to be an

FIG. 3.— WAVE PROPAGATION OVER A FLAT REFLECTING SURFACE. RADAR ANTENNA AT A, TARGET AT B

adequate reflector for microwaves. Under these circumstances, the ratio of the power actually reaching B to that which would reach it under free-space conditions is given by

$$W = 4 \sin^2 \left(\frac{2\pi h_1 h_2}{\lambda R}\right) \tag{8}$$

This ratio, as shown by eq. (8), varies between 0 and 4; the latter value being attained when the direct and reflected waves arrive at the target exactly in phase, as they will do when $4h_1h_2/\lambda R$ is equal to an odd integer. As the geometry of the problem is not afiected by interchanging source and target, the reflection must affect the return of the radar echo to the same degree as it affects the pulse transmission. Therefore the required modification of the radar equation is obtained by multiplying the radar equation for free-space propagation by W^2, giving

$$S = P\frac{G^2\lambda^2\sigma}{(4\pi)^3R^4} \cdot 16 \sin^4\left(\frac{2\pi h_1 h_2}{\lambda R}\right) \tag{9}$$

The effect of this modification is to introduce a strong dependence upon target height into the expression for the signal returned by a target to a radar which looks out over the surface of the sea. This is important for ship-based and coastal radar sets. Radar coverage under such circumstances shows a strong "lobe" pattern like that of fig. 4. At the maxima of the lobes, the received signal shows an increase by a factor of 16, leading to a doubling of the maximum radar range against a given target. An aircraft flying high enough to be well above the lowest lobe shown in fig, 4 will give a signal which flashes up and disappears repeatedly as the plane flies in toward the radar at constant altitude. Target height can be estimated by noting the ranges at which signal "fades" occur.

FIG 4 —LOBES OF SIGNAL-STRENGTH PATTERN RESULTING FROM INTERFERENCE OF DIRECT AND REFLECTED WAVES

For targets at low angles (*i.e.*, in the region where $\frac{2h_1h_2}{R\lambda} < 1$) we can replace the sine in eq. (9) by its argument, obtaining

$$S = 4\pi P\frac{G^2\sigma(h_1h_2)^4}{\lambda^2R^8} \tag{10}$$

In this region of angles, the signal strength falls off as the inverse eighth power of the range, rather than as the inverse fourth power, if all other factors are held constant. Since the range at which this eighth-power dependence begins varies as the reciprocal of the radar wave length for fixed heights of radar antenna and target, the shortest radar wave lengths have a very considerable practical advantage when the primary task of radar is to search the sea for low-lying targets, the radar antenna itself being mounted at no great height.

Experiments have borne out this conclusion. and microwaves were commonly used for ship-based sea-search radar sets during and after World War II.

The *Round* Earth— Since beams of microwave radio energy travel substantially in straight lines, the distance at which a radar whose antenna is at height h_1 can see a target at height h_2 will be limited by the optical horizon. Actually, the diminishing density of the air with increasing height above the surface of the earth gives rise to a vertical gradient of atmospheric index of refraction. with the result that a slight downward curvature is introduced into all rays. The effect of this curvature is to extend slightly the practical horizon for microwaves. Due to a chance numerical relation between units, the following easily remembered formula gives R,,, the range to the horizon under "standard" conditions, for a height h above the surface of the earth:

$$R_h(\text{statute miles}) = \sqrt{2h(\text{feet})} \tag{11}$$

If we desire to find the greatest range at which a radar whose antenna is at height h_1 can see a target at height h_2, we must add the corresponding horizon distances, obtaining

$$R = R_{h1} + R_{h2} = \sqrt{2h_1} + \sqrt{2h_2} \tag{12}$$

Radio waves in the ordinary communication bands (down to a few metres wave length) are propagated over the horizon by either of two eifects. At the longest wave lengths, the energy is bent over the horizon by the phenomenon of diffraction; but energy can also travel around the curve of the earth, far beyond the horizon, because of the reflection of radio waves from the ionosphere, the ionized layer in the upper atmosphere. At radio frequencies around 100 mc. there is little reflection from the ionosphere; in the microwave region, from about 1.000 mc. up to higher frequencies, the ionosphere is transparent to radio waves. Thus neither diffraction effects nor ionospheric reflection can enable microwave radar to detect targets over the horizon, but there is some extension of range due to refraction in the lower atmosphere.

FIG. 6.— ATTENUATION CAUSED BY WATER VAPOUR (CURVE *a*) AND BY OXYGEN (CURVE *b*) AS A FUNCTION OF WAVE LENGTH. CURVE a APPLIES TO AN ATMOSPHERE CONTAINING 10 GRAMS OF WATER VAPOUR PER CUBIC METRE. CURVE b APPLIES TO AN ATMOSPHERE WHICH IS 20% OXYGEN AND HAS A TOTAL PRESSURE OF 76 CM. OF MERCURY

Within the horizon. the curvature of the earth complicates somewhat the geometry of the interference problem involving reflection Eq (9) and (10) are not strictly applicable. for they were derived on the assumption of a flat reflecting surface The result of taking the earth's curvature into account can be shown by means of a coverage diagram (fig. 5). The curves of fig. 5 are contours of constant field strength. which means that the signal received from a given target will be the same no matter where it is located along a given contour.

Superrefraction.—It has already been mentioned that the atmosphere normally shows a vertical gradient of refractive index that results in a slight downward bending of rays of light or microwaves. Were this curvature only a few times greater, it would equal the curvature of the earth; under such conditions the "horizon" would vanish and a ray would bend around the earth aithout leaving the surface. Refractive index gradients of the magnitude necessary to produce such curvature amount to about five parts in 10^8 per ft. Under some conditions such gradients can be produced by temperature gradients alone, or, more commonly. by a vertical gradient in the concentration of water vapour in the atmosphere. Over the surface of the sea, the effects of evaporation of water into the air immediately above the surface and the diffusion of water vapour into still higher layers of air lead sometimes to the creation of a relatively shallow layer just above the water within which the vertical gradient of refractive index is negative and exceeds the critical value of five parts in 10^8 per ft.

In such circumstances, superrefraction takes place, and it is possible for microwaves to be propagated to distances many times the usual horizon distance. This phenomenon is specially common in certain parts of the world where climatic conditions favour its occurrence.

Atmospheric Attenuation —At the shortest microwave lengths, the earth's atmosphere is not entirely transparent, as it is for all practical purposes to waves of frequency lower than about 1.000 mc. The loss of energy, or attenuation, of a radar beam traveling through the atmosphere may be due to either of two causes: (1) direct absorption of energy in the gases of the atmosphere; or (2) absorption and scattering of energy by condensed matter such as raindrops. All such processes lead to an exponential decrease of energy in the beam with increasing distance from the source.

This exponential decrease is superimposed on the inverse-square decrease in energy with increasing range that was used in formulating the radar equation. Of the atmospheric gases. oxygen and water vapour absorb microwave energy in the frequency range experimentally used for radar. This absorption is due to the production thereby of a transition of the molecule of water vapour or of oxygen between two definite energy states. The observed absorption is thus characterized by "lines." such as those found in more familiar regions of the electromagnetic spectrum. Experimental results (solid lines) and their theoretical extension (dotted lines) are shown in fig. 6.

Energy is also absorbed and scattered by particles of solid and liquid in the atmosphere. Droplets of water, present as fog, cloud or rain. are practically the most important particles of this sort. The attenuation by water droplets is of little practical consequence at wave lengths of 10 cm. or more, although sufficient energy is scattered from storm areas to give radar echoes at all microwave lengths.

At wave lengths shorter than 10 cm., increasing attenuation is observed. Experimental results are given in fig. 7.

4. Target Properties. — Some useful things can be said about the radar cross section, σ, of various targets. In the case of the simplest single targets, σ can be calculated by electromagnetic theory; for other simple cases an approximate calculation will yield good results. A few values of radar cross section of such simple targets are collected.

(1) Dielectric sphere of radius small compared with wave length. Sphere radius a, dielectric constant ϵ, wave length λ.

(0.32 GRAMS WATER PER CU. METRE). CURVE Q FOR VISIBILITY ABOUT 100 FT. (2.3 GRAMS WATER PER CU. METRE)

$$\sigma = 4\pi\left(\frac{2\pi}{\lambda}\right)^4 \left|\frac{\epsilon - 1}{\epsilon + 2}\right|^2 a^6 \qquad (13)$$

(2) Metal sphere of radius small compared with wave length.

$$\sigma = 9\left(\frac{2\pi a}{\lambda}\right)^4 a^2 \qquad (14)$$

(3) Flat metal sheet of area *A* placed perpendicular to radar beam. Dimensions of plate large compared with wave length.

$$\sigma = \frac{4\pi A^2}{\lambda^2} \qquad (15)$$

(4) Cylinder of radius R and length 1, both large compared wirh wave length. Cylinder is viewed perpendicular to axis.

$$\sigma = 2\pi\frac{Rl^2}{\lambda} \qquad (16)$$

(5) Segment of spherical surface of radius R, viewed either on concave or convex side. Diameter of segment, perpendicular to the incident beam, must be greater than λ.

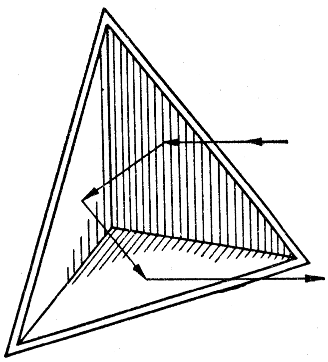
$$\sigma = \pi R^2 \qquad (17)$$

Eq. (17) is also valid for a nonspherical curved surface, if the geometric mean of the two principal radii of curvature is used for R.

An important type of simple target is the corner reflector. This is used when a compact radar' target with a large cross section in any direction oi observation is desired. It consists of an arrangement of three planes intersecting at right angles. The law of optical reflection yields the result that a ray directed into the corner formed by three such planes will undergo triple reflection and be sent back in the direction from which it came (set: fig. 8). The maximum radar scattering cross section of such a corner, which it exhibits when viewed along the axis of symmetry of a single corner, is

$$\sigma_{\max} = \frac{4\pi a^4}{3\lambda^2} \qquad (18)$$

where a is the length of an edge of the corner and λ the radar wave length. The cross section remains large over most of the octant for which a single corner is effective; all directions can be covered by making a cluster of eight such corners (fig. 9).



FROM RADIATION LABORATORY SERIES, MC-GRAW-HILL BOOK COMPANY, INC.

FIG. 8.—PRINCIPLE OF THE CORNER REFLECTOR

Radar cross section can be reduced by the use of materials absorbent at. radar frequencies. Such materials are of two principal types. In the first kind, reflections occurring at the front surface of the absorber are cancelled by destructive interference with the wave that enters the layer and subsequently re-emerges. Such absorbers are similar to the anti-reflection coatings applied to glass. Absorbers of the second kind are designed so that no reflection takes place at the front surface and high attenuation in the material extinguishe's the entering wave. A continuous gradation from one kind of absorber to the other exists.

During World War II, the Germans produced a material of the first kind which was used for the camouflage of U-boats, to lessen the likelihood of radar detection of a surfaced submarine. An absorber of the second kind, which was never actually used. was also produced by the Germans. Its absorption was excellent uver the wave length range from 4 to 13 cm.

Complex Targets.—Most radar targets are much more complicated than the simple ones so far mentioned in this section. For such complex targets. the effect of interference of waves reflected frorn various parts of the target is extremely important in determining the strength of the received signal.

Ground "Painting" by Radar.— Air-borne radar equipment mas extensively used in military aircraft during World War II for navigation by piloiage under conditions of restricted visibility. Point-to-point variations in the radar reflection properties of the earth's surface enable the radar indicator to display a picture which, at best, shows a good relation with a map. Radar displays a marked contrast between land and water surfaces because of the greater diffuse scattering of the radio waves by the iormer.

Cities and groups of structures on the ground return a bigger signal than open country. possibly in part because of the retrodirectivity of the corner reflectors formed by building walls and the ground. Mountains and ridges can be distinguished by increased intensity on the near side and shadows cast beyond. The higher definition available with narrow-beam equipment using the shortest microwave lengths is important in giving a display which is easy to interpret. In all cases. however, experience and skill of the operator are important in making a good correlation between the radar picture and the ground beneath, especially inland in rather featureless country. Misidentification is so easy under these and other circumstances that air-borne radar must be regarded as an aid to dead reckoning, rather than a complete means of navigation in itself.

When the aircraft position is known to an accuracy of 20 or 30 mi., the radar display can hardly be interpreted incorrectly, even by an inexperienced operator.

FIG. 9.—CLUSTER OF CORNER REFLECTORS

IV. CW RADAR SYSTEMS

Since radar echo signals are so very feeble in comparison with the transmitted energy, they must be detected by some property which differentiates them from the transmitted signal in a readily measurable way. In pulse radar, this is done by turning off the transmitter for most of the time, so that signals received during the "off" time of the transmitter can be identified as echoes. It is possible to recognize echoes, however, even while the transmitter is working, on any of several schemes. Radio detection devices that involve a transmitter duty ratio of as much as 10% (in pulse radar this duty ratio is typically 0.1%) will be lumped here under the name CW radar. Devices of this sort have found important practical applications. (See NAVIGATION.)

If the targets of principal interest all have a radial motion relative to the radar. their echo signals can be distinguished by the frequency shift which is a consequence of the reflection of waves from a moving mirror. This frequency shift. f_d, is given by $(2v_r/c)f$, where v_r is the radial velocity, c the velocity of light and f the unmodified radar frequency. Numerically, with v_r in statute miles per hour and f defined by a wave length λ in cm. (equal to c/f), the frequency shift, which is called the "Doppler frequency," is given by

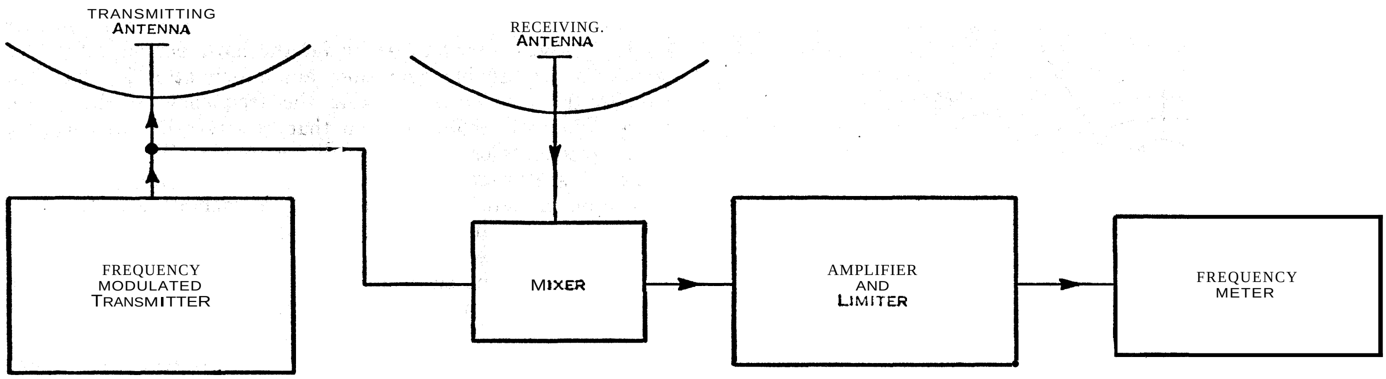
$$f_d = 89.4\frac{v_r}{\lambda} \qquad (19)$$

Thus at 10-cm. wave length. v_r amounts to about 9 c.p.s./m.p.h.

The Doppler-shifted return signal, when added to the transmitter voltage and rectified! gives rise to a voltage with small pulsations recurring at the Doppler frequency. The steady component can be removed by a high-pass filter (which may be simply a transformer or a series condenser) and the fluctuations then amplified and used to actuate an indicator. If the output signal is fed to ordinary telephone receivers, the ear can detect signals denoting the presence of a moving target over the range of World War II aircraft speeds. if the radar works at 10-cm. wave length.

CW radar systems of the type just described. with suitable technical modifications that do not affect the principle of operation, were built during World War II. 'Although they were not used in actual combat, they proved most useful in making precise measurements of the velocities of projectiles.

The system just described, though measuring the radial velocity of a target in a simple and accurate way, affords no information regarding target range. To measure range; the outgoing wave must be marked or modulated in some way, and the time re-



FROM RADIATION LABORATORY SERIES, MCGRAW HILL BOOK COMPANY, INC

FIG. 10.—SIMPLIFIED BLOCK DIAGRAM OF FREQUENCY-MODULATED CW RADAR SYSTEM FOR MEASURING RANGE

quired for the marks on the wave train to return as an echo must be measured. Either amplitude modulation (AM), or frequency modulation (FM), of the outgoing wave can be used.

The most familiar way of employing AM is that of pulse radar to determine the time delay between the transmission and reception of a pulse. However, we can also measure range by the use of two separate CW radar systems like the one described above, the transmitter frequencies of the two differing by an amount f_r. Let f_t be the frequency of one transmitter and $f_t + f_r$ that of the other. The Doppler frequencies developed by the two systems when they look at a single target moving radially will differ, since these Doppler frequencies involve the transmitter frequency, as eq. (19) shows.

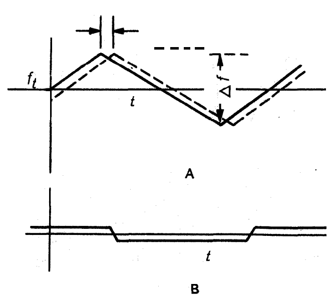
If the target is very close to the system, the number of wave lengths in the distance from transmitter to target and back is very nearly the same for the two systems, since their frequencies differ only slightly. Thus the transmitter signal and the target signal will be in phase or out of phase with one another at the two receivers simultaneously, and the two Doppler outputs will be in phase for very short range. As the target gets farther away, one Doppler signal shifts phase more rapidly than the other, so that a phase difference between the Doppler outputs of the two systems is developed. When the target is far enough away so that the number of wave lengths to the target and back is one greater for $f_o + f_r$ than it is for f_r, the phase difference in the outputs is 2π. This phase difference, which is given by

$$\phi = \frac{4\pi f_r}{c} r \tag{20}$$

where ϕ is the phase shift, r the range, and c the velocity of light. is a linear function of range and can be used as a measure of range. It becomes ambiguous for targets so far away that the phase shift is greater than 2π.

1. Range Measurement by **FM.**—One of the most important applications of CW radar systems during World War II was their use for the measurement of the altitude of aircraft with reference to the earth or sea below. A system employing frequency modulation of the transmitted signal was developed for this purpose in the U.S., and independently a very similar system was worked out in Germany.

A schematic diagram of the system components is shown in fig. 10; the operating principle of the system is illustrated by the curves of fig. 11. The transmitter frequency varies linearly with time in the fashion shown. Energy arrives at the receiver both directly from the transmitter and by reflection from the target. Since the trip to the target and back takes time, the received frequency (indicated by the dotted line) is displaced along the time axis relative to the transmitter frequency. The two frequencies combine in the mixer to give a beat of constant frequency (except during the short crossover intervals when the sign of the FM is changing). The greater the target distance, the greater this beat frequency; its magnitude is a direct measure of the range. The beat signal between transmitter signal and echo is therefore amplified, and its frequency measured by a direct-reading frequency meter which can be calibrated in terms of range.



FROM RADIATION LABORATORIES SERIES, MC-GRAW HILL BOOK COMPANY INC

FIG. 11—PRINCIPLE OF FM RADAR ALTIMETER

If it is desired to use this same principle for radar search, several targets may give return signals simultaneously. The receiver output will then contain several signals at different frequencies. These can be individually detected either by a frequency meter which will respond to and indicate several signals simultaneously, or by scanning a single-frequency meter over the frequency range corresponding to the target distances which must be covered. The vibrating-reed frequency meter will serve as an example of the first technique. In the second method, for example. a variable frequency can be added to the output signal and observations made when the beat frequency between the two signals falls in the pass band of a resonant circuit. Scanning devices are usually objectionable because they increase the time necessary to make an observation.

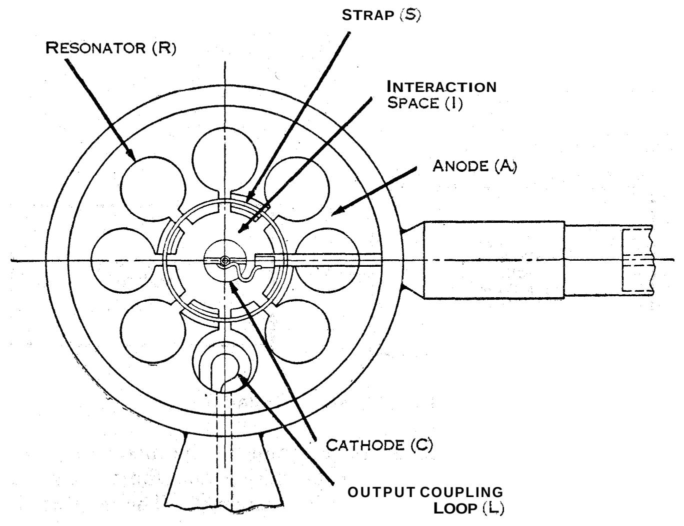
In addition to the CW radar systems whose operating principles have been sketched, there are many other types that involve different schemes of modulation of the transmitted signal and different techniques for handling the received echo. Though the amount of wartime development work which went into such CW systems was only a tiny fraction of that expended on pulse radar, there are applications for which CW radar is markedly superior.

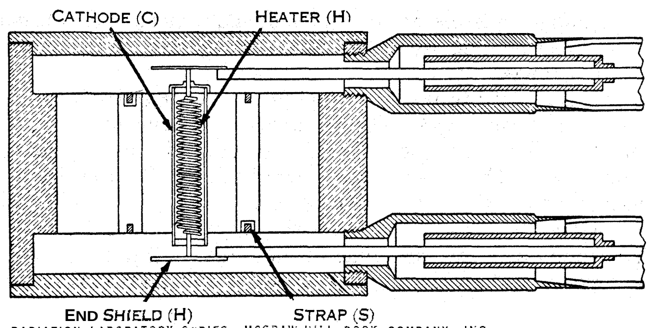
For example, in accurate measurement of ranges as small as ten feet, a CW system is simpler than pulse radar. A system making use of the Doppler shift in frequency will measure the speed of a bullet in an easy and direct way and to any desired degree of accuracy. Or again, simple equipment may be desired, as in the familiar speed-detector radar employed in policing highway traffic, involving operation at short ranges (using microwaves of about 1 cm. in length).

V. RADAR COMPONENTS

1. The Multicavity Magnetron.— Beginning about 1938, the British made strenuous efforts to develop sources of high-power pulses at microwave frequencies, because of the importance of narrow radar beams in the air-borne equipment they were then attempting to develop. The modification of conventional tube types offered little promise; since to a first approximation, the electronic characteristics of a low-frequency tube are maintained at high frequency only if all tube dimensions are scaled in proportion to the wave length, λ. Near 1,000 mc., the practical consequences of this reduction in tube dimensions become serious. Electrode clearances become so small they are hard to maintain, while the reduction in cathode and plate areas (proportional to X^2) rapidly reduces peak emission and plate power dissipation.

An entirely new type of tube, the multicavity magnetron. was invented to serve the new requirement. By the 1950s, magnetrons had produced pulse powers as high as 10,000,000 watts at fre-





FROM RADIATION LABORATORY SERIES MCGRAW-HILL BOOK COMPANY. INC.

FIG. 12.— CROSS SECTIONS OF A TYPICAL CAVITY MAGNETRON. MAGNETIC FIELD PERPENDICULAR TO UPPER FIGURE: VERTICAL IN LOWER FIGURE

quencies near 3.000 mc., and hundreds of kilowatts even at 24,000 mc. Klystrons are useful sources of continuous R.F. power at frequencies as high as 24,000 mc. and can also be designed to give high pulse power.

The magnetron is a self-excited oscillator capable of converting D.C. power into R.F. power with high efficiency. The main features of the design of a typical magnetron are shown in fig. 12. Between the indirectly heated cylindrical cathode C and the anode block A is an interaction space I, in which the conversion takes place. A constant! uniform, magnetic field is maintained in this interaction space in a direction parallel to the axis of the cathode. The anode block is pierced in a direction parallel to the field by a number of resonating cavities R, which open into the interaction space so that the inner anode surface consists of alternate segments and gaps. At the ends of the cavities are open "end spaces" which permit lines of magnetic flux to link one resonator to the next. Coupling between the resonators is increased by conducting bars called straps, S, which connect together alternate anode segments, An output coupling loop. L, extracts R.F. power from one resonator and feeds it to the output circuit.

Each of the eight resonant cavities shown in fig. 12 can be thought of as a simple oscillating circuit consisting of lumped inductance L_o and capacity C_r. When the magnetron is oscillating in the desired way, the capacities of the individual cavities are connected in parallel, and so are their individual inductances. The frequency of the magnetron as a whole is then about the' same as that of an individual cavity, since the frequency is proportional in either case to the product of inductance and capacity. The impedance of the oscillators, however, depends on L_o/C_o, and magnetrons of the same frequency but different impedance can be constructed by changing the shape of the individual resonators to keep L_oC_o constant while altering L_o/C_o.

Like all systems of coupled individual oscillators, the resonant systems of a magnetron can oscillate in different modes; in general these modes will have different frequencies. One of these modes has been found to be by far the most desirable from the standpoint of reliable operation, and much attention has been paid to the problem of making the frequency of the desired mode sufficiently different from that of any other to encourage the magnetron to oscillate in the desired mode. The straps shown in fig. 12 are primarily for this purpose of accomplishing mode separation in frequency; another way of achieving such separation is to make the alternate individual resonators of different natural frequencies.

Instead of a tube such as that of fig. 12, intended to be put between the poles of an electromagnet or a permanent magnet, a tube can be built in which the magnet pole tips are actually part of the construction of the magnetron proper. In this way, the air gap over which the magnetic field must be maintained is cut down, and as a result the required magnetomotive force (and the physical size of the magnet) can be greatly reduced. Permanent magnets are usually employed with magnetrons.

An electron in the interaction space is acted on by a constant magnetic field parallel to the cathode axis, a constant radial electric field resulting from the D.C. voltage applied between anode and cathode! and the rapidly-varying electric field extending into the interaction space from charges momentarily concentrated near the ends of anode segments. Such an electron is also part of a space charge subject to extreme variations in density. The very complex problem of the resulting electron motion has not been solved in detail, but a qualitative idea of the major processes responsible for magnetron behaviour can be given.

A simplified picture of the tnotion of individual electrons is offered in fig. 13. The distribution of charges shown on the anode segments is that appropriate to the desired mode of magnetron operation. The dotted lines with arrows show the resultant electric field. An electron located at point A at the instant shown will be speeded up by the R.F. field. The result of an increase in the tangential velocitv of an electron is. under the field conditions obtaining in the magnetron, to increase the curvature of the electron's path. The electron thus moves along the path shown, strikes the cathode, and plays no further role in the operation of the magnetron.

An electron at point B, however, is in a decelerating R.F. field; the curvature of its path will thus be decreased. If the frequency

FIG. 14.—SPACE-CHARGE DISTRIBUTION IN AN OSCILLATING MAGNETRON INSTANT SHOWN IS THAT OF ZERO R.F. ELECTRIC FIELD LINES OF R.F. MAGNETIC FIELD ARE INDICATED WITHIN CAVITY RESONATORS

of oscillation is appropriate to the motion of the electron, this electron will always be in a decelerating field as it passes before successive anode segments. It will then follow a path of the sort shown, and eventually strike the anode. Since the electron is always retarded by the R.F. field. it gives up to the R.F. field practically all of the energy gained in its fall through the D.C. field between cathode and anode. While this simple picture is qualitatively correct, the detailed operation of a magnetron is doubtless much more complicated. One experimental fact difficult to explain, for example, is that the anode efficiency of some magnetrons can be as high as 85%.

The behaviour of the space charge in the interaction space can be inferred from what has been said about the motion of an individual electron. The result is shown in fig. 14. Four spokes of high electron density contain those electrons which are in the proper position to be decelerated by the R.F. field. This configuration rotates about the cathode with an angular velocity which keeps it in step with the alternating R.F. charges on the anode segments. The R.F. current flowing in the oscillators is principally a displacement current produced by this rotating space charge. Fig. 14 shows the space charge at an instant when the R.F. electric field is zero; the lines of magnetic field in the resonators are shown.

The behaviour of a magnetron with changes of anode current and of pulse voltage can be displayed on a performance chart, which shows how these parameters affect frequency, power, magnetic field and efficiency under conditions of constant R.F. load.

The magnetron as it has so far been described is a fixed-frequency device. However, several different schemes have been worked out for tuning cavity magnetrons. In one way or another, each of these schemes involves loading the resonators so as to change their natural frequency of oscillation.

2. Pulse Modulators.—The modulator, or pulser, of a radar set is a somewhat unusual electrical device. It must supply, in the form of electrical pulses whose duration is in the range from 1/10 to 5 μ sec., currents of some tens of amperes at voltages as high as 50 or 60 kv. These pulses must be generated with a recurrence frequency of a few hundred to a few thousand per second, usually must be accurately spaced relative to one another and, since the magnetron is such a highly nonlinear load, they must be "flat" on top to better than 5% of the rated pulse voltage. In a typical case, a variation in pulse voltage of only 3 kv., will produce, in a magnetron operating at 25 kv. and 13.5 amp., a drop in anode current of 7 amp., which practically stops the oscillation of the magnetron.

In all pulsers, electrical energy stored in some circuit element is released rapidly during the pulse, and replenished during the interval between pulses. Energy can be stored either in the electrostatic field of a condenser or in the magnetic field of an inductance carrying a current. Pulsers employing electrostatic energy storage are far more common than those using an inductance as the storage element, largely because power losses in the latter type of pulser are ordinarily much greater for the same useful pulse output.

The following discussion refers to pulsers using electrostatic energy storage.

The basic circuit of a pulser is shown in fig. 15. If the energy-storage element is a condenser of capacity C, charged to a voltage V, the stored energy is $\frac{1}{2}CV^2$. At $t = 0$ the switch S is closed, and the condenser begins to discharge exponentially through the load resistance. If S is now opened suddenly at a time τ small compared with the time constant R_LC of the circuit, the voltage appearing across the load while the current is flowing is given by

$$V_L(t) = V(1 - \frac{t}{R_LC}), \qquad 0 \geqslant t \geqslant \tau \tag{21}$$

which is constant within a few per cent if $\tau < R_LC$.

In practice. vacuum tubes are the only switches that can be used to open the load circuit suddenly while it is still carrying a large current. The plate resistance of such tubes is always rather large, resulting in a high voltage drop across the switch during the pulse, and a corresponding loss in pulser efficiency. It would be desirable to use a very low-resistance switch, such as a spark or gaseous discharge, to eliminate this difficulty. However, all such devices have the property that the current flow through them, once started, cannot be interrupted until the voltage across the switch has fallen to an extremely low value. Thus, if such a low-resistance switch were used with a pulser having a simple condenser for an energy-storage element, the condenser would have to be completely discharged at each pulse. This is unsatisfactory, since the wave shape of the output pulse would then be exponential, instead of being substantially rectangular, as desired.

If, however, a transmission line is used as an energy-storage element instead of a condenser, its discharge properties under the appropriate load conditions are such that it will supply energy at constant current until it is completely discharged, This is exactly what is wanted for the generation of rectangular pulses. Elementary transmission-line theory shows that if a line of inductance L and capacity C per unit length is charged to a voltage V and then suddenly connected across a resistance R_L, a discontinuous current of magnitude $V/(Z_0 + R_L)$ will flow for a time $2t$, where Z_o is the characteristic impedance of the line $(= \sqrt{L/C})$ and t is its one-way transmission time. If $R_L = Z_o$, no current flows after a time $2t$, and a genuinely rectangular pulse has been generated. The time t is given by $l\sqrt{LC}$, where l is the physical length of the line.

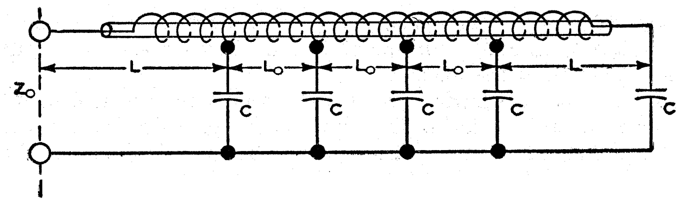
FIG. 15.—BASIC CIRCUIT OF A PULSER EMPLOYING ELECTROSTATIC ENERGY STORAGE



FROM RADIATION LABORATORY SERIES MCGRAW HILL BOOK COMPANY, INC

FIG. 16.— SCHEMATIC DIAGRAM OF A PULSE-FORMING NETWORK. NUMBER OF MESHES REQUIRED DEPENDS ON DURATION OF PULSE

Since the pulse durations desired in radar are usually a microsecond or more, it is ordinarily impracticable to use actual transmission lines or cables in pulsers; a cable to supply a 1-μ sec. pulse would be about 500 ft. long. Instead, an "artificial line" (fig. 16) made up of properly chosen inductances and condensers is used. Such an artificial line is sometimes called a "pulse-forming network." A pulser employing a network as storage element is less flexible than one which uses a condenser and hard-tube switch, since the properties of the network itself fix the pulse duration and the load impedance. Components available for network construction make it desirable to give the network a low impedance; 50 ohms is typical. The magnetron load usually has a much higher impedance, in the neighbourhood of 500 ohms. Specially designed "pulse transformers" are used to match the load impedance to that of the network.

Devices used as the low-impedance gas-discharge switch in a network pulser include rotary spark gaps, fixed spark gaps in series, fixed gaps with an auxiliary electrode for triggering (called "trigatrons"), and thyratrons using either mercury or hydrogen as the filling gas. Hydrogen thyratrons were developed specifically for radar pulsers, and have the advantage over heavy-gas thyratrons in that they can pulse at much higher frequencies, because of the higher ion mobility in hydrogen.

The charging circuit used with either type of pulser so far considered—the "hard-tube" pulser which uses a single condenser as storage element, or the "network" pulser which uses a low-voltage switch—is an important part of the circuit. In the hard-tube pulser, the energy source must clearly supply direct current for recharging. The isolating element prevents excessive power from being drawn out of the energy source when the switch is closed (fig. 15), and must also permit sufficient energy to flow in the interpulse interval to replace that used during the pulse. In the hard-tube pulser, it can be either a high resistance, an inductance or a series combination of resistance and inductance.

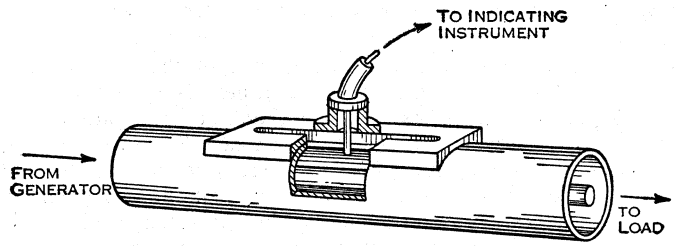
In the case of the network pulser, on the other hand, the full energy of the charged network must be supplied by the recharging circuit after each pulse. This means that a resistance is a very inefficient isolating element, for as much energy will be dissipated in it, each time the network is recharged, as is usefully stored in the network. Accordingly, an inductance is almost always used as an isolating element. Further. the network can be recharged from an alternating-current source, provided the pulse repetition frequency is a multiple of one-half the A.C. supply frequency. An extremely simple high-power pulser can be made by mounting a rotary spark gap switch directly on the shaft of the A.C. machine supplying the recharging current for the network. The hard-tube and the network types of pulser have different fields of usefulness. A comparison of their properties is shown in Table I.

TABLE *I.—Comparison of the Two Pulser Types*

Characteristics	Hard tube pulser	Network pulser
Efficiency	Lower; more power required for auxiliary circuits and for dissipation in switch tube	High, particularly when pulse-power output is high
Pulse shape	Better rectangular pulses	Poorer rectangular pulse, particularly through pulse transformer
Impedance matching to load	Wide range of mismatch permissible	Smaller range of mismatch permissible (+ 20–30%). Pulse transformer will match any load, but power input to nonlinear load cannot be varied over a wide range
Interpulse interval	May be very short; as for coding beacons (*i.e.*, 1 μ sec.)	Must be several times the deionization time of discharge tube (*i.e.*, 100 μ sec.)
Voltage supply	High-voltage supply usually necessary	Low-voltage supply, particularly with inductance as isolating element
Change of pulse duration	Easy; switching in low voltage circuit	Requires high-voltage switching to new network
Circuit complexity	Greater, leading to greater difficulty in servicing	Less, permitting smaller size and weight

3. Radio-frequency Components.—A considerable body of new theory and technique grew up during the development of microwave radar because of the necessity of handling power at frequencies so high that the wave length of the R.F. energy is of the same order as the physical size of the circuit elements. The length of a microwave transmission line may be. and usually is, several wave lengths. For a fuller description of R.F. techniques at microwave frequencies, reference should be made to the works quoted in the bibliography.

***Coaxial Line.*—A** transmission line is characterized, as already remarked, by a characteristic iinpedance which depends upon the inductance and capacity per unit length of line, and is thus a function of the geometry of the insulators and conductors of which the line is made. In a coaxial line, a type frequently used for the transmission of high-frequency energy (fig. 17), the



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 17.— SLOTTED SECTION OF COAXIAL LINE WITH PROBE FOR MEASURING STANDING WAVES

characteristic impedance, Z_o, is given by

$$Z_o = \frac{138}{k} \log_{10}(r_2/r_1) \text{ ohms} \tag{22}$$

where k is the dielectric constant of the material in the annular space between the conductors, r_2 is the inner radius of the outer conductor, and r_1 is the outer radius of the inner conductor.

A uniform line terminated at any point in a load duplicating its characteristic impedance behaves as if it were infinitely long; there is no reflection of energy from the termination. However. any impedance changes along the line (such as those introduced by dents. bends or obstacles in the line), or any departure of the load from the characteristic impedance of the line, will cause the reflection of energy. The reflected wave, which travels back toward the power source, interferes with the outgoing wave to produce standing waves in the line. These can be detected and measured by exploring the voltage along the line with a small movable probe, such as that shown in fig. 17. There will be voltage maxima spaced at half-wave length intervals with minima halfway between them. A line which is properly terminated and uniform, so that it exhibits no standing waves, is said to he "matched."

When a lossless transmission line a quarter wave length long and of characteristic impedance Z_o is terminated in an impedance Z_t, the input impedance of the line is

$$Z_i = Z_o^2/Z_t \tag{23}$$

This property enables two transmission lines of different impedance lo be matched to each other by joining them through a quarter-wave line whose characteristic impedance is the geometric mean of the impedances of the two lines. Such a quarter-wave section is called a "matching transformer." If a quarter-wave line is terminated by a short circuit, its input impedance is infinite; conversely, an open-circuited quarter-wave line appears at the input terminal to be a short circuit.

For a lossless line a half-wave length long,

$$Z_i = Z_t \qquad (24)$$

irrespective of the characteristic impedance of the line.

At microwave frequencies. the losses in the solid dielectrics used to insulate the inner from the outer conductor in a coaxial line are prohibitive at the power levels usually encountered. "Stub-supported" lines have therefore been developed (fig. 18), in which the "insulators" are short-circuited quarter-wave lines. Since the input impedance of such a quarter-wave line is infinite: it has no effect when placed in parallel with the main line. The stub is exactly a quarter-wave long only at one frequency, however, and it is often desired to make R.F. fittings which can work over a frequency band several per cent wide. In the stub support shown in fig. 18. this frequency sensitivity is compensated. over a band of $\pm 15\%$ of the base frequency. by the quarter-wave transformers formed by the fat sections of the centre conductor near the stub support.

Rotary joints which permit mechanical motion while transmitting R.F. power without reflection or mismatch are often required.

Standard coaxial line usually has a characteristic impedance of 50 ohms. this corresponding to a ratio of 2.3 for the radii of the outer and inner conductors. This is a compromise between a ratio of 3.6 (77 ohms) which, for a given outer diameter, gives the lowest attenuation due to conductor losses, and a ratio of 1.65 (30 ohms) which enables the maximum power to be carried at a given breakdown voltage gradient across the dielectric.

The size of a coaxial line is limited by the wave length of the radiation transmitted. The electric fields within a coaxial line have axial symmetry if the line is small enough. If, however. the mean circumference of the annular dielectric space between the conductors exceeds one wave length, a second "mode" of propagation of the R.F. energy can be excited. In this second mode, the field distribution has diametral symmetry. Since serious design complications arise if it is possible for two modes of propagation to be excited simultaneously in an R.F. line, the over-all size of coaxial line is always kept so small that only the axially symmetric mode of propagation can exist. The resulting limitation on power-handling capacity has restricted the use of coaxial lines to wave lengths of 8 cm. and more.

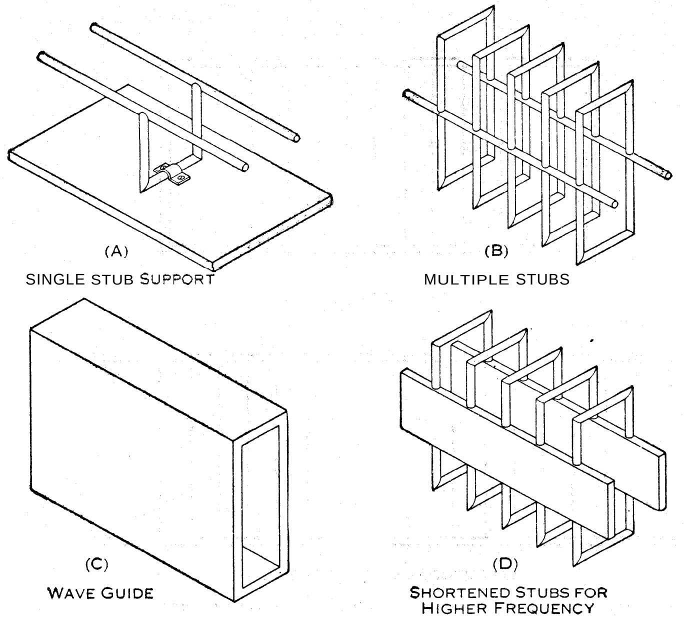
FIG. 18.— BROAD-BAND STUB SUPPORT FOR CENTRE CONDUCTOR OF COAXIAL LINE

Wave Guide.—At shorter wave lengths, and for handling the highest powers even in the 10-cm. band. a ware guide is used. Though a metallic pipe of almost any shape will transmit or guide electromagnetic waves whose wave length is short enough. rectangular tubing whose internal dimensions have a ratio between 2.0 and 2.5 is ordinarily used to transfer micro ave energy. Though a detailed understanding of the propagation of R.F. energy in wave guide demands the solution of Maxwell's equations with the appropriate boundary conditions. we can get a picture of the mechanism of this propagation by considering the resemblance between a rectangular wave guide and a two-wire transmission line.

Fig. 19(A) shows a two-wire line with a single short-circuited stub support. analogous to the coaxial quarter-wave stub support already described. At the proper frequency, the input impedance of the stub is very high and the stub has no effect on the propagation of the wave on the line. In fig. 19(B) a great many stubs, extending both ways from the two-wire line. have been added, still without affecting the propagation of the frequency in question. In fig. 19(C) the stubs have been coalesced into a rectangular tube which looks like a wave guide. For a single stub, a slight



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC

FIG. 19.— TRANSITION FROM STUB-SUPPORTED TWO-WIRE TRANSMISSION LINE TO WAVE GUIDE. (A) SINGLE STUB SUPPORT. (B) MULTIPLE STUBS. (C) WAVE GUIDE. (D) SHORTENED STUBS FOR HIGHER FREQUENCY

correction to the length must be made to compensate for the inductance of the crosspiece, but when the stubs become a solid tube, no lines of force can link the narrow side, and the quarter-wave distance becomes exact. This also shows why the length of the narrow side of the rectangular tube is not critical.

All frequencies higher (wave lengths shorter) than that for which the quarter-wave stubs of our model were designed can be transmitted by wave guide. In such a case (fig. 19(D)) the two wires become broad bus bars with only as much of the wide side given over to stubs as is required by the now shorter wave length. Wave lengths greater than twice the broad dimension of the guide cannot be propagated because then the stubs become less than a quarter-wave long and shunt the line with a rather low inductive impedance which would extinguish the wave.

Fig 20 shows an instantaneous picture of the electric and magnetic fields in a rectangular wave guide whose wide dimension is slightly more than half the free-space wave length of the radiation being transmitted. Lines of current-flow in the walls are also shown. As the dimensions of the wave guide increase relative to the wave length of the radiation being transmitted, modes of propagation different from that illustrated (*i.e.*, having different space distributions of electric and magnetic field) can be excited.

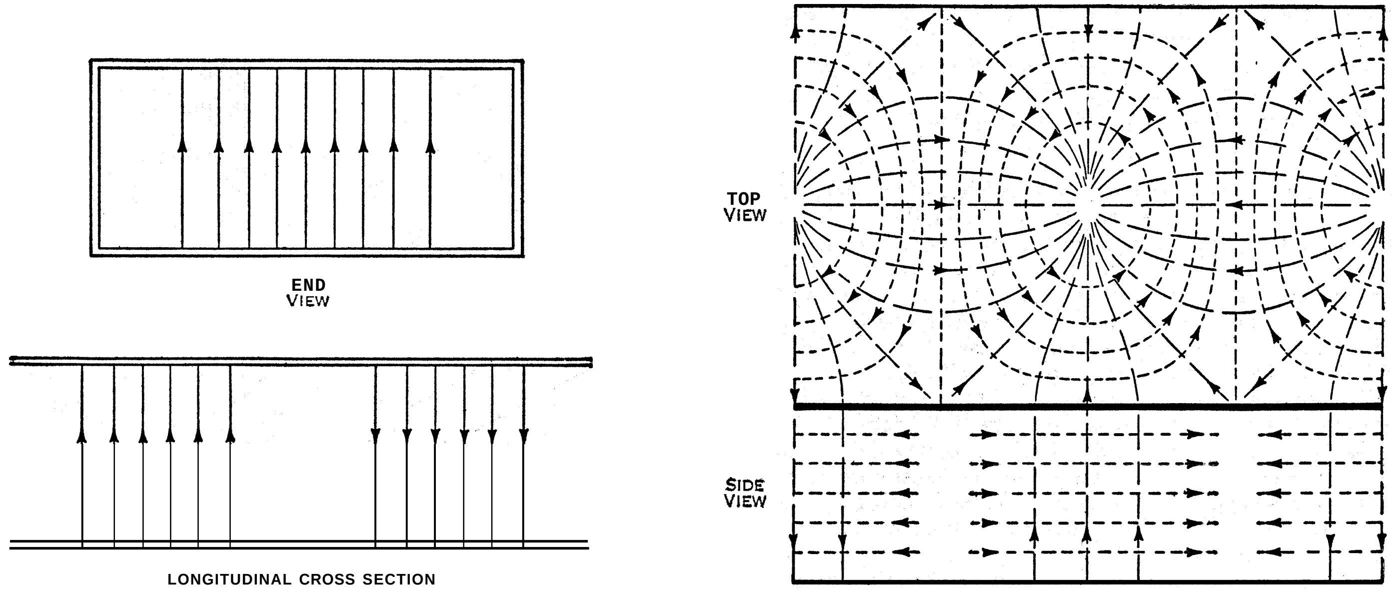
As in the case of coaxial line, this is almost always objectionable, and the maximum size of the broad dimension of a rectangular guide is usually chosen to be less than 0.95 of the free-space wave length of the radiation to be transmitted.

Each type of wave guide has a cutoff frequency for propagation in the lowest mode. Waves of higher frequency are transmitted; those of lower frequency are rapidly attenuated. The wave length of the radiation inside the guide is longer than the free-space wave length and is given by

$$\text{Guide wave length} = \lambda_g = \frac{\lambda}{\sqrt{1-\left(\frac{\lambda}{\lambda_c}\right)^2}} \qquad (25)$$

where λ is the free-space wave length and λ_c is the cutoff wave length. For the lowest mode in rectangular guide, as we have seen. the wave length corresponding to the cutoff frequency is twice the broad dimension. This sets a lower limit to the practical size of wave guide. Its broad dimension is usually chosen to be greater than 0.6 times the free-space wave length, because of design complications that ensue if the cutoff value of $0.5\ \lambda$ is approached too closely.

The narrow dimension of rectangular guide is chosen as large



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC

FIG. 20.— FUNDAMENTAL MODE OF WAVE PROPAGATION IN A RECTANGULAR GUIDE. SOLID LINES ARE THOSE OF ELECTRIC FIELD: DASHED LINES SHOW CURRENT FLOW IN WALLS: DOTTED LINES SHOW MAGNETIC FIELD

as possible to raise the breakdown field strength (the electric field being across this narrow dimension); but it must be less than half a free-space wave length of the radiation to be transmitted, so that there is no possibility of transmitting a wave polarized at right angles to that shown in fig. 20.

Transitions between wave guide and coaxial lines usually take the form of a quarter-wave stub antenna on the coaxial line projecting into the wave guide at the proper distance from a reflecting end plate, as shown in fig. 21. Rotary joints make use of quarter-wave choke sections. The power-handling capacity of wave guide is more than double that which can be realized by the largest coaxial line it is practical to use; the attenuation in a given length of wave guide is about half that encountered in coaxial line. Mechanically. wave guide is superior, being easier to fabricate and more difficult to damage in use.

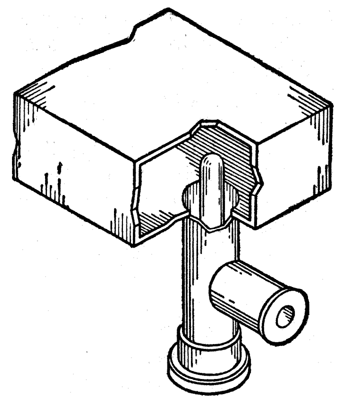
Resonant Cavities.—If both ends of a wave guide are closed by short-circuiting plates, and energy is introduced by a probe or through a hole so small that the properties of the enclosure are not affected, the resulting box is called a resonant cavity. When its length is an integral number of half-wave lengths of the radiation in the guide, the reflections from the end plates will reinforce one another and cause a resonant build-up of the energy in the cavity. Because the wave length in the guide differs from that in free space, as shown by eq. (25), the shortest resonant piece of a wave guide whose broad dimension is $1/\sqrt{2}$ free-space wave lengths is also $1/\sqrt{2}$ free-space wave lengths long. The narrow dimension of the cavity does not affect the resonant wave length, though it should be less than $\lambda/2$ to avoid the possibility of exciting the cavity in a mode polarized at right angles to the one desired.

The sharpness of resonance exhibited by a resonant cavity at microwave frequencies is very great. It is usually measured by a number called the Q of the cavity. If f_o is the resonant frequency and f_1 and f_2 are the two frequencies, one above resonance and one below. at which the voltage in the cavity is 0.707 that at resonance, then

$$Q=\frac{f_0}{f_1-f_2} \tag{26}$$

The Q of a 10-cm. cavity made of copper is typically as great as 15.000. This is much higher than the Q of resonant circuits made of coil-and-condenser combinations, for use at lower frequencies, because of the great effectiveness of a resonant cavity as a device for the storage of energy.

TR and ATR Switches.—Resonant cavities are used in the construction of the TR and ATR switches needed to permit duplex operation of a radar transmitter and receiver on a single antenna. Fig. 22 shows schematically how gas-discharge switches, fired by the high-power R.F. pulse from the magnetron, can be mounted to perform the TR and ATR switching functions. Breakdown of the TR tube puts a low-resistance short circuit across the receiver line, thus protecting it: but since this short circuit is a quarter-wave length away from the junction with the antenna line, there is no attenuation of the wave traveling toward the antenna. Breakdown of the ATR closes the circuit from magnetron to antenna; when the pulse is over and the ATR discharge goes out, the impedance at the T junction looking toward the magnetron is infinite because there is an open circuit half a wave length away. Looking toward the receiver, there is a matched line, so that all the echo power goes into the receiver.



FROM RADIATION LABORATORY SERIES, MC-GRAW-HILL BOOK COMPANY, INC.

FIG. 21.—TRANSITION FROM CO-AXIAL LINE TO WAVE GUIDE

To reduce the voltage necessary to break down the discharge gaps of the TR and ATR switches. they are filled with gas at a pressure of about 1/200 atmosphere. Further reduction is accomplished by mounting the discharge gap across a resonant cavity. to make use of the build-up in voltage accompanying resonance. Fig. 23 is a cutaway view of a TR tube used in the 3-cm. band. The resonant cavity is part of the tube envelope, and is made to be bolted between standard wave guide coupling flanges. Energy is coupled into and out of the cavity by means of round holes (filled with glass to retain the gas) in each side of the cavity. The discharge takes place between the two conical electrodes in the centre of the cavity; tuning is accomplished by moving one of them. mounted on a flexible diaphragm, toward or away from the other. To ensure rapid breakdown of the gap at the beginning of a pulse (within 0.01 μ sec.). a supply of ions is maintained in the gap by a discharge taking place constantly inside one of the cones.

ATR tubes are similar, except that they need have no output window, being mounted on the side of (*i.e.*, in series with) the R.F. line. Ordinarily they are made with lower Q, to reduce the chance of accidental maladjustment of tuning.

FIG. 22.—PRINCIPLE OF A **DUPLEXING** SYSTEM SHOWN **IN** TERMS OF **TWO-WIRE R.F.** TRANSMISSION **LINE**

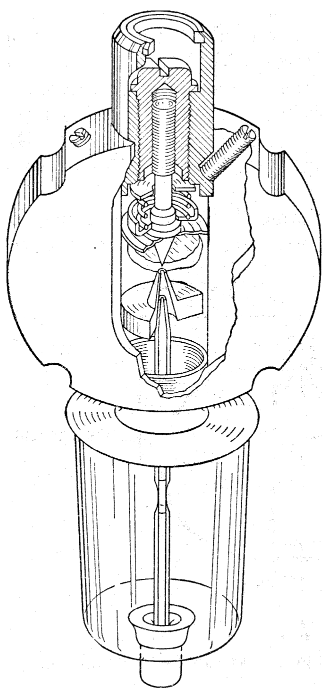
In the years following World War II, use of the newly developed ferrite materials. which exhibit a very pronounced Faraday effect at microwave frequencies, permitted the construction of circuit elements which were highly nonlinear, in the sense that they behaved differently for microwave energy traveling in opposite directions. This made possible the design of duplexing and isolating elements less complicated and more effective than the gas-discharge devices of wartime radar.

4. Antennas **and** Scanners. — The antenna of a radar set must radiate into space the energy fed to it as R.F. pulses, and must gather in the echo signals and send them down the R.F. line to the receiver. A good transmitting antenna is also a good receiving antenna; thus only the former function need be considered. Sharp beams are needed to make radar direction-finding possible: and a great deal of attention has been paid to the design of highly directional antennas that are capable of producing beams of the desired shape and dimensions. The nature of the beam wanted depends, of course, on the radar application.

Antenna Design.—The beam width, Θ, produced by an antenna is directly proportiona! to the wave length of the radiation used, and inversely proporiional to the width of the antenna. Beam width as usually defined is the full angular interval between the points at which the power radiated from the antenna has fallen to half its maximum value (fig. 24). Fig. 24 shows also the "side lobes," small subsidiary maxima unavoidably produced by a directional antenna. Their effects are usually objectionable, and attention is paid in antenna design to reducing the power in the side lobes. The beam width in degrees is given approximately by

$$\Theta = 70\lambda/D, \qquad (27)$$

where λ is the wave length and D the width of the antenna in the same dimension as that for which Θ is measured. D and λ should be given in the same units.



FROM RADIATION LABORATORY SERIES, MC-GRAW-HILL BOOK COMPANY, INC.

FIG. 23.—CUT-AWAY VIEW OF 1B24 3-CM. TR SWITCH

Among the simplest microwave antennas is a reflecting paraboloid of revolution illuminated by a source of radiation, or "antenna feed," placed at its focus. Since the diameter of the reflector is several wave lengths, this antenna can be regarded from the standpoint of ray optics (fig. 25). Fig. 25 does not explain the side lobes or the beam width, but it does emphasize that the feed for such an antenna must itself be directive.

In accordance with eq (27). a paraboloid whose top and bottom have been cut off to leave a reflector wider than it is high will produce a fan-shaped beam whose vertical beam width is larger than its beam width measured horizontally. A "beaver-tail" beam wider in the horizontal than in the vertical direction can be produced by cutting off the sides of a paraboloid to leave a tall, narrow reflector. Further adjustment of the energy in the beam can be accomplished by altering the shape of the reflector without changing its over-all dimensions. Instead of a paraboloidal reflector with a feed at its point focus, a parabolic cylinder with a linear feed located along its line focus can be used as an antenna.

Mechanical Scanning.—In order to cover the necessary volume

FIG 24.—A TYPICAL ANTENNA PATTERN. **MAIN** LOBE HAS BEAM WIDTH *θ*. **SIDE** LOBES ARE SHOWN

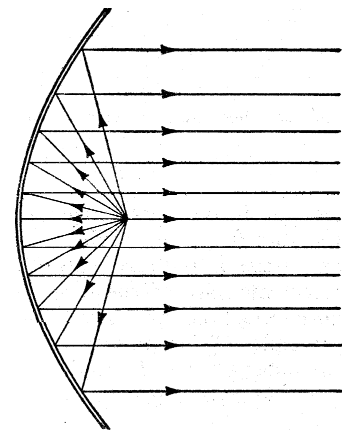
of space with the narrow beam produced by a directional antenna, the beam must be swung around. or scanned In most cases, the permissible rates of beam motion, fixed as they are by the desirability of receiving several echo pulses from each target per scan, are so low that scanning can be accomplished by mechanical motion of the antenna array. The assembly of an antenna on its supporting structure, or pedestal, is called an antenna mount, or scanner.

Radar scanners are of many different sorts. the detailed design being dictated principally by the size of the antenna (this being determined by the wave length used and the beam width desired), and by the scanning pattern used to cover the volume being searched. A few simple scanning patterns are:

(1) *Azimuth* scan.—The beam is swung around the horizon at a uniiorm rate. The desired vertical coverage is obtained by fanning the beam in the vertical direction.

(2) Helical scan.—If information on the elevation angle of targets is wanted, a pencil beam can be used. uniform azimuth rotation employed and the elevation angle of ;he. beam altered constantly at a slow uniform rate (fig, 26). When the full elevation-angle range of interest has been covered, the motion in elevation angle is reversed.

(3) *Conical* scan.—For accurate direction-finding on a single target, a pencil beam can be rotated rapidly in- a cone whose angular opening is smaller than the beam width. Only when the axis of the cone is directly pointed at the target will the signals received in various phases of the rotation oi the beam have constant intensity. A change in signal strength will accompany conical scan when the axis of the cone is not quite on the target. The magnitude and phase of this change in signal strength as the beam rotates indicates the direction and the magnitude of the pointing error. The direction of the cone axis is changed to make the "error signal" zero. By the use of this scheme, radar direction-finding can be given a precision of about one-fiftieth of a beam width; this is far greater precision than can be obtained by noting the direction of maximum signal return when a beam is swept over a target.



FROM RADIATION LABORATORY SERIES, MC-GRAW-HILL BOOK COMPANY, INC.

FIG. 25.—RAY DIAGRAM OF A **PARAB-**OLOID ANTENNA

(4) Spival scan.—If a rapid axial rotation of a pencil beam, like that used in conical scanning, is combined with a siow change in the cone opening, a spiral scan (fig. 27) results. This permits rapid coverage of a fairly large area, with facilities for determining roughly both the azimuth and the elevation of targets.

Data *Transmission.*—In order to make use at the radar indicator of the directional information afforded by scanning, means must be provided for transmitting to the indicator a knowledge of the scanner position in all important co-ordinates. Only azimuth must be transmitted for an azimuth scan, azimuth and elevation for a helical scan, and azimuth, elevation and phase of rotation for a conical or a spiral scan.

This "data transmission," as it is called, is almost always accomplished electrically. The flexibility of mechanical means of data transmission is not sufficient to meet radar requirements. Self-synchronous generators and motors of the type used in other applications for transmitting position information are frequently employed. So are precision adjustable resistors. The latter have the advantage that they can be wound in such a way that the output voltage is any desired function of angle of rotation. Further, the applied voltage, to which the output voltage is proportional, can be varied in any fashion desired. Thus computation can be performed directly by the data transmission device.

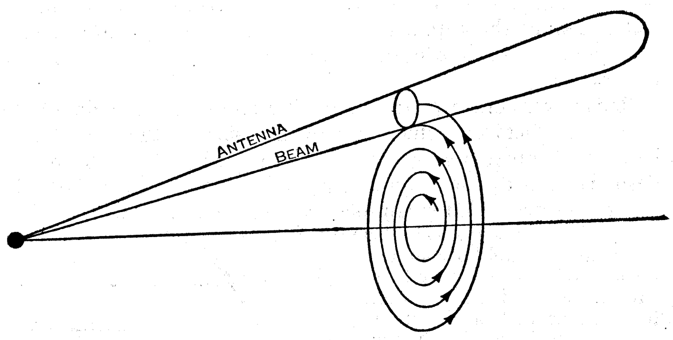
FIG. 26.—HELICAL SCANNING PATTERN

For example, suppose it is desired to find target height, h, from a measurement of range, R, and elevation angle, ϕ; it will be given by

$$h = R \sin \phi \tag{28}$$

If the resistance card of the adjustable resistor used to measure elevation angle is so wound that its output voltage for an elevation



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 27.— SPIRAL SCAN

angle ϕ is proportional to sin ϕ, and the voltage applied to this resistor is developed from another adjustable resistor used to measure range and having an output linear with R, then the voltage at the output terminals of the elevation-angle resistor will be a direct measure of the height of the target. A highly successful antiaircraft computer was built during World War II on this principle. When used with radar, the data-transmission units of the radar actually formed part of the computing mechanism.

Rapid Scanning.—In some radar applications, such rapid scanning is desired that mechanical motion of a large antenna mount is not feasible. A number of devices have been developed to permit rapid scanning in one dimension by relatively subtle mechanical motions of parts of the antenna. These devices are sometimes referred to as "electrical" scanners, although rapid mechanical motion is almost always fundamental to the scanning.

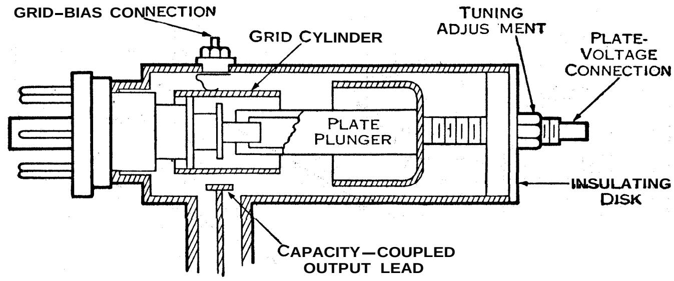
FIG. PI.— STANDARD MICROWAVE MIXER CRYSTAL

Stabilization.—When a radar scanner is mounted on an unstable platform, such as a ship or an aircraft, readings of azimuth and elevation relative to the platform must be converted into readings



FROM RADIATION LABORATORY SERIES, MCGRAW HILL BOOK COMPANY, INC.

FIG. 29.— LIGHTHOUSE TUBE MOUNTED IN A COAXIAL CIRCUIT

of these angles with respect to a stable set of reference axes. Compasses, directional gyros, and gyro stable verticals are commonly used as reference devices, and the stabilization of the radar data, as this conversion process is called, can be performed in a variety of ways.

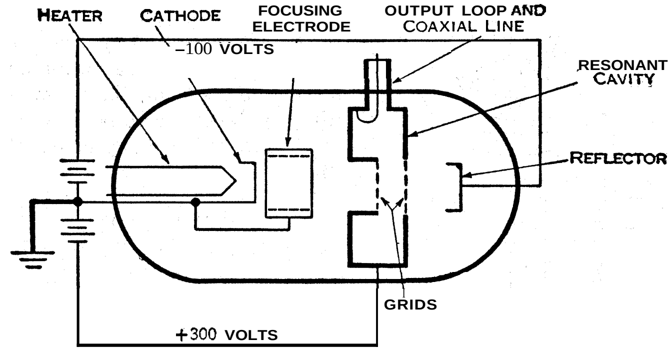
5. **Radar** Receivers. — Under the term "receiver" is classed that part of the radar equipment which accepts the feeble echo pulses from the R.F. line, amplifies them, rectifies them and delivers to the terminals of the indicator or display equipment unipolar pulse signals at a level usually of several volts.

Most radar receivers are of the superheterodyne type, in which a local oscillator supplies CW signals at a low level to a mixer, where the echo signal and the local oscillator signal beat to give a signal at a frequency (called the intermediate frequency) equal to the difference between the frequencies of the signals mixed. This beat signal is modulated with the same intelligence as that conveyed by the R.F. echoes, and its frequency is chosen to permit fairly standard techniques to be used in the I.F. amplifier.

The I.F. amplifier is normally tuned to a fixed frequency, and the receiver tuning is changed by altering the frequency of the local oscillator. Arrangements, called AFC (for automatic frequency control), are incorporated in most radar receivers for keeping the local oscillator properly tuned with respect to the radar transmitter. Demodulation of the amplified I.F. signal is accomplished by a second detector followed by a filter for the intermediate-frequency signal. The resulting signals, called "video signals" because their frequency range is about that of television video signals, are further amplified and sent to the indicator.

R.F. Amplifiers.—Development of the idea that an electron stream can interact and exchange energy with a traveling electromagnetic wave led to the development soon after the close of World War II, of a type of vacuum tube called a traveling-wave tube. Some embodiments of this principle were useful for the hitherto impossible problem of amplifying energy at microwave frequencies.

By the early 1960s there were suitable R.F. amplifier tubes for all microwave frequencies in common use. They had not yet



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 30.— SCHEMATIC DIAGRAM OF REFLEX KLYSTRON OSCILLATOR

altered the need for mixer crystals as first detectors in superheterodyne receivers used in radar, but they gave substantial promise of improving radar performance.

Microwave Mixers.—Conversion to intermediate frequency in the mixer at the low level of received signal power requires that' the nonlinear element used in the mixer be as efficient as possible and introduce a minimum amount of random noise. The most satisfactory element was the rectifying contact between a metallic point and a silicon crystal. The whole assembly was sealed up in a cartridge, referred to as a "crystal," for protection and stability. One standard form for this cartridge is shown in fig. 28.

The contact area between the metal and the silicon is only about 10^{-6} cm^2. High current densities are therefore produced even by lo currents, and a crystal can readily be burned out, especially by a pulse so rapid that heat cannot be conducted away from the contact.

The R.F. circuit in which the crystal is installed is called the "mixer." It has input terminals for the signal and for the power from the local oscillator. Its output terminals are connected to the first stage of the I.F. amplifier. Care is taken in mixer design to make the crystal appear as a matched load to the incoming signal; to prevent, as far as possible, loss of echo-signal power into the local-oscillator input line; and to provide a reasonably good match looking into the mixer from the local oscillator.

Local Oscillators.—The magnetron, although a very efficient source of high pulse powers, was not employed in wartime radar as a source of the low-level CW signal required from the local oscillator of a superheterodyne receiver. Quite satisfactory tubes of other types were developed for this purpose.

Some World War II radar sets used a special triode, called a "lighthouse" tube because of its construction, as a local oscillator. The lighthouse tube is designed with planar electrodes and extremely small interelectrode spacing to reduce electron transit time. External connections to its electrodes are provided in the form of disks and cylinders (fig. 29), so that a cylindrical R.F. circuit can be built directly around the tube. An average power output of a few watts can be obtained from a lighthouse tube, and the tube can also be pulsed to give peak power of about 1 kw. It has been used as a transmitter in some low-power radar sets.

Most radar sets used a reflex klystron as a local oscillator. Fig. 30 is a schematic diagram of such a tube. Integral with the tube structure is a doughnut-shaped resonant cavity with grids across its central portion. An "electron gun" focuses a stream of electrons through the grids. Upon arrival at the first grid, the electrons have a velocity corresponding to the 300 volts applied to accelerate them. If oscillations exist in the cavity, electrons will either be accelerated or decelerated by the R.F. field which they encounter as they pass through the space between the cavity grids. An electron which goes through just as the R.F. field is passing through zero will not have its velocity changed, and will be described as a reference electron. In the space just beyond the second grid there is a strong retarding field produced by a reflector electrode maintained about 100 volts negative with respect to the cathode, The path of the reference electron in this retarding field is similar to that of a ball thrown into the air. It will return to the grids after a time proportional to the retarding field. An electron that leaves the second grid earlier than the reference electron will have been accelerated by the R.F. voltage which then existed across the cavity, and, because of its higher velocity, it will spend a longer time in the reflection space than will the reference electron. By proper adjustment of the retarding field, the delay can be made to compensate for its earlier departure, so that it arrives back at the grids at the same time as the reference electron.

Similarly, an electron leavirig later than the reference electron has been decelerated by the R.F. field! has a lower velocity, and thus catches up with the reference electron because it spends less time in the reflection space. The net effect is that the electrons gather in a bunch which is formed about the reference electron. At certain reflector voltages, the bunch will return through the cavity grids in such a phase that the R.F. field retards the electrons, and thus receives from them energy to sustain the oscillations in the cavity. Oscillation is observed for more than one reflector voltage, since drift times differing by a whole R.F. period still produce satisfactory bunching.

The net energy given to the electrons during their first passage through the cavity is negligible when averaged over a whole R.F. cycle, being balanced between acceleration and deceleration. On the return passage, most of the electrons go through in a bunch at the most favourable phase to aid the oscillation. Very few electrons pass through on the return trip half a cycle later, when they would absorb energy from the R.F. field. Power is coupled out of thecavity through a loop feeding into a coaxial line. Power outputs in the range irom 20 to 50 mw. and efficiencies of about 1% were typical of such tubes produced in the postwar years.

Tuning over a wide range is accomplished by changing the size of the cavity mechanically; a small amount of tuning can be done by varying the reflector voltage.

Automatic Frequency Control.—The problem of keeping a radar set properly in tune consists in maintaining the difference between the local-oscillator frequency and the magnetron frequency constant at the value appropriate to the I.F. amplifier, with an accuracy of perhaps 0.5 mc. AFC is a practical necessity in scanning radar, for the magnetron frequency can be altered several mc. by changes in standing-wave ratio occurring in the R.F. system either in consequence of unsymmetrical rotary joints or because of strong reflections from nearby objects such as the masts of a ship or the engine nacelles of an aircraft carrying the radar. Further, variations in voltage, temperature and pressure all produce changes in frequency. Manual tuning is quite unsatisfactory, and AFC has come to be a standard part. of all radar.

In the AFC system, part of the local-oscillator power is mixed, in a crystal, with a small fraction of the magnetron power drawn out during transmission of the pulse. The resulting signal at the difference frequency is applied to a discriminator circuit similar to those used in a frequency-modulation receiver. The crossover or no-output frequency of the discriminator is set at the intermediate frequency of the radar. The pulses which come from the discriminator are integrated to produce a voltage that is applied to the reflector of the local oscillator in the proper sense to change the frequency toward that value which will bring the discriminator output to zero. It is desirable to use an AFC mixer which is separate irom the signal mixer, but it is possible to make an AFC system which obtains its information from the leakage power which inevitably reaches the signal mixer during the transmission of an R.F. pulse from the magnetron.

The I.F. *Amplifier.*—Because of the low power level of the input signal to a radar I.F. amplifier, the greatest attention must be paid to minimizing the inherent noise of the amplifier itself. Further, since strong pulses several hundreds of μ sec. in length may be followed immediately by weak signals which must not be missed, the transient response of the I.F. amplifier must be excellent. The amplifiers which resulted during World War II from attention to these requirements were rather different from anything which had previously existed.

The intermediate frequency is usually chosen in the range from 15 to 60 mc. The over-all gain of the I.F. amplifier is usually around 120 db. or 1,000,000 times in voltage. The desired over-all band width of the amplifier is ordinarily about 2 mc. Since the cascading of amplifier stages results in an over-all band width much less than the band width of an individual stage, it is very important to attain the highest possible product of gain and band width in the individual stages.

The design of the interstage coupling circuit used in an I.F. amplifier has an important effect on the gain-band-width product that can be achieved with given tubes. The characteristics of the tubes themselves are also of the greatest importance, the leading property being the ratio of transconductance to input and output capacity.

It is important that regenerative feedback of signals does not take place from later stages to earlier stages of the I.F. amplifier, or from plate to grid circuit in a single stage. Circuit layout and shielding must be carefully planned to avoid regeneration.

Second Detector.—The second detector produces a rectified voltage proportional to the amplitude of the I.F. waves. In most radio receivers it is important that this proportionality be exact;

in a radar receiver the response of the second detector may be proportional to a higher power of the I.F. amplitude, so long as reasonable efficiency is maintained. Either a thermionic diode or a rectifying metal semiconductor contact ("crystal") is used as the nonlinear rectifying element. Second-detector crystals usually employ germanium, instead of silicon, as the semiconductor, since germanium crystals can be made to stand a somewhat higher reverse voltage.

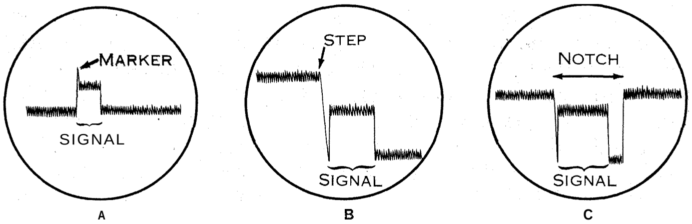
Video Amplifier.—The unipolar signals from the second detector, usually at a level of a few volts, are further amplified by a wide band resistance-capacitance-coupled amplifier called the video amplifier, because of its similarity to the video amplifiers used in television.

When the line from the radar proper to the indicator must be long, it is economical to drive the line at a low video-signal level and provide video amplification at each indicator. Since the standard dielectric-filled coaxial cable ordinarily used for the transmission of video signals has a low impedance—in the neighbourhood of 75 to 100 ohms—a "cathode follower" stage is frequently used to drive the line.

6. Radar Indicators.— The device which presents radar data in observable form is called the indicator. It is almost always a cathode-ray tube (CRT). The CRT presents a representation of electrical phenomena in terms of a picture painted on a phosphorescent screen by a sharply-focused beam of electrons controlled in position and intensity by electrical signals. The CRT is capable of using and displaying many millions of separate data per second, and the geometrical expression which it gives to radar data is particularly appropriate, since a geometrical situation involving the various radar targets is usually precisely what must be represented.

CRT Screens.—Both inagnetic and electrostatic CRT types are used, the terms referring to the means of deflecting the stream of electrons (fig. 1). The properties of the materials (phosphors) making up the luminous screen are of particular importance to the performance of the tube. If, as is usually the case, the scanning of the radar antenna interrupts the display in a given sector of the screen for longer than the retentivity time of the eye, it is desirable to introduce persistence into the screen—that is, to use a phosphor which will glow for some time after having been excited.

If little or no persistence is needed, the green willemite phosphor used in ordinary oscilloscope tubes and known as type P-1 is satisfactory. This material is extremely efficient in converting the energy of the electrons which strike it into luminous energy; it has an exponential decay with a time constant of a few milliseconds. If a rather short persistence is needed, a zinc-magnesium



FROM RADIATION LABORATORIES SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 81.— RANGESCOPES: (A) PIP MARKER; (B) STEP MARKER; (C) NOTCH MARKER

fluoride phosphor designated as P-12 is used.

Most radar applications demand even a longer persistence. This can be achieved by a "cascade" screen consisting of two layers of different phosphors. The electrons strike and excite an inner layer of silver-activated zinc sulphide, which glows with a blue light. This blue light excites a layer of persistent phosphor, usually copper-activated zinc-cadmium sulphide. The zinc-to-cadmium ratio determines the decay characteristics.

FIG. 32.— J-SCOPE. ANOTHER TYPE OF RANGE SCOPE SHOWING READING IN (A) THOUSANDS OF YARDS: (B) HUNDREDS OF YARDS

Because the long-persistence phosphor emits a predominantly yellow or orange light, an orange filter is used to remove the blue "flash" of the inner phosphor, which is annoying to the observer.

Radar Displays.—Because of the many special purposes that radar can serve, a considerable variety of different forms of display have been developed and used. The A-scope and the PPI have already been mentioned. These are typical of two general classes in which the radar echo signals are used either (1) to deflect the CRT electron beam, or (2) to alter its intensity. Displays of the first type (deflection-modulated displays) are useful for giving precise information on the strength and character of the signals delivered by the receiver, but leave only one dimension of the tube face free to represent a geometrical quantity. Displays of the second type (intensity-modulated displays) permit the presentation of a two-dimensional figure on which the signals appear as bright spots or patches, but the intensity response of CRT electron guns is so nonlinear that the brightness of each patch offers only qualitative information about signal intensity.

When a three-dimensional picture must be presented on the two-dimensional face of a CRT indicator, either more than one display must be used, or a formalized way of presenting the third dimension in an understandable, though unnatural, fashion must be devised.

The vast majority of radar displays use as one co-ordinate the value of slant range to the target. Range is displayed by causing the electron beam of the CRT to sweep across the tube at a uniform rate starting from a given point or line at a definite time in each pulse cycle. Distances on the tube face from the starting point are then proportional to increments of range.

The angle at which the scanner is pointing, either in azimuth or elevation. may enter the display (1) directly as a polar angle, (2) directly as a Cartesian co-ordinate, or (3) as the basis for resolving a range sweep in a particular direction.

FIG. 33.— DISPLAYS PERMITTING COMPARISON OF STRENGTH OF ECHO FROM A GIVEN TARGET ON TWO ANTENNAS. OR IN TWO POSITIONS OF A CONICAL SCAN. (a) SIDE-BY-SIDE PRESENTATION (K-SCOPE). (b) BACK-TO-BACK PRESENTATION (L-SCOPE)

Usually markers are employed to assist in making measurements of range or angle on a radar indicator. These may be "electronic" markers introduced into the signal channel as artificial video signals generated by a precision timing circuit (for range markers) or an angle-measuring circuit (for angle markers). Alternatively: they may be mechanical grids or markers placed over the face of the CRT.

A few of the most important radar displays are catalogued below, according to the spatial geometry represented.

One-dimensional Deflection-modulated *Displays.*—The simplest display of this type is the A-scope described earlier. Range is invariably the spatial co-ordinate presented on a display in this class. If it is desired to do accurate range-finding with the help of an indicator in this category, arrangements are made to delay the start of the range sweep by any desired amount, so that the interval displayed will include the target of interest. The sweep speed is then greatly increased to give higher resolution in range. Usually a movable electronic marker is provided for the precise measurement of range. Such a display is called an R- (range) scope. Fig. 31 shows R-scope displays with various types of movable range markers.

FIG. 34.— THE RANGE-HEIGHT INDICATOR (RHI). THIS IS A POLAR SCALE FACTORS ALONG THE TWO CARTESIAN CO-ORDINATES. THE VERTICAL STRETCHING IS SHOWN BY THE TWO-MILE GRID SHOWN DOTTED IN THE DIAGRAM. LINES OF CONSTANT ARE STRAIGHT AND HORIZONTAL ON THIS DISPLAY

Greater sweep length can be obtained by bending the range sweep into a circle on the face of the tube, and using the radar echo signals to deflect the beam radially from the centre of the CRT. Fig. 32 shows such a display called a J-scope.

Simple deflection-modulated range displays can be used for comparing the signal strength from two antennas whose patterns make a small angle with one another, or from a conically scanning antenna in two positions 180" apart. The K-scope is so arranged that the range sweeps to be compared start from different origins, so that the echoes to be compared are side by side. In the L-scope, signals from the two antennas produce deflections of opposite sign, the range origin being common (fig. 33).

Two-dimensional Intensity-modulated Displays.—The PPI is the most generally useful of the indicators in this category. For certain purposes, it is altered by moving the range origin (off-centre PPI), or by expanding the zero-range origin of the PPI into a circle (open-centre PPI), or by delaying the start of the sweep, so that a ring-shaped area is collapsed into a solid circle (delayed PPI).

A PPI can also be deformed by "stretching"; that is, by giving different scale factors to the two Cartesian co-ordinates of the display. Straight lines remain straight but, except for those parallel to the Cartesian axes, their directions are changed. If elevation, instead of azimuth. is the angular co-ordinate used on the scope, the resulting display is called a range-height indicator, or RHI. Lines of constant target height are horizontal and equally spaced. (See fig. 34.)

FIG. 35.—THE DOUBLE-DOT INDICATOR, A B-SCOPE IN WHICH EACH TARGET ECHO APPEARS TWICE. ANGLE OF LINE JOINING TWO SIGNALS SHOWS ELEVATION ANGLE OF TARGET RELATIVE TO AXIS OF RADAR SCANNER. TARGET A IS LEVEL SCANNER. 1.5 MI. AWAY. AND DEAD AHEAD. TARGET B IS 4.5 MI. AWAY, 25° LEFT AND SLIGHTLY BELOW TARGET C IS 2.5 MI. AWAY. 12° RIGHT AND

A plane surface can also be represented in a deformed manner useful for certain radar applications by presenting range and angle in Cartesian rather than in polar co-ordinates. This is accomplished by moving a range sweep laterally across the tube face in synchronism with the scanner motion so that the range origin is stretched out into a line. If the angular field shown by such a display is small enough, it can be "normalized" to reduce the distortion to modest limits. Normalization is performed by keeping the angular dispersion proportional to the range to the centre of the display.

Three-dimensional Displays.——As already remarked. no real three-dimensional display can be presented on the two-dimensional face of a CRT. However, certain formalized ways have been developed for indicating target elevation on a display which already shows target range and bearing. An example of this type is the "double-dot" display. On alternate range sweeps the origin of this modified Type-B indicator is moved to the right and left respectively by a fixed amount. On the sweeps occurring in the right-hand pattern the origin is simultaneously shifted vertically by an amount proportional to the sine of the elevation angle.

Any single echo then appears in two neighbouring positions, and the slope of the line joining the two dots is a rough measure of elevation angle. accurate to two or three degrees under the usual circumstances of use. (See fig. 35.)

A Simple Indicator.—The electrical means of achieving the rapid and accurate sweeps necessary for radar indicators are beyond the scope of this article, and the interested reader is referred to the works quoted in the bibliography. However, it will be useful to outline the functions of the important parts of a simple display system.

The parts of the indicator circuit concerned with the pulse repetition cycle are called the "timer." The timer provides a synchronization with the modulator, sweeps and markers for the display and measurement of range, blanking of the CRT during unused parts of the pulse cycle, and other related operatiocs.

In some cases; the timer exerts control of the firing time of the modulator by sending it a trigger pulse; in others it responds to a trigger from the modulator. The latter type of system is shown in fig. 36. Waveform b is used to turn the CRT on during the useful display cycle. The linearly increasing (or sawtooth) waveform *c*, is used to provide the uniform range sweep for the indicator.

Timing of this wave is controlled by waveform b. Electronic range markers (waveform d) are also generated by the timer and mixed with the radar video signals before they are sent to the CRT.

For illustrative purposes: fig. 36 shows provisions for either an A-scope or a R-scope display. For the former presentation. the range-sweep voltage is applied to one pair of deflecting plates and the mixed signal and range-mark voltages to the other pair. The square wave controlling the CRT intensity is applied to the cathode in the proper polarity to brighten the tube during the range sweep.

In the Type-B display, the range sweep is applied to one pair

FIG. 36.— BLOCK DIAGRAM OF A SIMPLE INDICATOR SYSTEM PROVIDING FOR EITHER A-SCOPE OR B-SCOPE DISPLAY. BELOW. WAVE FORMS IN CIRCUIT OF FIGURE

of deflection plates, as before. Signal modulation is applied to the control grid, and the second set of deflection plates receives a voltage which produces the azimuthal deflection. This voltage may be furnished. for example, by a linear potentiometer geared to the axis of rotation of the scanner.

The arrangement shown is equally applicable to a magnetic CRT, the only changes being in the deflection amplifiers.

VI. ACCESSORY DEVICES

1. Radar Beacons.—In nearly all cases where it would be advantageous if a particular radar echo could be made much stronger or more readily distinguishable from other confusing echoes, a radar beacon is indicated. By the use of a beacon, particular aircraft can be identified among heavy ground echo signals, or in the midst of a large formation of aircraft; the exact location of a specific point on the ground can be indicated, and so on.

A beacon is a repeater of radar pulses. It has an antenna and receiver that convert pulses of energy received at high frequency from a radar set or a special beacon interrogator into triggering signals. Each such triggering signal fires the transmitter in the beacon and causes it to radiate one or more pulses of radio energy that may have almost any desired characteristics in regard to power, frequency, number, duration and spacing. A short time is required for the beacon to reply to an incoming pulse, so that the first reply pulse is slightly delayed beyond the radar echo which would be received from an object at the beacon location. This delay can be made as small as a few tenths of a microsecond (a few tens of yards in range); if this small delay is still not negligible, it can be made extremely constant and allowed for in interpreting the beacon signals.

To permit the display of beacon signals alone, without radar echoes. the beacon transmitter frequency is ordinarily chosen to be different from the radar frequency. Beacon signals can be received at a radar set either by retuning the receiver to the beacon reply frequency, or by providing an extra independent receiver tuned to the beacon. Since the power of the beacon transmitter can be made as great as desired, there is no limit to the strength of the beacon reply. The range at which a beacon can be seen will then be limited only by the power of the radar transmitter and the sensitivity of the beacon receiver, which together determine whether the beacon will be triggered or not.

Since the beacon interrogation and reply links are independent, instead of being two paths for the same energy (as in the case of radar echoes), the range at which beacons can be challenged and their replies received is usually very great, and ordinarily limited only by the optical horizon. The interrogation signal at the beacon falls off as the inverse square of the range to the challenging radar; the reply of the beacon has a power at the radar which is the same function of range.

Beacons of the synchronous sort just described are variously called radar beacons, responder beacons, racons or transponders, there being no important distinction among these terms. Free-running beacons that are not triggered by a pulse challenge are seldom used in conjunction with radar sets, since from them only the bearing of the beacon can be determined. and not its range. Range is so useful a part of the data supplied by radar that beacons which enable its measurement are far preferable to those that do not.

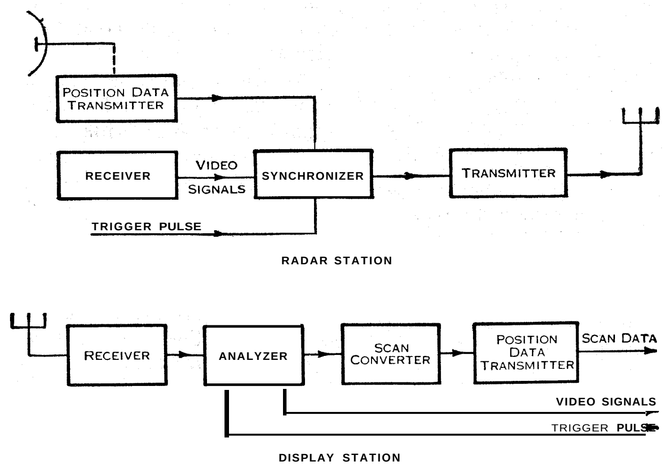
In order to avoid overloading a beacon located where there are many radar sets. it is usually desirable to provide an interrogation coding arrangement whose purpose is to limit the beacon responses to only those interrogation pulses specifically intended to elicit such a response. The decoder is intended to serve this purpose. In the case of ground beacons serving as navigation check points for air-borne radar, it is customary to use pulse-width discrimination in the decoder. The usual radar pulses of an air-borne set are one microsecond or less in duration; the beacon decoder is arranged to produce a trigger for the beacon transmitter only if it receives a pulse whose duration is two microseconds or more.

The air-borne radar is then fitted with a control which lengthens the transmitter pulses and simultaneously retunes the receiver to the beacon reply frequency when it is desired to look at beacon signals instead of at radar echoes.

Reply coding is intended to identify the particular beacon whose response is seen. In the case of microwave radar beacons, this reply coding is usually "range coding," involving the transmission of a closely-spaced series of short pulses from the beacon transmitter.

Other possibilities for coding both interrogation and reply are numerous. Distinct frequencies can be chosen. Simultaneous challenge on two or more frequencies may be necessary to unlock the beacon and elicit a reply. Combinations of properly timed multiple pulses can be used. The beacon reply may be keyed on-and-off to send letters in Morse code. The particular coding system chosen will depend on the application.

Sometimes it is desirable to use, as the device intended to trigger a beacon and to display its replies, instead of a radar set,



FROM RADIATION LABORATORY SERIES, MCGRAW-HILL BOOK COMPANY INC

FIG. 37.— ELEMENTS OF A SIMPLE RADAR RELAY SYSTEM FOR THE DIRECT TRANSMISSION OF RADAR INDICATIONS TO A REMOTE POINT BY RADIO MEANS

a much lower-powered device intended only to work with beacons. Such an equipment is called an interrogator-responsor. It is a radar set in all respects except that its transmitter power is so low that radar echoes cannot be obtained at useful ranges. This reduction in power output enables the equipment to be made much lighter and simpler than a radar set at the same frequency would be.

The interrogator-responsor can be especially small and light if only range information is wanted from the beacons, so that a scanner is not necessary and fixed antennas can be used. By providing two sets of fixed antennas aimed in slightly different directions, homing on a beacon can be done by turning the aircraft or ship carrying the interrogator-responsor until equal beacon responses are received on the two antennas.

By altering the interrogation and reply coding of a beacon to correspond with intelligence which it is desired to transmit, two-way communication using a radar-beacon link is feasible and has been accomplished.

2. Radio Relay of Radar Displays.— It frequently happens that the best site for a radar equipment is not the best location for the organization which is to make use of the information provided by the radar.

For example, in the World War II organization for fighter defense of the British Isles against. hostile air attack, the operating centre was maintained at Stanmore, north of London; information was sent there from radar sets located all around the coasts.

During World War II it was customary to transinit radar information from one point to another by "plotting and telling." The radar echoes seen were entered at the proper range and bearing on a map with a superimposed rectangular grid; this was plotting.

The letters and numbers comprising the grid reference for the location of the plot were "told" vocally over telephone lines or radio circuits to the control centre. where the targets were replotted.

This particular type of system has several drawbacks. Not only are there many chances for the introduction of errors in the target position, but also the speed and traffic-handling capacity of the system are severely limited. It has already been remarked that a radar indicator presents several million units of data per second. By no means are all of these significant, but in a situation involving hundreds of targets, which may not be at all uncommon, it is clearly impossible for even many tellers to give as useful a picture of the air situation as is available at the radar set.

For these reasons, methods were worked out during the war for transmitting, by a radio link, radar video information, synchronizing signals and signals giving the direction in which the radar scanner was pointing at any instant. At the receiving station, these data could be used to construct a radar indication whose quality was just as good as that of the indicators located at the radar set itself.

The problems are mainly those of any wide-band radio link, complicated by the fact that both pulses and long blocks of video signals must be transmitted and received. The elements of a system for accomplishing radar relay are shown schematically in fig. 37. Radar data are delivered to a "synchronizer" which arranges them in proper form to modulate the transmitter. At the receiving station, the receiver amplifies and demodulates the incoming signals and delivers its output to an "analyzer." The latter sorts out separately video signals, trigger pulse and scanner data. The video signals and the trigger are delivered immediately to the display system.

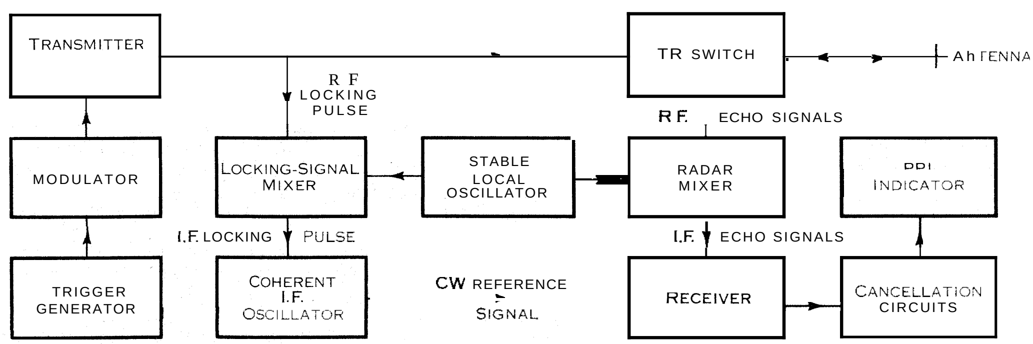
The scanner data must usually be modified in a "scan converter" before being used in display synthesis, because a code is ordinarily used for the transmission of scanner angle.

The scan converter uses the coded data to construct a duplicate of the scanner motion that can be used to drive a position-data transmitter connected to the indicators. The over-all requirements of the system are quite similar to those of television, since the band of frequencies which must be transmitted is about the same.

Comparative PPI photographs may be taken simultaneously at a transmitter and receiver several miles apart.

The direct relay of radar video signals is preferable to televising an indicator at the radar station and transmitting the information by television means, for the following reasons: (1) Persistent indicators do not televise well; their light is too far toward the red end of the spectrum. This leads to a loss in signal-to-noise ratio and in definition; (2) the display available at the receiving end must be identical with that scanned by the televison camera at the transmitting end. If video signals are transmitted directly, any desired type of indication can be synthesized at the receiver. The first, but not the second, of these objections can be removed by storing the radar information on an orthicon or other television pick-up tube directly, instead of viewing a CRT with a television pick-up.

3. Moving Target Indication.— "Ground clutter," the system of strong permanent radar echoes returned by hills and buildings in the vicinity of a radar set, is often a limiting factor on the performance of radar, especially in mountainous terrain. Similarly, the echo signals returned by waves to a radar set carried on a ship or located on the shore ("sea clutter") can be most troublesome. CW radar often makes use of the Doppler shift



FROM RADIATION LABORATORIES SERIES, MCGRAW-HILL BOOK COMPANY, INC.

FIG. 38.— SCHEMATIC DIAGRAM OF MOVING TARGET INDICATION (MTI)

in frequency of the signal returned from a target in radial motion relative to the radar, and thus responds only to moving targets. This same property can be conferred on pulse radar by special techniques, which will be described below, called MTI (moving target indication).

In pulse radar, the effect of the Doppler shift is to cause a phase shift from pulse to pulse of the echo from a moving target. If the radial velocity of the target is v, and the repetition period, or time between successive pulses, is T, each pulse travels a distance $2vT$ different from that traveled by the preceding pulse. This difference is $2vT/\lambda$ wave lengths, so that the phase change between each pulse and the one which follows it is $2\pi \times 2vT/\lambda$ radians. The Doppler frequency is $2v/\lambda$, in agreement with eq. (19).

The basic idea of MTI is to compare the phase of each echo on successive pulses. If there is no phase change, the target is stationary, and its signal is not passed to the indicator. If the phase changes from pulse to pulse, the target is moving, and its signal is displayed. The phase comparison is made in terms of a very stable oscillator which is adjusted, at the instant each pulse is transmitted. to have a standard phase with respect to the outgoing pulse. Beating the echo'signal with that of this "coherent oscillator" will give a signal whose amplitude depends on the relative phase of the echo and the output of the coherent oscillator. If the echo comes from a stationary target, the amplitude of the signal which results from beating the echo with the coherent oscillator output will not change from one pulse to another. If the echo comes from a moving target, the amplitude of the beat will change from pulse to pulse.

It is not important in principle whether the coherent oscillator used as a phase reference runs at radio frequency or at the intermediate frequency of the superheterodyne receiver, provided that the local oscillator of the superheterodyne is stable. Since it is easier practically to have the coherent oscillator run at intermediate frequency, this scheme has been used. A schematic diagram of a practical MTI system is shown in fig. 38.

A stable local oscillator supplies a signal to two mixers: one of which provides a "locking signal" for adjusting the phase of the coherent oscillator to its standard value with reference to the outgoing R.F. pulse. The other mixer is the signal mixer of the receiver. When the I.F. echo signals and the I.F. reference signal beat against one another, the phase of the receiver output signal depends on the number of cycles executed by the local oscillator and by the coherent oscillator during the out-and-back time of travel of the pulse. The result is shown in fig. 39(A). Four successive sweeps of an A-scope are shown, corresponding to four successive pulses.

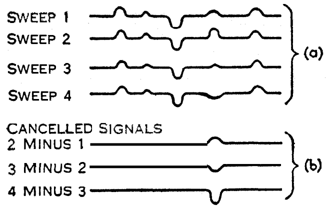
It will be seen that four of the five echo signals seen on each trace are of constant amplitude from pulse to pulse, and thus correspond to stationary targets. The other echo signal shows a changing amplitude from pulse to pulse; this corresponds to a changing echo-signal phase, and indicates radial target motion.

The way in which stationary targets can be cancelled is shown in fig. 39(B). If the signals from successive pulse cycles are subtracted from one another. echoes of constant amplitude vanish, while echoes of changing amplitude do not.

The actual subtraction is performed by sending the receiver output to a "subtraction circuit" both directly and through a delay line which introduces an amount of delay exactly equal to the interpulse interval. Thus the subtraction circuit receives and compares echo signals from the immediately preceding pulse (direct from the receiver) and from the next earlier pulse (through the delay line).

The length of the usual interpulse interval is so long—some hundreds of microseconds—that electrical delay networks are impracticable for use in MTI. Instead. an ultrasonic delay device is often employed. Signals from the receiver output are turned into sound waves in a liquid or solid by a piezoelectric transducer, allowed to travel through the liquid or solid medium as ultrasonic waves for the distance necessary to introduce the required delay, and turned back into electrical signals by a transducer at the end of the medium.

The velocity of sound waves in such a medium as mercury permits the necessary delays to be produced by sonic paths of reasonable length (17.6 μ sec./in.). Alternatively, an electronic "storage tube," which works in a manner related to that of a television iconoscope can be used as a delay element.



FROM RADIATION LABORATORY SERIES, MC-GRAW-HILL BOOK COMPANY, INC.

FIG. 39.—PULSE-TO-PULSE CANCELLATION OF ECHO SIGNALS HAVING CONSTANT PHASE. (a) FOUR SUCCESSIVE SWEEPS OF AN A-SCOPE. (b) THE RESULT OF SUBTRACTING EACH SIGNAL FROM CORRESPONDING ONE ON THE SUCCEEDING PULSE

As the applications of MTI (and subsequent pulse-Doppler radar) came into wider use in postwar years, many advances were made. For example, mercury delay lines were replaced by quartz types that have a better signal-to-noise characteristic, entail smaller losses per unit of delay time and are more stable than the mercury lines they replace.

4. Pulse-Doppler. — The development of pulse-Doppler (PD) radar types in the 1950s for specific military needs (*e.g.*, ground surveillance) also made it possible to locate moving targets (distinguishing them from innumerable fixed objects on the ground and the resultant radar clutter) and to determine their range. CW emission is theoretically best for the discrimination of moving targets because of the frequency change, or Doppler effect, which is imparted to the reflected signals by the radial velocity of the target relative to the radar set. But since CW generators at centrimetre wave lengths tend to lack adequate power output, and since CW does not of itself enable range measurement to be made (unless frequency-modulated, as in the radio altimeter), PD radar employs powerful pulse transmission that also effectively measures the distance to the target.

The PD system employs the Doppler shift phenomenon that occurs within the pulse reflected from a moving object and enables the moving object to be detected in a background of fixed echoes.

The Doppler shift that denotes target motion can be detected in either of two ways. One method, called coherent MTI (described above), involves maintaining a stable reference frequency at the transmitter-receiver set to beat with the Doppler-shifted frequency of echoes received from targets in motion. The other method, termed noncoherent MTI, is used in military surveillance radars. It depends upon the presence of echoes from fixed objects in the same vicinity as the moving target under search. In this case the unchanged frequency of pulse-echo return from the fixed objects beats with the Doppler-shifted echo from the moving target to produce an aural or visual radar indication.

RADAR METEOROLOGY generally signifies the use of radar to observe and study the state of the atmosphere. It may be considered a division of radio meteorology. which also includes the study of the effects of the atmosphere on radio and radar propagation; *i.e.*, bending and attenuation of electromagnetic waves. Radar meteorology comprises the study of radar echoes received from natural reflecting sources within the atmosphere and the relation of the echo characteristics to the nature of the atmospheric processes influencing the reflecting mediums. Some natural reflecting sources are hydrometeors (raindrops. cloud droplets, ice crystals and snowflakes), sharp invisible discontinuities in temperature and humidity, and the highly ionized paths of lightning discharges.

History. — The first verified report of a precipitation echo occurred on Feb. 20. 1941, when a 10-cm. wave length (3,000 mc. per second frequency') radar tracked a shower to a distance of seven miles off the English coast. Prior to that time the unavailability of the microwave magnetron restricted radar equipment to relatively low transmitted powers at the longer wave lengths. Under these conditions the relatively small precipitation particles could not be detected. although weak echoes were thought to be associated with storms as early as 1938 in England. The first detection of what are now believed to have been clear air echoes from the lower atmosphere was made by R. A. Watson-Watt. A. F. Wilkins and E. G. Bowen in England in 1935, using a 50-m. wave length pulsed system intended to explore the ionosphere. The earliest documented observation of lightning echoes was made by M. G. H. Ligda with a 10-cm. radar on July 20. 1949. in Cambridge. Mass. With the development of shorter wave length (1.25 cm.) radars toward the end of World War II. it became possible to detect some of the larger particles in nearby nonprecipitating clouds. while the increasing use of radar throughout the world brought with it the more widespread detection of both clear air echoes and lightning discharges.

Theory. — The radar transmits extremely short pulses of electromagnetic energy in a well-defined beam which is aimed by a parabolic reflector. When the beam is directed toward precipitation. a small fraction of the energy is scattered, a small fraction is absorbed and the remainder is transmitted through to be scattered and absorbed by particles deeper in the storm. The portion of the energy which is scattered or reflected back to the radar is amplified and displayed on an indicator in a position relative to the origin. This position depends upon the time taken for the energy to travel the round path between radar and target at the speed of light. If the beam is held in a fixed direction. the echoes are usually displayed on an A-scope (*see* RADAR: *How* Ruder *Works*) which shows their amplitude or intensity versus distance. If the beam is made to rotate in azimuth around a vertical axis, the echoes brighten a spot on a cathode-ray tube at a distance out from the centre (radar position) depending on the target range and at a direction determined by the direction of the beam. This display is known as the PPI scope or plan position indicator. Since energy is usually reflected from the entire depth of the storm, the geographical position and extent of precipitation may be mapped accurately on the PPI scope to ranges limited mainly by the earth's curvature. For example; a storm at a range of 200 mi. must extend above 20.000 ft. to be detectable above the radar horizon. With this restriction, the PPI display enables the meteorologist to watch the motion and development of precipitation areas. When the beam is made to scan in a vertical plane, the echoes are displayed on the range height indicator or RHI scope showing a vertical cross section of the storm. On this scope, the meteorologist determines the height and growth rate of the storm, and its physical nature such as snow or rain, in addition to other storm features.

When the wave length of the electromagnetic radiation is large with respect to the size of the scattering particle. the energy returned to the radar is given by the Rapleigh scattering law and is proportional to the 6th power of the particle diameter; *i.e.*, doubling the diameter of a drop increases the echo by a factor of 64. In addition, the echo power is inversely proportional to the 4th power of the wave length; *i.e.*, doubling the wave length decreases the echo by a factor of 16. Since a raindrop is roughly 100 times as large as a cloud droplet, its echo is about 1,000,000 times as strong as that from a cloud droplet. However. since there may be 1.000 times as many cloud drops as raindrops, the total rain echo is about 1,000 times as strong as that from a water droplet cloud. Cloud radars operate at wave lengths near 1 cm. while precipitation radars operate between 3 and 23 cm. Clouds comprised of ice crystals are more readily detected because the crystals are usually much larger than the cloud droplets.

Of course. at any instant the radar receives the energy scattered back from a large number of particles confined within a volume defined by the beam width and half the pulse length in space. This is called the pulse volume. A 1 μsec. pulse intercepts a 492-ft. depth of precipitation while a 1° beam intercepts a width of about 9,200 ft. at a range of 100 mi. Since there are roughly 100 raindrops per cubic foot of air. an individual echo from such a range may include the energy scattered from about 4,000.000,-000.000 (4×10^{12}) raindrops. At a particular instant, the drops may be so distributed as to cause their individual echoes to reinforce each other; at another time. their individual echoes may cancel each other. Because the drops change position with respect to each other as a result of wind shear and turbulence. the total echo received from such a group of particles fluctuates rapidly from one pulse to the next. However. since the drops are randomly distributed within the pulse volume. the average echo intensity over a number of pulses is the sum of those from the individual particles; *i.e.*, it is proportional to the sum of the 6th powers of the particle diameters. This quantity summed over a representative unit volume of space within the pulse volume has been designated by the symbol Z by radar meteorologists. When they measure the average echo power from a storm. they are interested in the Z or reflectivity factor of that storm.

For a small target such as an airplane, the incident and reflected energy both spread out and decrease in intensity as the square of the target range. Thus, the echo from such a target decreases as the 4th power of the range. However, storms usually intercept the entire area of the radar beam so that the total energy incident on it does not depend on its range: it is only the reflected power which decreases with distance. For this reason. the average echo intensity from a storm decreases only as the square of its range, provided its reflectivity or Z remains constant.

Water drops scatter microwave radiation about five times as well as ice particles of the same mass because of their higher index of refraction. Therefore. when snowflakes begin to melt as they fall into warm air with temperature above 32" F.. their echo suddenly increases by a factor of 5 over that of the dry snow above. When the particles melt completely. however. the resulting raindrops quickly begin to fall at an average of about five times as fast as the original snowflakes. decreasing the number of particles per unit volume and the echo intensity proportionally. This causes the echo from the melting particles to be about five times as strong as that from both the dry snow above and the completely melted raindrops below. The exact variation of echo intensity through the melting zone depends on a number of other factors. In any case, the echo intensification in that layer makes it appear as a horizontal "bright band" on the RHI scope. Such "bright bands" are characteristic of most widespread precipitation in temperate latitudes and indicates that the rain originates in the form of ice crystals aloft.

The storm reflectivity factor or Z has also been found to be related to the precipitation rate, R, in both snow and rain. and to the water content per unit volume in clouds. Although the exact relation between Z and R depends on the nature of the particle size distribution, and it is possible to have equal rainfall intensities comprised of a large number of small drops with small Z or a few large drops with large Z, under average conditions the storm Z as measured by the echo intensity can provide an estimate of the precipitation rate within a factor of about 2. If the echo intensity is averaged over long periods, the estimates of total rainfall can be made with greater accuracy. Since a calibrated radar can measure the average rainfall over an area approximately 50 mi. in radius (about 7,500 sq.mi.) with an accuracy comparable to that from a network of several hundred rain gauges, and can secure these data quickly, it has great value for flood warning purposes.

One of the facts which limits the use of radar for the quantitative measurement of distant rainfall is the attenuation of the radar energy by scattering and absorption in intervening rain. Attenuation reduces the echo power by an amount which is unknown or difficult to determine; the echo may then be a useless measure of rainfall. At wave lengths of 10 cm. and larger, the attenuation in normal rains is negligible. and such wave lengths are therefore preferable for quantitative measurements. As the wave length decreases below 10 cm., the losses due to both scattering and absorption increase so that 1-cm. wave length radars can only penetrate a few miles into moderately intense rains. Even at 3 cm., only the front edge of an intense rainstorm may be seen on the radar scope.

Attenuation in snow is due only to the scattering and is generally negligible except at the very short wave lengths and in the most intense snowstorms.

Echo Interpretation and Uses.—In addition to the measurement of average echo intensity, the radar meteorologist studies the rate of pulse-to-pulse fluctuation of the echoes as an indication of the turbulence and wind shear in a storm. This technique is believed to have promise in identifying severe storms and tornadoes since the violent winds move the particles about rapidly. Use is also made of circular polarization, a technique which permits the cancellation of echoes from spherical particles. Those echoes which are not canceled with circular polarization are due to large nonspherical raindrops and hailstones which also occur in violent storms, and to wet snowflakes in the melting layer. Aircraft echoes are also only slightly reduced by circular polarization. Such a radar can therefore detect aircraft when they might be obscured in the weather echoes on a linearly polarized radar.

The greatest use of weather radar is in the observation of the geometric structure and motion of clouds and storms. Widespread precipitation such as that associated with warm fronts in middle latitudes is generally seen on the PPI scope as a fairly uniform echo mass covering large areas of the scope. On the RHI, the advance deck of alto-stratus clouds and evaporating precipitation lowers slowly as the storm centre approaches until snow or rain finally starts at the ground. On the PPI, some pattern may usually be discerned within the larger echo masses associated with trails of ice crystals released from occasional discrete cloud cells; these trails twist and turn as the ice crystals fall into layers of different wind velocity. On the RHI scope, the trails frequently take the form of hooklike cirrus clouds such as may be seen visually in the sky on a clear day. Their slope on the RHI and pattern on the PPI are helpful in determining the variation of winds with height.

While individual trails or small precipitation areas move with the winds at the heights of the cloud cells from which the precipitation is released, the entire region of precipitation echo moves with the velocity of the large-scale pressure pattern or storm system.

The precipitation echoes associated with a cold front most frequently take the form of lines of shower or thunderstorm cells several hundred miles long oriented along the front. Individual cells tend to move with the mean winds or those near the 10,000-ft. level, and may be less than 10 mi. in diameter, although some lines fail to show any separation. On the RHI. the echoes appear as tall vertical columns with sharply defined edges and tops which may become diffuse as the water particles are transformed to ice crystals and form the anvils of cumulo-nimbus clouds. Such storms do not display the "bright band" except in their decaying stages. Similar echoes are associated with isolated showers and thunderstorms on hot days when the atmosphere is unstable. Their severity may be indicated on the radar by their height, sometimes exceeding 50,000 ft., their rate of growth which may exceed 2,000 ft. per minute, their strong echo intensity due to large raindrops and hailstones, and an attenuation shadow cast on other storms behind (at the shorter wave lengths). Tornadoes have occasionally been identified by a figure-6-shaped tail extending out from the edge of a larger thunderstorm echo.

The PPI pattern of a hurricane shows a number of spiral bands each perhaps several hundred miles long and 20 mi. wide which spiral into the vicinity of the hurricane eye or pressure and wind minima. The centre of spiral is readily identified making it possible to pinpoint and track the "eye" by radar with an accuracy of about $\pm$ 7 mi.

In the tropics where the storms generally move slowly the spiral bands may be more like complete concentric rings; however, as they move into middle latitudes the major precipitation tends to occur in the forward right sector. The outer bands are comprised of individual shower cells, while the inner bands are more continuous and display the "bright band" near the melting level.

Echoes are also detected from sharp discontinuities in moisture and temperature without the presence of particulate matter. These echoes, unidentified in the early days of radar, are called "angels." Isolated angels occur under a wide range of conditions though preferably in a turbulent atmosphere when moist parcels of air rise through a relatively dry environment into the bases of cumulus-type clouds. Widespread angel echoes have also been observed from the sea breeze front.

At wave lengths of 10 cm. and longer, the highly ionized columns produced by lightning discharges may also be detected. However, since the ionized path dissipates rapidly, the radar beam must be directed at the lightning region just at the discharge time. Cloud-to-cloud lightning is more readily discernible on the scope because of its greater horizontal extent than the cloud-to-ground variety; also it tends to occur in the upper and weaker snow regions of the storm so that its echo is not so easily obscured by the more intense rain echoes. Lightning echoes as long as 100 mi. have been observed.

For more information on radar theory, terminology and equipment, *see* RADAR.

RADCLIFFE, ANN (1764–1823), English novelist, only daughter of William and Ann Ward, was born in London on July 9, 1764. She was the author of four famous novels: *The Sicilian Romance* (1790), *The Romance of the Forest* (1791), *The Mysteries of Udolpho* (1794) and *The Italian* (1797). When she was 23 years old she married William Radcliffe, an Oxford graduate and student of law. He gave up his profession for literature, and afterward became proprietor and editor of the *English Chronicle.* After *The Italian* she gave up writing for publication. She died on Feb. 7, 1823. *Gaston de Blondeville* (1826) was published after her death, as were her *Poems* (1834). In the history of the English novel, Ann Radcliffe deserves at least the credit of originating a school of which she was the most distinguished exponent. She had a genuine gift for scenic effect, and her vivid imagination provided every tragic situation in her stories with its appropriate setting. Sir Walter Scott wrote an appreciative essay for the edition of 1824, and Christina Rossetti was one of her admirers.

RADCLIFFE, JOHN (1650–1714), English physician, born at M'akefield. a well-known physician in the reigns of William III and Anne. He left property to University college for founding two medical travelling fellowships and for building the Radcliffe observatory, hospital and library at Oxford, and enlarging St. Bartholomew's hospital in London. Radcliffe was elected M.P. for Bramber in 1690 and for Buckingham in 1713. He died at Carshalton on Nov. 1, 1714.

See J B Nias, *Life of John Radcliffe* (Oxford, 1918); A. B. Luckhardt, *Surg., Gynec. and Obst*, 72 674–677 (1941).

RADCLIFFE, a municipal borough (1935) in the Bury and Radcliffe parliamentary division of Lancashire Eng., on the Irwell, about 8 mi. N.N.W. of Manchester by road. Pop. (1961) 26,720. Area 7.7 sq.mi. In the church of St. Bartholomew the tower arch dates from the early 1jth century.

Industries include cotton, paper, chemicals and other manufactures and engineering.

RADCLIFFE-BROWN, ALFRED REGINALD (1881–19j5), British social anthropologist. whose great contribution was his systematic framework of concepts and generalizations relating to the social structures of simple societies, was born on Jan. 17, 1881, in Birmingham. After being educated at Trinity college, Cambridge, he took up the study of anthropology. In 1906 he went to the Andaman Islands! where his field work later won him a fellowship at Trinity college. In 1910 he carried out a second field expedition to Western Australia. concentrating on kinship and family organization. In 1916 he became director of education in the kingdom of Tonga and in 1921 took the chair of social anthropology at the University of Cape Town. In 1925 he accepted the chair of anthropology at Sydney university. where he built up a vigorous department for teaching and for research in both theoretical and applied anthropology. A brilliant lecturer and conversationalist, he became a well-known personality in Australian intellectual circles in spite of a somewhat aloof and critical temperament. Between 1931 and 1937 he was professor of anthropology at The University of Chicago, after which he held the chair of social anthropology at Oxford until his retirement in 1946. Among many academic honours he received were the Rivers and Huxley Memorial medals of the Royal Anthropological institute, of which he was president in 1939–41. He died in London on Oct. 24. 1955.

Together with Bronislaw Malinowski (*q.v.*), Radcliffe-Brown revolutionized the study of social anthropology in founding modern functionalist theory. His basic postulate was that every social system has a "functional unity" in which "all the parts work together with a sufficientdegree of harmony or internal consistency.'! He defined a social system as consisting of "the total *social structure* of a society together with the totality of *social usages* in which that structure appears and on which it depends for its continued existence." As his theory developed he laid increasing stress on the comparative analysis of social structure as the primary aim of social anthropology. Claiming social anthropology to be a natural science of society to which the conjectural history resorted to by older anthropologists was irrelevant. he sought to establish general tendencies or laws underlying the diversities of human social life. In the comparative sociology of kinship and juridical and political institutions. Radcliffe-Brown was an acknowledged master and his generalizations won wide support and inspired modern research in this field. He showed that the patterns exhibited by kinship systems, notably those that have a classificatory terminology, arose from particular combinations of the laws of the unity of the sibling group. the unity of the descent group and the separation of successive generations, in association with other specific variables such as distinctions of age and sex (*see* KINSHIP TERMINOLOGY). Applying these principles, he swept away the fog of pseudohistorical misunderstanding of the social basis of clans, totemism, alleged matrilineal survivals and other classical problems of anthropology.

Among Radcliffe-Brown's works are *The Andaman Islanders* (1922; new ed.. 1948) and *Structure und Function in Primitive Society* (1952).

RADEGUNDA, ST. (d. 587), Frankish queen, was the daughter of Berthaire, king of the Thuringians. Berthaire was killed by his brother Hermannfried, who took Radegunda and educated her, but was himself slain by the Frankish kings Theuderich and Clotaire (529), and Radegunda fell to Clotaire, who later married her. She left him when he unjustly killed her brother, and fled to Medardus, bishop of Poitiers, who consecrated her as a nun. Radegunda stayed in Poitiers, founded a monastery there, and lived for a while in peace. The queen died on Aug. 13, 587.

RADEK, KARL (1885–), Russian politician, was born in Lwów (Lemberg) and he was educated at the universities of Cracow and Berne. In 1904 he became a member of the Social Democratic party of Poland and Lithuania. During the revolution of 1905 he spent a year in prison, and subsequently became a member of the editorial staff of social democratic newspapers in Poland. Leipzig and Bremen which supported the left wing of the German Social Democrats. During World War I, after some months of illegal antimilitarist activity in Germany, he established himself in Switzerland where he wrote for the Berne *Tageblatt*. He took part in the Zimmerwald and Kienthal internationalist conferences in September 1915 and April 1916. After the Russian revolution of March 1917 he crossed Germany, together with V. I. U Lenin, G. E. Zinoviev, Julius Martov and others, and remained in Stockholm as the representative of the central committee of the Bolshevik party, issuing a weekly bulletin on the Russian Revolution in French and German. After the second revolution, in Nov. 1917, he took part in the Brest-Litovsk peace negotiations. When the German revolution broke out in 1918 he made his way illegally to Germany, where as a representative of the central committee of the Soviet Communist party he took an active part in reorganizing the German Communist party, working in its central committee after the murders of Karl Liebkneckt and Rosa Luxemburg on Jan. 16, 1919. He was imprisoned in Germany from Feb. to Dec. 1919. On his release from prison Radek returned to the U.S.S.R., where he became one of the leading members of the presidium of the Communist International. He returned illegally to Germany, however. and took part in the organization of the joint congress of German Communists and Left Independents. He was made a scapegoat for the failure of the German Communists to seize power in the autumn of 1923, and, on account of his support of the "right" groups of the German Communists, he lost his authority in the Communist International, losing his place in its executive committee and in the central committee of the Soviet Communist party. He was a prolific writer in the Soviet press on questions of international politics. Expelled from the Communist party in 1927, he was readmitted in 1930. In Jan. 1937, he was tried with 16 others for plotting against the Soviet Union and was sentenced to 10 years' imprisonment. He was released after serving only four years of his term in order that he might serve as a propagandist.

RADETZKY, JOSEF, COUNT OF RADETZ (1766–1858), Austrian soldier, was born at Trzebnitz in Bohemia in 1766, of an old noble family, originally Hungarian. He joined the army as a cadet in 1785. Next year he became an officer, and in 1787 a first lieutenant in a cuirassier regiment. He served as a galloper on Count Franz Moritz Lacy's staff in the Turkish War, and in the Low Countries during the Revolutionary War. In 1795 he fought on the Rhine, and next year with Beaulieu against Napoleon in Italy. His personal courage was conspicuous; at Fleurus he had led a party of cavalry through the French lines to discover the fate of Charleroi, and at Valeggio, with a few hussars, rescued Beaulieu from the enemy. Promoted major. he took part in Dagobert S Wurmser's Mantua campaign. As lieutenant colonel and colonel he displayed bravery and skill at Trebbia and Novi (1799), and at Marengo was hit by five bullets.

In 1801 Radetzky received the knighthood of the Maria Theresa order; in 1805 he was promoted to major general and given a commdnd in Italy under the archduke Charles, and thus took part in the successful campaign of Caldiero. Peace again afforded him a short leisure, which he used in studying and teaching the art of war. In 1809, now a lieutenant field marshal, he fought at Wagram, and in 1810 received the commandership of the Maria Theresa order and the colonelcy of the 5th Radetzky hussars. From 1809 to 1812. as chief of the general staff, he was active in the reorganization of the army and its tactical system, but, unable to carry out the reforms he desired because of the opposition of the treasury, he resigned the post. In 1813 as chief of staff to the prince of Schwarzenberg. he had considerable influence on the councils of the allied sovereigns and generals. He had a considerable share in planning the Leipzig campaign and as a tactician won great praise at Brienne and Arcis sur Aube. He entered Paris with the allied sovereigns in March 1814, and returned with them to the Congress of Vienna.

He then resumed his functions as chief of the staff, but his ardent ideas for reforming the army came to nothing in the face of the general apathy. His zeal added to the number of his enemies, and in 1829, after he had been for twenty years a lieutenant field marshal, it was proposed to place him on the retired list. The emperor, unwilling to go so far as this, promoted him general of cavalry and shelved him by making him governor of a fortress. In 1834. however, his services were again required in Italy. first under Frimont, and then in chief command.

In 1836 Radetzky became a field marshal. Apathy and parsimony caused the authorities again to neglect his many suggestions. and the outbreak of the wars of 1848 found the Austrian army in an unprepared condition through no fault of Radetzky's. Nevertheless. recalled to command. he conducted his famous operations in the Quadrilateral, leading up to the triumph of Novara on March 23, 1849. (See ITALIAN WARS.) To the soldiers of his army who idolized him, he was always simply "Vater Radetzky." He died on Jan. 5, 1858.

RADIATION (RAYS): see COSMIC RAYS; ELECTROMAGNETIC WAVES; PARTICLES, ELEMENTARY; RADIOACTIVITY, ARTIFICIAL; RADIOACTIVITY, NATURAL; X-RAYS; LIGHT.

RADIATION: BIOLOGICAL EFFECTS. All life is constantly being bombarded with various kinds of radiation—visible light, infrared, ultraviolet, radio waves, X-rays (from cosmic and terrestrial sources)—all of which are basically similar in that they are all transfers of energy from one place to another. In a wide sense any consequence of the transfer of radiation energy to a living organism is a biological effect of radiation. This definition includes both the normal effects on many life processes (*e.g.*, photosynthesis in plants and vision in animals) and the abnormal or injurious effects resulting from the exposure of life to unusual types of radiation or to increased amounts of the radiations commonly encountered in nature. This article, devoted chiefly to the discussion of the deleterious effects of radiation, is divided into the following sections:

I. DEFINITIONS AND CONCEPTS

For a better understanding of the later sections of this article a review of the two main types of radiation—electromagnetic waves and moving atomic particles—their measurement, sources and mechanisms, is in order.

A. TYPES AND MEASUREMENT OF RADIATION

1. Electromagnetic Waves.—Energy can be transferred through matter or through space by means of oscillatory variations in electric and magnetic fields originating at various sources. Electromagnetic wave radiation is classified into several types. depending on frequency and wave length. The various types (in order of decreasing wave length and increasing frequency) and their sources are summarized in Table I.

TABLE I.—*Electromagnetic Waves*

Wave type	Sources
Hertzian (Radio waves and Microwaves)	Radio transmitters
Infrared	Hot bodies
Visible	Hot bodies
Ultraviolet	Hot bodies; excited gases
X-rays and gamma rays*	Atoms struck by high-energy particles; radioactive materials; cosmic sources

*X-rays emitted during the disintegration of radioactive materials.

2. Particulate or Corpuscular Radiations.—Simply speaking, an atom consists of a nucleus (composed chiefly of neutrons and protons) surrounded by a cloud of electrons; in addition there are other special particles. When separated, either by natural radioactive disintegration or by artificial means (as in a cyclotron, for example), these particles, charged or uncharged, are capable of transferring their energy, wholly or in part, to any substance through which they pass. Streams of such particles constitute particulate radiations. The more important types of particle, the magnitudes and signs of their charges (relative to that of an electron, defined as the unit negative charge-), their masses (relative to the mass of a hydrogen nucleus. defined as the unit mass) and their main sources are summarized in Table II. The rate of transfer of energy by a particulate radiation depends on the mass of the particle, its velocity and, if charged, the magnitude of its charge.

TABLE 11.—Particulate ***Radiations***

Particle type	Charge	Mass	Sources
Electron*	−1	1/1843	Accelerating machines, radioactive materials
Protont	1	I	Accelerating machines
Alnha (α) particle‡ . . .	2	4	Radioactive materials
Neutron	0	1	Nuclear reactors, accelerating machines

*Electrons emitted by radioactive nuclei are called beta (ti) particles.
†Protons are the nuclei of hydrogen atoms.
‡Alpha particles are the nuclei of helium atoms.

3. Measurement of Radiation.—The physical quantity of a radioactive substance is measured in curie units (see RADIOACTIVITY. NATURAL). Radiation acts biologically by depositing energy within living cells through the process of ionization or excitation of some of their constituent molecules (see the following section).

Roentgen Unit—The original biological unit of X- (or gamma) ray exposure, the roentgen unit (r), is defined as that quantity of radiation that produces a given number of charged ions in a given quantity of air under standard conditions.

Rad.—A more general and more accurately defined measure of local exposure to all types of radiation is the rad, the radiation dose absorbed in tissue itself.

Rem.—The comparative unit called the rem (roentgen equivalent man) expresses the dosage of any radiation that produces biological effects in man equivalent to 1 rad of X-rays. The rem is the measure of the "relative biological effectiveness" (RBE) of radiations; *i.e.*, the ratio of doses of ionizing radiation from different sources that have the same biological effect.

For more technical definitions see RADIOLOGY. A detailed discussion of radioactivity may be found in RADIOACTIVITY, NATURAL, and RADIOACTIVITY, ARTIFICIAL.

B. MODE OF ACTION

1. Mechanisms of Energy Transfer. — There are several mechanisms by which energy is transferred from radiations to biological materials. Wave radiations yield up their energy through resonance. In general, the smaller a body, the higher its resonant frequency and therefore the higher the frequency of the radiation from which it will absorb energy. The energy of infrared and visible radiation is absorbed mainly by whole molecules and atoms and therefore appears mainly as heat. The energy of ultraviolet radiation is absorbed partly by the planetary electrons of atoms; an electron jumps to a higher-energy orbit. thereby bringing the atom into a state of excitation, in which it is chemically reactive. The energy of X-rays is also absorbed mainly by the planetary electrons of atoms, but the amount absorbed is usually great enough to produce ionization; *i.e.*, to induce an electron (or electrons) to escape altogether from the atom, which latter is thus ionized; an ionized atom is highly reactive, even more so than one in a state of excitation.

Particulate radiations yield up their energy through collision with the planetary electrons or atomic nuclei of the material through which they pass. Charged particles usually react with the planetary electrons and therefore leave the atom in an excited or, more commonly. ionized state. Neutrons, being uncharged, are able to pass through the orbits of the planetary electrons and collide with the nucleus of an atom. The nucleus may then recoil. or it may capture the neutron. In biological material neutrons yield up most of their energy through collision with hydrogen nuclei, which recoil as hydrogen ions (*i.e.*, protons). The neutron is eventually captured by some nucleus, and capture is usually followed by the ejection of one or more charged particles, often accompanied by a gamma ray.

2. Ionization and Penetrating Power. — Although all higher-energy radiations (*i.e.*, X-rays and particulate radiations) produce ionization in biological material, the spatial distribution of the ionization depends on the type and penetrating power of the radiation, the nature of the material irradiated and the spatial distribution of the radiation source or sources. High-energy X-rays produce ionization that is rather sparsely but uniformly distributed along the track of the radiation; alpha particles cause intense ionization along their tracks; in between these come neutrons, protons and beta particles. In general, the lower the speed of a particle, the denser the ionization along its track, so that all particles tend to be more densely ionizing toward the ends of their tracks. High-energy X-rays penetrate deeply (X-rays commonly used in medicine are less penetrating), but most beta particles penetrate only a few millimetres in biological tissues and alpha particles only a small fraction of a millimetre. Animal tissues such as bone and teeth which contain elements of fairly high atomic weight. such as calcium, absorb much more energy from a given radiation than do soft tissues, which are composed mainly of elements of low atomic weight. Ultraviolet radiation is of very low penetrating power.

3. Mechanisms of Biological Action. — The biological effects of the higher-energy electromagnetic radiations and of all the particulate radiations are mediated through the ionization (and, to a lesser extent, the excitation) that they produce in biological tissue. Thus all ionizing radiations have broadly similar biological effects; such differences as are found are the result of differences in the spatial distribution of the ionization. Ionization in biological tissues is largely intracellular. Therefore, an explanation of its mode of action must be sought at the cellular level; effects on the whole organism are likely to be secondary. Two main types of intracellular action have been distinguished: first, direct action through ionization of biological structures along the ionized track; and second, indirect action through the formation of reactive chemical substances that diffuse away from the ionized track and subsequently undergo further reaction elsewhere.

Direct *Action.*—Direct biological actions were studied in great detail in the period between 1927 and 1947. The leaders in this work included H. J. Muller in the U.S., N. Timofeeff-Ressovsky and K. G. Zimmer in Germany and D. E. Lea in Great Britain. A detailed quantitative theory was elaborated, the target theory or *Treffertheorie*, whereby a tissue undergoing irradiation was likened to a field traversed by the fire of a machine gun. It was supposed that to produce a given effect there must be one or more hits by an ionized track on a sensitive target, so that the probability of obtaining the effect was dependent on the probability of obtaining the requisite number of hits on the appropriate target. This theory was very successful in giving a quantitative treatment of many of the biological effects of radiations, particularly in the field of genetics

Indirect Action. — In the field of radiation chemistry, however, the target theory had little application, and from about 1940 the interest of radiation biologists tended to shift toward the indirect actions of radiations. This shift was given impetus by the discovery in 1947, by J. M. Thoday and J. Read, that the induction of chromosome breakage, which had until then been viewed as a target-theory effect par excellence, was enhanced if the tension of oxygen was increased in the material irradiated. This led on to the discovery of protective substances, such as cysteamine and cysteine, which reduce some of the biological effects of radiation exposure; Z. Q. Bacq (Belgium) and H. M. Patt (U.S.) were leaders in this field. Many other studies followed in which it became apparent that, although there certainly were indirect actions of radiations, the distances over which indirect action could occur were always small, usually no more than a few microns.

II. GENERAL BIOLOGICAL EFFECTS

The biological effects of radiations may conveniently be subdivided into somatic effects — short-term somatic effects (*i.e.*, short-term effects on the body of the individuai) and long-term somatic effects — and genetic effects. Historically, they were discovered in that order. But as the genetic effects are nearest to the cellular level, and the short-term somatic effects farthest from it, it is more convenient to consider them in the reverse order.

A. GENETIC EFFECTS

The genetic effects of radiations arise through damage to those intracellular bodies in the germ cells that are the material basis of heredity (*q.v.*). These are the chromosomes, with their constituent genes (see GENE). Genetic effects therefore occur only if the radiation reaches the germ cells. Thus in those animals (man is one) and plants in which the germ cells are fairly well covered by tissue, radiations of low penetrating power, such as ultraviolet light and alpha and beta particles, cannot produce genetic changes; however, radiations of high penetrating power. such as X-rays and gamma radiation, can induce genetic effects.

Radiation-induced genetic effects on animals and plants are probably not qualitatively different if consideration is given to the physiological variations between these two kinds of life. For obvious reasons, more research has been done on the changes induced in the genetic material of animals. However, mutations induced by irradiation of seeds have been of interest to plant breeders: many new varieties have been produced, some of which show improvement over the original stock in respect to hardiness, resistance to disease, etc. Genetic changes of two sorts are induced, namely, gene mutations and chromosome mutations They differ in important respects and will be considered separately.

1. Gene Mutations. — Radiation-induced gene mutations were first demonstrated by H. J. Muller in 1927. They are all of the same types that occur spontaneously in nature. Most gene mutations, whether spontaneous or radiation-induced, are harmful. They reduce the fitness of the organism in the sense that an individual carrying a mutated gene is less capable of surviving and leaving descendants than is an individual carrying the gene in its unmutated form. This is an empirical observation, but it may also be expected on theoretical grounds: any advantageous mutation that could occur spontaneously would probably have occurred at some time in the past and, being advantageous, would have spread through the species, thereby coming to represent the normal form of the gene; any mutation away from the normal form would therefore be a mutation to a less advantageous form.

Although the mutations induced by radiations are all of types that occur spontaneously, the relative frequencies with which any two particular genes mutate under irradiation may not be the same as the frequencies with which they mutate spontaneously; however, if whole classes of genes are considered, the mutational idiosyncrasies of particular genes are lost, and the over-all picture shows that exposure to radiation causes a proportionate increase in the mutation frequency of all classes of genes.

Experiments with animals and plants, notably by Muller and Timofeeff-Ressovsky and their co-workers, in the period between 1927 and 1935 established a number of factors influencing the induction of mutation by radiations. The yield of mutation is directly proportional to the amount of energy absorbed in the germ cells; *i.e.,* to the radiation dose. This linear dependence of mutation on dose, which is to be expected on target-theory considerations if gene mutation is the result of a single hit by an ionized track. has been demonstrated experimentally for doses down to a few r and is believed to be valid for all doses, though for statistical reasons it would be difficult to obtain experimental verification at doses much lower than this. The implication is that there is no threshold dose for the induction of gene mutation; *i.e.,* any dose, no matter how small, will induce some mutation.

Radiation quality has little effect on the amount of mutation induced, approximately the same amount of mutation being induced per unit dose, whatever the type of radiation, provided that the radiation intensity is the same.

Radiation intensity was originally thought to have no importance, the total amuunt of mutation induced being dependent only on the total accumulated dose. However, in 1958 it was shown by W. L. Russell that this does not hold good for mutation induced in immature germ cells (spermatogonia and oocytes) of the mouse, the amount of mutation induced by a dose accumulated at a rate of about 1 r per day being only about a third of that induced by the same dose accumulated at about 100 r per minute. If this is true of mammalian spermatogonia and oocytes generally, it holds important implications for man, whose germ cells are present mainly in the form of spermatogonia in the male and oocytes in the female.

The amount of mutation induced by radiation is usually expressed in terms of the mutation-rate-doubling dose, which is the dose that induces as much mutation as occurs spontaneously in each generation. This is merely a mathematically convenient way of relating the amount of induced mutation to that arising spontaneously; there is no special biological significance in a mutation rate twice the spontaneous rate. The more sensitive the genes to radiation, the lower the doubling dose. Doubling doses for high-intensity exposure of several different organisms have been found experimentally to lie between about 30 r and 150 r; for seven specific genes in spermatogonia of the mouse the doubling dose is about 30 r for high-intensity exposure and about 100 r for low-intensity exposure. Very little is known about the doubling dose for human genes: studies of the children of survivors of the atomic bomb explosions at Hiroshima and Nagasaki indicate that it must be higher than 10 r, but how much higher is not known; most geneticists assume that it is about the same as the doubling dose for the mouse.

The existence of a linear law relating induced gene mutation to radiation dose holds an important implication for populations: it implies that very small doses of radiation given to very large numbers of individuals may introduce into the population as many mutant genes as would be introduced through large doses to small numbers of individuals. Furthermore, it is necessary to take into consideration the probability that an exposed individual will contriburr to the next generation at some time after exposure. It follows that exposure of individuals below reproductive age (including unborn fetuses) is genetically of the greatest importance, and exposure of those above reproductive age is of no importance.

The effect on a population of a rise in its mutation rate depends on the role played by mutation in determining the characteristics of the population. Deleterious genes enter the population through mutation but, because they reduce the fitness of their carriers, they tend to die out; thus a genetic equilibrium is set up at a point where the flow of deleterious genes into the population through mutation is counterbalanced by the loss through reduction in fitness. At equilibrium a constant fraction of the population will be handicapped by deleterious genes. Increasing the mutation rate would increase the gene-handicapped fraction proportionately. However, the full increase would not be manifest immediately; this would occur only when genetic equilibrium had again been established, which would probably require several generations.

2. Chromosome Mutations. — Ionizing radiations not only cause genes to mutate but also may break the chromosomes in which the genes are carried. Chromosome breaks often heal spontaneously, in which case no damage becomes apparent. If a break fails to heal, a germ cell may be formed that lacks an essential part of the gene complement; such a germ cell may be capable of taking part in the fertilization process, but the ensuing zygote is usually incapable of full development and dies in an embryonic state. When two chromosomes in the same nucleus are broken, it sometimes happens that the broken ends join together, but in such a way that the order of the genes in the chromosomes is changed: for example, part of chromosome A may join onto part of chromosome B and vice versa. A germ cell carrying such a chromosome structural change may be capable of giving rise to a zygote that may develop into an adult individual, but the germ cells produced by the latter include many that lack the normal chromosome complement and so give rise to zygotes that are incapable of full development. An individual of this sort is called semisterile, and the number of his descendants is correspondingly lower than normal. Chromosome structural changes therefore usually die out of a population; for this reason they are of little importance in human populations. In some species, however, there are mechanisms that reduce the loss of fertility usually associated with chromosomal changes, and in them such changes may be present in the majority of individuals. They include the evening primrose, *Oenothera,* and some species of the fruit fly *Drosophila.* As would be expected from target-theory considerations, the induction of two-break chromosome changes is not dependent on radiation dose in a simple linear fashion. High doses, and doses given at high intensities, induce proportionately more changes of this sort.

B. Bodily (Somatic) Effects

Somatic effects due to radiation include all the injuries, long-term and short-term, to all the cells of the body of an organism—plant or animal.

1. Long-Term Effects. — Long-term somatic effects include damage to cells that are continually proliferating, so that the injury is passed on to succeeding cell generations. Such cells are found in embryonic tissues and in those tissues of the adult in which cell division normally continues throughout life; in vertebrates these include the blood-forming tissues, the basal layer of the skin, the intestinal mucosa and, in the male, the germ cells. Furthermore, the radiation may affect the rate of cell division: the cells may be killed or otherwise rendered incapable of further division; division may be slowed down; or, conversely, tissues in which cell division normally ceases in the adult may escape their normal biological control and cell division may continue. Mosaic sectors have been observed in many organisms exposed to radiations during embryonic development. They include humans who have been exposed in *utero* during diagnostic examination of the mother; in some fetuses there was a brown sector in the otherwise blue iris of an eye; in others there was a black patch in an otherwise blond head of hair. Unilateral arid nonheritable expression of a congenital defect of a type that is normally bilateral and heritable Is also believed to arise sometimes through somatic mutation. Sometimes the mutant region includes some of the germ cells, and the genetically mutant nature of the mosaicism can then be confirmed by a breeding test.

Slowing down or suppression of cell division, including radiation-induced cell death, may have important end results where embryonic tissues are exposed. This is because the rate of cell division is not uniform throughout an embryo; at any one stage of development the cells in some parts will be dividing rapidly, while in other parts there will be relatively little cell division. Exposure to radiation will affect the rapidly dividing tissues more strongly than the others. with the result that the pattern of development will be distorted and the individual, when adult, will have disproportionate parts. This phenomenon, which is well known in experimental plants and animals, is also known in man. (Among the persons exposed as early embryos to the atomic bomb radiations in Japan were a number with abnormally small heads and mental defect. Such children have also occurred following exposure *in utero* to medical X-rays.)

Radiation exposure of the blood-forming tissues leads to a reduction of cell division and therefore to a reduction in the blood-cell count which may, if sufficiently great, amount to clinically recognizable anemia (for this reason regular blood-cell counts used to be carried out on all radiation workers). Radiation exposure of the germinal tissues likewise leads to a reduction of cell division, which may be sufficient, if the dose is large enough, to induce sterility; a dose of 200 r to the gonads of the human male induces temporary sterility, lasting a few months; a gonad dose of about 500 r to either sex induces permanent sterility. Opacity of the lens of the eye. which may develop into a full cataract, has been observed following exposure to ionizing radiation, especially neutrons.

A further long-term effect of radiation exposure is a general shortening of the life span, not associated with death attributable to any specific cause. It is a phenomenon well established in laboratory animals, but evidence about its extent in humans is conflicting; the mechanism, whether through gene mutation in somatic cells, a reduction of cell division or some other cause, has not been established.

Loss of biological control over cell division, *i.e.*, the induction of cancer in animals and distortion of parts in plants, is one of the more serious long-term somatic effects of excessive radiation exposure. It may occur in any tissue. Cancer of the skin was the first long-term effect to be observed; it may result from exposure to ultraviolet as well as to ionizing radiation.

The nature of the dependence of the long-term effects of radiation on radiation dose, type and intensity is not yet established with certainty. Many authorities assume that the relationship is of a nonthreshold type, meaning that any additional exposure increases the probability of long-term effects occurring. It is a characteristic of the induction of cancer that there may be a long period of time between the causal exposure and the appearance of the effect: for some skin cancers in man induction periods of 40 years have been recorded.

2. Short-Term Effects.—A sufficiently large dose of radiation will kill any organism, but the dose required varies greatly from species to species; mammals are killed by less than 1,000 r, but fruit flies may survive 100.000 r, and many bacteria and viruses even higher doses.

This lethal action of radiation can be used as an alternative to heat treatment for sterilizing materials such as surgical sutures. It has found little application in the sterilization of foodstuffs, mainly because the high doses required induce chemical changes in the food that render it unpalatable.

III. RADIATION AND HUMAN HEALTH

A. MAN'S RADIATION BURDEN

1. Natural Sources.—Throughout the ages man has been exposed to what is called natural background radiation. This includes radiation from cosmic as well as terrestrial sources. It has probably played the major role in evolution of life by providing mutations upon which natural selection has acted.

Cosmic rays (*q.v.*) rain down incessantly on the earth's atmosphere. Interacting with atoms in the air, such rays resolve themselves into various components—chiefly penetrating electrons, gamma rays and mesons (a class of atomic particles)—by the time they reach the earth. There is considerable variation in the intensity of cosmic radiation, both geographically and temporally, since sun spots and solar flares influence the primary intensity. For about every 5,000 ft. of altitude the intensity approximately doubles (*see* Table III). (Posing an obstacle to man's space travel is a belt of "trapped" radiation that surrounds the earth at a height of several thousand miles [*see* VAN ALLEN RADIATION BELTS].)

TABLE III.—*Cosmic Radiation Exposure at Different Altitudes*

Altitude	Mean dose in rads per year	Maximum variation due to solar flares
Sea level	0.021 to 0.010	50 ×
5,000 ft.	0.040 to 0.060	
10,000 ft.	0.080 to 0.120	
40,000 ft.	2.8	
30 km.–600 km.	7.3	1,000 X ?
22,000 km. (Van Allen belt)	about 8,800	very large ?

Man also receives external and internal radiation from natural radioisotopes, particularly radium and its daughters, members of the thorium series. potassium-40, carbon-14 and hydrogen-3 (tritium). The latter two are produced by cosmic rays. The greater part of external radiation comes from the radioactivity of minerals, whereas radioactive contamination of drinking water and food plays an integral part internally. Drinking waters vary by a factor of 10,000 in their radioactivity content. Among the foods, radium content of nuts and cereals is higher than that of milk or meat. Internal doses in normal persons from natural radioactivity are listed in Table IV.

TABLE IV.—*Internal Dose Due to Natural Radioactivity*

Isotope	Radioactivity in curies	Radiation	Dose in rads per year	Critical organ
Carbon-14	9×10^{-8} per g	Beta rays	0.0016	Gonads
Potassium-40	10.4×10^{-8} per g	Beta rays	0.0165	Gonads
Potassium-40	1.15×10^{-8} per g	Gamma rays	0.0023	Gonads
Radium and daughters	1×10^{-10} in body	Alpha, beta gamma rays	0.0380	Bones

2. Artificial Sources.—Since the discovery of radioactivity, man has substantially added to his natural radiation load. Medical X-rays are often necessary for the diagnosis or treatment of disease. In some countries almost the entire population is exposed to periodic diagnostic X-rays and a significant fraction to therapeutic doses. Therapeutic doses vary widely depending on. among other things, the disease being treated. Routine diagnostic doses, though they may vary somewhat depending on the apparatus and the operator, usually fall within certain limits (*see* Table V).

TABLE V.—*Typical Doses Received in Routine X-ray Diagnosis*

Examination	Dose per exposure
Chest X-ray	0.04–1 rad
Gastrointestinal X-ray	1 rad
Extremities	0.25–1 rad
Fluoroscopy	10–20 rads per minute
X-ray movie	25 rads per examination

High-voltage power supplies for radar or television. X-ray machines in shoe stores, dental X-rays, luminous-dial watches and phonograph static eliminators frequently give significant doses of radiation, often more than is warranted. A further contribution of man, one that has become of considerable concern, is fallout (see *Radioisotopes and Fallout*, below), the radioactive debris proceeding from atomic explosions. Unlimited nuclear testing may have serious consequences to world health.

B. INJURY FROM IONIZING RADIATIONS

Although all forms of radiation, if intense enough, may produce some adverse effects on man, the "hard" or penetrating ionizing rays, including X-rays and moving atomic particles, present the greatest hazard. Paradoxically, these same ionizing rays, when judiciously used in medicine, constitute a formidable weapon against cancer and an invaluable aid in diagnosis *(see* RADIOLOGY).

The concept of maximum permissible exposure to radiation is a much-debated point, subject to change as more information accumulates. Although the body may not be noticeably affected, genetic damage may occur and pass unnoticed for several generations, as was mentioned earlier. Maximum permissible exposures are proposed for persons who, by the nature of their work. are exposed to amounts of radiation beyond that to which the general population is exposed. (Recommendations vary somewhat in different countries; those given in Table VI are for the U S.)

TABLE VI.—*Maximum Permissible Exposures to Ionizing* **Radiations**

Organ exposed	Exposure
Whole body	3 rem in 13 weeks
Professional emergency dose (once in life)	25 rem
Accumulated dose under 18 pears	So professional exposure permitted
Accumulated dose over 18 years	Average of 5 rem per year less than 15 rem in any single year
Skin	6 rem in 13 weeks or 30 rem per year
Gonads	5 rem per year
Bone	3.8 rem per year

1. Historical Background.—In Dec. 1895 the German physicist Wilhelm Conrad Rontgen demonstrated the first X-ray pictures. among them that of the left hand of Mrs. Rontgen. Within a few weeks the news of the discovery spread throughout the world, and the penetrating properties of the rays were soon exploited for medical diagnosis without immediate realization of possible deleterious effects. The first reports of X-ray injury to various human tissues and to vision came from the Italian F. Batelli (1896). In that same year Elihu Thomson. the physicist, deliberately exposed one of his fingers to X-rays and provided accurate scientific observations on the development of roentgen-ray burns.

Also in 1896 Thomas Alva Edison discovered "fluoroscopy"; he was engaged in developing a fluorescent roentgen-ray lamp when he noticed that his assistant, Clarence Dally, was "poisonously affected" by the new rays so that his hair fell out and his scalp became inflamed and ulcerated. By 1904 Dally developed severe ulcers on both hands and arms; these lesions, which soon afterward became cancerous, caused his early death. During the next few decades many investigators and medical doctors developed radiation burns and cancer, and more than 100 persons died. presumably as a result of their exposure to X-rays. These sad early experiences eventually led to an awareness of radiation hazards for professional workers and stimulated development of a new branch of science, radiobiology.

Radiations from radioactive materials were not immediately recognized as being related to X-rays: In 1906 A. H. Becquerel. the French physicist and discoverer of radioactivity (1896). accidentally burned himself by carrying radioactive material in his pocket. Noting this. Pierre Curie. the co-discoverer of radium. deliberately produced a similar burn on himself. A few months later it was found that radium could be useful in medicine: this discovery led to the founding of the Radium hospital in Paris in 1906. It was soon recognized, however, that radium could also be very toxic. Beginning about 1925 a number of women in the painting industry who were exposed to luminescent paint containing radium became ill with anemia and lesions of the jawbones and mouth: some of these persons later developed bone cancer. The same thing happened to some patients who had received radium internally to relieve arthritis and other diseases. In the 1930s H. S. Martland and others called attention to these radium hazards and the practices were stopped.

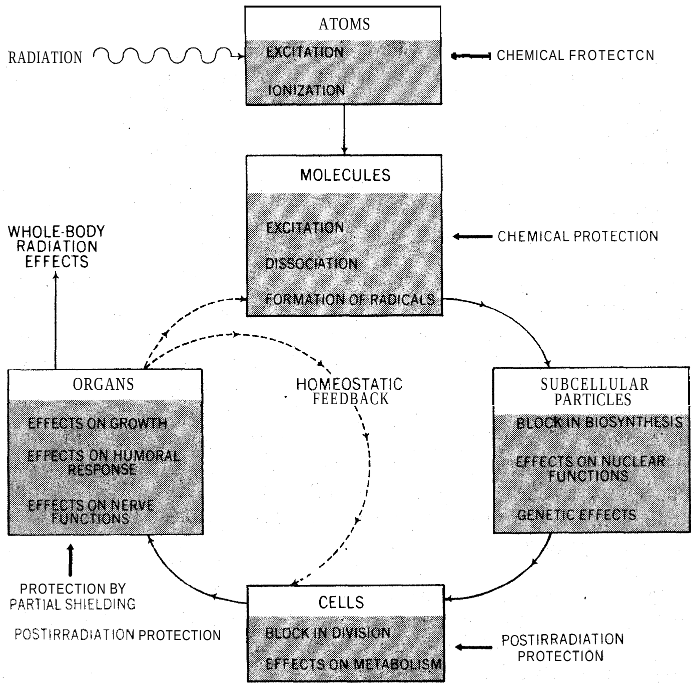
In 1933 Ernest Lawrence and his collaborators completed the first full-scale cyclotron, at Berkeley. Calif. This machine was a copious source of the neutron rays that had at that time just been discovered by Sir James Chadwick, in England. This time, however: human guinea pigs were spared. Ernest, his brother John Lawrence and Paul Aebersold exposed rats to the beam of the cyclotron; they found that fast neutron radiation was about $2\frac{1}{2}$ times more effective in killing power than were X-rays. These facts indicated the need for protection for investigators engaged in research with the cvclotron; thus a form of shielding mas devised for the machine. Since that time new and more powerful radiation sources have become available, and radiation health protection has become an elaborate discipline.

2. Exposure of the Embryo and Fetus.—Most of the information on effects of radiation in the human embryo has been based on results of studies on laboratory animals. From these data it has been concluded that babies, children and the aged are somewhat more sensitive to radiation than is the adult. In the embryo (the first eight weeks of pregnancy) radiosensitivity is greatest. Radiation delivered to the embryo can lead to miscarriage or stillbirth. Exposure of the fetus (eight weeks to birth) can lead to congenital malformations! stunted growth and premature aging. The embryo and the fetus are probably several times more radiosensitive than is the adult.

The developing nervous system is particularly sensitive. and even a relatively mild dose of radiation may have discernible effects. Pathological studies by S. P. Hicks (U.S.) have shown this in great detail. M. N. Livanov and his associates (U.S.S.R.) demonstrated the stunted development of the central nervous system using studies on induced reflexes.

3. Effects on Cells, Tissues and Organ Systems.—To understand radiation effects it is necessary to study the cellular and subcellular events that succeed a radiation insult and that give rise to gross effects. The work done in this area has already contributed a great deal to the understanding of normal and diseased states. How radiation may inflict biological damage is shown in the accompanying diagram.

The radiosensitivity of individual human cells in culture was first measured by T. T. Puck, in the 1950s. He used the progeny of



GENERAL SCHEME OF EVENTS IN RADIATION ACTION

Radiation acts on atoms, which in turn cause modification in molecules, cells and organs as shown. The existence of homeostatic regulation in the human body causes highly complex "feedback" interactions. The levels at which various protective agents act are also shown

human cervical cancer cells (of the strain named HeLa) kept alive in tissue culture. HeLa and other available human cells are so sensitive to radiation that half of them are killed by doses of 80 to 300 rem. The killing effect manifests itself when the cells attempt to divide but cannot do so since their chromosomes are broken and abnormally jointed as a result of radiation. Neuroblasts (nerve cell initials) and cells of the intestinal epithelium, of mucous membrane and of blood-forming organs exhibit the greatest sensitivity. Most resistant are adult nerve cells, which owe their resistance to the fact that they do not normally divide; specialized nerve endings and synapses (*e.g.*, in the retina), however, may exhibit great radiosensitivity. At sublethal doses human cells exhibit delay of cell division following radiation, perhaps as a consequence of a block in the synthesis of new genetic material ideoxyribonucleic acid or DNA). while the synthesis of proteins goes on. Such cells frequently turn into "giants," having several hundred times normal volume. Late effects, *e.g.*, the initiation of cancerous growth, no doubt have their origin in sublethally injured cells and are in part due to genetic and chromosomal alterations.

Inhibition of epithelial tissues with cellular breakdown and increased permeability leads to invasion by pathogens, inflammation, ulceration, loss of fluids, nausea and diarrhea.

Inhibition of blood formation leads. in the course of days or weeks, to leukopenia (reduction in the number of white cells), which lessens defense against infection: anemia (reduction in the number of red cells), which results in defective oxygen transport; lassitude; anoxia (reduction of oxygen in tissue) ; bleeding, due to a failure of platelet synthesis; and loss of immunity. None of these effects is as yet completely understood by medical science.

It is known that, because of the varied cellular effects of radiation, the function of individual organs can become imbalanced. Since the body has widespread humoral and neuronal interconnections. irradiation of a single organ can modify the functions of the rest of the body. A dramatic example of this effect is given by irradiation studies on the pituitary of animals and humans, as shown by C. A. Tobias and others. In the former pituitary irradiation can arrest the growth of a young animal and can affect his sexual development and metabolism. In humans irradiation of the pituitary can arrest proliferation of certain hormone-dependent cancer cells. thereby causing regression of this type of cancer wherever it may be located in the body.

Radiation effects due to whole-body radiation can be lessened by the shielding of particular parts of the body. L. O. Jacobsen and others demonstrated in mice that shielding of part of the blood-forming system, *e.g.*, the spleen, increases the radiation tolerance by a factor close to two. Shielding of other parts of the body also protects. but to a lesser extent. Least protection is afforded by head shielding.

In addition to the effects discussed in an earlier section (see *Long-Term Effects*, above), some investigators also claim a chronic deterioration of the central nervous system (although others have shown in experiments with monkeys that radiation doses up to lethal levels do not impair learning ability).

4. Acute Lethal Effects. — Prior to Xug. 6. 1945, there was no known case of widespread loss of human life due to penetrating radiation. On that day the first atom bomb used in warfare was exploded over Hiroshima, causing the death of ,about 66.000 persons. many of whom died of the effects of radiation. In persons exposed to very large doses of radiation painful, ugly and repulsive symptoms occur prior to a delayed death. The violence and combination of these symptoms is perhaps unmatched by any single known disease.

In the lethal radiation syndrome the greater the dose given, the sooner and more profound the radiation effects. Follo ing a single dose of 400–800 rem to the whole body. survival is improbable. Very high doses, 5,000 rem or more, cause immediate and discernible effects on the central nervous system. States of intermittent stupor and incoherence vary with hyperexcitability resembling epileptic seizures. Death is certain within several days. This syndrome has been carefully studied in animals; a human case has been described by S. G. Wilson (see *Bibliography*).

When the dose is between 600 and 1,000 rem, the earliest symptoms are nausea and vomiting, followed by prostration. watery and bloody diarrhea. abhorrence of food. and fever. The blood-forming tissues are profoundly affected, and in a few days the white blood cell count may decrease from about 8,000 per mm.3 to as low as 200 per $mm.^3$. The body loses its defenses against bacterial infection, and inflammation of mucous membranes and intestinal lining occurs. As a result of the reduction in blood platelets the blood loses its ability to clot, and spontaneous internal or external bleeding may result. Return of the early symptoms. often accompanied by delirium or coma, presages death. There can be great individual variation in the symptoms. At lower doses they may be delayed for a few days. Loss of hair within ten days has been taken as an indication of the lethal severity of the exposure.

As alluded to earlier, in the dose range 250 to 800 rem survival is possible (though in the upper range improbable), and the symptoms appear as above, but in milder form and generally following some delay. Nausea, vomiting and malaise may begin on the first day, then disappear. and a latent period of relative well-being follow. Anemia and leukopenia set in gradually. After three weeks internal hemorrhages may occur in almost any part of the body, but particularly in mucous membranes Susceptibility to infection remains a very great hazard, and some loss of hair occurs. Weight loss, lassitude. emaciation and fever may last for many weeks before recovery or death occurs.

Man is generally able to survive a single dose of less than 250 rem The symptoms are similar to those already described, but much milder and delayed A number of patients with advanced cancer have received doses in this range. In doses under 100 rem the discernible radiation effects-may be so slight that the patient is able to continue his normal occupation though there is a measurable depression of his bone marrow. Sublethal doses may have chronic sequelae many years later.

5. Protection Against External Radiation. — Great effort? have been made by scientists of many countries to find agents that will increase radioresistance of the body.

The findings by H G. Crabtree and W Cramer in 1933 that living systems deprived of oxygen are more radioresistant. and by A. Lacassagne in 1942 that newborn rats kept in carbon dioxide atmospheres were twice as resistant as their litter mates kept in air, went largely unnoticed until 1950. In that year H M. Patt demonstrated that large doses of the amino acid cysteine given prior to irradiation provided substantial protection against radiation effect Following this latter discovery many substances were found with some protective action. Although the matter is still under debate. it appears that all these substances act by producing anoxia or by competing for oxygen with normal cell constituents and radiation-produced radicals. Since anoxia is in itself a highly hazardous physiological state and all protective compounds tried thus far are toxic. it cannot be said that protection of humans by these drugs prior to radiation exposure is a practical matter

For many years it was held that cure of radiation disease was hopeless since events were thought to be irreversible once a person had received a lethal dose. It was historically important, therefore. when L. O. Jacobsen and E. Lorenz demonstrated in mice that ground substance of embryo spleen or bone marrow administered following irradiation allowed the animals to survive what would otherwise be a lethal dose of X-rays. It is hoped that detailed study of this finding will lead to the understanding of various physiological processes and disease control.

It has been shown that most of the effect of transfused bone marrow depends on the provision of intact. living cells which then migrate to the marrow of the irradiated host and proliferate there, repopulating the host's marrow with cells characteristic of the donor. Bone marrow transfusion between animals of different strains is successful in these cases because the irradiated animal loses its ability to develop antibodies against the injected "foreign" tissue. If the injected bone marrow proliferates rapidly enough. it may save the host from acute lethal effects of radiation only to develop another disease several months later. This latter syndrome, sometimes called "wasting disease" (or homologous disease). is due to development of antibodies by the proliferating donor cells against the irradiated host and is usually rapidly fatal

It is obvious that if bone marrow could be taken with ease (as blood is taken) from various normal human volunteers, cultured and preserved under refrigeration, then injected only into immunologically compatible individuals. it might prove to be a powerful therapeutic agent against radiation disease.

Transfusion of fresh normal human bone marrow has already demonstrated some worth in alleviating radiation effects. In 1958 an unfortunate accident occurred at a nuclear reactor in Yugoslavia in which five persons were exposed to near lethal doses of mixed neutron and gamma radiation. They were flown to the Radium hospital in Paris. where four of them. received human bone marrow transfusions. As judged by their recovery, these men were considerably benefited.

Bone marrow transfusion, as well as transplantation of other organs, may be of importance in future control of various seemingly incurable conditions; *e.g.*, leukemia. A special radiation technique has been applied in conjunction with bone marrow transfusion in some very desperate cases. Leukemia patients. usually in the terminal stages of their disease: first receive a whole body "lethal" dose of X-rays or some other form of radiation. This is presumed to kill all the cells in the marrow. including the leukemic ones. Somewhat later, compatible normal bone marrow is injected to repopulate the patient's bone marrow with normal cells of the donor, thus ending the leukemic condition. There is some hope that this treatment may be of benefit to some leukemia patients and that it may be used against other diseases; *e.g.*, hereditary anemia. (The clue to successful bone marrow transplantation is the complete understanding of immunological compatibility. Only when this knowledge is attained will transplantation of bone marrow [and also of essential organs such as the kidney] become established as a feasible medical practice.)

6. Radioisotopes and Fallout.'— Much of the present radiation hazard to man comes from radioactive isotopes. which usually emit electrons or positrons. alpha particles and/or gamma rays. or even characteristic X-rays. The exposure may be external, in which case penetration is an important factor. Alpha particles do not penetrate deeply enough in the skin to cause damage. Beta particles or X-rays over 30 kv. can be hazardous to the skin, causing redness, loss of hair or ulceration. (Large doses may cause skin cancer.)

Isotopes can also enter the body by ingestion, inhalation or injection. Their radiation effects then depend on their internal distribution, duration in the body. energies and rate of radioactive decay (half-life or half-value period). The problem is enormously complicated since isotopes have different and sometimes elaborate distribution patterns.

The definition "critical organ" has been assigned to that part of the body that is most vulnerable to a given isotope. The critical organ for plutonium, radium. strontium and many other fission products is bone and the adjacent bone marrow. For soluble fission products. which will distribute in the entire body (and also for some forms of uranium), the critical organs are the gonads or sometimes the kidneys. For iodine the critical organ is the thyroid gland. Insoluble air-borne radioactive dust often deposits in the alveoli of lungs, while colloidal particles of very small size can reach the bone marrow. liver or spleen. Table VII is an abbreviated list of the maximum permissible concentrations (U.S. recommendations'~for man of some radioisotopes. (Maximum permissible concentration is the greatest amount of a radioisotope that

TABLE VII.—*Maximum Permissible Concentration* (*MPC*) of *Some Radioisotopes*

‡MPC in drinking water: 0.0001 microcurie/litre.

can be accumulated in the body without producing noticeable damaging effects. Compare with maximum permissible dose. which is applicable to radiation received from external sources [see *Studies on Human Populations,* below].)

Since isotopes continuously deliver radiations to the surrounding tissue, one must distinguish between the effect of protracted continuous exposure and single acute or periodically repeated exposures. For beta. gamma and X-radiations, utilizing split dose delivery, it has been found that 15% to 40% of an acute radiation effect "disappears" within several hours; the body is, therefore, able to tolerate a greater total dose when the dose is protracted or when part of it is given at later times. For neutron and alpha radiation the recovery is less. (Neutrons are generally more effective than X-rays: for acute effects. by a factor of 2 or **3;** for chronic effects. by a factor up to 10.)

Fallout is the deposition of air-borne radioactive contamination on the earth. Radioisotopes may be produced naturally in the air by cosmic radiation or may enter the air from stack gases of atomic reactors following industrial accidents or from bombs or bomb tests. (Since 1954 bomb tests carried out by several nations have produced fallout measurable on the surface of the entire world. arousing great attention and controversy with respect to its health and genetic effects.)

Several of the radioisotopes contained in fallout are especially hazardous because they remain radioactive for relatively long periods (have long half-lives). Cesium-137 and strontium-90 may be the most important (*see* FALLOUT). On the ground fallout material can cover external surfaces and foliage and later be washed into the soil. From here plants incorporate strontium-90 along with the chemically similar calcium. and cesium-137 with potassium. Persons obtain these radioactive materials mostly from drinking water and from plant and animal foods, including milk. In the sea much of these materials can eventually lodge in the bodies or skeletons of fishes snd in plants near the coast.

Strontium-90 becomes concentrated in bone and remains there, in steadily decreasing amounts. for almost 30 years, producing local irradiation. Its actual concentration within the body is difficult to measure because of the softness of its rays. There is generally lower concentration of strontium-90 in man than in other animals or in plants or soil. Newborn babies who have actively growing bones retain relatively greater amounts of strontium-90 than do older persons.

7. Studies on Human **Populations.**—Several groups of persons have been exposed to large amounts of radiation. Among these arc the survivors of the atomic bombings of Hiroshima and Nagasaki, and some Marshallese and Americans exposed on Rongelap and neighbouring islands in the course of atomic bomb tests. In the former group the incidences of leukemia and cataracts are higher than in the general population. Fertility seems somewhat reduced and life span possibly shortened. These effects. which depend on the dose. thus far have not been noticed in the latter group.

Hundreds of persons have a measurable radium burden in their bodies. Many of them received the radium as a method of treatment for arthritis and other diseases in the early 1930s. By the use of modern counting methods the amount entrapped in the body of this long-lived alpha-particle-emitting isotope (half-life of over 1.500 years) may be determined and may eventually provide accurate information on the dose that can cause bone cancer.

Certain groups of persons receive considerable doses of X-rays during radiation therapy for various ailments. In England a survey indicated the late results of X-ray therapy to the lumbar spine of persons having ankylosing spondylitis (a rheumatic ailment). The incidence of leukemias and bone tumours among these patients was higher than that of the general population. In a separate study suggestive evidence was obtained that children of women given abdominal X-rays for diagnostic purposes during pregnancy may develop more leukemia than children whose mothers were not so X-rayed. Children who received X-irradiation to the thymus at an early age appeared to show greater than normal incidence of cancer and leukemia in subsequent years. As a result of these studies it seems prudent to limit radiation exposure for children and embryos as much as possible. Practices such as X-raying feet in shoe stores seem completely unwarranted. Attempts should be made to reduce the numbers of necessary exposures received in dental X-rays, in fluoroscopy, in chest X-ray procedures and in diagnosis with radioisotopes.

The possible effect of radiation on radiologists is a much debated question. An earlier study in the United States indicated that their life span may be several years shorter than that of other doctors and that they have more leukemia and more stillborn children. However. no significant differences were found between English radiologists and their colleagues.

Localities with higher radium content seem generally to have more congenital malformations. though radiation as a direct cause has not always been established. A study in New York state correlated the incidence of such malformations with radioactive mineral content of the soil and water of the locality. In Jachymov, Czech.. where for many generations miners have mined radioactive ore. lung cancer is quite prevalent; though the radioactive ore is undoubtedly involved. genetic factors (due to inbreeding) and silicosis of the lungs from inert ore may also be partly responsible for this high incidence of cancer. In Sweden many persons are constantly exposed to comparatively high radiation background due to the uranium in the building blocks of their houses.

TABLE VIII.—*External Dose Due to Natural Radioactivity*

Source	Dose in rads per year
Ordinary regions	0.025–0.160
Active regions	
Granite in France	0.180–0.350
Houses in Sweden (Alum shale)	0.158–0.220
Monazite alluvial deposits in Brazil	Mean 0.500 max 1.0
Monazite sands, Kerala, India	0.37–2.8

An entire segment of the coast-line state of Kerala, India, is composed of radioactive monazite sands. Since the inhabitants and their ancestors have lived in this same locality for many generations, India, with the help of the Cnited Nations, has initiated a study of the possible harmful effects of this long-term radiation exposure by comparing the health of this population segment with another group living on uncontaminated soil nearby.

As mentioned earlier. radiation with its deleterious effects causes a person to become "physiologically" older than his actual age would indicate. Using mortality studies of survivors of the Hiroshima blast, it appears that where very large doses are absorbed each rem received by the whole body physiologically ages a person 2 to 15 days. Statistical fluctuations, however, are very great and experimental results difficult to interpret. It is not yet known whether this concept of aging holds for doses smaller than 50 rem or for protracted radiation exposure.

8. Cancer and Radiation.— The role of large doses of radiation in increasing the incidence of cancer and leukemia cannot be questioned. It has been demonstrated in all animal species tested thus far. Exposure of the whole human population, even to minute doses in fallout. may lead to some thousands of new leukemia and cancer cases in the world. Thus far no data exist that would clearly demonstrate whether leukemia (or cancer) incidence is proportional to dose or whether a "threshold" dose level exists below which carcinogenic effects are negligibly small. In order to acquire adequate data, a population of several million would have to be studied for several years. There is a large school emphasizing that all good studies of the origin of cancer point to a number of factors, including genetic, hormonal and injurious factors (chemical or virus). that must act together before cancer is produced. The great majority of cancer and leukemia cases in the earth's population is probably not caused by radiation but by other agents. (See also CANCER; LEUKEMIA.)

C. EFFECTS OF HERTZIAN WAVES AND INFRARED RAYS

1. Hertzian Waves.—The effects of Hertzian waves (electromagnetic waves, radio waves and microwaves or radar waves) and of infrared rays are usually equivalent to the effect produced by heating. The longer radio waves induce chiefly thermal agitation of molecules and excitation of molecular rotations, while inirared rays excite vibrational modes of large molecules and release fluorescent emission as well as heat. Both types of radiation are preferentially absorbed by fats containing unsaturated carbon chains

Nikola Tesla in 1891 was the first to record the fact that heat production resulted from bombardment of tissue with high-frequency alternating current (wave lengths somewhat longer than the longest radio waves) and to point out the possibility of its utilization for medical purposes. At the same time J. A. d'Arsonval. using the same current, began to experiment on animals and human beings. In 1898 R. von Zeyneck used high-frequency current to produce heat within the organism. and was followed in this by Von Berudt and other workers. To this form of treatment F. Nagelschmidt applied the term "diathermy." This method of internal heating is beneficial for relieving muscle soreness and sprain. Diathermy can be harmful however. if so much internal heat is given that the normal cells of the body suffer irreversible damage. Since man has heat receptors only on his skin, he cannot be forewarned by pain when he gets a deep burn from diathermy. Sensitive regions easily damaged by diathermy are those having reduced blood circulation; e.g , bone or the lens of the eye. Cataracts of the eye lens have been produced in animals by microwave radiation applied in sufficient intensity to cause thermal denaturation of the lens protein.

In the radio-television industry and in the radar divisions of the military, persons are sometimes exposed to high-energy densities of microwave radiation. For occupational exposure, tolerance levels that have been set in the U.S. are summarized in Table IX.

The heating effect of high-frequency waves and currents has had some use in surgery. The first surgical use of short waves (8 megacycles) was made by L. H. Stiebock. who successfully destroyed a patient's tonsils without the necessity of giving an anesthetic. This procedure produces cutting by heat coagulation of tissue without producing bleeding. It has been used to cut certain structures (*e.g.*, the dura membranes) in brain surgery and in minor skin operations. Higher-frequency electromagnetic waves (about 10 megacycles) are also used in brain surgery for producing "heat lesions" in the treatment of Parkinson's disease and cerebral palsy.

TABLE IX.—*Maximum Permissible Exposures to Microwave Radiation*

Frequency (megacycles)	Part exposed	Single exposure level (watts/cm.^{2})	Continuous exposure level (watts/cm ^{2})
1,000–3,000	Whole body	0.3	0.01
3,000	Eye	17	0.15
3,000	Testes	1.3	0.005

Such heat lesions produced in certain parts of the brain may temporarily relieve the tremors accompanying these diseases.

2. Infrared Rays.—An important part of solar energy reaches the earth in the form of infrared rays. Absorption and emission by the human body of these rays plays an important part in temperature exchange and regulation of the human body. Principles of infrared emission and absorption must be considered in design of air conditioning and of clothing.

Overdosage of infrared radiation, usually resulting from direct exposure to a hot object (including heating lamps) or flame, can cause severe burns ("flame burns"). While infrared exposure is a hazard near any fire, it is particularly dangerous in the course of atomic chain reactions. In the course of an atomic detonation a brief but very intense emission of inirared occurs together with visible and ultraviolet light emitted from the fireball ("flash burns"). Of the total energy of nuclear explosion, as much as one-third may be in the form of thermal radiation, moving with the velocity of light (186,000 mi. per second). The rays will arrive almost instantaneously at regions removed from the source by only a few miles. Smoke or fog can effectively scatter or absorb the infrared components, and even thin clothing can greatly reduce the severity of burn effects. (See also BURNS.)

D. EFFECTS OF VISIBLE AND ULTRAVIOLET LIGHT

Life could not exist on earth without light from the sun. Plants utilize the energy of the sun's rays in the process of photosynthesis to produce carbohydrates and proteins, which serve as basic organic sources of food and energy for animals. The strong ultraviolet rays of the sun, which are hazardous, are effectively absorbed by the upper atmosphere. At high altitudes and near the equator the ultraviolet intensity is greater than at sea level or at northern latitudes.

Very short-wave ultraviolet light, below 2,200 Å, is highly toxic for cells; in the intermediate range the greatest killing effectiveness on cells is at about 2,600 Å (1 A = 1/10,000,000 mm.). The nucleic acids of the cell, of which the genetic material is composed, strongly absorb rays in this region. This wave length, easily available in mercury vapour, xenon or hydrogen arc lamps, has great effectiveness for germicidal purification of the air.

Since penetration of visible and ultraviolet light in body tissues is small, only the effects of light on skin and on the visual apparatus are of consequence. When incident light exerts its action on the skin without additional external predisposing factors, scientists speak of intrinsic action. In contrast, a number of chemical or biological agents may condition the skin for action of light; these latter phenomena are grouped under photodynamic action.

1. Intrinsic Action.—Light is essential to man because of its biosynthetic action. Ultraviolet light induces the conversion of ergosterol and other vitamin precursors present in normal skin to vitamin D, an essential factor for normal calcium deposition in growing bones. While some ultraviolet light appears desirable for formation of vitamin D, an excess amount is deleterious. Man has a delicate adaptive mechanism that regulates light exposure of the more sensitive deeper layers of his skin. The transmission of light depends on the thickness of the upper layers of the skin and on the degree of skin pigmentation. All persons, except albinos, are born with varying amounts of melanin pigment in their skins. Exposure to light further enhances the pigmentation already present and can induce production of new pigment granules. N. R. Finsen of Denmark realized the therapeutic possibilities of sunlight and ultraviolet light around 1900. He was an exponent of the idea that exposure of the whole body to sunlight promotes health.

The French physician J. M. Charcot in 1858 was the first to recognize that large doses of ultraviolet radiation caused "sunburn." The wave length of about 2,800 & is most effective. It induces reddening and swelling of the skin (due to dilation of the blood vessels), usually accompanied by pain. In the course of recovery epidermal cells are proliferated, melanin is secreted and the outer corneal layer of dead cells is thickened.

G. Findlay in 1928 was the first to clearly show that prolonged or repeated exposure to ultraviolet light leads to the delayed development of skin cancer. The fact that ultraviolet light, like X-radiation, is mutagenic (induces mutations) may explain its ability to cause skin cancer, but the detailed mechanism of cancer induction is not yet completely understood. There seems very little doubt, however, that skin cancer in man is in some cases correlated with prolonged exposure to large doses of sunlight. Among coloured persons who are protected by rich melanin formation and thickened corneal structure of the skin, incidence of cancer of the skin is several times less frequent than it is among white people living at the same latitude.

2. Photodynamic Action.—There are a number of diseases in man and animals in which light sensitivity is involved; for example, hydroa, which manifests itself in blisters on parts of the body exposed to sunlight. It has been suggested that this disease is due to a light-sensitive porphyrin compound found in the blood of certain persons.

Actually there are many organic substances and various materials of biological origin that make cells sensitive to light. When eosin is added to a suspension of human red blood corpuscles exposed to light, the red corpuscles will break up, or hemolyse. Other typical photodynamic substances are rose bengal, hematoporphyrin and phylloerythrin. All these are dyes capable of fluorescence. Their toxicity manifests itself only in the presence of light and oxygen.

Some diseases in domestic animals result from ingestion of plants having photodynamic pigments. For example, St. Johnswort's disease is caused by the plant *Hypericum*. Fagopyrism results from eating buckwheat. In geeldikopp (yellow thick head) the photodynamic agent is produced in the animal's own intestinal tract from chlorophyll derived from plants. In humans the heritable condition of porphyria is frequently associated with light sensitivity, as are a number of somewhat ill-defined dermatological conditions that result from exposure to sunlight. The recessively inherited rare disease xeroderma pigmentosum is also associated with light exposure: it usually results in death at an early age from tumours of the skin developing on exposed areas. Certain drugs (*e.g.*, sulfanilamide) sensitize some persons to sunlight. Many cases are known in which skin contact with a photodynamic substance was followed by increased light sensitivity.

3. Deleterious Effects on the Eyes.—The wave length of light that produces sunburn can also cause inflammation of the cornea of the eye. This is what occurs in "snow blindness" or after exposure to strong ultraviolet light sources. Unusual sensitivities have been reported. Ultraviolet light, like infrared or penetrating radiations, can also cause cataract of the eye lens, a condition characterized by denatured protein in the fibrous cells forming the lens. The retina is usually not reached by ultraviolet light, but large doses of visible and infrared can irreversibly bleach the visual pigments, as in "sun blindness." Numerous pathological conditions of the eye are accompanied by abnormal light sensitivity and pain, photophobia. The pain appears to be associated with reflex movements of the iris and refiex dilation of the blood vessels of the conjuntiva. In order to avoid injury to the eyes while working with ultraviolet light sources or while being exposed to atomic flashes, protective glasses are worn.

RADIATION BALANCE OF THE EARTH. The earth receives from the sun 13 × 10^{23} cal. of radiant energy each year. Since the mean temperature of the earth and its atmosphere does not change perceptibly from year to year, and since solar radiation is the main source of energy received by the earth's surface and atmosphere, the same amount of energy must be radiated from the earth to space.

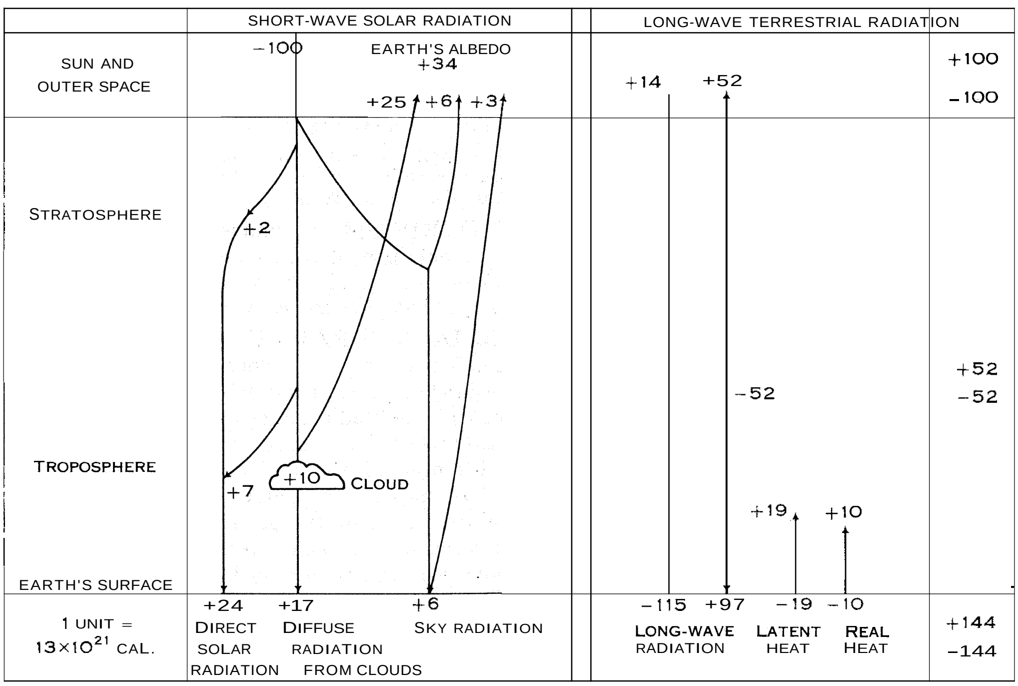
The visible and infrared spectral intensity of solar radiation is approximately that of a black body radiator at 6,000° K. The ultraviolet and X-ray regions of the spectrum differ from the 6,000° K. black body, and moreover become greatly intensified during some types of solar disturbances. The maximum intensity in the solar spectrum is found at 0.48μ (μ, the micron, equals 10^{-4} cm.), and roughly half the energy is contained in the visible band between 0.38μ and 0.77μ, the remainder is in the invisible ultraviolet and infrared bands. As the incoming solar radiation encounters the outer layers of the earth's atmosphere, some of the air becomes ionized, forming the stratified ionized region known as the ionosphere (50–300 mi. high) which reflects radio waves of broadcast frequencies. Farther down! in the stratosphere, certain bands in the ultraviolet are absorbed by oxygen. some of which form ozone, itself a strong absorber of ultraviolet radiation. Indeed. principally because of the presence of ozone. dangerous ultraviolet radiation of wave lengths below 0.3μ is not received at the earth's surface. Closer to the earth's surface (within three miles) water vapour serves as a powerful absorbing agent.

For simplicity in arithmetic let the earth's annual income of 13 × 10^{23} cal. of solar energy equal 100 units. Total absorption of the solar radiation as it passes through the atmosphere is 19 units. Because of reflection from clouds and the earth's surface and by scattering in the atmosphere 34 units (the "albedo" of the earth) are returned to space without increasing the energy of the earth and its atmosphere. The remaining solar radiant energy, amounting to 47 units, reaches the surface of the earth and is used primarily to raise the temperature of the surface layer of the land and ocean; a smaller fraction is utilized in evaporating water and in producing photochemical changes.

The earth. radiating as a black body at its observed mean temperature of 59° F., has its maximum intensity of 10μ and practically all of its radiation (the long-wave radiation) is contained between 4μ and 120μ. Because of the peculiar absorbing properties of water vapour, the normal atmosphere is practically transparent to the short-wave solar radiation but much more opaque to the long-wave terrestrial radiation.

Atmospheric water vapour and carbon dioxide absorb most of the energy emitted by the earth's surface. However, since the atmosphere radiates energy both upward and downward, it would undergo a net cooling were it not for the transfer of energy upward from the earth's surface by convection and evaporated water (latent heat).

In the figure there is presented a graphical summary of the various vertical streams of energy and their totals. This shows that clouds reflect about 25 units. the atmosphere and earth's surface reflect about 9. The clouds absorb 10 units. the clear atmosphere absorbs 9 and the earth's surface 47 units. One hundred fifteen units of long-wave (infrared) energy are radiated upward by the earth's suriace which, however, receives back 97 units irom the atmosphere. Eventually 66 units leave the "top" of the atmosphere to space, 52 of which are emitted by the atmosphere. Finally 19 units are released into the atmosphere from the latent heat of condensation released during the precipitation process, and 10 units are given to the atmosphere in the form of real heat by heat transport from the earth's surface. Note that there is a balance of incoming and outgoing energy at the outer limit of the earth's atmosphere, within the atmosphere. and at the surface of the earth. thus representing an equilibrium condition whereby the mean temperature of the earth's surface and its atmosphere remains essentially unchanged from year to year. at least within the period of systematic meteorological observations made over a large portion of the earth's surface. It is the lack of heat balance averaged over seasons that causes the seasonal variations in temperature and weather observed in extratropical latitudes. It is the lack of heat balance at various latitudes that causes the day-to-day weather changes.



ANNUAL HEAT BALANCE OF EARTH AND ITS ATMOSPHERE

Equatorward of latitude 38° there is a net radiative heating averaged over the year. poleward of this latitude there is a net radiative cooling. This lack of latitudinal radiative heat balance is counteracted by atmospheric and oceanic transport of heat between polar and tropical regions, resulting in a net transport of heat poleward.

The atmospheric transport is effected mainly by large moring cyclonic and anticyclonic eddies, which create alternate periods of stormy and fair weather. (H. WR)

RADIATION CHEMISTRY: see PHOTOCHEMISTRY.

RADIATOR. In practice. what is commonly referred to as a radiator consists of a heat exchanger used to heat enclosed spaces. A room radiator normally consists of a cast iron or steel. multi-section, heat exchanger through which steam, hot water or hot gases are circulated to heat its exposed surfaces. Heat is transferred from these hot surfaces to the relatively cooler room air by natural convection and to surrounding surfaces and occupants by direct thermal radiation. To the extent that the convective heat transfer from such a device often constitutes the major portion of the total heat transferred, it becomes evident that the conventional radiator acts also as an effective convector. Hence. in its everyday usage the word radiator as referred to a room or space-heating device is to some extent a misnomer. In room heating applications, radiators are located in a vertical position underneath windows whenever possible. Condensing steam or hot water is circulated from a central boiler through a number of such radiators interconnected in series, in parallel, or both. (See HEATING AND VENTILATION.)

With the increasing popularity of air conditioning and radiant panel heating and cooling installations after mid-20th century, the conventional radiator was rapidly being superseded in residential as well as commercial installations (*i.e.,* offices. hospitals. theatres, stores, etc.). As compared with the use of radiators. in radiant panel heating installations the practice is to use a lower panel surface temperature (about 140° F.) in conjunction with the much larger surface areas of ceilings, walls or floors to achieve the heating effects desired. This procedure allows a greater fraction of the total heat exchange to take place through direct radiation between these surfaces and occupants. Radiant panels are commonly heated by hot water circulated in serpentine copper tubing embedded in plastered ceilings, walls or concrete floors. (Y. S. T.)

RADIĆ, STJEPAN (1871–1928), Yugoslav statesman. was born at Trebarjevo, near Fiume (Rijeka), on July 11. 1871. He studied in Zagreb and Prague, being once expelled from the Lycée and twice imprisoned in Zagreb for Croatian and anti-Hungarian demonstrations. From 1897 to 1899 he studied in Paris and later lived for a time in Semlin as Balkan correspondent to various newspapers, coming into contact with Serb political leaders, and settled in 1902 in Zagreb. In the same year he began to publish the *Hrovatsko Misao,* in which he outlined the program of the Croatian Peasant party, which first entered the Croatian Sabor. with 9 seats, after the elections of 1910, but soon became the most powerful political force in Croatia. In 1911–12 Radii was again imprisoned by the Magyar Ban of Croatia. During World War I he became an Austro-Hungarian Legitimist, but on the collapse of Austria-Hungary converted his party. which followed him implicitly. to republicanism. In Feb. 1919 he demanded self-determination for Croatia, and union with Serbia and Montenegro "with equal rights." Disagreement with the Serbs; however, led him back to prison during 1919–20.

Radii then condemned his party to a long and singularly sterile period of opposition and parliamentary abstention. until, tiring oi this. he left Yugoslavia in July 1923 for a prolonged visit to London. Moscow and Vienna. He returned to Zagreb in Aug. 1924 with fresh ideas on Pan-Slavism and the co-operation of workmen and peasants, and was imprisoned in Jan. 1925. In March, however, his nephew Pavle Radii effected a reconciliation. Radii was released, his party entered the government, he himself became an enthusiastic supporter of King Alexander. and for a time was a member of the Yugoslav cabinet. His habit of embarrassing his colleagues as often and as much as possible led to his resignation. He returned to opposition, which he conducted with such verve that a government deputy named Račić shot him in the Skupština on June 20, 1928. On Aug. 8, 1928. he died at Zagreb from the effects of his wound.

RADIĆ, PAVLE (1880–1928), Yugoslav statesman, nephew of the above, was born at Trebarjevo, near Fiume on Jan. 1. 1880. He settled in Zagreb as a banker. The coalition of Serb Radicals and Croat Peasants which existed fitfully in 1926–27 was mainly his work; but when it broke down, he rejoined the opposition. On June 20. 1928, he was murdered in an unsuccessful attempt to save his uncle's life.

RADICAL, one who desires extreme change of part or all of the social order. The word (Lat. *radix,* "root") was first used in a political sense in England. and its introduction is generally ascribed to Charles James Fox, who in 1797 declared for a "radical reform" consisting of a drastic expansion of the franchise to the point of universal manhood suffrage. The term radical thereafter began to be used as a general term covering all those who supported the movement for parliamentary reform. After the passage of the Reform act of 1832, which extended the suffrage only to part of the middle class. a group of Radicals allied with the Whig faction in parliament continued to press for an extension of the vote to include even the working class. When the Reform act of 1867 further widened suffrage, the Radicals, notably in London and Birmingham. took the lead in organizing the new voters. helping to transform the Whig parliamentary faction into the Liberal mass party of the later Victorian era. Because of their efforts on behalf of the working-class vote the Radicals earned the loyalty of the trade unions; from 1874 to 1892 every trade unionist who sat in parliament regarded himself as a Radical.

In France before 1848, the term radical designated a republican or supporter of universal manhood suffrage; the open advocacy of republicanism being technically illegal. republicans usually called themselves radicals. After 1869, a self-styed Radical faction led by Georges Clemenceau began to drift away from the moderate democratic-republicanism of Léon Gambetta. These Radicals regarded themselves as the true heirs of the French Revolutionary tradition. In 1881 at Montmartre they adopted a platform calling for a wide range of social reforms, and at the turn of the century the Radical-Socialist party (*q.v.*) was formed.

The English Radicals of the 19th century were influenced by philosophical ideas assuming that men are able to control their social environment by collective action. a position held by the so-called philosophical radicals. These assumptions also underlying Marxist theories of social reform. in time the label "radical" was affixed to Marxists and other advocates of violent social change, thus becoming inapplicable to the gradualist reformers whom it had described previously.

In the United States, although the term is usually one of opprobrium. this was not always true in the postdepression years of the 1930s; and it is generally not true in less stable and prosperous societies. In popular U.S. usage, radicalism stands for political extremism of any variety. of the left or right. communism serves as an example of the former, fascism of the latter. See also LIBERALISM; MARXISM; SOCIALISM; ANARCHISM; COMMUNISM.

For a discussion of philosophical radicalism *see* Elie Halévy, *La Formation du radicalisme philosophique,* 3 vol. (1900–03; Eng. trans., *The Growth of Philosophical Radicalism,* 1928). (S. MR.; H. M. S.)

RADICAL EMPIRICISM, in philosophy, is the theory that experience is the only test of reality and truth. This is the view of William James (*q.v.*), and was so named by him.

Sre W. James. *Essays* in *Radical Empiricism* (1912).

RADICAL-SOCIALIST PARTY (PARTI RÉPUBLICAIN RADICAL ET RADICAL-SOCIALISTE; commonly called the RADICALS). one of the major political parties of modern France. Founded in 1901 on the reunion of the Radical-Socialists with the Radicals from whom they had broken away, this party dominated the third republic in the 20th century as the old Radicals had done in the 19th (see FRANCE: *History*). The party was loosely organized and drew its funds from a small number of subscriptions. being primarily representative of sectional interests. Its power was founded on the influence of local personalities (mayors and departmental councilors), of various committees (notably those of Freemasonry) and of provincial newspapers with large circulations (*e.g.,* La *Dépêche de Toulouse,* owned by the Sarraut brothers). Its supporters were mainly people of the urban middle class (*petit bourgeois* rather than business magnates), professional men (lawyers. doctors and teachers), farmers and craftsmen. It was strongest round Lyons and in the south of France, particularly in the southwest.

Radical ideology comprised (1) loyalty to the principles of the Revolution of 1789, with ready use of Jacobin slogans; (2) rationalism and anticlericalism; and (3) the systematic protection of group interests. particularly those of small tradesmen. small businesses, people with small private incomes and the lower ranks of the civil service.

Albert Thibaudet makes a distinction between the authoritarian, patriotic radicalism of such men as Clemenceau and the individualist radicalism of "the citizen against the ruling powers"—as propounded. for instance, in Alain's *Éléments d'une doctrine radicale.* There are. however, several other varieties of radicalism; *e.g.,* the technocratic (represented by Joseph Caillaux), the anticlerical (Émile Combes) and the presidential (Édouard Herriot—a statesman most adroit at combining heterogeneous elements).

Men of the centre, between the right and the Socialists. the Radicals were essentially the governing party of the third republic. A Radical. Édouard Daladier, was premier at the time of the Munich agreement (1938) and at the outbreak of World War II (1939). Immediately after that war the Radical party seemed just a relic of a past age: and in the elections of Oct. 1945, under a form of proportional representation, the Radicals won only 6.8% of the votes and 35 seats. whereas in 1936. under a single-member majority system of election. they had won 14.6% and 116.

Subsequently the party underwent three phases. First, its opposition to "three-party rule" by Communists. Socialists and Christian Democrats (M.R.P.) and. after the Communists had left the government in 1947, its holding of the balance between the parties enabled it to restore its fortunes (1945–53). The party itself was reconstituted. its newspaper propaganda revived and public confidence in it recovered. Thus several coalition governments were formed under Radical leaders (René Mayer, Henri Queuille, André Marie): and in the elections of 1951 the Radicals won 72 seats. Next followed the attempt (1953–56) by Pierre Mendès-France to consolidate the party, to attract more youth into it and to make its propaganda more cogent (*e.g.,* in the newspaper *L'Express*), identifying it moreover with a progressive economic policy and with a liberal attitude toward the countries of the French union. &lend&-France. however, was only partially successful in the elections of Jan. 1956 and was very adversely criticized by other Radicals, so that he had eventually to retire from leadership of the party. The parliamentary group splintered, and divisions within the party became more acute than ever before. In the elections of Nov. 1958. under a majority system again; the Radicals won 11.5% of the votes and 35 seats. which, however, had to be divided between four parliamentary groups. (J. TD.)

RADIN, PAUL (1883–1959), U.S.-Canadian anthropologist. was born April 2, 1883, in Poland and was taken to the U.S. as an infant. He was significantly influenced during his university years by James Harvey Robinson and Franz Boas. After work at the College of the City of New York, he received the Ph.D. in anthropology at Columbia university.

Radin was primarily interested in the folklore. religion and language of primitive peoples. contributing such works as *The Winnebago Tribe* (1915–16) and *Primitive Man as Philosopher* (1927). His view of anthropology as a branch of history and his emphasis on primary documentation are reflected in *The Road of Lije and Death* (1945), *Culture of the Winnebago: as Described by Themselves* (1949), as well as in his major critical-theoretical work, *Method and Theory of Ethnology* (1933). Radin pioneered in what later became important fields of anthropology (culture-personality studies, cultural contact) and in the use of autobiographical documents; see, *e.g., The Autobiography of a Winnebago Indian* (1920), republished as *Crashing Thunder* (1926). From the 1930s on. a growing interest in Marxian sociology led him to a reinterpretation of some of his earlier formulations; see *Primitive Religion* (1937).

Though not primarily active as a teacher, Radin at various times taught at the University of California. The University of Chicago, Cambridge university, Kenyon college, Gambier. O., and Brandeis university. Waltham. Mass. For many years he was field ethnologist for the geological survey of Canada. Radin died Feb. 21, 1959. (A. M. H.)

RADIO, the radiation and detection of signals propagated through space as electromagnetic waves to convey information. Radio is one of the chief branches of telecommunication. It embraces telegraphy, telephony and television without wires, and radar.

Wireless was the original term for radio and is still widely used in Great Britain. The word radiotelegraphy was substituted generally for wireless telegraphy (and similar terms in other languages, following international conferences on radio communication held in Berlin. Ger., in 1903 and 1906.

This article, in the sections outlined below. describes the historical development of radio technology and the theories of radio wave propagation. Basic material on the nature and behaviour of radio waves may be found in ELECTROMAGNETIC WAVES. The growth of the industry that produces scheduled programs of entertainment. news and educational material is traced in BROADCASTING. while the article TELEVISION describes the technical aspects of that subject as well as the production of programs. Additional material on telecommunication may be found in the articles RADIO RECEIVER; TELEGRAPH; TELEPHONE; and FACSIMILE TRANSMISSION. Examples of radio aids to navigation are given in the article NAVIGATION. The following article is divided into these sections:

I. FORMS OF RADIO COMMUNICATION

Any form of telecommunication by radio requires a transmitter to furnish the energy for transmission: an antenna or aerial from which the energy may be propagated; the medium of propagation. which is the same as that pervading free space outside the earth's atmosphere. although its electrical transmission properties are modified by the atmosphere and the proximity and character of the earth's surface; and, finally. the receiver. In the receiver. the weak signal is resonated (tuned), amplified and demodulated (detected) to recover the original signal, which is reproduced by a teletype printer, loudspeaker or television picture tube. The highest rate of information reproduction is about 10 bits per second for high-speed code. 10.000 bits for high-fidelity sound and 10,000,000 bits for high-definition television. (A bit, or binary digit, is the binary unit of information, capable of expressing such quantities as 0. 1;' yes, no; off. on, etc. *See* INFORMATION THEORY.)

These basic requirements are essentially the same for both radiotelegraphy and radiotelephony. The various forms of telecommunication are distinguished by the way that the continuous radio-frequency power generated in the transmitter (usually called the carrier wave) is interrupted or varied (that is. modulated) from moment to moment. In radiotelephony the primary controls to modulate the carrier in the transmitter are directly responsive to the human voice or to music and other sounds.' In radiotelegraphy the elemental modulation is led to the transmitter in the form of a signal unit, or pulse of power. successive combinations of which. in various time patterns and usually in opposite senses (such as on-off. present-absent, plus-minus, high-low, mark-space) are given either arbitrary language code meanings or various functions in the remote interconnection of machines. In television two simultaneous (multiplexed) modulations are employed. One modulation is radiotelephonic (audio) and the other consists of signals (video) representing a range of light values of successive elemental areas into which a scene can be divided by a process called scanning. In basic radar the transmitter is pulse-modulated in a continuous manner. but without information. The informational content of radar is supplied as modulation en route at a point or points of reflection.

The modern concept of radiotelegraphy does not confine it to the system of reducing messages to Morse code signals for the purpose of transmitting and transcribing them for delivery as telegrams. or even to the system of accomplishing the same end by use of remotely actuated printing telegraph machines, important though both systems are to the world-wide radiotelegraph business. In modern usage. all information to be conveyed—words to be typed. a speech to be reproduced, a song to be sung, a snitch to be operated. a card to be punched. a piece of Linotype text to be set. a television scene to be displayed or a calculating machine to be operated—can be reduced to a stream or succession of elemental units in a time domain. Radio telecommunication concerns itself with the collecting and processing of such information. if necessary its compression through codification. its propagation without wires. its detection, re-expansion or decodification and, finally. its dissemination and utilization for purposes of intelligence or control. Radiotelegraphy concerns itself with that portion of the radio telecoinmunication product which is a matter of record (hence often called record communication) or control. as distinguished from radiotelephony, radio broadcasting and television, in all of which the information is only momentarily made audible or visible. Generally speaking, the pulse-transmission techniques associated with radiolocation (radar), radio navigation (loran) and radio direction-finding are considered specialized branches of radiotelegraphy.

II. EARLY HISTORY

James Clerk Maxwell was the first scientist to foresee the propagation in space of electromagnetic energy from waves originating in wires and the first to show mathematically the laws of the transfer of such energy through space at the speed of light. Maxwell built upon and united the expressions of earlier mathematicians and physicists in his own equations expressing the relationship of electromagnetic forces within, and at the boundaries between. conductors and dielectrics.

In 1845 Michael Faraday was first to bridge the existing gap between light and electricity by observing the phenomenon of magnetic gyration. When he passed a beam of polarized light through transparent glass, application of a strong magnetic field was capable of rotating the axis of polarization of the light. Faraday's. experiment led him to conclude. with Thomas Young, that light waves represent transverse vibrations. Later. William Thomson. Lord Kelvin. calculated the oscillatory character of electricity in a condenser discharge (1853). Kelvin passed on to Maxwell the theory that these oscillations represented successive transformations of energy between magnetic and electrostatic fields much like the kinetic-potential energy transformations in the swinging of a pendulum or in surface waves.

George Green, an English mathematician, introduced the imperfect analogy of space as an elastic medium whose dynamic properties of compression, shear and rotation—in relation to the transmission of transverse and longitudinal waves—were mathematically determinable (1828). This idea later served Maxwell for an ether model, by use of which he was able to identify light and electricity as two forms of electromagnetic wave propagation occurring at the velocity of light.

Maxwell's equations are given with their derivatives and implications and discussed at length in the articles ELECTRICITY: *Electromagnetic Waves;* ELECTROMAGNETIC WAVES: *Maxwell's Field Theory;* LIGHT: *History.* Published in 1863 and 1873. they remain a working tool of radio and telecommunication research despite the questions raised by the relativity, electron and quantum theories. the wave-corpuscular controversy and the shortcomings of the ether model.

1. Experiments by Hertz.—Radio is a superb example of a phenomenon whose principles were known to mathematicians some time before they were demonstrated practically. Maxwell made no attempt to prove physically his thesis of the identity of light and electricity, and his writings were known only by other mathematicians. Among these was H. L. F. von Helmholtz. who held the chair of physics in Berlin and whose best-known work was on the resonance of sound (1862). However, his other work in electrical oscillations and electrodynamics involved his theories in controversy with Maxwell's (1874). Among Helmholtz's pupils was Heinrich Hertz. who in 1886–88 brought into electrical resonance, at a wave length of approximately 4 m. (or at a frequency of about 75,000,000 cycles per second [c.p.s.]), a pair of plates radiating electrical energy and a detecting loop of wire some feet away. A micrometer gap in the loop. by producing sparks that could be seen in the dark, revealed a transfer of energy as predicted by Maxwell (fig. 1).

Hertz had the benefit of the induction coil as a generator of radiation, besides laboratory types of electrical influence machines. Using these. he established that radiated electrical energy, like light. was emitted as transverse waves in all directions. Electrical waves, moreover. could be brought to a focus, reflected. refracted and polarized. Like sound. they could be set up as standing waves on wires. He also established. by measuring wave lengths and calculating frequency, that the velocity of electrical transmission through space was the same as the velocity of light, as predicted by Maxwell. He found that radio waves, because of the difference in frequencies between radio and light, would pass through certain

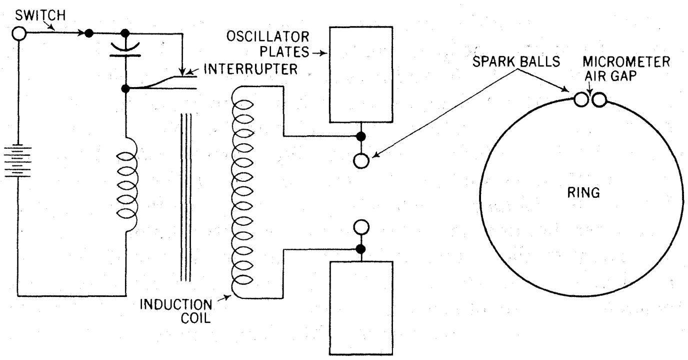


FIG. 1.—HERTZ OSCILLATOR. 1887

substances opaque to light but were stopped by metallic screens. However. Hertz had no interest in using his discoveries for actual communication.

2. Hertz to **Marconi.**—The decade between Hertz and Marconi was marked by the development of a great deal of interest in electrical waves. The commercial successes of the wire telegraph in the first half of the 19th century and of submarine cables and the telephone in the latter half, directed speculation toward wireless modes of operation. Experiments in conducting galvanic currents through earth and water without wires took place. Inductive devices requiring primary and secondary coils of very large dimensions were used. The principles of the first sensitive detector of faint signals—the coherer—were demonstrated, and radio signals were employed to convey intelligence for the first time.

3. The **Coherer-Decoherer.**—The coherence of dust particles in air when electrified was discovered by Pierre Guitard of France in 1850. In 1879 D. E. Hughes. an Anglo-American electrician. while investigating the resistance of loose contacts between carbon granules in his microphone transmitter, discovered the phenomenon on which the action of coherers depends. The coherence when electrostatically charged, and a resulting decrease in the resistance of loose brass and copper filings to the flow of a current, were noted by C. Onesti of Italy in 1884. E. Branly. a French physicist, published in 1890 his discovery that the resistance between loose iron filings in a glass tube decreases with the impact

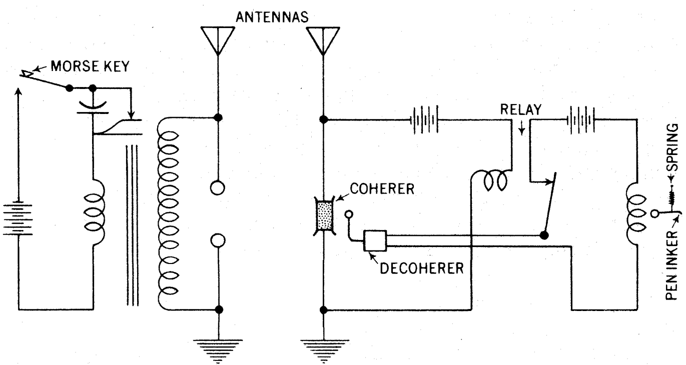

FIG. 2.—MARCONI-LODGE APPARATUS, 1896

of radiated electric waves. Branly did not apply his coherer to the reception of electromagnetic waves as communication signals, but he found it necessary to tap the cohering filings mechanically to make them "decohere." Sir Oliver Lodge. an English physicist, demonstrated improvements in Branly's coherer in 1894. He used the device, in place of a Hertz loop, for the detection and pen recording of Morse signals transmitted in a laboratory by radio. Included in the inker circuit was Lodge's "trembler" or decoherer, which automatically shook the filings to restore their high resistance, thus making the device responsive to no-current as well as to marking-current conditions in the dipole radio-frequency receiving circuit (*see* fig. 2). In 1895 A. S. Popov, a Russian physicist, in his study of distant lightning flashes, used Lodge's receiver with two improvements. One was the use of choke coils to nullify the effect of local sparking at the inker-decoherer circuit relay contacts; more important was the use of an external insulated wire and a ground (earth) connection, between which the coherer was inserted. He sent Hertzian signals into his receiver over a distance of 300 yd. in 1896. Further improvements in the coherer were made by Marconi.

4. Wireless by Conduction.—Practical wire telegraphy began more or less simultaneously in Germany, England and the United States during the decade 1835–45. and quickly spread. The use of the earth as one of the two needed guides for conduction currents flowing in extended electrical circuits was discovered in 1838 by K. A. von Steinheil of Germany. It was found that two separate remote paths through earth and water could be joined in emergencies to afford telegraph communication of sorts. Samuel F. B. Morse is said to have telegraphed across the Susquehanna river in 1842 without wires or cables, by means of two pairs of plates immersed in opposite banks, one upstream and another downstream. With the coming of the microphone and a sensitive telephone receiver in the late 1870s this method found other applications, especially when the combination used was a buzzer and telephone receiver. Thus, Sir William Henry Preece, electrician to the British post office, satisfactorily communicated across the Solent (1882). In 1889 the Indian Telegraph department employed the system during floods. The buzzer telegraph became a useful military device for a few years.

5. Wireless by Induction.—Meanwhile the induction system, another method not requiring wires, appeared. Preece demonstrated in 1855. over a distance of a quarter-mile, that messages could be sent by induction, *i.e.*, using low-frequency transformer action and convection currents, instead of high-frequency displacement currents in space. In 1892 Preece signaled between two points $4\frac{1}{2}$ mi. apart. These experiments predisposed a sympathetic attitude on Preece's part toward Marconi, who came to London in 1896 to put forward his first proposals for establishing wireless telegraphy in Great Britain.

6. Early Experiments and Proposals.—The periods of these probings for wireless telegraphy bracketed the years (1886–88) of Hertz's work. The same was true for another series of experiments and ideas more directly concerned with radiation. Mahlon Loomis conceived a wireless system wherein "disturbances in the static sea" would cause electric waves to travel through the atmosphere and ground; a U.S. patent was issued on it in 1872. Thomas A. Edison reported (1875) transfers of "etheric forces" in his laboratory that caused sparks of an oscillatory nature to appear in a micrometer gap between two carbon blocks mounted in a black box with a window, but with no external connections. In 1883 George FitzGerald suggested a method of producing electromagnetic waves in space by discharge of a conductor. In 1882 and 1886 A. E. Dolbear was granted U.S. patents on "a mode of electric communication for sending signals through the ether of space," but there is no record of the apparatus having worked.

Sir William Crookes made a remarkable prophecy of wireless telegraphy in the Fortnightly *Review* (1892). He foresaw the need of better wave generators than the induction coil, of a complement of wave lengths measured in miles down to feet, of more delicate receivers, of sharper tuning and the means of concentrating power in a single ,direction. The article came to the attention of Marconi and profoundly stimulated him. The radio industry that Marconi founded was to be preoccupied with Crookes' telegraphy specifications for a half-century. But during the latter half of that time it would be sharing attention with radiotelephony, which Crookes did not foresee and in which Marconi evinced only casual interest. .

7. Guglielmo Marconi.—A native of Italy, but from 1896 identified quite as much with England, Marconi early came under the influence of Lodge's demonstrations and Crookes' prophecy of wireless telegraphy. He was the pupil of Augusto Righi, professor of physics at the University of Bologna, who was working with waves 2.5 to 20 cm. in length and had invented an early quenched-spark emitter. Unlike his predecessors, Marconi was not a laboratory scientist but an entrepreneur with a driving purpose—to find the way to unguided electrical communication through space. He dedicated his life to translating radio from the laboratory to the market place, always looking for the slightest advance in reliability of wireless equipment and in the distances over which it would work. Marconi saw the commercial usefulness of a method of electrical transmission that, because it was not restricted by wires or cables, could reach an unlimited number of receivers anywhere at the same time.

Marconi was first to transmit and receive signals by Hertzian waves purposefully directed but without wires (1895). He used an induction coil with a telegraph key in the primary circuit. Across the secondary circuit was an untuned spark gap. Marconi did not terminate the gap in a dipole. as had Hertz and Lodge, but in a ground plate for one pole and in an elevated metal cylinder for the other. For a receiver he used a simple coherer with improvements in sensitivity. By the end of the year he had increased the transmitting range to more than a mile.

In 1896 Marconi went to London, secured patents on his system and interested government officials in it. Ranges of 2 to 9 mi. obtained that year were gradually increased to 200 mi. by 1901.

III. MARITIME WIRELESS AND THE VACUUM TUBE

Marconi set the pace for widening the transmission range of wireless. In 1897 he established the station at Needles, on the Isle of Wight, that took part in several records in wireless: 1897—first maritime use of wireless in England, to a tugboat 18 mi. away; 1898—first paid-for wireless telegram; 1899—first newspaper published aboard ship using press matter sent by wireless, 56 mi.; 1901—first 200-mi. communication. Marconi also was the first to bridge the English channel by wireless, in 1899.

1. Maritime Wireless.—The fact that radiated waves carried well over water led to the entrance of commercial wireless into the maritime field. where it filled a need not served at all by wire telegraphs. Apart from its obvious usefulness to ship owners in communicating with ship captains and pursers during the course of a voyage. it was quickly put to use by the press, by the military and in sea rescues.

By 1904 the role of wireless in summoning help to ships was so important that adoption of a universal code call of distress was in order. Addition of the letter D (for danger) to the "all stations" collective call CQ gave the CQD signal, eventually replaced by the Morse mnemonic SOS. When radiotelephones became common. especially on aircraft, the voice of distress, "May Day" (from the French *m'aidez,* "help me") was added.

2. Spread of Commercial Wireless **Telegraphy.**—Marconi's influence rapidly spread to other countries. A. K. H. Slaby saw Marconi's apparatus in England and introduced it into Germany in 1897, and the first German commercial wireless station was established on Borkum Island in 1900. Pioneer wireless work in Germany was also done by K. F. Braun, G. W. A. von Arco. Alexander Meissner and the firm of Siemens and Halske. Out of an amalgamation of these interests the Telefunken company was created in 1903.

Two outstanding names appear in the early wireless annals of the U.S.—those of R. A. Fessenden. physicist, and Lee De Forest. Fessenden lectured on Hertzian waves and experimented with them prior to 1900. when he was engaged by the U.S. weather bureau to develop wireless as a weather forecasting aid. He became a prolific producer of wireless inventions. De Forest, while a student in 1898. was attracted by demonstrations of the Hertz experiments. As Marconi had been, De Forest was influenced by the predictions of Crookes regarding the future of wireless. He set out to produce a better detector of waves than the coherer, and he produced several inventions of great importance.

3. Transoceanic Operation.—In 1900 Marconi built a station at Poldhu. Cornwall. Eng.. that established a number of records, and in 1907 he built another station in Clifden, County Connemara. Ire. The Federal Telegraph company opened a radiotelegraph service between San Francisco, Calif., and Honolulu. Hawaii, in 1912. The American Marconi company opened a similar circuit in 1914 and extended service across the Pacific to Japan by manual relaying in Hawaii during the next year.

4. Improvements in Transmitters.—The improvements in transmitter equipment and antennas in the first quarter of the century greatly extended the range and reliability of long-ware and medium-wave radiotelegraphy. Until the introduction of the vacuum tube, spark gaps, arcs and alternators took many forms during the 20-year period beginning around 1903.

Rotary Spark Gap.—Invented by Fessenden, the rotary spark gap consisted of a toothed or spiked wheel turning between two electrodes. A whistlelike note could be produced to any desired audible pitch by proper selection of wheel speed and number of teeth. Self-cooling. the gap could be decreased to any minimum length desired. The rotary spark gap was widely used in the 1906–20 period.

Quenched Sparks.—As the power supplied to ordinary open spark gaps and their associated oscillatory circuits was increased over the years, it was found that the sparking rate could be increased if ionization of the gas between the electrodes could be prevented. A technique was discovered by the German physicist, Max Wien. in 1906. wherein sparks—which in that day mere thin and often several inches in length—were increased in volume but reduced to a fraction of a millimetre in length. This resulted in an abrupt decay (or quenching) of the oscillation produced by the spark. The frequency emitted was therefore that of the circuit coupled with the antenna, excited by rapid, successive impacts from the quenched gap. Arc-over was prevented by using large electrode areas cooled by circulating air or water. For very rapid sparking rates a high-voltage direct current could be used, with an oscillating circuit in series with the quenched gap. As installed by the German Telefunken organization for telegraph use in 1909–15. the quenched gap was fed from alternators producing 500 to 1.000 c.p.s.

Rotary gaps and quenched gaps made the emitted telegraph signals more distinctive and more easily identifiable by the receiving operator. who often had to read them through the interference of static and other transmitter signals.' Rotary and quenched gaps produced tones more or less unique to each station. Despite such advances, it was clear that the intervals of no power, between bursts of rapidly decaying ether disturbances caused by discrete sparks. could not be reduced so long as sparks were employed; some source of continuous-wave production had to be found.

Marconi Timed Spark.—Marconi's timed-spark system made it possible to approach continuous-wave generation. It used staggertoothed wheels rotating on a common axis. These wheels drew off sparks at a faster rate than the single spider used by Fessenden and others. By careful design the wheels could be timed so that the decaying oscillations produced by one set of teeth and its associated spark gap were overlapped in phase by oscillations developed by a second set, and so on. The system was adapted only to very long waves (very low radio frequencies). it required bulky equipment to maintain the necessary stability. it had to be designed so that the frequencies produced matched the natural frequency of the antenna and its operation involved many other critical factors.

Arc *Oscillators.*—W. B. Duddell, an English engineer. discovered in 1900 that an arc lamp could be made to "sing" a musical note if it was placed in a direct-current circuit containing an inductance and a capacitance. V. Poulsen of Denmark, by cooling the lamp electrodes and enclosing the arc in an atmosphere of hydrogen, raised Duddell's limit of 10 kc. per second to 100 kc. per second: and. when coupled to an antenna, the arc generated and emitted the first pure continuous waves in the low-frequency wireless field. However. Poulsen's arc was not tested successfully until 1908. when it worked over a distance of 150 mi. Meanwhile, in 1906, the German Telefunken arc appeared; by 1913 Telefunken's Nauen station used it over a range of 1.550 mi. In 1910 the Federal Telegraph company brought the Poulsen arc to the United States. It was installed as standard equipment by the U.S. navy in 1912 and continued in use through World War I.

High-Frequency *Alternator.*—Fessenden applied in 1901 for a U.S. patent on a high-frequency alternator for the generation of continuous waves that would make possible the transmission of the human voice by wireless telephony. To Fessenden's specifications, E. F. W. Alexanderson, a pupil of Slaby working in the U.S., built in 1903 a 10,000-c.p.s. alternator. Later he built one of 80.000 cycles, with which, at Brant Rock: Mass., Fessenden was the first to broadcast music and speech (1906). Alexanderson's

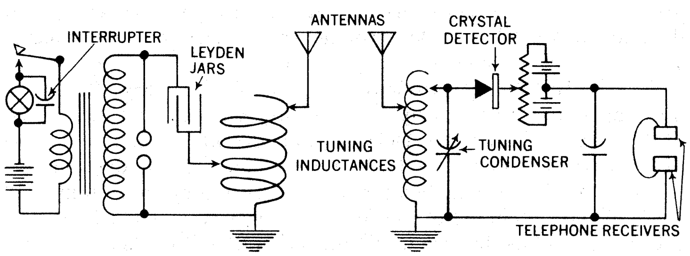

FIG. 3.— TUNED CIRCUITS AND CRYSTAL DETECTOR. ABOUT 1903

problem was the design of multipolar machines (*e.g.,* 300 poles mounted on the stator) with rotor speeds of about 20.000 r.p.m. and air-gap clearances of about 0.015 in. Such a machine, developing 100,000 c.p.s., was built by Alexanderson in 1909 for radiotelegraph use.

Resonance and Tuning.—Lodge patented in England in 1898; the use of adjustable inductance in the transmitter. antenna and receiving circuits of wireless systems. Lodge called this syntonic tuning (see fig. 3). While the patent was in conflict with some of Marconi's claims. Lodge had an influence on early tuning theory and the adaptation of antenna sizes and configurations to the frequencies being emitted and detected. John S. Stone applied for four-circuit tuning patents in 1900 and was the first in the U.S. to assert that antenna circuits and spark and detector circuits could be independently tuned and loosely coupled together, thus increasing selectivity (*see* fig. 4). Stone also studied the tuning of telephone wires and their adaptation to the guidance of electromagnetic waves.

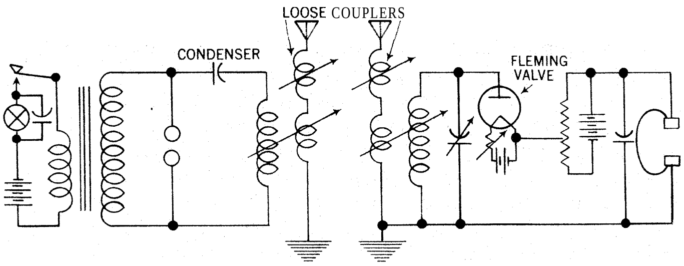

FIG. 4.—LOOSE COUPLING AND FLEMING VALVE. ABOUT 1907

In wireless, as in wire telephony. a parallel attack on the problems of .resonance had been made.

Antennas.—Antennas were found to have a natural resonance period important to the tuning of a circuit consisting of antenna. ground and coupling inductance. Marconi and his organization, Lodge. Fessenden and many others developed formulas for antennas of various virtual heights, for optimum ratios of antenna lengths to wave lengths and for various configurations—notably the vertical antenna and the flat-top antenna supported between towers and between ships' masts. Alexanderson invented the multiple-tuned panel transmitting antenna. It divided a directionally pointed, horizontal, tower-supported antenna into sections connected through down leads and tuning inductances to ground at various points throughout its length of approximately 900 ft. Alexanderson and his assistant. Harold Henry Beverage, developed a "barrage receiver" that incorporated directional discrimination and required long horizontal antennas (1916). In 1921 Beverage patented the "wave antenna" that became standard for long-wave reception throughout the world. It consisted of a wire supported on a straight-pole line of the length of one wave (approximately nine miles in practice) and oriented to the direction of arrival of the wave. It had the useful property of rejecting static that came from any other direction.

5. Improvements in Receivers.—The counterpart of increased power in transmitters was increased sensitivity in receivers. The single step of most significance was the substitution of a pair of head telephone receivers or headphones for the early pen inker as the receiving device used by the operator. Headphones were sensitive enough to work directly in a rectifying receiving circuit when a series potentiometer and a shunt-blocking condenser were added (see fig. 3). Between about 1903 and 1916 the standard method of telegraphing by wireless was headphone reception of hand-keyed Morse code (ship-to-shore) or slow-speed automatic Wheatstone (transoceanic) transmission.

As in the case of spark gaps in transmitters. many improvements were made in the rectifier element (detector) of receivers. These improvements served a vital purpose in the interval 1902–20, before the De Forest three-eleinent vacuum-tube circuit became available for general use after World War I. In Marconi service the coherer was replaced by the magnetic detector. As developed by Marconi in 1902, it was capable of moving a relay so that the relay could produce recordings of signals on paper tape. By 1907 the coherer had been generally outmoded by magnetic, electrolytic and crystal detectors in circuits of the kind shown in fig. 3.

Before 1900, Hughes in England had found that a steel needle resting lightly on a carbon block would rectify radio-frequency waves in a manner similar to a coherer but without requiring a decoherer. With headphones. the steel needle became the earliest form of crude wireless rectifier. but its use was short-lived. Contemporary with the magnetic detector was the electrolytic detector. an invention of Fessenden in 1902. consisting of platinum wire dipped in nitric acid. Beginning in 1903 G. W. Pickard. an American engineer, began experimenting with the rectifying properties of magnetite and other crystals that had surface spots sensitive to radio signals upon contact with wire probes called "cat whiskers." In 1906 Pickard discovered a superior crystal in silicon, and in that same year Gen. H. C. Dunwoody of the U.S. army discovered that carborundum and carbon in contact were less sensitive to vibration than other combinations and therefore were adaptable to shipboard use. Pickard used a combination of zinc oxide and chalcopyrite in contact; also tried were galena. molybdenum and other crystals. The independently conducted, trial-and-error search for these materials was in marked contrast to the organized scientific research in 1948. involving point contacts on germanium, that resulted in development of the transistor. Crystal rectifiers were the mainstay of wireless until they were gradually replaced by electron tubes.

6. The Electron Tube.—Sir John Fleming's vacuum diode valve of 1904, based upon his discovery that the "Edison effect" could be applied in a wireless receiver circuit for the detection of incoming waves. was a rectifier. It fulfilled the function of a crystal as a detector of high frequencies (see fig. 4). It was the first of a long series of electron tubes that had a heated source of a stream of electrons (cathode) and a collector plate, both in a partially exhausted glass housing with external electrical connections. The development of the electron tube is traced in the article ELECTRON TUBE: History. The De Forest triode audion of 1907 was the most important of the electron tube series. It contained two features absent in Fleming's valve: an external local battery. connected between plate and cathode, from which the tube derived its power to amplify weak input signals; and a third electrode, the grid. interposed in the electron stream and capable of controlling the plate current in accordance with incoming radio-frequency signals. Under optimum conditions. De Forest's triode displayed high amplification characteristics as a detector, although Fleming's valve had not. However, it was not until 1912 that the triode's amplification was stabilized and its versatility became clear. In that year H. D. Arnold and Irving Langmuir independently found that the triode amplifier could be stabilized if pumped to high vacuum, and De Forest increased amplification by operating his tubes in cascade—the plate output of one tube fed into the grid input of a second tube, etc. De Forest discovered that the audion could be made to oscillate, in suitable circuits, so as to generate radio frequencies. This meant that the vacuum tube could be used for transmission as well as reception. E. H. Armstrong in 1913 and De Forest in 1914 filed conflicting patent applications on the feedback circuit (*see* RADIO RECEIVER: *History*). The feedback circuit led a portion of the amplified plate current back into the grid of the same tube, greatly increasing its sensitivity by regenerating weak signals.

7. Developments During World War I.—Maritime wireless telegraphy was generally in use on ships and between ships and shore stations by the outbreak of the war. Arc transmitters up to 500 kw. in capacity had been installed at naval stations in the United States. and the Marconi timed-spark system linked units of the British commonwealth. New German Telefunken stations erected in the U.S. were among those that warned German ships, upon the declaration of war, to make for neutral ports. The British fleet was recalled by radio. During this period very long-wave transoceanic radiotelegraphy became well established for military purposes. using arcs and alternators for transmitting and triode tubes for receiving. In 1918 the U.S. army erected its Lafayette station at Crois d'Hins near Bordeaux. France, for transatlantic communication. It achieved world ranges on a wave length of 20.000 m. The original plant comprised two Poulsen-Federal arcs rated at 1.000 kw.

The Heterodyne Principle.—Radio frequencies generated by arc and alternator were above the range of audibility in a telephone receiver. so that they had to be modulated at a steady audible tone before being turned on and off with a telegraph key. This modulation was accomplished at either the transmitter or receiver. The German inventors modulated their alternators by means of a tone wheel. Poulsen tone-modulated his arc with an interrupter. Fessenden invented a method of tone-modulating a circuit at the receiver instead of at the transmitter by generating at the receiving station another high frequency.that differed from the transmitter frequency by a value within the audible range. The device that produced this steady interference pattern was called a heterodyne apparatus (1902). Fessenden used the heterodyne principle at his Brant Rock station in 1904, and it was necessary to generate the beat frequency by a ponderous local arc. Kevertheless, U.S. navy experiments in 1913 demonstrated the superiority of this method for radiotelegraphy. With the introduction of the vacuum tube as an oscillator in 1912, a simple receiving circuit component became available to generate a heterodyne beat-note audible in headphones. To solve a military problem with the U.S. army signal corps in Europe in 1918, Maj. E. H. Armstrong converted a received radio-frequency signal into an intermediate, supra-audio frequency by beating it with the output of a local oscillator, detecting signals twice before giving them audio amplification. He called this the superheterodyne method and patented it in 1919–20. It possessed advantages of stability over other methods of amplifying signals above the audio range. With the advent of the screen-grid tetrode in 1927, the superheterodyne became the most widely used receiver circuit.

Radio Direction-finding.–Direction-finding. or radiolocation, began in wireless telegraphy as a specialty of wave-direction measurement. In modern aviation and in some marine work direction-finding is an auxiliary function of radiotelephony. The original work on direction-finding was performed by Stone in 1904 and by E. Bellini and A. Tosi in 1906. The patents of the Bellini-Tosi system were acquired by Marconi in 1912, and in that year the first English merchant vessel was equipped with a direction-finder. Credit for major improvements thereafter is shared by an American, F. A. Kolster (1913) ; Marconi's assistant: Capt. H. J. Round, whose devices tracked down the German fleet in the battle of Jutland (1916) ; and R. L. Smith-Rose, a British physicist. Because of its usefulness in World War I, direction-finding equipment did not find full commercial use until the period 1921–25, by which time it employed vacuum-tube circuits. By 1925 the radio compass had come into widespread shipboard use.

8. Radiotelephony. — The technique of radiotelephony represents the coinbination of two developments: high-powered radiotelegraphy and weak-current wire telephony. From the time of Alexander Graham Bell and Hertz until 1906. the two modes of communication had been separated in orders of magnitude of power and frequency, even though they derived from a common theoretical source in Maxwell's equations. As early as 1896. Stone and M. I. Pupin were involved in a patent controversy in applying telephony to Hertzian waves.

The Microphone.—The first type of transmitter for voice pickup was the telephone instrument patented in 1876 by Bell. He originally used the same type of coil-diaphragm instrument for talking and listening, Bell, and also Elisha Gray, used transmitters in which the voice sound varied the electrical resistance and thus caused variations in the currents in telephone circuits. In 1877 Émile Berliner and Edison discovered that sound pressures on a diaphragm could be made to produce variable electrical currents. Edison invented the carbon-granule telephone transmitter in 1386. The term microphone. coined by Sir Charles Wheatstone in 1827 to describe an acoustical amplifier! was first used in connection with telephony by Hughes in 1878. In that year Hughes devised a sensitive microphone transmitter in which the variable circuit resistance consisted of a carbon rod resting in grooves in two carbon blocks. Improvements in detail upon the Edison and Hughes transmitters led to the development of modern microphones. Subsequent refinements that resulted in the high-quality microphones used in radio. television and recording studios are traced in the article MICROPHONE.

Modulation by Microphone.—The direct-current singing arc was made to "speak" audibly and its light to vary when a microphone was coupled ro its circuit by a transformer. Such a "photophone" was built by H. Hays and Bell in 1897. It was not devised to generate radio frequencies but to transmit audio frequencies over a light beam. A number of attempts were made to introduce a microphone at various points in spark-energized wireless circuits without success: although Fessenden is generally credited with having been first to transmit speech over a distance of a mile, using a high-speed. interrupted-spark transmitter (1900). A. F. Collins used a microphone in the primary of an induction coil, with antenna and ground but without spark balls. to transmit over a distance of three miles in 1902. Spark telegraph signals, especially on low radio frequencies, were too powerful and too widely spaced in time to be modulated, even by water-cooled microphones.

Use of *Arcs* and Alternators. — Poulsen used his hydrogen-arc generator of continuous wireless telegraph waves in 1904 to transmit voice over short distances. In Germany H. T. Simon and M. Reich (1903) and O. Nussbaumer (1904) suggested the application of high-frequency alternating currents to the purposes of wireless telephony. In 1906 the Telefunken arc of Von hrco was voice-modulated, making it possible to talk by wireless over a span of 25 mi., and in the same year Fessenden staged the first demonstration of the broadcasting of music and voice by radio, using a water-cooled microphone and an Alexanderson 80.000-cycle alternator at Brant Rock. Reception was reported by radio operators aboard many ships at sea. De Forest demonstrated an arc radiotelephone in 1907 in tests between a ferryboat on the Hudson river and its terminals in New York and New Jersey. Using a liquid microphone to modulate an arc. F. Majorana in 1908 telephoned from Rome, Italy. to Sicily. a distance of 300 mi.. and in 1910 H. P. Dwyer used a Poulsen arc to telephone from San Francisco to Los Angeles. Calif. (490 mi.). In 1911 Xlexanderson built a high-frequency alternator with a laminated-iron field. designed to act as a self-contained magnetic amplifier. Its input was a microphone and its output a varying field flux that amplitude-modulated the generated continuous waves. In 1914 Marconi long-wave radiotelephone signals originating at Clifden. Ire., were received aboard two Italian war vessels off the coast of Sicily, 1,750 mi. away.

IV. THE RISE OF BROADCASTING

Medium-frequency telephone broadcasting and short-wave telecommunication dominated the decade 1920–30. The radiotelephone, useful for private conversations, became most valuable in public mass communication and entertainment. Public demand for broadcasting service and equipment caused manufacturers to demand new electronic devices. circuits and equipment. Broadcasting studios. feeder networks and overseas remote pickups became commonplace. Early radio by-products, including public-address systems and telephotography, presaged the decade of electronics that was to follow. Short-wave transmission also came into its own during the 1920s.

1. Improvements in Transmitters. — Better performance in transmitters stemmed in part from transmitting tubes of larger size and greater efficiency. Two important improvements were the copper-to-glass seal and the water-cooled tube (1922). Broadcasting transmitters. which in 1922 operated at outputs of less than 500 w.. were increased in power; 50-kw. stations were common in 1928. and by the early 1960s outputs had reached 500 kw. Efficient use of power by the transmitter was found to be economically important, and efficiencies were increased by such advances as the constant-current system of modulation of R. A. Heising (1921).the class C amplifier (1932) and W. H. Doherty's linear radio-frequency power amplifier (1936).

Jacques and Pierre Curie discovered the piezoelectric effect in 1880, and they later found that if a high-frequency field is applied to a crystal held under pressure, and if the applied frequency exactly coincides with the natural period of vibration of the crystal. the crystal will oscillate and produce useful alternating voltages between its surfaces. This property proved invaluable in preventing radio transmitters from wandering off assigned frequencies. G. W. Pierce found that the resonance of a crystal is very sharp. He was issued several patents on applications (1924 to 1931) for vacuum-tube circuits containing quartz crystals as oscillating-circuit stabilizers. The first use of crystal-controlled master oscillators took place in 1923.

There are other less precise but effective ways of accomplishing frequency control. Pierce investigated magnetostriction effects in nickel, while W. H. Eccles, of the Marconi staff, used tuning forks as early as 1901 to keep stations on frequency. Identically ground crystals were employed on a wide scale during World War II in transmitters and receivers, and the practical subdivision of the radio-frequency spectrum among thousands of users in the middle of the 20th century was made possible only by crystal frequency controls.

2. Amateur Radio.—Young men had turned to wireless telegraphy as a hobby in the period 1903–12 in the same spirit that their fathers had strung rooftop wire telegraphs between houses. Thousands of the long-wave transmitters shown in fig. 3 and 4 (but without receiving tubes) were installed. Unfortunately amateurs increasingly interfered with commercial and government wireless, and in 1911–12 they became subject to licence restrictions. During World War I amateur sets were sealed; however, the operators' talents proved so valuable in military service that they were encouraged to resume amateur operations after the war. Amateurs adopted vacuum tubes when these became available around 1919, and they became an important source of listening material for the many thousands of people who bought broadcast receivers in the years following 1920.

In resuming operations in 1919, the amateurs had been crowded into a medium-frequency band that was not broad enough to accommodate them. They had also been assigned a medium-high-frequency portion of the spectrum believed unsuitable for long-distance operation. The good use to which they put these bands in 1920–21 was their most valuable contribution to the development of radio. In 1921 a U.S. amateur, P. F. Godley, with the co-operation of British amateurs and the post office, set up a receiver in Ardrossan, Scot., through which he received from a group of six American amateurs at Greenwich, Conn., a 12-word message in radiotelegraphic signals. The distance was 3,200 mi.. the power 1 kw. and the wave length 230 m. (1,300 kc.). Soon American. British, French and other European amateurs by the hundreds were in frequent communication at low power in this band as well as on 180 m. In 1923 amateurs used low-power, 100-m. waves to talk between New York and California.

3. Commercial Short-Wave Radio.—Commercial interests were caught off guard by the amateurs' successful exploitation of the upper medium-frequency (MF) and the lower high-frequency (HF) bands. Marconi had never lost faith in the possibilities of short waves, but he had dropped the investigation of them in the 1890s in favour of long waves that were yielding him quicker results. He had taken out a patent on "beamed transmission" in 1905, and in 1916 assigned C. S. Franklin to investigate short waves. Franklin's results, published in 1922, indicated that short waves, 15 to 100 m. in length, were suitable only for distances less than 200 mi. This conclusion was controverted by the experience of the amateurs, whose records spurred more experimentation by Marconi. the Radio Corporation of America and the American Telephone and Telegraph company. The first commercial long-distance radiotelegram dispatch by short waves was sent from Belfast. Me., to Buenos Aires, Arg., in 1923. In the same year Marconi dispatched his yacht "Elletra" to test 100-m. short waves at sea as received from Poldhu, using reflectors designed by Franklin to concentrate the transmitted energy in a beam. The signals from Poldhu were heard 1,200 nautical miles in the daytime and double that distance at night. In 1926 beam transmission was considered practical for commercial use, and by 1928 Marconi stations had been erected in England, Canada, Australia, South Africa and elsewhere throughout the British empire. The Radio Corporation of America had abandoned its ambitious plans for a long-wave radio central station and was installing short-wave equipment. By 1930 the American Telephone and Telegraph company had made an almost complete transition to short wave.

Opening up of the extensive short-wave portion of the radio spectrum made room for thousands of long-distance and other services that could not have been accommodated on longer waves. Antennas became snialler and less expensive to build. had increased radiation efficiency and had substantial portions of their energy directed toward desired reception points. Directivity of antennas reduced the interference between stations and permitted world-wide sharing of channels. Interference by static caused by distant thunderstorms was less. Because of these advances, transmitter power could be reduced or the existing power could be used to make transmissions more reliable. Short-wave radio was adapted to long-distance telephony and to high-speed. multichannel telegraph operations. After 1927 virtually no new long-wave radio circuits were established, and most of those in use at that time were gradually abandoned. The long-wave spectrum is still useful! to a limited extent, for specialized military radiotelegraph services and for navigation.

The Kennelly-Heaviside Layers.—In 1902, long before short waves were being used, A. E. Kennelly of Harvard university and the British mathematician Sir Oliver Heaviside independently reasoned that a stratified layer must exist in the upper atmosphere; between that layer and the surface of the earth the long waves of wireless must be contained, and this fact accounts for the waves not leaving the earth tangentially at the horizon as light waves do. With the beginning of short-wave investigations, this theory was rapidly expanded. A. H. Taylor accounted for the ground- and sky-wave components of short waves; L. W. Austin reasoned that sky waves underwent refraction rather than reflection; and Ernest Rutherford attributed refraction to the presence of free electrons in the layer. Frank Conrad developed the "multihop" theory of repeated refractions in the layer and reflections from the earth's surface. The height of the layer was measured by Sir Edward Victor Appleton in England. by triangulation, and by George Breit and Merle A. Tuve in America. who measured the echo of a transmitted pulse. The latter method eventually revealed the existence of several concentric layers rather than one. (*See* IONOSPHERE.)

Diversity Reception.—H. H. Beverage and H. O. Peterson, observing transoceanic short-wave signals in 1925. found that fading does not occur simultaneously in two receivers working on antennas spaced a short distance apart. 'This led to the development of space-diversity reception. in which the combined (or overriding) signals from two or more receivers. working off carefully placed. separate antennas, govern the operation of a receiving relay, which automatically selects the strongest available signal.

V. SPECTRUM EXPANSION AND ELECTRONICS

Continued progress in broadcasting: and a new probing of the ionosphere by short waves, tied the decade 1930–40 to its predecessor. In the period between 1933 and 1937, improved designs for broadcast antennas made possible higher efficiencies and better control of directional effects, thus further reducing interference between stations. Continuing research in the high-frequency portion of the spectrum led inevitably to exploitation of the short-wave band for international broadcasting. By 1932 broadcast transmitters were operating with sidebands 8.000 c.p.s. in width, making it possible to transmit undistorted voice and music tones as high in pitch as 8,000 c.p.s.; this meant better fidelity in reproduction (FM broadcasting almost doubled this tonal range two decades later). but unfortunately the quality of the receivers then in use was not equal to that of the transmitters.

1. Electronics.— A widespread movement to apply radio theory and apparatus to other fields began in the middle 1930s. The radio industry contributed the electron tube. the photoelectric cell, the oscilloscope. electronic amplifiers: the principle of feedback for automatic control and techniques for utilizing both audio and radio frequencies in many ways. The term electronics came into use in the mid-1920s to designate all of the theoretical and applied work involving the movement of electrons in a vacuum. About 1928 electronics began to be used as a collective term for all the applications of the electron tube and its associated circuitry to purposes not directly associated with radio emissions.

2. Marine Radiotelephony.— The earliest demonstration of two-way marine telephony was aboard the U.S.S. "New Hampshire" in 1915. In World War I the long-wave radiotelephone was used to communicate with submarine chasers and other small vessels and aircraft. Ship-to-shore radiotelephony was tested in 1920 on low-power long waves, and commercial radiotelephone service between land and steamships began in 1929 with the installation of radiotelephone equipment on the "Leviathan" By 1933 long-distance, short-wave, ship-to-shore radiotelephony was commonplace on the North Atlantic. Extensive use was made after 1934 of short-wave radio in commercial telephone service to small craft in coastal waters, as well as to private aircraft.

3. Commercial Radiotelephony. — Thefirst commercial long-wave radiotelephone circuit was established in 1920 between Long Beach. Calif.. and Catalina Island. a distance of 30 mi. One-way transatlantic tests on long waves occurred in 1923. and commercial transoceanic radiotelephone communication began in 1926. using long waves; short-wave transoceanic radiotelephony came in 1929. The multiple-unit, steerable receiving antenna was first used in 1934. Independent double-sideband transmission on a common carrier frequency originated on the Ketherlands-Java short-wave circuit in 1937, and by that year the principal countries of the world mere interconnected by 92 groups of radiotelephone circuits, making it possible to talk between any of about 93% of the world's telephones.

4. Aviation Radio. — Radio serves aircraft not only as a means of communication but as a navigational aid. The problems of designing aviation radio equipment are similar to those encountered in marine equipment, but they are aggravated by restricted space for equipment and antennas. as well as by interference from other electrical equipment, by unusual types of static and by a varying power supply. Also, in order to maintain continuous communication and navigation facilities, it is necessary to work several channels independently and simultaneously, and two or more transmitters and receivers therefore are required.

In the United States) the first navigational aids to aviation appeared in 1920, when the post office department established ground stations for the airmail service. By 1930 a radio-range beacon system had been developed for universal application to airways, and in 1931 a radio beacon system had been devised for the "blind" landing of aircraft, although it was not officially adopted until later. In Europe and the United States very short waves (above 30 mc.) were being used in instrument-landing systems in 1935. A rotating radio compass, making possible automatic direction-finding for airplanes, was developed in 1936. It worked as a homing device in connection with radio beacons. Radio altimeters, working on the principles of the marine depth-finder, became available in 1938. The first U.S. blind-landing system. in which a definite radio slope of descent could be followed by a pilot. was installed at Indianapolis, Ind., in 1940. (See Aircraft Instruments.)

5. Mobile Radio. — The Detroit, Mich., police department in 1928 became the first to dispatch police squads by radio, and by 1935 about 400 cities in the U.S. had police radio service, some in the 30- to 40-mc. bands. Widespread two-way operation from police cars and private vehicles came with the opening of the ultra-high-frequency (UHF) spectrum after World War II.

Broadcast receivers for automobiles were introduced in 1932, and within a year they were in wide use.

6. Advances in Techniques. — The principles of negative feed-back. set forth by Stuart Ballantine in 1923. were spectacularly applied by H. S. Black in 1934 to produce wide-band, noise-free amplifiers having marked stability of operation. These amplifiers also were capable of a high degree of linearity (the ability to produce an amplified output signal with a wave form as similar as possible to that of the input signal over a wide range of frequencies); thus they could reproduce a much wider range of modulations without distortion.

In 1930 a widely published graph of the radio spectrum showed all waves shorter than 10 m. (30 mc.) as "not now useful." Yet there was general agreement that radio would have to expand into the higher frequency bands. Marconi's 1896 patent had contemplated using waves having a minimum length of about 25 cm. (10 in): *i.e.*, a maximum frequency of about 1.200 mc. When tubes capable of generating such ultra-high frequencies did become available. no time was lost. Report was made of experiments with 3-m. VHF waves in 1930. and in the period 1930–35 there were many more reports, covering UHF as well as VHF The first important microwave telephone circuit was established across the English channel (Dover-Calais) in 1931. using an 18-cm. wave (UHF) The first multichannel telephone microwave circuit joined Belfast, Ire, with Stranraer. Scot. in 1937, on 3 to 6 m. (VHF) Transmission of super-high-frequency (SHF) electromagnetic waves in hollow wave guides was reported by W. L. Barrow in 1936 and by G. C. Southaorth in 1937.

VI. PULSE TECHNIQUES AND TELEVISION

During World War II radio development was cloaked in military secrecy. but the easing of restrictions in 1946 disclosed as many accomplishments as in any previous decade. The most important advance had been radar, not alone because of its military successes but because radar theory and the electronic apparatus and techniques that arose from it were basic to the further utilization of the highest-frequency reaches of the radio spectrum. Out of military research, too. came such new concepts as printed circuits. modular construction and miniaturization. The end of the war also permitted resumption of work on television. which rapidly began to overtake radio as the most important entertainment medium in many countries.

1. Modulation. — The continuous wave of power (the carrier) delivered into an antenna by an oscillating electron tube may be varied or modulated, in its strength or amplitude, by voice signals from a microphone. The process is called amplitude modulation (AM). As an extreme example, amplitude may be varied suddenly between zero and full strength by working a telegraph key. thus either interrupting a steady musical tone that modulates the carrier or interrupting the carrier itself; wireless began by using such coded interruptions of a train of sparks. The process of amplitude modulation, as used in standard radio broadcasting. consists in varying the amplitude of the carrier wave at a rate identical to the frequency of the sound to be transmitted; *e.g.,* if a tone with a frequency of 1.000 c.p.s. is to be broadcast, the strength of the transmitter carrier is varied 1,000 times per second. Frequency modulation, as its name suggests, consists in varying the frequency of the transmitter carrier wave (while its strength remains constant) at a rate identical to the frequency of the sound to be transmitted. The outstanding advantage of FM is its freedom from interference by atmospheric and man-made electrical noises. These unwanted noises are of an amplitude-modulated nature and hence are not detected by circuits in FM receivers.

It also is possible to transmit signals by other types of modulation, some of which are important to radiotelephony. radiotelegraphy, picture transmission, television and radar. In FM telegraphy, for example. two tones. differing in pitch, convey the dots and dashes of the code signals; this was done with Poulsen arcs in the period 1912–22. Alternatively. the carrier itself may be varied in frequency by changing certain circuit constants; this is called frequency-shift keying and was developed during World War II. FM was applied generally to telegraph carrier transmission over wires in the U.S. during and after 1937 In 1945 it was applied to microwave radio for public telegraph service. Frequency modulation also is used to transmit the sound for television.

Pulse *Modulation.*—An electron tube can be overloaded drastically but safely if the overloads are of extremely short duration and are interspersed with relatively long periods of inactivity. One electron tube especially designed for this type of service is the magnetron, a two-plate version of which was described by A. W. Hull in 1921. A water-cooled magnetron was available in 1930 having an output of 5 kw. at 20 mc. and 1 kw. at 85 mc. (in the HF and VHF frequency ranges). However, successful ultra-high-frequency radar had to await development of the British 10-kw multicavity magnetron tube (1940), public announcement of which was withheld. for security reasons, until 1946.

The signals sent by radar and other pulse methods may be likened to a line of poles along a roadway. So long as the poles are equally spaced and of equal height they convey no information. It is possible, however. to convey information in any of three ways: (1) by varying the height of the poles (pulse-amplitude modulation — PAM); (2) by moving individual poles a short distance one way or the other from their normal, equally spaced

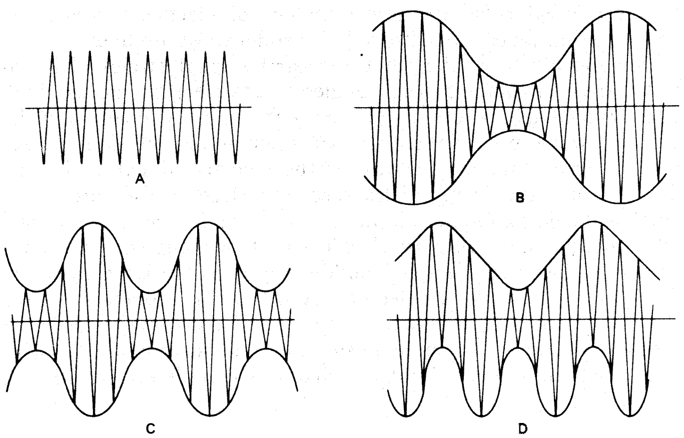

FIG. 5 — PRINCIPLES OF SINGLE-SIDEBAND OPERATION (A) WAVE FORM OF UNMODULATED CARRIER. (B) CARRIER MODULATED NORMALLY WITH UPPER AND LOWER SIDEBANDS. ONE REDUNDANT. (C) DIFFERENT SIGNAL DOUBLE SIDEBANDS AS IN (B); (D) SIGNALS OF (B) AND (C) IN SINGLE SIDEBANDS. REDUNDANCIES SUPPRESSED. WITH NO INCREASE IN NORMAL TOTAL BANDWIDTH.

positions (called both pulse-position and pulse-time modulation — PPM or PTM—developed in 1944); or (3) having grouped the poles into sets of five, for example, by omitting certain poles in accordance with a prearranged code (pulse-code modulation — PCM—developed in 1947). Pulse-modulation methods were adapted to multichannel telegraphy and eight-channel telephony. and pulsing was found particularly adaptable to microwave relay transmission in the super-high frequencies. Because of steepness of the wave fronts of the pulses and because the signals could be completely regenerated (*i.e.,* rejuvenated) at each repeater point. they were singularly free of noise, approaching the reliability and continuity of a wire line.

Single-Sideband Techniques.—Single-sideband (SSB) operation had been applied to long waves in 1927–37, but its potentialities for full utilization of the radio spectrum did not begin to be realized until the late 1940s. Before the advent of SSB, it was necessary to transmit both the upper and lower sidebands of speech. each of which is the mirror image of the other (fig. 5[B]); one sideband is the sum of, the other is the difference between. the carrier radio-frequency and the voice-modulation band of frequencies. In single-sideband operation. one sideband (*e.g.,* the lower) is suppressed, leaving only the upper, with its carrier. A second voice modulation (fig. 5 [C]), consisting of a lower sideband whose upper sideband image has been suppressed, can "ride" the same carrier (fig. 5[D]), and the carrier is thus doing double duty. However, the two voice sidebands are not limited to a single conversation; each can carry a number of them. closely packed into the spectrum like teeth in a comb. In addition. any of the voice channels may be further broken down into radiotelegraph channels. like teeth in a finer comb.

2. Television. — Television is an outgrowth of the techniques developed in (1) the transmission by wire of graphic material; (2) the utilization of the cathode-ray tube; (3) the perfection of the motion picture with its synchronized sound track; and (4) radio broadcasting. The period of early television development from 1924 to 1939 was interrupted by World War II, and when work in the U.S. was resumed in 1946. transmission was in the VHF band that had been opened during the. war. Coaxial cables were first used for intercity network television in 1946. and microwave radio transmission. using relay towers. began in 1947. The first coast-to-coast television broadcast over a nationwide system of microwave radio relay took place in 1951. Attempts were made. with better technical than commercial success; to introduce television into the UHF band in 1950. *See* TELEVISION: History of *Television.*

VII. MICROWAVES AND REMOTE CONTROL

The introduction of microwave radio relay systems after 1950, to replace wires and cable for general intercity communications throughout the world. ranked with any of the previous important developments in radio technology. Dissimilarities in the troposphere and ionosphere, and even meteor trails. came to be used in the propagation of high-power radio waves. Discoveries in solid-state physics brought a number of important developments in ceramics, phosphors and crystals, one of which — the transistor— replaced the electron tube in many of its applications and supplemented it in others. Radio communication took new forms, especially in aviation. Nonlanguage data transmission became important in the control of machines, missiles and space vehicles.

1. Microwaves. — By 1928, short-wave radiotelephony circuits among the principal nations had been completed, and microwave transmissions began in Europe in the 1930s. During World War II, microwave installations in the UHF band were used by military signal units in Europe, and in the United States the first practical SHF microwave radio system for transmitting commercial telegrams was placed in operation in 1945. In 1946 'the first radio relay system for long-distance telephone service was reported. Microwave radio techniques were applied in 1950 in France and Germany to public telephone service and in the U.S. to pipeline and railway communication and dispatching. Wave-guide techniques already had been used for antenna feeders and other SHF purposes. Coaxial cables had been tested comparatively with microwave radio relay systems in the U.S. for intercity telephone and television transmission; the microwave systems proved more economical and reliable. and by 1951 the Bell Telephone systems had begun a general adoption of microwave radio. By the end of the next decade. about one-third of the intercity telephone circuits and most television network programs were carried by radio relay links. The transmitter and relay towers were usually located on mountain tops or on tall city buildings and spaced about 30 to 40 mi. apart for line-of-sight transmission.

Antennas und dl-rays. — Antennas for microwave service include parabolic reflectors, electron lenses and horns. The size of an efficient antenna depends upon the wave length it is designed to transmit or receive; thus. as higher frequencies came into use, the size of antennas decreased. A familiar contrast is the 500-ft. broadcasting tower and the SHF "whip" antenna for police patrol cars.

Arrays of antennas may be so arranged and fed by transmission lines that they produce strongly directional signal patterns. In the 1960s there was increased use of pedestal-mounted, servo-operated. steerable paraboloid (dish) antennas. Another type was a stationary array of phased elements disposed in the form of crossed combs. The length, spacing and configuration of the "teeth" determined the pattern of the transmitted beam.

Ionospheric and Tropospheric Scatter Propagation. — Thomas L. Eckersiey reported in 1932 that cloudlike ionization concentrations in the Kennelly-Heaviside layers might be used to propagate VHF signals beyond horizon distances. D. K. Bailey. of the U.S. national bureau of standards, and several associates reported in 1952 that such propagation was observable over long distances. By 1955 Bailey and his associates reported transmissions of VHF signals through the ionosphere, using radar super-power pulsing techniques.

Henry G. Booker and others developed the hypothesis in 1950 that heterogeneity of turbulent volumes of the troposphere also propagates VHF radio waves beyond the horizon. Thus. it became possible to employ scatter techniques in inaccessible terrain, on sea routes and in the arctic where other radio systems meet unstable refraction conditions. By 1958 a dependable range of 650 mi. had been achieved by tropospheric scatter. using a power of 50 kw. in the CHF spectrum arid single sidebands carrying a 24-channel telephone-teleprinter traffic load. Commercial scatter systems ior combined telephony and television were inaugurated in 1957.

Meteor-Burst Communication.—Unseen meteors and meteoric dust particles bombard the earth's atmosphere day and night, often in quantities sufficient to support a type of sporadic radio communication that takes advantage of the propagation scattering effect of a trail of free electrons left in the upper atmosphere by each meteor. Since meteor bursts last only a matter of seconds. messages must be prepared in advance and high-speed data handling systems must be provided. The reflection paths of contact are automatically established by the occurrence of a meteor burst. resulting first in an instantaneous exchange of "trigger" signals between the two stations involved, followed by transmission of the message. When the signal strength falls below a predetermined level. communication is positively terminated so that no message material is lost, and transmission is resumed automatically upon the occurrence of a subsequent burst. Measurements of radar-type signals reflected by meteoric ionization were reported as early as 1948. The technique of applying such reflections to point-to-point radio was considered in Canada, Australia and the United States in 1952 in connection with other types of forward-scatter transmission, and two-way communication of this kind was first achieved in Canada in 1953.

2. Extremely High Frequencies **(EHF).**—Millimetre and submillimetre waves (4 mm. and less) were undergoing experimentation in the late 1950s. with prospects of great advantages for long-distance communication through multimode wave guides. Dielectric wave guides. containing no metal, were investigated in Germany before 1920. and in Great Britain, the Cnited States and Italy between 1936 and 1948.

At extremely high frequencies the thermal noise inherent in a vacuum tube severely limits the amplification of a very weak signal. The search for a solution to this problem led to a solid-state device called the parametric microwave amplifier in 1957. It consisted of a germanium diode detector, "pumped" at a lower frequency by a miniature pencil-type electron tube. to amplify the signal. Another type of EHF amplification was accomplished in 1957 by the maser (*q.v.*)—an ammonia- or helium-filled oscillator operating at temperatures close to absolute zero. The maser uses a cavity resonator tuned to the molecular resonance frequency of the gas.

John Bardeen and W. H. Brattain introduced another kind of semiconductor in 1948 that became kno n as the transistor (*q.v.*). They discovered that a metal point resting on a germanium crystal, when emitting a forward current into the crystal. would influence the reverse current in a nearby metal collector point. W. B. Shockley. an associate of Bardeen and Brattain, developed the theory and distinguished the different types of transistor junctions. The 1956 Nobel prize in physics was awarded to Bardeen, Brattain and Shockley for their work in this field.

3. Radiotelemetry for Missiles and Satellites.— The age of rockets and missiles brought with it the need for providing great amounts of information from test flights, so that performance could be evaluated. The process of encoding instrument readings. transmitting them on multichannel radio circuits and recording the data at ground stations developed into a special engineering field called telemetry. Later, with the advent of artificial satellites, and especially in the case of manned space flights, radio played an indispensable role in controlling orbital paths and relaying back to ground stations data that were obtained outside the Earth's atmosphere.

The transparency of the atmosphere to the passage of UHF and SHF radio waves was verified by reception of radar echoes from the Moon, first accomplished in 1946. By 1958 UHF voice transmission by lunar reflection had been proved feasible. opening the way to communication between any two points on Earth that were simultaneously within sight of the Moon. Extending this idea, successful experiments were conducted in communication by means of signals reflected from artificial satellites as well as signals received and retransmitted by satellites. Plans were under way in the U.S. in the early 1960s for a system of international communication utilizing a number of relay satellites in orbit about the Earth.

See also SPACE EXPLORATION.

VIII. FACTORS AFFECTING RADIO PERFORMANCE

1. Mechanism of Propagation.— When a charge of electrons is guided along a wire in response to the application of an electromotive force to one of its ends, a concentric electromagnetic field (which takes a form roughly analogous to parallels of latitude about the earth's axis) is formed about it. in a direction determined by the familiar righthand screw analogy of electric current. At the same time an electrostatic field is produced whose lines of force (again roughly by analogy like the earth's great circles of longitude) are everywhere at right angles to the electromagnetic field. This twofold field is formed outwardly to great distances from the wire, the wave front of the disturbance, involving collision of electrons in space, moving forward at the velocity of light. In this field is stored the energy of the electric charge on the wire. The combined field should not be thought of as having been established in a static manner. Because the electron flow along the wire takes the form of a wave, there is a building up of potential, a transformation of energy and a reflection from the wire's open end after the manner of a sound wave in an open organ pipe; possibly a second reflection from the opposite end, and so on until the wire is charged and the energy of the charge is completely stored in a steady field.

At this stage. removal of the electromotive force from the end of the wire causes collapse of the field and return of the energy to the wire. In an electromagnet the wire is wound in a coil about an iron core for the purpose of confining the field to a small area. The collapse of the field when the circuit is broken and the oscillating nature of the return of energy to it are made evident by the spark which occurs at the open contacts. In this case the inductive component of the collapsing field is high, the radiation component low. In the antithetical case of a straight antenna wire, the induction field is low and the radiation field is purposely made high. Radiation is promoted — indeed it is made possible — by applying to the antenna continuously reversing polarities of electromotive force, created by an alternator or more often by vacuum tubes or valves oscillating in tuned inductance-capacitance circuits in the transmitter. at radio frequencies (10,000 c.p.s. or more). The rapidity of reversals results in the forming of successive oppositely poled fields before the initial ones have had time to restore. to the antenna to which they were bound, the energy due to the initial fields! collapse. Thus the initial fields are detached and set free to continue onward and outward at the velocity of light in air. At frequencies lower than those used in radio, such detachments of energy are entirely insignificant. Even at radio frequencies there is little radiation from a transmission line electrically balanced with respect to the earth, consisting of a pair of parallel wires. closely spaced, fed simultaneously with opposite polarities; such low-loss transmission lines are often used to conduct power from transmitters to certain types of antenna proper. Radiation does occur when the parallel wires are moved apart or to an angle with each other; maximum radiation occurs under conditions of maximum unbalance, which is the general condition of an aerial or antenna wire in vertical relationship to the horizontal plane of the earth's surface. Another condition of unbalance is represented by the doublet, or dipole, consisting of a straight wire or rod fed from a discontinuity at its middle. In both these cases. controlled unbalance may be said to have produced effective coupling of guided power in the transmitter and antenna to the medium of propagation — that is, the transformation to radiated power is efficient. Receiving antennas and receivers are also effectively coupled to the medium of propagation by the same considerations of design. In fact, except for complications of economics, site limitations, the direction of arrival and polarization of the wave front and the necessity to discriminate between the wanted signal and interfering signals, sending and receiving antennas are alike in form and purpose and by the theorem of reciprocity are interchangeable.

The respective functions of transmitters and receivers is to emit and extract power to and from the medium of propagation. At the point of reception. the transverse wave associated with each ray of propagation may be represented by electrostatic and electromagnetic vectors lying at right angles in a plane normal to the ray. the electrostatic field being measurable in terms of potential gradient (microvolts) per unit of wave-front length (the metre), as applied against the effective height of the receiving antenna. In free space. away from complications resulting from proximity to the earth and from the constitution of the earth's atmosphere. the receiving field intensity can be calculated in terms of the current in the transmitting antenna. the frequency or wave length of the electromagnetic disturbance and the distance between transmitter and receiver. In the case of low frequencies at all distances, mathematical calculations can give useful figures of field intensity as foundation for further consideration of the variables of the transmitting medium.

Sky *Waves.*—Much effort has been expended by researchers in theoretically establishing, examining and measuring the now well-understood complexities of the propagating medium. The original Kennelly-Heaviside concept of stratified ionization of the upper atmosphere has been expanded to account for the observed and measured behaviour of radio sky waves. When solar radiation impinges upon the atmosphere from above, it is absorbed unequally at various levels. giving rise to the formation of layers with differing refractive (hence reflecting) properties. In the process of absorbing solar radiation, electrons are detached from gas molecules. The density of the electrons during the daytime and the rate of their recornbination with the ionized particles at night determine the changing usefulness of the layers to return radio waves to the earth. Several successive layers are postulated, each characterized by partial inversion of the vertical gradient of ionization density. with the highest value in the mid-position of each layer. The layers have been given designations and their approximate virtual daytime elevations above the earth's surface have been determined as follows: D. 50–90 km. (30–55 mi.); E. 110 km. (70 mi.); F_1, 175–200 km. (110–125 mi.); F_2, 250–400 km. (155–250 mi.). Ionization density is greatest in the outer F_2 and least in the inner D layer. At night the D layer disappears and F_1 loses its identity by combining with F_2 at 300 km. (185 mi.). Sunset and sunrise produce diurnally unstable conditions, as the layers rise and fall. Ionization and height vary also with the seasons and with latitude, in accordance with the altitude of the sun and duration of the hours of daylight. While all layers absorb some energy of the wave front by electron collision in the process of refraction. the air density in the D layer produces absorption with little refraction. In the other layers, propagation is best at night, and attenuation of high-frequency signals by absorption in the daytime increases sharply as the frequency used is lowered.

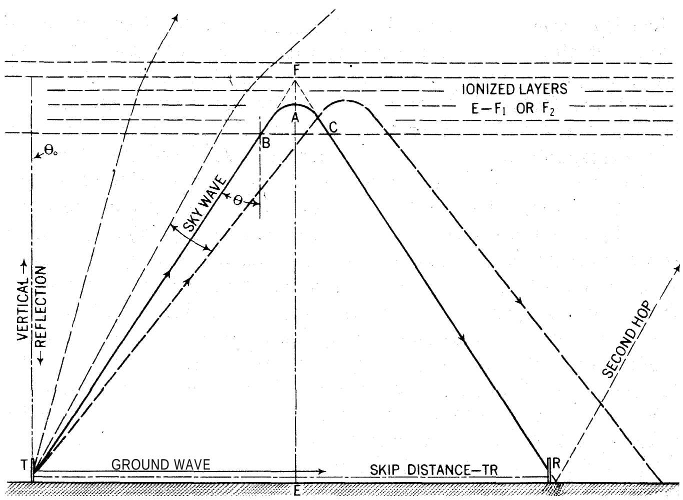

FIG. 6.— RADIO WAVES, SKY PROPAGATION (*see* TEXT)

Double Refraction.—Because of magnetoionic interaction between the earth's magnetic field and the free electrons whose progressively increasing drnsity refracts radio waves, the latter undergo double refraction and are split into two elliptically polarized components. The refraction indices and the absorption of the medium are both different for the two, so that a somewhat unstable, emergent resultant wave exhibits elliptical polarization. This has negligible effect upon the handling of message traffic, but does adversely affect the degree to which direction finders yield correct bearings for navigational purposes.

Critical *Frequencies.*—Important to the course which radio waves take through the refractive layers is the discrimination offered to their transit by virtue of their frequency. As frequencies are increased. experimental waves directed straight up toward the zenith have been found to require ever higher electron densities if they are to be reflected downward. There is a critical frequency, f_c, higher than which the waves will pass on through the layer and not be returned. This property of frequency discriminatiop is still effective when the angle of incidence, θ_0, is changed from the experimental 0° at vertical incidence to its practical value. θ, shown in fig. 6. Here the wave passes from point of transmission T to point of reception R through refraction along the arc BAC within a layer having an effective height of FE. The highest frequency which will travel the course TBACR has been called M.U.F., the maximum usable frequency for distance TR. height FE and the electron density in the layer. The M.C.F. bears to f_c the relationship: M.C.F. $= f_c$ *secant* θ. Government laboratories make available to radio station technicians graphs and nomograms predicting what M.U.F. will be under given circumstances, taking into account f_c, the time of day at longitude of FE. the latitude of FE, the season of pear! conditions related to the 11-year cycle of sun-spot maximum, the electron density and distances approximating TR and height FE. Transmitting station T will use if available an optimum working frequency of about 85% only of the M.U.F. to afford leeway for approximations used in the predictions and for propagation abnormalities. It is evident that if the frequency used exceeds M.U.F., the signal will follow the straight line TBF and be lost to R, instead of taking the trajectory TBACR. On the other hand, if the working frequency is reduced too much, the layer will absorb too much of its energy: signal strength at R will be too low, or an uneconomical power level will be required at T. The lowest useful high frequency, called L.U.H.F., is roughly half the M.U.F.; its calculation is complicated by variables connected with receiving conditions.

Modes of Transmission.—Fig. 6 depicts what is known as "one-hop" transmission from T to R. If R were twice as far removed from T. the same frequency could be used in two-hop propagation. As a matter of practice, two-hop and three-hop propagations are common and offer no difficulties compared with single hops so long as conditions in the reflecting layer are uniform. Along great circles of the earth, like meridians, which do not cut through the ionospheric transitional effects of sunrise and sunset, multihop transmissions girdle the globe, not only once but several times. and have required that special precautions be taken to prevent unwanted "echo" signals.

Skip Distance.—Assume that in fig. 6 the transmitter is emitting the M.U.F. but that the wave, as is ordinarily the case, is not the single ray TB but a rather wide solid cone of rays with apex at T, fanning out a few degrees with TB as an axis. Confining attention to the plane of the paper, all the rays in the cone to the right of TB will be reflected and fall at points to the right of R. All the raps to the left of TB (by definition of M.C.F.) will pass through the layer unreflected. No signals will reach the ground between T and R from the sky. TR is the skip distance. If the antenna at T is omnidirectional. TR defines the radius of a ground circle about T lying within the skip distance associated with the M.U.F. used.

2. Propagation Variables.—In relation to its medium of propagation. telecommunication has to concern itself not only with the fairly stable complexities which have been described but also with instabilities. For at times the refracting ceilings which the layers present to radio waves from below are almost mirrorlike and still, at other times they undulate. giving rise to shifting transmission paths that change phase interference relationships and polarization of wave fronts at points of reception. Again, especially in the auroral regions, extending 23° in radius about the earth's geomagnetic poles, and particularly around times of the equinox, ionization. also giving rise to aurora polaris, causes severe turbulences and abnormal absorption in the ionosphere. The earth's magnetic field converges on the arctic regions, leading charged particles from the sun to bombard them. The F_2 layer. especially, is adversely influenced during periods of abnormal earth currents. A statistical correlation has been observed between high sunspot numbers. the location of spots on the sun's limbs) the period of rotation of the sun on its axis and poor sky-wave propagation due to effects of extraordinary ultraviolet radiation into the upper atmosphere. A more recent theory identifies sunspots, earth currents, aurora and ionospheric turbulence as concurrent effects that find a common cause in critical juxtapositions of planets in the solar system. Sudden solar flares or eruptions, accompanied by direct ultraviolet radiation which reaches down into the low D layer on the light side of the earth. results in abnormally high absorption in that layer, whose normal characteristic is to absorb. rather than to refract, wave-front energy. The result is radio blackout. lasting minutes to hours. to which the names Dellinger effect and SID (sudden ionospheric disturbance) have been applied. Radio communication using sky-wave propagation is stopped for the duration of SID because of the inability of radio waves to reach the E and F layers.

Sunspots rotate with the surface of the sun and thus exhibit a periodicity of 27 days in repeating their influence upon radio transmission. The number of sunspots varies over an uneven 11-year period.

Sporadic Transmission.—Not all the variables of the atmosphere are adverse to the propagation of radio waves. Some of them make possible transmissions which otherwise would not occur. One has been given the name Sporadic E. to designate what behaves like a cloud stratum of ionization. E_s, with a "blobby" subsurface from which propagation is neither by refraction or reflection but is the summation of contributions of scattering. by secondary emission. from a multiplicity of sources closely spaced. Because integrated. such sources may give reliable transmission of very high frequencies below 150 mc. if the beam is aimed nearly tangential to the earth's surface. These transmissions are at frequencies exceeding the M.U.F. of the E layer. They are at a maximum in summer and in zones of visible aurora. Unlike refraction. the mechanism of scattering transmits in all directions from the ionized layer. This may cause direction-finder inaccuracies if, unknown to the manipulator taking a bearing, he happens to be standing within the skip zone of the transmitter. In that event he will be receiving the transmitter's signal not upon the observed bearing of a primary source but upon that of a secondary. scattering source located at some point in the E_s zone having no valid geographical relationship to the point of primary signal emission. The error may amount to 180°.

In the heterogeneous troposphere there exist, as a result of air turbulence, eddies demonstrating deviations from mean dielectric constants (and hence refractive indices) with which they are surrounded. These discontinuities produce scattering effects that at times cause abnormally strong signals. at others abnormally strong interference. In the troposphere. also, where the very high frequencies are transmitted. the air may stratify as to its quasi-optical refractive index, under meteorological influences; in such a way that radio waves are either led along a plane of maximum index between layers of lower index, or are confined between a layer and the earth. In either event, being trapped as though in a duct or wave guide leading over the horizon to distances beyond line of sight. attainable distances of communication are increased. Some observed instances have proved amenable to wave-guide analysis.

Diffraction.—Somewhat akin to scattering is diffraction. the bending of super-high-frequency waves around an obstacle. building or the protuberance of the horizon, thus increasing the service range of a transmitter. The intersection of the beam with the horizon defines a point above which the atmosphere may be thought of as a radiator of secondary emissions. In microwave beam practice. passive reflectors are sometimes employed to make definitive the jumping of an obstruction in lieu of diffraction.

3. Interference.— Proper reception of radio signals depends upon ability to receive wanted signals that are stronger than unwanted signals and accompanying noise. Another station using the same frequency in a different part of the world is an example of an unwanted signal. Another instance is a station whose frequency has been assigned so closely to that of the wanted signal that the harmonic content of the unwanted signal overrides or beats with the wanted wave. If the interference is caused by the interfering station's exceeding its authorized tolerance for frequency drift, the remedy lies in having the offending station put back on its assignment. Assuming the interfering station to be on its proper frequency, unless the situation can be cured by use of directive receiving antennas, relief must be sought from the authorities who made the assignments. Regulatory authorities have adopted and enforce standards of frequency departure tolerances! maximum harmonic content of emitted waves and authorized maximum power to be employed. in order to keep interfering signals within practical control. Based upon these factors, with additional allowances for filter inefficiencies and frequency drift inherent in receivers. the width of bands for all types of emission and modulation rates have been specified on a world-wide pattern.

Among the types of interference sometimes encountered for which there is no ready remedy at the receiver is cross modulation. When a powerful transmitter's wave strikes the ionosphere, the free electrons. which determine the dielectric constant and therefore the effect of refraction, are agitated to collide with ionized molecules at rates varying from high to low in accord with the wave's modulation. The wave front from another transmitter, striking the agitated layer at that point and at that time with a modulation pattern of its own. will be subjected to cross modulation from the more powerful wave.

4. Signal-to-Noise Relationships.— If a received signal is clear of interference from unwanted signals, its field strength can be amplified to any degree permitted by the thermal noise and vacuum tube shot effects in the initial stage of the receiver. These place a final limitation upon amplification, but serve to limit it only in the very high-frequency and super-high-frequency bands where other forms of interference are absent. All efforts at the receiver are therefore bent upon improving signal-to-noise-level ratio. S/N. The three avenues of approach are to improve S, to mitigate N or to introduce some distinguishing characteristic into S at the transmitter (frequency or phase modulation. for example) so that the receiver will be more responsive to S than to N.

Improvement of the signal may be achieved by increasing power at the transmitter. by choosing a type of modulation such as pulse-position modulation in which bursts of high power are obtainable without overloading vacuum tubes, by adopting directive antenna arrays or by frequency-diversity transmission. At the receiver many manipulations are possible, including choice of suitable space-diversity antennas. crystal-driven stabilizers and filters designed to accept all possible power of the carrier and its necessary side-bands and harmonics and to reject all other signals.

Antenna *Gain.*—Modern antennas for nonmobile use are designed to favour concentration in azimuth. or direction toward the correspondent station. of as much as possible of the transmitter's power. They are of two general classes: antenna arrays and wave antennas. Arrays take advantage of interference between two, three or more like antenna structures so placed with respect to wave length and the line of desired propagation that their power adds in the forward direction and cancels toward hack and sides. In a receiving array this results in desirable discrimination between a wanted signal and an interfering disturbance or signal arriving from a different direction. The power advantage which an array or other form of directive antenna achieves is called the antenna's gain. It is greatest for multielement VHF arrays and SHF reflectors and lenses. A wave antenna is generally less effective in concentrating its beam than an array, but in the larger forms associated with the lower frequencies it has economic advantages and will effectively handle a 2:1 ratio of frequencies. Some large wave antennas are steerable in range. Such a steerable antenna is in the shape of a rhombus or diamond floating on pulleys attached to four poles and so arranged that if the short diagonal is purposely altered in length by force applied through the pulleys, a counterweight pill correspondingly adjust the length of the long diagonal. keeping the antenna taut. The antenna wires at one end of the long diagonal are connected to the station feeder; wires at the opposite end terminate in resistors. When the long diagonal is altered. the angle which the sky wave, emitted from it, makes with the earth plane is modified. By manipulation of antenna configuration, therefore, the vertical angle of the wave's departure can be aimed at the point of reflection in the ionosphere. If the long diagonal was put in proper azimuth when the supporting poles were set. the beam will fall directly upon the point of reception. There an array of similar rhombic antennas a mile long may be lined up along the path of propagation for phasing and integration of their outputs. some having been steered low on the horizon to receive the one-hop mode of propagation and others steered higher to respond to other modes.

Fading.—Of the variables in propagation encountered in maintaining received signal strength at a high level, fading is the most widespread and serious. The term fading is broad enough to comprehend temporary loss of field strength at a receiver for any cause associated with the medium of transmission. Already discussed have been the common causes of fading experienced by waves taking any one path between transmitter and receiver. There remain to be considered the complications arising when a wave front takes more than one path at a time. By the same principles of wave interference met with in the study of optics and sound, if the wave front be reflected at two or more points and the reflected rays arrive at the receiving antenna in phase, their effects will add and the signal will be strengthened; if the rays arrive 180° out of phase, their effects will cancel and the signal will disappear; if the out-of-phase condition takes an intermediate value. there will be a corresponding change of signal strength. This phenomenon is evident whenever the ground wave interferes with a sky wave; when two sky waves take modes of propagation involving a different number of hops; or when one of the modes is along a layer. or between two layers; when, in communication between two airplanes in flight or between two beam radio towers. a direct wave beats w th another reflected from the ground or from air-layer interfaces caused by temperature-density inversion; or when the arrival waves have taken different routes in the horizontal plane; or one in the horizontal. the other in the vertical; or when polarization rotation occurs in a different manner or to different degree over two routes, or is caused by double refraction. Fading of all these types is called multipath interference. It is rare at very low frequencies. At other parts of the spectrum the fading occurs in cycles whose rapidity increases from around 60 times an hour at 1.000 kc, up to millions of times a second in the SHF and EHF bands. This rapid increase in the fading rate as transmitted frequencies are raised explains the occurrence of selective fading within sidebands so wide that the effects at the top of the sideband do not coincide with those at the bottom. The discovery that fading of a received signal does not occur simultaneously at two points that are three to ten wave lengths apart led to the invention of space-diversity systems of reception. The outputs of separated antenna-receiver systems, equipped with independent automatic volume controls and tuned to the incoming wave, are fed into a common mixing and limiting system that delivers a substantially constant signal to the terminal apparatus, even during periods when the fading is severe.

5. Radio Noise.—Industrial *Noise.*—Upon the assumption that in achieving the best possible signal-to-noise (S/N) ratio everything has been done to favour S, the qualities of N remain to be examined. Noise may be divided into two categories, man-made and natural. Man-made or industrial noise is greatest in the cities, least in rural or isolated localities. The latter are therefore preferred for receiving sites. The chief cause of man-made noise is electrical circuit transients which cause radiation from portions of circuits where sparks occur. Switches, motors, ignition systems are offenders; so are X-ray apparatus, diathermy machines and industrial precipitators, high-frequency heating and other equipment employing radio frequencies. Mitigation at the receiver is difficult. The use of directive antennas, wave traps and narrow-band receiver filters is sometimes effective. Usually the correction of industrial noise conditions is sought at their sources, by shielding or isolating radio-frequency circuits.

Atmospherics.—Noise from natural sources, entering the receiver by way of the antenna and affecting the receiver output in the same way as amplitude-modulated signals, takes two forms: atmospheric and extraterrestrial. The super-high-frequency band (centimetre waves) is the only one free from both forms of extraneous noise; so that in that band, receiver thermal (or resistance) noise alone limits the amplification level. Atmospheric noise, or static, is the characteristic natural interference which has to be dealt with in radio. At point of reception it represents the integration of the field strengths there apparent from nearby and distant thunderstorms going on within signaling distances, transmitted by means of ground wave and sky waves of all modes in accordance with the same laws which govern signal propagation. Atmospherics are at a maximum at night on account of sky-wave transmission from great distances. They are stronger in summer than in winter. weaker in high latitudes than in the tropics. Their sources are concentrated somewhat in geographical areas like the eastern Caribbean sea, where median values of field strength are shown by measurement to be high. Directive antennas are frequently oriented to discriminate between direction of arrival of atmospherics and the wanted signal. Since natural atmospherics, like man-made disturbances, contain random frequencies over a wide band, filters are introduced into receivers to reject sharply all noise except the components necessarily admitted with the signal sidebands. Amplitude limiters are also used.

Extraterrestrial *Noise.*—Extraterrestrial noise interferes with radio telecommunication in the very high-frequency band (metric wave lengths) and down to 20 mc. There its strength is. roughly, 20 times the thermal noise in the receiver. It is attributable to influences classified as galactic (stellar or cosmic), solar and meteoric. Galactic noise is at a maximum from the direction of the region of Scorpio and Sagittarius, in the galactic centre of the Milky Way.

Solar noise is of lower field strength than galactic noise at frequencies below 30 mc. but is appreciable at 100 mc. and more. Like cosmic noise it is of random nature, fairly constant in amplitude except at times of abnormal solar disturbances. At such times its strength. at 100 mc.. may exceed galactic noise. Solar noise increases are often concurrent with other effects of solar eruptions already mentioned—the influence of ultraviolet light in increasing D-layer absorption of radio-wave energy, and turbulences in the E and F layers which make them temporarily incapable of refraction and reflection. See RADIO ASTRONOMY.

IX. USE OF THE RADIO-FREQUENCY SPECTRUM

The value of the radio spectrum depends upon the skilful management of this natural resource. Radio waves recognize no political boundaries and therefore hold the threat, unless controlled, of interfering with radio operations in neighbouring and even far distant countries. Governments enforce within their own territories agreements upon such matters as call signs for identification;' allotment of frequencies to specified services; limitations upon the type of emissions (modulations), bandwidths and power which may be employed; and specifications leading to full occupancy of each band.

1. Frequency Sharing.—Congestion makes it necessary to adopt expedients for making maximal use of the various available frequency channels by assigning a single frequency to simultaneous use in different parts of the world, and by requiring stations to share their frequencies with others, to take advantage of differences in time zones or paucity of traffic to be handled. The urge to conserve spectrum space is made evident, in large transoceanic radiotelegraph operations, by the practice of assigning a single transmitter to cover the requirements of more than one circuit, Such forked use of a transmitter will cover from 1.5 to 2.0 channels of communication. On the most important circuits two transmitters are often allotted for dual operation, so that if transmission on one fails, service will not thereby be interrupted. Pairs of frequencies in a station's complement are also involved in dual emission on most circuits during twice-daily periods of transition between optimum uses of either wave.

2. Modulations, Bandwidths and Tolerances.—The bandwidth occupied in the spectrum by any emission depends upon the type of modulation, being narrow for hand-keyed Morse telegraphy, considerably wider for voice broadcasting and very wide for television. Bandwidths are therefore specified in accordance with emission types. A bandwidth may be considered the minimum safe separation between adjacent carriers so modulated. It includes the "guard-band" protection necessary to prevent overlap of its fundamental and harmonics with those of adjacent channels, if frequency deviations are held within specified tolerances. Except for single-sideband (SSB) operation, the band is considered as bisected by the assigned frequency of its carrier.

The types of emissions permitted and bandwidths specified in the international regulations annexed to the Buenos Aires convention of 1952 are shown in Table I.

TABLE I.—Radio Emissions and Their Bandwidths

Low Frequencies.—Groups 1 and 2 in Table III, the VLF and LF or ground-wave ranges; alone are capable of following the curvature of the earth. These ranges! called collectively terrestrial radio, are therefore used for long-distance communications as well as for navigational radio.

In the absence of any available alternative. VLF and LF radiotelegraphy was the favoured method for transoceanic use prior to 1927. After that year it rapidly gave ground to transmission on higher frequencies, but served as stand-by to protect short-wave circuits, especially where routes cut the auroral zones that exist around the earth's geomagnetic poles. Even this utility largely disappeared when: around 1946, electrical relay points located in or near the tropics were found capable of dividing east-west circuits between terminals into two coupled links, the one availing itself of relatively dependable north-south transmission, the other conducting the east-west circuit components through the tropical belt where auroral zones could be by-passed.

The longer VLF and LF waves interested Marconi and other early workers in transoceanic wireless telegraphy because of the results, measured in working mileages, that they yielded. Transmission is dominated by a ground wave propagated to distances up to about 1,000 mi.. plus a relatively stable mode of multiple mirrorlike reflections between the two concentric spheres consisting of the earth's or sea's surface and the troposphere and low ionosphere. These act as an effective and efficient wave guide. The rate of decay of the ground wave depends upon the conductivity and dielectric constant of the ground; except for the very lowest frequencies and extreme distances the decay rate is less over water than over land. The wave-guide effect tends to conserve signal strength over global distances. Except for sunrise and sunset effects, fading of signals is not a factor with long waves. The three chief drawbacks to long-wave operation are: the prevalence of noise and static (lightning disturbances are also propagated to global distances by the wave-guide mode of transmission) ; the requirements of large amounts of power to radiate from an antenna at the very low frequencies and to override the static; and the necessity for building large, high and consequently expensive antenna structures. VLF waves are generally not suitable for telephony because of the low ratio of the modulation to the carrier frequency.

Medium and High Frequencies.—MF transmission, Group 3 of Table III, occupies a mid-position between ground-wave and sky-wave propagation and is best understood by reference to conditions in adjacent bands. The lower part of the band found early use in ship-to-shore wireless telegraphy. Antenna sizes and power requirements are adapted for marine work; distances workable, however, are shorter than for high frequencies. The middle part of Group 3 is reserved for broadcasting. Its characteristics are well known to the public, a ground-wave service area of greater or less extent depending upon power assigned and a night area served by sky-waves subject to fading. Static conditions are moderate. Beaming of antennas and sharing of hours of operation among stations are practices that prevent mutual interference and increase public service.

Group 4, the high frequencies or short waves, are transmitted over global distances by multiple-hop refractions through the ionosphere. The HF band is one of the most crowded portions of the spectrum. It is generally true that ionospheric transmission ceases to be practical beyond 30 mc.

Higher Frequencies.—Groups 5 and 6 of Table III, VHF and UHF, the metre and decimetre waves, were extensively investigated during World War II. VHF transmission is primarily limited to line of sight, but it is stable and suitable for such uses as television broadcasting. With the advent of UHF transmitters of very high power, a new type of UHF transmission called UHF scatter propagation, was discovered. This effect was largely attributed to wave refractions in the troposphere (altitudes below 10 mi.). UHF scatter permitted the reception of weak but stable signals far below the horizon. Television transmission over several hundred miles by means of scatter propagation was accomplished in 1953.

Super-High Frequencies.—Group 7 (centimetre) frequencies are often referred to as microwaves. While Groups 6 to 8 are all quasi-optical, Group 7, SHF, is particularly adaptable to quasi-optical devices such as focusing antennas using parabolic reflectors, dielectric lenses and horns for concentrating and directing narrow beams of communication power. Expansion of use of this band was a spectacular development of the 1950s. Because of their extremely high carrier frequencies, microwaves furnish an ideal medium for such high-speed communication as multiplex telegraphy and telephony and television relays.

Microwave beams at 4,000 mc. ($7\frac{1}{2}$ cm.) have been used in the U.S. transcontinental television network, relaying video signals and hundreds of telephone channels from coast to coast. At an average span of 25–30 mi. between stations, more than 130 repeaters were used in each direction. Most of these relay stations were fully automatic and were installed in unmanned shelters, some accessible only from the air. A telegraph microwave is similar. Working on a frequency of about 4,000 mc., its paraboloid reflectors behind dipole antennas are located at the tops of towers and within line of sight over the horizon. Changes in the atmosphere seldom attenuate the signals beyond the ability of terminal equipment automatically to compensate, and diversity reception makes the outage record all but perfect. The frequency is not high enough (as at 10,000 mc., for example) to be interfered with by effects of scattering from hail. raindrops or snow; nor in the region of 0.5- to 2-cm. wave length where resonance of particles in water vapour. clouds and oxygen gas interferes. Again, 4.000 mc. is not low enough to be affected by atmospheric or industrial noise. The limiting transmission factors are the thermal agitation and vacuum tube shot effects in the first stages of the receiver, made troublesome because they are amplified along with the received signals. Transmitting power tube output is the order of one-tenth watt to ten watts. Double-frequency modulation is employed, the subcarrier being one megacycle. Signaling intelligence occupies the broad band from 30 cycles to 150 kc., accommodating 32 voice-frequency bands each capable of transmitting 16 teleprinter (or 32 multiplex printer) telegrams per minute.

The EHF or millimetre waves were at the forefront of radio research in the 1960s, and EHF held great promise for long-distance communications. Millimetre waves can propagate with low loss per mile through straight, hollow pipelines, if the so-called circular-electric mode is set up in the lines. In this mode, the lines of the electric field close upon themselves without touching the wall of the guide. In this way, wall currents in the guide are avoided and losses actually decrease with increasing frequency.

4. Radio **Spectrum** Management. — International agreements on radio take the form of conventions and annexed regulations. Like other treaties under international law they are, in general, binding only upon the ratifying states. Nations are not bound to attend the conferences. Delegations are not bound to sign. In signing they may take reservations that release them from particular provisions. Sovereign states may refuse to ratify, or in ratifying may also take reservations. Nevertheless, so greatly does national advantage lie in international co-operation in the radio field, and so unlikely is it that any other method will prevent chaotic conditions in the radio spectrum. that refusals to sign or ratify are rare. By ratifying, a state agrees to pass laws to enforce the provisions of the treaty, subject to its reservations.

International Telecommunication Treaties. — The first radiotelegraph conference of an international nature was called by invitation of the German government in Berlin in 1903, seven years after Marconi's successful demonstration of wireless. This preliminary conference produced the initial draft of an international convention, which was considered, revised and signed by delegates of 27 nations, together with its annexed Radio regulations, at the Berlin Radiotelegraph conference of 1906. At that time the Radiotelegraph union was formed, a governing body modeled after the International Telegraph union, which since its formation at Paris in 1865 had been responsible for the Telegraph convention and the International Telegraph regulations. The London conference of 1912 revised the convention and the regulations. The Washington Radio conference of 1927 inaugurated the subsidiary International Radio Consultative committee (C.C.I.R.), to take its place beside the already functioning consultative and exploratory technical committees on telegraph (C.C.I.T.) and telephone (C.C.I.F.); it also initiated an action, supplementing that of the International Telegraph union (Paris, 1925), to amalgamate the Radiotelegraph and Telegraph conventions. This objective was accomplished through creation of the International Telecommunication union at Madrid, Spain, in 1932, which codified and combined the 1875 Telegraph and the 1927 Radiotelegraph conventions. The regulations annexed to the Telecommunication convention were drawn up separately by a telegraph-telephone conference and by a radio conference at Madrid, as they were again at Cairo, Egy., in 1938.

The Madrid convention and the Cairo Radio regulations were revised at Atlantic City in 1947, at Buenos Aires in 1952 and at Paris in 1959; the Cairo Telegraph regulations were revised at Paris in 1949, with the United States a signatory to telegraph regulations for the first time, and again at Paris in 1558.

Agreements on Frequency Spectrum. — The history of the radio and telecommunication conferences after 1927 traces the shifting emphasis from marine radiotelegraphy to the later wide diversity of telecommunication. The complexity of making frequency allocations to users increased exponentially over the years despite the expansion of the usable spectrum into the upper frequencies.

The Washington conference was the first to produce a comprehensive frequency allocation table covering services other than marine. Its work was carried on at the Madrid, Cairo and Atlantic City conventions. As a result of work at Madrid. an official list of frequencies was produced, showing, among other things, the date of notification to the bureau of the ITU at Berne. Switz., of each use of each frequency and the date each service commenced, as a basis of establishing priority rights to such use. At Atlantic City in 1947 the delegates were faced with the de facto aftermath of World War II. during which the use of radio had expanded at an unprecedented rate under circumstances of enforced inactivity of the Berne bureau.

International Organization. — By the early 1960s there were about 100 member states in the International Telecommunication union. Headquarters had been with the Cnited Nations at Geneva, Switz., from 1948, when the former headquarters arrangement at Berne with the government of Switzerland was terminated. The ITU became a specialized agency of the Cnited Nations by resolution of the UN general assembly, Nov. 15, 1947.

The International Scientific Radio union, with headquarters in Brussels, Belg., is a member of the International Council of Scientific Unions (ICSU), a nonpolitical world organization of scientists maintaining relationships with Cnited Nations and its specialized agencies, particularly UNESCO. ICSU embraces several fields of science, including radio.

Donzestic Regulation. — In accordance with the international conventions, every important country enacted domestic legislation to enable the international provisions to be enforced. In Great Britain and Northern Ireland, control was in the hands of the postmaster general. by virtue of the Wireless Telegraphy act of 1904, subsequently renewed each year. The application of the act to shipping is regulated under the Merchant Shipping (Wireless Telegraphy) act. 1919, and the rules made by the board of trade under this act. In Jan. 1947 the British government. in harmony with other nationalization programs. purchased the assets of the British company which from 1929 had represented the merged international telegraph interests of cable and wireless; in the self-governing dominions similar action was taken. The government-owned operating company continued in control of operating the world-wide network until April 1950, when operations and assets in the United Kingdom were transferred to the British post office. In 1952 the post office put its international telecommunications under an external telecommunications executive.

In the United States, commercial radiotelegraph services are operated by private enterprise, regulated by the Federal Communications act of 1934, as amended in 1943. The law is administered by an appointive group of seven members constituting the Federal Communications commission. Among the features regulated by licences or rules of the commission are: assigned frequencies of transmission, tolerances of departure from assigned frequency, types of emission, transmitter power, specifications of performance relating to distortion and interference, hours of operation and qualification of operators and technicians.

RADIOACTIVITY, ARTIFICIAL. Artificial radioactivity was discovered by Irene and Frédéric Joliot-Curie early in 1934. They made the exciting and important observation that the positrons which were emitted when aluminum was bombarded with alpha-particles (HE'') from polonium continued to be emitted after the source of alpha-particles was removed. The intensity of positrons decayed exponentially with a half-life of about three minutes. Immediately following the discovery oi Curie and Joliot. many more artificial radioactivities were produced by several groups of workers. mainly as the result of bombardment with high-speed charged particles from artificial sources. Many substances were rendered radioactive by bombardment with protons and deuterons which were accelerated in various types of high voltage apparatus; H. R. Crane and C. C. Lauritsen used a "cascade transformer" potential source, J. D. Cockcroft. C. W. Gilbert and E. T. S. Walton employed a voltage-multiplier circuit. R. J. Van de Graaff and M. A. Tuve and L. R. Hafstad used the "electrostatic generator." while E. O. Lawrence and co-workers accelerated the charged projectiles in the magnetic resonance accelerator or cyclotron (see ACCELERATORS. PARTICLE). A large addition to the list of radioactivities was made during 1934 and 1935 as a result of the work of E. Fermi and his associates, who produced the activities by the neutron bombardment of the elements. Since the Coulomb field of the nucleus does not oppose the entry of a neutron, as it does that of a charged particle, a large number of elements throughout the entire range of the pefiodic table were rendered radioactive in this manner.

By the end of 1935 about 100 artificial radioelements were known, and a review of the subject of artificial radioactivity, which included a discussion of the methods of production, was published by L. N. Ridenour and D. M. Yost in Chemical Reviews. Further work with deuterons. neutrons and protons, and in addition, high-energy alpha-particles and gamma-rays, from artificial sources: made a large increase in the number of induced radioactivities. A number of tables of radioactivities have appeared in various physical journals listing the radioactive isotopes, their properties and methods of production. For example, J. J. Livingood and G. T. Seaborg published, in the Reviews of Modern Physics (Jan. 1940), a table which described the properties of about 330 artificial radioactivities and Seaborg compiled a table which appeared in the same journal in Jan. 1944, which described the properties of about 420 artificial radioactivities.

The large currents and high energies available, especially with the cyclotron, have resulted in the discovery of a large number of radioactive isotopes (see ISOTOPE). The accomplishment of the self-sustaining nuclear chain-reaction in uranium marked another milestone in the field of artificial radioactivity. As a result, by 1961 there were known more than 1,000 induced radioactivities, there being at least one radioactive isotope for each of the elements of atomic number 1 to 103 inclusive. Because of the prodigious number of neutrons generated by the chain-reactor, it is possible to produce easily weighable amounts of artificial isotopes, and hence tremendous intensities of radioactivities, where the transmutation can be induced by neutrons.

GENERAL CONSIDERATIONS

The decay of the artificial radioelements follows, of course, the well-known exponential law, just as for the natural radioactive bodies, and the decay rate for each element is described in terms of a half-life. (The half-life is the time required for one-half of the initial number of atoms to decay.) Likewise the growth of a radioactivity when an element is under constant bombardment follows the familiar growth law, that is, the fraction of the saturation number of atoms formed in a time t is equal to $1 - e^{-\frac{0.69t}{T\frac{1}{2}}}$, where $T\frac{1}{2}$ is the half-life. After a time of activation long compared with the half-life of the substance, the activity reaches a saturation value which can not be increased by further activation (see RADIOACTIVITY, NATURAL).

Although the nomenclature for the artificial radioelements had not reached a standardized form by 1947, most of the investigators in the field had adopted the practice of using the contracted form "radioelement" rather than the more cumbersome term "radioactive element." For example, the well-known radioactivity of 14.8 hours half-life induced in sodium, as the result of bombardment with either neutrons or deuterons. is often referred to as being caused by "radiosodium" rather than the "radioactive isotope of sodium." The former, simpler nomenclature will be used here.

The radiations from the artificial radioelements are very similar in properties to those from the natural radioelements of the well-known uranium, actinium and thorium families (see RADIOACTIVITY, NATURAL and NUCLEUS). Single decay predominates, although numerous examples of chain decays, *i.e.,* cases where the product of the first decay is also radioactive, are known in artificial radioactivity. The beta-particles emitted during the decay of artificial radioactivities have the same continuous type of distribution in energy, with a definite upper energy limit, which has long been known to exist for the natural radioelements. (It is this continuous distribution of beta-particle energy which has led to the introduction of the neutrino, a particle of small or zero mass, one-half unit of spin ($\frac{1}{2}\cdot h/2\pi$) and no charge, in order to preserve the laws of conservation of energy and momentum in beta-decay.)

The upper energy limit for beta-particles decreases as the half-life increases; this Sargent relation (log half-life proportional to log energy) holds only roughly over a range of mass values and must be modified when the nuclear spin change accompanying the disintegration is greater than zero.

Decay by alpha-particle (He^{4+}) emission is fairly common among the artificial isotopes of elements above bismuth just as it is among natural radioactive isotopes in this region of the periodic table. While only the negative beta-particles (electrons) are emitted by natural radioelements, some of the artificial radioelements emit negative beta-particles and some of them emit positive beta-particles (positrons). Examples of radioelements which decay by the emission of both negative and positive beta-particles are known. Some of the decays are accompanied by gamma-rays (high-energy electromagnetic radiation) and some are not, just as in natural radioactivity, and these gamma-rays may be slightly or largely internally converted. (When a gamma-ray is "internally converted" or undergoes "internal conversion," it means that instead of the emission of a gamma-ray there is the ejection of an electron from the extranuclear structure of the same atom that contains the nucleus which is radiating, the kinetic energy of the ejected electron being equal to the difference between the energy of the gamma-ray and the binding energy of the electron.) Radioelements which give off gamma-rays can be detected through interposed material since gamma-rays cause much less ionization than charged particles, and hence are much more penetrating, than beta-particles of similar energy.

Positron emitters may decay by the alternative process of orbital electron capture, a method of decay which, up to 1947, had been observed only with the artificial radioelements. It was suggested by H. Yukawa and others, from considerations based upon the Fermi theory of beta-ray emission, that an unstable nucleus might reach stability by the capture of an extranuclear electron. The first experimental observation of decay by "K-electron capture" (often so called because by far the largest proportion of the orbital electrons captured by the nucleus come from the K-electron shell) was made by L. W. Alvarez, who found that an unstable gallium isotope of 83 hours half-life decayed by this mechanism. Many examples of this type of decay are now known. Decay by orbital electron capture may be unaccompanied by any detectable ionizing radiation except for the X-rays which must be emitted (since the vacant place in the inner shell must be filled with the emission of an X-ray or an Auger electron). However, many examples of orbital electron capture are known where the resultant nucleus is left in an excited state which drops to the ground state with the emission of a gamma-ray or a line of internal-conversion electrons or both. (The name "line of electrons" is often used to describe the monoenergetic electrons which are emitted from, *e.g.*, the K-electron shell, when gamma-rays undergo internal conversion. Some of the gamma-rays are converted in the L-, M-, etc., electron shells. The term "line" arises from the fact that with an electron magnetic spectrograph these groups of monoenergetic conversion electrons appear as lines on a photographic plate in contrast to the beta-particles from a beta-ray emitter, whose continuous distribution in energy darkens the plate continuously over a very broad energy range.) Some radioelements decay by both positron emission and orbital electron capture, some by orbital electron capture alone, and some entirely by positron emission.

Another class of radioactive substances, not peculiar to artificial radioactivity but most thoroughly studied here, are "nuclear isomers." Each member of a pair of nuclear isomers has the same atomic number and the same atomic weight (isotopic isobars) ; they represent two different energy states, the upper and the ground state, of the same nuclear species, differing in energy content and degree of stability. A theory which C. F. v. Weizsacker proposed in order to account for the existence of nuclear isomers ascribes the long lifetime of the upper, metastable state to a difference of several units of angular momentum between the metastable and ground state. This large spin difference forbids the transition from the upper to the lower state in a manner analogous to the forbidden transitions in optical spectra. Each isomer of a pair may be radioactive and decay independently of the other by beta-emission with its own characteristic half-life, or the isomer corresponding to only one energy state may be beta-active, and that corresponding to the ground state may be stable. Some isomers are genetically related to each other; the upper state, rather than decaying by beta-particle emission to a neighbouring isobar, decays by an isomeric transition to the ground state with the emission of a gamma-ray. (The present theoretical explanation for the phenomenon of nuclear isomerism leads to the prediction that the gamma-rays corresponding to an isomeric transition will undergo high internal conversion when the energy is small—of the order of tens or hundreds of kilovolts.) The first evidence for nuclear isomerism in artificial radioactivity was presented in 1935 by B. Kourtchatow and co-workers, and in 1937 A. H. Snell and also W. Bothe and W. Gentner simultaneously showed that an 18-minute period and a 4.4-hour period must both be ascribed to a bromine isotope of atomic weight 80.

METHODS OF CHEMICAL IDENTIFICATION AND CONCENTRATION

The chemical identification of artificial radioelements is based on the fact that isotopes are not appreciably separated by ordinary chemical reactions and the radioactive isotopes of a given element behave in the same manner as the stable isotopes of the element. The property of radioactivity does not influence the chemical behaviour (except in the case of extremely strong activities and then in the same way as an external source would do). Thus, after a transmutation has taken place leading to the formation of a new and unstable nucleus. the new atom has properties determined solely by its new atomic number and will behave chemically in all respects like its stable isotope or isotopes. Often only a few millions of atoms of the unstable transmutation product are formed. The behaviour of an element at such low concentration may be uncertain in many chemical procedures. For this reason, in order to establish the chemical identity of the transmutation product, it is usually expedient and often absolutely necessary-to add a small quantity of that element which is isotopic with the expected or suspected transmutation product. This added material is usually designated by the term "carrier." The carrier element is separated out chemically along with its unstable isotope and in this manner one can establish a radioactivity, with a characteristic half-life, which is isotopic with the carrier element.

In many cases, when the radioelement is not isotopic with the element from which it is formed, the radioactivity can be concentrated in a small amount of material by adding and separating out only a small amount of carrier. Such a high ratio of activity to carrier material (high specific activity) is desirable in many of the investigations which employ radioelements, especially in biological chemistry and physiological and biological studies. The ***specific*** activity may be defined as the ratio of the number of radioactive atoms to the total number of isotopic atoms with which the radioactive atoms are mixed.

When the radioactivity is isotopic with the element which is bombarded, the active isotope is necessarily mixed with a larger quantity of its inactive isotopes. However, it is sometimes possible to effect a separation of the radioactive isotope from the inactive isotopes and hence a concentration of the radioactive isotope in a small amount of material. L. Szilard and T. A. Chalmers were the first to show that radioactive iodine could be separated from ordinary iodine after irradiating with neutrons a nonionizing organic compound such as ethyl iodide. After the irradiation, a small amount of free iodine was added to act as a carrier for the free radioactive iodine, and after this iodine was reduced and precipitated as silver iodide it was found to contain practically all of the radioactivity. This method of concentration, which has subsequently been used to concentrate a number of radioelements, is now known as the "Szilard-Chalmers method." Its success depends upon the removal of the newly-formed radioactive nucleus from its chemical bond in the irradiated compound. The breaking of this bond is a result of the large amount of energy furnished by the recoil from the gamma-rays emitted during the neutron-capture process. The method is not limited to radioelements formed by irradiation with neutrons, but in principle can be applied to other methods of activation. It is, of course, essential that the radioactive atoms set free during the bombardment do not interchange with their isotopic atoms in the irradiated chemical compound. As examples of the application of this method, radioactive iodine, bromine and chlorine can be concentrated, using either organic compounds or the inorganic halogenates. Similarly, manganese dioxide precipitated from an irradiated permanganate is found to carry most of the radiomanganese under certain conditions. Whenever it is desired to use this method in order to produce a radioactive isotope with a high specific activity, a search is made for a compound which contains the element in a form which will not interchange with the freed radioactive atoms and from which the radioactive atoms will be liberated during and separable after the irradiation process.

O. Erbacher and K. Philipp; C. S. Lu and S. Sugden; and S. Roginsky and N. Gopstein developed a number of excellent methods for the extraction with high yields of concentrated radioactive halogens from neutron-irradiated organic halides. One of the techniques employed by Erbacher and Philipp depended upon the adsorption of the radioactive atoms on active charcoal, and Roginsky and Gopstein used aluminum oxide and active charcoal as adsorbents. V. Majer used a trace of colloidal gold to supply condensation nuclei for the deposition of active gold atoms formed in a neutron-irradiated, alkaline gold chloride solution.

A method for the chemical separation of genetically related nuclear isomers, which is a modification of the Szilard-Chalmers method, was invented by E. Segrb, R. S. Halford and G. T. Seaborg. The element which contains the radioactivity corresponding to an upper isoméric energy state is made into a compound suitable for the application of the Szilard-Chalmers method of concentration; the daughter radioactivity, which corresponds to the ground state and which is liberated from this compound as a result of the isomeric transition, is then chemically separable from the parent radioactivity. Segrb, Halford and Seaborg used this method to extract the bromine radioactivity of 18 minutes half-life, in the form of hydrobromic acid, from its parent isomer of 4.4 hours half-life, which was present as tertiary butyl bromide. D. DeVault and W. F. Libby made the same separation by precipitating silver bromide from an ammoniacal solution which contained the 4.4-hour radioactivity in the form of the bromate, while L. J. Le Roux, Lu, and Sugden separated the 18-minute radioactivity as silver bromide from both ethylene dibromide and *n*-butyl bromide. A number of chemical separations of nuclear isomers have been made, employing this principle, and these have been of aid in isotopic assignments and establishing the genetic relationships between the isomeric pairs.

In some cases when the transmutation product is not isotopic with the target element, it is possible to separate it from the target element without the use of carrier. This often gives the pure radioactive element, or compound of the element, in much too small an amount to be seen, detectable only by its radioactivity. A few examples will serve to illustrate the type of physical and chemical properties which may serve to make such a separation feasible.

M. Haïssinsky separated pure radiocopper, produced by neutron bombardment of zinc, by means of electrochemical deposition on lead, while J. Steigman effected the same separation by electrolysis. Segrè found that the radiosodium present in a sample of magnesium hydroxide, after the deuteron bombardment of the magnesium, could be dissolved out of the hydroxide quantitatively by treating it with water.

Partition between solvents affords another method for separating the radioactive isotope in its pure form in the absence of carrier material. D. C. Grahame and Seaborg have used the partition between ether and 6 N hydrochloric acid to separate pure radiogallium from zinc as well as radiomanganese and radiocobalt from iron.

When there exists a large difference in the boiling points, this may be used to effect a separation. For example, a gaseous, radioactive transmutation product can easily be separated from a nongaseous target element or parent element. Alvarez, A. C. Helmholz and E. Nelson have separated practically pure radiocadmium by collecting the vapour after heating deuteron-activated silver to its melting point.

When the radioactive transmutation product forms an extremely insoluble compound, it should be possible to collect the invisible precipitate on the walls of the containing vessel after centrifugation, as has been done for many of the naturally radioactive elements.

Another method of separation depends on the fact that the newly formed radioactive atom may have lost one or more of its extranuclear electrons at the moment of formation as a result of the recoil given to it by the gamma-ray emitted during the capture process. The charged atoms formed in this manner may be collected, during the bombardment of either a gaseous or a liquid substance, with the aid of an electric field. This method of concentration, which is sometimes applicable even when the radioactive product is isotopic with the target element, has been employed by Fermi and his associates and by F. A. Paneth and J. W. J. Fay and J. Govaerts. The collection of recoil radioactive atoms produced during bombardment with charged particles can also be used as a method for obtaining concentrated radioactive samples. A special use is sometimes made of the recoil technique in identifying the daughter isotopes of an alpha-emitter. Because of the great momentum of the alpha-particles, they impart enough recoil energy to the residual nuclei to dislodge them from the surface and allow collection free of other activities.

The use of adsorption techniques, analogous to "chromatography," has proved very effective. By the use of adsorbents of the ion exchange type in columns, and some organic types have proven especially effective, it has been possible to make difficult separations quite efficiently. This method was introduced and the early pioneering work done by G. E. Boyd and F. H. Spedding and W. E. Cohn and their co-workers. Cohn and E. R. Tompkins were the first to show the extreme power of the method by using it to separate neighbouring rare-earth elements.

The chemical work in connection with the identification and extraction of radioactive isotopes can usually be done in laboratories with rather usual facilities. However, in the extraction of radioactive isotopes at high levels of radioactivity special facilities are needed. Thus laboratory facilities for radiochemical research and production work can be classified according to the level of radioactivity involved in the operations—microcurie, millicurie and multicurie. (The "curie," originally the name for the amount of radon in equilibrium with one gram of radium, is now usually taken as the name for the general unit of intensity in radioactivity; a curie of any radioactive material undergoes the same number of disintegrations per unit time as one gram of radium, namely, 3.7×10^{10} disintegrations per second.) Since problems often require manipulations at more than one of these levels it may be necessary to have separate facilities for work at more than one level in a single laboratory. Ordinary chemical facilities are satisfactory for work at the microcurie level. Shielding material is needed between the operator and the equipment, thus requiring specially designed hoods, for work at the millicurie level. Manipulations at the multicurie level must be completely remotely controlled and carried out behind heavy, permanent shielding material.

METHODS FOR DETECTION OF RADIATIONS

There are a number of different types of instruments that are used for the measurement of the intensity of the radiations from radioactive substances. All of the common instruments depend upon the ionization, direct or indirect, produced by radiation. No attempt will be made to describe all of them, but some of those which were being used in 1947 by workers in this field will be mentioned briefly. The best type of instrument for a given problem depends upon the type and energy of the radiation and upon the sensitivity and stability which is required. A knowledge of the absorption curve for the radiation to be measured is often very important, especially if the radiation is of very low energy (*i.e.*, very soft), since this will make it necessary to pay particular attention to the effect of self-absorption in the sample and to use a detection device of the proper design.

One of the simplest instruments, widely used, is the Lauritsen modification of the electroscope, known as the "quartz-fibre electroscope." The electroscope is usually used inside an ionization chamber, which may be filled with any gas, although air is usually used for convenience, and the rate of drift of the fibre across a scale is measured. This instrument, which is suitable for the detection of all types of radiations from radioactive substances, is one compact unit and requires for its operation only a D.C. (direct current) potential source of the order of 200 volts. Its sensitivity is not as large as that of some of the other detection devices. The quartz-fibre electroscope can be used to best advantage with a radioactivity whose intensity is of the order of microcuries (10^{-6} curies), although intensities which are 1%, or even 0.1%, as strong as this can be measured.

A more sensitive arrangement of the integrating type, also suitable for the detection of all types of radiation from radioactive substances, is obtained with an ionization chamber connected to some kind of an electrometer. These chambers which usually consist of an outer cylinder with a central, coaxial electrode, normally use 300 to 400 volts of D.C. potential for their operation and may be designed so as to contain any gas. The gas may be at atmospheric pressure, which is necessary when a thin window is used, or higher pressures may be used to increase the detection sensitivity for penetrating radiation such as gamma-rays. The measurement of extremely soft radiation can be accomplished by introducing the sample into the inside of the ionization chamber. Any sensitive electrometer can be used; both the Edelmann electrometer and the Perucca electrometer have been used in practice and found to be satisfactory. Various vacuum tube electrometer systems have been used and this is the type which is generally used. The ionization current is amplified by a D.C. amplifier and is read as a deflection on a sensitive galvanometer; a modification in which the "rate of drift" of the galvanometer current is read increases the sensitivity for the measurement of the radiations from weak samples. Recently the vibrating reed electrometer has-been developed. This device converts the D.C. voltage, obtained by passing the ionization current through a high resistance, into an A.C. (alternating current) voltage which can be greatly amplified with very high stability. The "rate of drift" method can also be used with this instrument to increase its sensitivity. In general, electrometers are characterized by being useful over a tremendous range of sensitivities from 10^{-4} microcuries (limited by the type of electrometer) to several curies (limited by the design of the ionization chamber).

An ionization chamber of a different design can be used to detect single, heavily ionizing particles, such as protons, alpha-particles, etc., when connected to a high-gain, multiple-stage, A.C. (pulse) amplifier. Complete electrical circuits for the operation of such ionization chambers were commercially available from several sources in 1947. Electrons and gamma-rays (which show themselves only by the electrons liberated from the material they pass through) are not recorded with this arrangement. In a special arrangement, known as the "alpha pulse analyzer," such a type of ionization chamber can be used in connection with a multichannel circuit in which alpha pulses are sorted electronically according to size, hence making it possible to detect and identify the individual components in mixtures of alpha-emitters.

The most sensitive detection device is the Geiger counter, also known as the "point" counter, an instrument which detects individual ionizing particles of all kinds. A modification of the original Geiger counter which was widely used in 1947 is the Geiger-Muller counter, which was also known as the "tube" counter and the "Zahlrohr." With this instrument it is possible to detect the ionizing particles from a source as weak as 10^{-5} microcuries. The Geiger-Muller counter consists of a conducting cylinder and coaxial wire which is insulated from the cylinder. It is filled with some gas such as air or argon at reduced pressure, together with a "quenching" component such as an oxygen-containing gas like alcohol. and is operated with a negative voltage of 500 to 5,000 volts on the outer cylinder. The passage of an ionizing particle through the counter causes a temporary electrical breakdown (*i.e.*, an avalanche of ionization initiated by the first ion pair which is produced and greatly augmented by secondary ionization from collision processes, etc.) between the outer cylinder and the central wire, and this pulse is usually amplified by an A.C. (pulse) amplifier to a stage where it is capable of operating a mechanical recorder in a recording circuit. Complete electrical circuits, together with recorder, as well as counter tubes of many different designs are commercially available from many sources. The circuit which operates the mechanical recorder, and this is generally true wherever such a recorder is used, is usually the "scaling" type, *i.e.*, is so designed that the recorder needs to record only a certain known fraction of all the pulses from the counter and amplifier.

When the particle radiation from the radioactive element is of very low energy; the radioactive material, in the form of a gas, can be introduced into the interior of an ordinary ionization chamber or Geiger-Muller counter. An arrangement which allows a radioactive sample of solid material to be introduced into the interior of a counter and which allows background counts to be made while such a sample is inside, is the "screen-wall" counter described by Libby. Of course, when the low-energy particle radiation is accompanied by gamma-radiation it may not be necessary to introduce the sample into the interior-of the counter or ionization chamber. However, the lower efficiency of gamma-ray detection makes it necessary to have strong samples for measurements which depend entirely upon gamma-radiation.

The "proportional" counter, first described by H. Geiger and O. Klemperer, is a modification of the Geiger and the Geiger-Muller counter which is operated at a lower voltage (and with a higher gain pulse amplifier), so that only heavily ionizing particles such as protons, alpha-particles, etc., are detected.

For most work involving the radioelements the choice of detection device will be made from the following group: (1) electroscope, (2) Geiger-Muller counter, (3) integrating ionization chamber or (4) nonintegrating ionization chamber with linear amplifier. These instruments can be used to obtain absorption curves in order to determine the energy of radiations from radioactive substances. The upper energy limits of beta-particles are usually determined with the help of the relationship of N. Feather, $R=0.543E-0.160$, where R is the range in grams per cm.^{2} of aluminum and E is the energy in Mev (good only for $E>0.6$ Mev), while for gamma-rays the correlation of energy with absorption coefficient as listed in the tables compiled by Gentner and others can be conveniently used.

Brief mention should also be made of other experimental arrangements which are used primarily for detailed studies of the properties and energy of radiations. The beta-ray spectrograph or spectrometer uses a magnetic or electric field to bend. to an extent dependent upon their energy, alpha-particles, beta-particles, internal-conversion electrons, or the secondary electrons from gamma-rays. The particles are detected either by a photographic method or by a counter or ionization chamber. Another arrangement involves two or more counters connected to an amplifier of a type which records the counts only when the counters discharge simultaneously. This "coincidence counter" arrangement is often used to determine the energy of gamma-rays by determining the absorption curve of the secondary electrons which are producing the coincidence counts. In addition, there is the expansion chamber or cloud chamber of C. T. R. Wilson (usually used with a magnetic field), in which can be seen and photographed the water drops which condense along the path of an ionizing particle.

Another instrument which should be mentioned is the secondary electron multiplier tube as adapted to counting purposes. This device, which detects single positive ions, electrons and photons by producing a large current of secondary electrons inside a single vacuum tube, is most useful for special problems in physics where work in a vacuum and an extremely low background (less than one count per minute) are paramount factors. A device proposed by P. J. Van Heerden is the "crystal counter" for detecting electrons. In this method the dielectric properties of a crystal of some material, *e.g.*, silver chloride, are used in such a manner that a pulse suitable for detection and recording can be generated upon the passage of an ionizing particle through the crystal.

An ingenious adaptation, introduced by A. J. Dempster and co-workers. of the mass spectrograph to the determination of the mass of radioactive isotopes has led to a powerful method for making the isotopic assignment of radioactivities. In this method a portion of the sample, containing a radioactivity whose mass number needs to be established, is placed on the filament source of a mass spectrograph. Operation of the instrument then separates the isotopes and deposits them on a detecting surface. The position of the radioactive isotope on this surface can be determined by the use of some radiation detection device, such as a counter or photographic plate, and the mass corresponding to this position can be learned from calibration experiments. An increasing number of isotopic identifications are being made by this method.

TYPES OF REACTIONS AND METHODS OF PRODUCTION

The artificial radioelements are prepared chiefly from the stable isotopes of the elements (see NUCLEUS) with the help of various kinds of bombarding particles, such as neutrons, deuterons, alpha-particles (helium ions), protons, high-energy gamma-rays and X-rays. Any charged particle which can be accelerated to a sufficiently high energy to enter the nucleus is a potential projectile for producing nuclear transmutations. The long-lived, heavy, radioactive elements, such as uranium, plutonium (the synthetic element with atomic number 94), 'thorium, etc. serve as the source of many radioactive (fission product) isotopes as a result of the fission reaction. In some cases artificial isotopes, even though relatively short-lived, serve as the source for the production of other such isotopes; such higher order reactions are more common in the case of neutron irradiations because of the extremely high neutron intensities available. The artificial radioisotopes with mass numbers smaller than those of the stable isotopes of the same element reach stability by the emission of positrons (or by orbital electron capture) ; those with larger mass numbers attain stability by the emission of negative beta-particles. A radioelement whose mass number lies between the mass numbers of two stable isotopes is usually a negative beta-particle emitter although many examples exist in which the isotope decays in both directions.

In order to identify completely a radioactivity it is necessary to establish the mass number of the active isotope as well as the atomic number. The latter assignment is usually made by chemical separations. The mass number of the radioactive isotope can be deduced sometimes from a study of the known mass numbers of the stable isotopes of the target element after the chemical separation has established the type of reaction; often the identification must be made by the method of "cross bombardment," *i.e.*, the preparation of the radioactive isotope by several independent nuclear reactions. A new radioactivity is sometimes found to decay to or grow from, in one or more steps, a previously known radioactivity. In this case the mass number of the parent or daughter may be established through the genetic relationship. The bombardment of separated isotopes offers a powerful method for the isotopic identification of induced radioactivities, in view of the excellent isotope separation methods which have been recently developed. When a radioactive isotope is formed as the result of a reaction which involves a rare isotope, the bombardment of the pure, separated isotope will, of course, result in a larger yield. Isotope separation experiments performed after bombardment (see above) also are useful for isotopic identification. For the use of a radioactive substance as a tracer (see below) in a chemical or biological problem a knowledge of the atomic number is sufficient, and radioactive isotopes whose mass numbers have not been established are nevertheless valuable.

The types of reactions leading to thé formation of the artificial radioelements. will now be described (these reactions also often lead to the production of stable isotopes). For brevity it will be convenient to use a simplified notation, rather than to write out the entire reaction each time. For example, the bombardment of iron with neutrons to produce radiomanganese will be described by $Fe^{56}(n,p)Mn^{56}$, rather than by the more cumbersome equation

$$_{26}Fe^{56}+{}_0n^1\rightarrow{}_{25}Mn^{56}+{}_1H^1$$

(where the superscripts denote mass numbers and the subscripts atomic numbers). The notation n$-$neutron, p=proton, α=alpha-particle, d=deuteron and γ=gamma-ray will be used.

The discussion which follows will also include a few statements regarding the yield of radioelements formed in the various reactions. It must be emphasized that only rough qualitative statements can be made, since the situation is too complex to allow a quantitative treatment in a few words. No summary of experimental data on the various reaction yields and the variation of the yields with energy and atomic number has been published; a summary of this type awaits more systematic data.

It may be helpful to point out that the considerations of Bohr have led to the view that the transmutation which occurs as the result of the impact of any particle with an atomic nucleus (with a few exceptions) proceeds by a mechanism which must be treated as two independent processes: namely, (1) the amalgamation of the particle with the nucleus to form an intermediate metastable compound nucleus, and (2) the eventual breaking up of the intermediate nucleus into the end products. All of the reactions in step (2) which are energetically possible will take place but the rates for the competing reactions may differ so greatly that some reactions can not be detected.

Neutron Reactions.— Neutrons are obtained from three types of sources: (1) chain-reacting piles; (2) indirectly from charged particle accelerators; and (3) those which utilize the radiations from the natural radioelements.

The neutrons from the latter type are usually produced by the reaction $Be^9(\alpha,n)C^{12}$ and the sources may be prepared by mixing powdered beryllium with alpha-particle emitters such as radium, radon or polonium. Neutrons produced in this manner have a more or less continuous distribution in energy extending up to about 13 Mev (million electron volts) for radon alpha-particles. (The electron volt, a unit of energy widely used in atomic and nuclear physics, is equal to 1.59×10^{-12} ergs, and is the amount of energy acquired by a particle of electronic charge when it falls through a potential difference of 1 volt.) The action of monoenergetic gamma-rays (of sufficient energy) on beryllium and on deuterium gives rise to monoenergetic neutrons, usually known as "photoneutrons," with energies of the order of hundreds of kilovolts when gamma-rays from the natural radioelements are used.

Artificial sources of indirectly produced neutrons are obtained by bombarding various elements with fast-moving charged particles, the energy of the neutrons depending upon the energy of the bombarding particles. However, the neutron energies have a strong dependence upon the reactions used for their production, so that, taking into account the experimental conditions used for their production, certain rough statements can be made with regard to the energies of neutrons from various artificial sources. Two common sources are (1) deuterons (say 5 to 10 Mev on beryllium (the Be+d source), giving neutrons with energies extending up to about 13 Mev and (2) deuterons on deuterium (the D-d source). The D-d source is used to most advantage when deuterons with energy of the order of a few hundred kilovolts are available and under these conditions gives rise to neutrons within the narrow energy range of 2.5 to 3 Mev. The bombardment of lithium or boron with deuterons (5–10 Mev) produces neutrons with energies extending up to about 25 Mev. Neutrons in this high energy range are produced also by the bombardment of beryllium with high energy (*e.g.*, 20 Mev) deuterons. With extremely high energy deuterons (200 Mev), neutrons with energy in the range of 100 Mev are produced, probably with all target materials.

The uranium chain-reacting "piles" give rise to sources of neutrons of intensities which are huge by comparison with these other sources. Such sources give rise to neutron fluxes which are larger than those mentioned above by orders of magnitude, and furthermore tlie area over which these fluxes are maintained is larger by many, many orders of magnitude. With such "neutron factories" it is possible to transmute elements on a weighable scale; in fact, it is possible to produce radioactive isotopes on a scale of not only micrograms or milligrams, but also grams, or even kilograms in some cases. Also it is possible to use second and higher order reactions in their production, *i.e.*, produce by transmutation an isotope which in turn can be used to produce another isotope by neutron absorption, and so on. Neutrons from this type of source extend in energy up to some 10 Mev, with all lower energies present, and often the pile is so designed as to give a high flux of predominantly "slow" neutrons (see next paragraph).

Previous to the advent of neutrons with energies in the 100

Mev area, common usage had evolved a rough classification of neutrons into groups on the basis of their energy; "very fast" neutrons, often called "fast" neutrons, were those, *e.g.,* from a lithium plus deuterons ($Li+d$) or boron plus deuterons ($B+d$) source, with energies extending from about 20 Mev to about 10 Mev, while neutrons with energies within the range starting at about 10 Mev and extending down to an indefinite energy region (of the order of thousands of electron volts) were known as "fast" neutrons or "medium fast" neutrons (especially those at the lower end of this energy range). "Slow" or "thermal" neutrons is the name given to those neutrons which have suffered a sufficient number of collisions usually with hydrogen or carbon nuclei as the result of passage through paraffin or water or graphite, to slow them to thermal velocities, *i.e.,* about 0.025 electron volt of energy. Slow neutrons were discovered by Fermi and co-workers, and these authors as well as many others give a discussion of their properties and of the slowing process. Neutrons in the energy range immediately above the thermal range are sometimes designated as "resonance" neutrons, a result of the fact that many nuclei absorb such neutrons only within extremely narrow energy ranges, that is, absorb them in a resonance fashion.

Reactions between medium fast neutrons and nuclei produce artificial radioelements by the following main types of transmutations: (1) the simple, radiative capture, known as the n,γ reaction; (2) neutron capture followed by proton emission, or the n,p reaction; (3) neutron capture with alpha-particle emission, the n,α reaction; and (4) neutron capture followed by the emission of two neutrons (net expulsion of one neutron), or the $n,2n$ reaction. With very fast or very high energy neutrons (10 to 100 Mev or higher) more than one proton, alpha-particle or neutron may be ejected, and in all combinations, the relative yields depending on the particular energy of the incident neutron and upon the atomic number of the target element. The n,γ and $n,2n$ and $n,3n$, etc. reactions give radioelements which are isotopic with the target element, and hence the Szilard-Chalmers method of concentration is used when it is desired to obtain a high ratio of active to inactive material, *i.e.,* a high specific activity. When the n,p or n,α or $n,p\alpha$, etc., reactions are used or the Szilard-Chalmers method employed, large amounts of material can be used effectively in order to obtain large specific activities. Radioelements formed by the $n,2n$ or $n,3n$, etc. reactions are largely positron emitters, while the n,y reactions usually lead to negative beta-particle emitters.

The n,γ type of activation occurs most efficiently with slow neutrons and to a smaller extent with fast neutrons. It is the most common and widely studied of all nuclear reaction types. Elements throughout the entire range of the periodic table can be activated in this manner; the cross sections for slow neutron absorption, which are extremely large for some elements, vary in an irregular manner from element to element and from isotope to isotope. The n,p and n,α, etc. transmutations require fast neutrons (except for two or three cases in the lightest elements). The energy required increases regularly as one proceeds up the periodic table, since the outgoing charged particles must escape the nuclear potential barrier, and for atomic numbers as high as 50 only the neutrons with energy greater than 10 Mev are effective. The $n,2n$ reaction requires neutrons with energy above about 10 Mev for good yields because the net result is the expulsion of a neutron whose binding energy amounts to about 8 Mev for most of the elements.

There is another type of activation by fast neutrons which involves those isomers in which the ground state is stable. The kinetic energy of the captured neutron excites the nucleus to its upper, radioactive, isomeric state, a neutron being re-emitted, with reduced energy, after the excitation process. In keeping with our method of writing nuclear reactions, this method of excitation is known as an n,n process and a typical example is written $In^{115}(n,n)In^{115*}$. (The asterisk, as used here, denotes a radioactive isomer of a stable nucleus.)

Deuteron Reactions.—Moderately intense radioactivities can, in general, be induced as the result of bombardments with high-energy deuterons which are produced in the cyclotron of Lawrence and M. S. Livingston. Most of the cyclotrons which were in operation in 1947 were producing deuterons of 5- to 15-Mev energy and currents of 10 to 200 microamperes; the 60-in. cyclotron at Berkeley, Calif., was furnishing 20-Mev deuterons and the 184-in. cyclotron at Berkeley was furnishing 200-Mev deuterons. Other types of artificial deuteron sources induce radioactivities of lower intensities, since they produce deuteron beams of much lower energy.

Artificial radioelements, both negative and positive beta-particle emitters, are produced by deuterons of moderate energy (say up to about 10 Mev) in the following ways: (1) deuteron capture and proton emission, known as the d,p reaction, which is, since the net result is the capture of a neutron, equivalent to the n,γ reaction; (2) deuteron capture followed by neutron emission, or d,n reaction; and (3) deuteron capture with alpha-particle emission, the d,α reaction. The yields from all of these reactions increase with increasing energy of the deuterons up to a point and, for a given deuteron energy, decrease with increasing atomic number of the target element. This decrease is most marked for the d, α reaction, since the outgoing, doubly-charged alpha-particles must penetrate the Coulomb barrier of the nucleus (*e.g.,* with 8-Mev deuterons this reaction is not observed for nuclei of atomic number as high as 50, while the d,p and d,n reactions are observed throughout the entire range of the periodic table). It should be pointed out that the d,p reaction occurs largely by a mechanism known as the Oppenheimer-Phillips process. wherein the deuteron, upon approaching the nucleus, is polarized in such a manner as to give rise to the capture of the neutron without the usual amalgamation of the bombarding particle (deuteron) to form a temporary intermediate nucleus. This obviates the necessity for the deuteron to penetrate the potential barrier of the nucleus.

With energies in the range 10 to 200 Mev and higher, more than one proton, alpha-particle or neutron may be ejected, and in all combinations, depending on the particular energy of the incident deuteron and upon the atomic number of the target element. The name "spallation" reaction has been suggested for this type of nuclear transformation in which many small particles are chipped from the nucleus as the result of a collision with an extremely high energy particle.

A few examples will serve to illustrate the intensity of radioactivities which are induced with deuterons. The bombardment of copper for 20 minutes with 20 microamperes of 8-Mev deuterons produces Cu^{64} (half-life 12.8 hours), by the reaction $Cu^{63}(d,p)Cu^{64}$, with an intensity of about 5 millicuries (*i.e.,* 5×10^{-3} curies). Such a sample would give a discharge rate corresponding to about 10^{7} times the natural background of an ordinary Lauritsen, quartz-fibre electroscope. In a typical experiment a 4-hour bombardment of phosphorus with 100 microamperes of 16-Mev deuterons produces about 50 millicuries of P^{32} (half-life 14.3 days or $1\;24\times10^{6}$ seconds) by the reaction $P^{31}(d,p)P^{32}$. With the aid of the relation $-dN/dt=\lambda N$, where $-dN/dt$ is the number of disintegrations per second and λ the disintegration constant, we find for N, the number of active atoms, $3.7\times10^{10}\times0.05\times1.24\times10^{6}/0.69=1/3\times10^{16}$. (The disintegration constant, λ, defined by the equation $-dN/dt=\lambda N$, is equal to 0.69 divided by the half-life.) *See* RADIOACTIVITY, NATURAL. This corresponds to approximately one-sixth of a microgram of radioactive P^{32}.

Alpha-Particle (Helium Ion) Reactions.—Helium ions which are accelerated by electrical means are entirely equivalent to alpha-particles from the natural radioelements and therefore are often called alpha-particles. However, artificially accelerated helium ions, because of the larger intensity of particles available and the higher energies attainable, have largely displaced the natural alpha-particles for the production of radioelements. For example, 100 mg of radium (with its decay products) emits about 10^{10} alpha-particles per second, spread out in all directions, while 1 microampere of alpha-particles corresponds to 3×10^{12} particles per second, directed upon the target. When the cyclotron is in adjustment for deuterons, it is also almost in adjustment for alpha-particles, since deuterons and helium ions have nearly the same value of e/m; and, because the alpha-particles have the same velocity and twice the mass, they attain twice the energy that deuterons do when they are accelerated with the same voltage. Most of the cyclotrons in operation in 1947 furnished alpha-particles of 10- to 90-Mev energy. The 60-in. Berkeley cyclotron was producing 40-Mev alpha-particles and the 184-in. cyclotron at Berkeley was furnishing alpha-particles with 400 Mev of energy.

Artificial radioelements, both negative and positive beta-particle emitters. are produced as the result of alpha-particle capture followed by neutron emission, the α,n reaction, and by alpha-particle capture and proton emission, the α,p reaction. The yields increase with increasing energy of the projectile and, for a given energy, decrease with increasing atomic number. In the heavier elements, say above lead, a helium ion of less energy than about 20 Mev can not enter the nucleus;, so no reactions are seen.

With higher energies more than one particle is ejected, and in all combinations, depending on the particular energy of the incident alpha-particle and upon the atomic number of the target element.

The excitation of nuclei by a process which might be designated as an α,α reaction is another method of activation which occurs with alpha-particles. Theoretical considerations suggest, however, that this activation often occurs as a result of an interaction between the electric fields of the alpha-particle and the nucleus and not as a capture and re-emission of the bombarding particle as in the case of the n,n reaction.

Proton Reactions. — Just as in the case of deuterons and alpha-particles, the cyclotron offers the best source of high-energy protons. Many investigators have prepared a large number of radioelements by means of proton bombardments.

A most common reaction is the capture of the proton followed by neutron emission, or the p,n reaction, producing mainly elements which decay by positron emission (or orbital electron capture). The yield increases with the energy of the proton and decreases with the atomic number of the target element. This type of transmutation is observed throughout the entire range of the periodic table when protons greater than about 10 Mev are used. If the radioactive substance formed in a p,n reaction emits positrons and thus returns to the target element, the energy threshold for the reaction is equal to the difference between the neutron and hydrogen mass (0.8 Mev), plus the mass of two electrons (1.0 Mev) plus the upper energy limit of the positron spectrum from the radioactive substance. (Similarly the energy threshold for the formation of a positron emitter from a $d,2n$ reaction is equal to 4.0 Mev plus the positron upper energy limit.) When the radioactive product decays by orbital electron capture, the energy threshold may be as much as 1 Mev lower than that which would be calculated for the formation of an emitter of zero-energy positrons.

The radiative capture of the proton, known as the p,γ reaction, is observed with the very lightest elements, and it has also been observed with a few elements of medium weight ($Z=30$). This reaction is important only at energies below or near the threshold for the p,n reaction. The yield from this reaction, especially for the very lightest elements, exhibits sharp maxima at certain sharply defined energies of the protons corresponding to definite "resonance levels."

As is the case for the other incident particles, at higher energies reactions occur in which numbers of particles are ejected, the number and type depending on the energy and atomic number. Also the utilization of the kinetic energy of protons to excite nuclei by the p,p reaction occurs, as in the case of the n,n and the α,α reactions.

Gamma-Ray Reactions. — Gamma-rays of sufficient energy are capable of ejecting neutrons from atomic nuclei to produce radioelements by the γ,n reaction, a type of transmutation also known as "photo-disintegration." Bothe and Gentner, who studied this reaction using the 17-Mev gamma-rays produced in the reaction of protons with lithium and the 12-Mev gamma-rays from boron plus protons, found that the yield varied irregularly from element to element. Mainly positron emitters are formed and the yield is comparatively low. The reactions giving rise to gamma-rays of high energy are of the resonance type, occurring at voltages below 1 Mev and hence the direct acceleration type of apparatus, operating at high beam currents, is the best source.

The betatron and synchrotron can be used to accelerate electrons to extremely high energy, in fact any energy up to hundreds of Mev and these electrons can in turn generate X-rays up to this energy. Such X-rays lead to the ejection of neutrons, protons, alpha-particles, and in all combinations, depending on the energy and atomic number.

Lower energy X-rays have been used to excite certain stable nuclei to their isomeric, radioactive states. This type of excitation has also been effected by bombardment with high-energy electrons.

The Fission Reaction. — In Jan. 1939, O. Hahn and F. Strassmann reported their important discovery that the bombardment of uranium with slow or fast neutrons resulted in the cleavage into pairs of radioactive products of medium atomic weight. The existence of this entirely new type of nuclear reaction was immediately confirmed in many laboratories throughout the world, and L. Meitner and O. R. Frisch, after confirming the reaction, suggested the name "fission" for the process. Subsequent work by a large number of investigators resulted in the chemical identification of many of the fission products. Hahn and Strassmann and others found that thorium also undergoes nuclear fission when bombarded with fast neutrons, and A. V. Grosse, E. T. Booth and J. R. Dunning found that the same is true for protactinium (slow neutrons are ineffective in these cases). The products of these cleavage processes, because of the high neutron to proton ratio of uranium, have an abnormally high neutron to proton ratio; hence all are negative beta-particle emitters and many chains of successive decay are found. Some of the radioactive isotopes formed in this manner can be formed in no other way and others can also be formed by some of the methods outlined in the sections above.

The events leading to the discovery of the fission process present an interesting history. In their original work Fermi and co-workers bombarded uranium with neutrons and obtained a series of radioactivities which, on the basis of chemical experiments, they were led to assign to "transuranium elements," *i.e.*, elements with atomic number greater than 92. The experiments of Hahn, Meitner, and Strassmann and others appeared to confirm this point of view, and for several years the transuranium elements were the subject of much experimental work and discussion. I. Curie and P. Savitch, in 1938, found a product of 3.5 hours half-life which had the chemical properties of a rare earth. but they failed to give a complete interpretation of this astonishing discovery. Early in 1939 Hahn and Strassmann described experiments which made it certain that they had observed the production of radioactive barium isotopes as the result of the bombardment of uranium with neutrons. Subsequent work has shown that practically all of the radioactivities formerly ascribed to transuranium elements are actually the result of fission products. N. Bohr suggested on theoretical grounds, and it was soon confirmed experimentally, that it is the rare isotope U^{235} which is the most susceptible to this fission process, *i.e.*, undergoes fission with the highest probability per incident neutron and does so even with neutrons of small energy (slow neutrons). (About 300 radioactive fission products were known by the late 1950s.) The fission of uranium and thorium by charged particles and by high-energy gamma-rays has also been observed.

It was soon shown by H. von Halban, Joliot and L. Kowarski as well as Szilard and W. H. Zinn, and confirmed by many others, that secondary neutrons are emitted during the fission of uranium. The secondary neutrons could themselves produce still more fissions and the possibility of the occurrence of a chain reaction, under the proper conditions, was immediately recognized. The large energy per fission (approximately 200 Mev) shows that the propagation of such a chain could involve the release of immense amounts of energy.

The attainment of the self-sustaining nuclear chain reaction with natural uranium, mixed with material such as graphite for producing thermal neutrons by the neutron-slowing process, has been successful and such "piles," as they are called, serve as neutron sources of tremendous intensity. Such uranium piles are used to manufacture the famous Pu^{239} isotope of the synthetic element plutonium (atomic number 94) and, in conjunction with thorium, can be used to manufacture the new isotope U^{233} of uranium. The isotope Pu^{239} and presumably also U^{233}, share with U^{235} the property of readily undergoing the fission reaction with neutrons and therefore these three isotopes are the fuel material for much smaller piles, giving higher neutron intensities, than those which operate on natural uranium. The chain-reacting pile serves as a source for the production of radioactive isotopes, both the fission product isotopes and those which can be produced by neutron irradiation, in large amounts. Among the valuable fission product isotopes for tracer research is eight-day I^{131} which has been much used in biological studies.

In 1947 I. Perlman, D. H. Templeton and J. J. Howland made the observation that a number of elements well below the thorium-uranium region undergo the nuclear fission reaction when subjected to bombardment with very high energy particles. This work was done at the University of California and the source of their high energy particles was the 184-in. cyclotron. They observed that the elements starting with bismuth (atomic number 83) and on down to tantalum (atomic number 73) undergo the nuclear fission reaction when irradiated with 400-Mev helium ions and that a number of these elements also undergo this reaction when irradiated with 200-Mev deuterons or 100-Mev neutrons. For these elements the fission process is characterized by a distribution of the radioactive fission product isotopes leading essentially to one broad peak in the distribution-yield curve rather than the characteristic two peaks with a pronounced minimum between them in the curve for the fission products produced in the slow neutron irradiation of uranium and plutonium. The fission product distribution extends to lighter elements as might be expected in view of the lighter mass of these elements as compared with uranium and plutonium. Thus, some of the fission product radioactive isotopes formed in these reactions are different from any which are formed in the fission of the heavy elements such as uranium and plutonium.

It should be emphasized that this observation of the fission reaction in relatively common elements such as lead opens no possibility for the production of self-sustaining nuclear chain reactions with these elements and there is no possibility for their employment as sources of atomic energy. One reason for this stems from the fact that any secondary emitted particles which might conceivably be eligible for perpetuating such a chain reaction have much too small an energy to be able to do so.

APPLICATION TO CHEMISTRY AND MEDICINE

The artificial radioactive isotopes have found, and will continue to find, a wide application as research tools in many scientific fields such as chemistry, biochemistry, medicine, physics, biology, physiology, zoology, botany, industrial operations, etc. This application arises chiefly as a result of their use for tracer or "atom tagging" experiments. It is beyond the scope of this article to give a complete discussion of the results, but because of the importance of such work, a brief discussion of the results and possibilities in the fields of chemistry and medicine, and their related fields, will be given.

In the tracer or atom tagging method of investigation, the element is usually present largely in the form of its natural mixture of inactive isotopes and is "tagged" by the addition of an adequate amount of one of its radioactive isotopes. The mixture which has been "labelled" in this manner is then put into the experiment and the course of the added element, often present in some complicated molecule, is followed by means of the measurement of the radioactivity. By use of this principle it is possible, even in the presence of more of the element throughout the system, to trace the course of that particular amount and form of the element which is under investigation.

One of the most important and interesting uses to which artificially induced radioactive isotopes have been put has been the investigation of the properties of those elements which do not exist in nature. In most cases so far, this type of chemical investigation has used a "tracer" technique in which the chemical properties of the radioactive elements are investigated by using amounts so small as to be unweighable and the course of the element in the reactions is followed by means of its radioactivity rather than by chemical means. Thus the orders of magnitude of solubilities of the compounds of the radioactive elements are inferred on the basis of "carrying" experiments, it being generally true that tracer amounts are carried well only if the anion of the precipitate forms an "insoluble" compound with the cation being carried. Other chemical properties such as oxidation potentials can be deduced, making use of this technique. A great deal about the chemical properties of an element can be learned by this method of investigation which is the only possible method when only submicrogram amounts are available.

The most spectacular examples of the application of the tracer technique lay in the discovery and in the study of the chemical properties of ***new*** elements nonexistent in nature, *i.e.,* with the transuranium elements of atomic numbers 93 and higher. In the case of element 94 (plutonium) a long and complex process for its separation from uranium and fission products was to a considerable extent worked out before anyone had ever seen any plutonium even under the microscope. These studies also led to the elucidation of the electron structure of the heaviest elements, the evidence indicating that these form a series of actinide elements with the added electrons for most of the 14 successive elements starting with thorium going into the *5f,* an inner electron shell, similar to the addition of successive electrons to the inner 4f shell in the case of the 14 previously known lanthanide earths.

The first transuranium element was discovered by E. M. McMillan and P. H. Abelson at the University of California in May 1940. Using the neutrons from the cyclotron, they were able to show, on the basis of their chemical and physical experiments, that a beta-particle emitting radioactivity of 2.3 days half-life formed during the irradiation of uranium with neutrons is caused by the isotope 93^{239} (neptunium), which is the decay product of the 23-minute U^{239} formed by radiative neutron capture in U^{238}. Their experiments on the tracer scale showed that element 93 (neptunium) has at least two oxidation states, an upper state (or states) and a lower state (or states), with chemical properties quite analogous to the VI and IV (or III) forms of uranium. For example, they showed that the Np^{239} under reducing conditions is carried and under oxidizing conditions is not carried from aqueous solution by lanthanum fluoride, indicating that the fluoride of the lower oxidation state of neptunium is insoluble and the fluoride of the higher state is soluble. They found that a greater oxidizing power is required to oxidize neptunium to its upper state than is the case for the corresponding oxidation of uranium.

After the discovery of neptunium, the next transuranium element to be investigated was the element with atomic number 94. This element was produced by Seaborg, McMillan, A. C. Wahl and J. W. Kennedy at the University of California late in 1940. The isotope involved was the one of mass 238 formed by the deuteron bombardment of uranium. These investigators were able to show that the deuteron bombardment of uranium in the cyclotron leads to a new isotope of neptunium, the 2.0-day beta-particle emitter, Np^{238}, formed from a *d,2n* reaction on U^{238}. They found that this isotope of neptunium decays to an alpha-emitting isotope of element 94 (plutonium), namely, Pu^{238}, and that this alpha-emitter has a half-life of about 50 years. Early tracer experiments with this isotope showed that plutonium has at least two oxidation states, an upper state (or states) and a lower state (or states), and that it requires even stronger oxidizing agents to oxidize plutonium to the upper state than is the case for neptunium.

The experiments of Seaborg, R. A. James, L. O. Morgan and A. Ghiorso in the Metallurgical laboratory at the University of Chicago have led to the identification of isotopes of elements 95 (americium) and 96 (curium), making it possible to study the chemical properties of these elements by the tracer technique. Deductions from work on the tracer scale with these isotopes led to the conclusion that the III oxidation state is the most stable and by far the most important state for these elements in aqueous solution. In fact in the case of curium the evidence indicates that the III state is the only one that exists in aqueous solution, and its chemical properties are similar to those of the tripositive rare earths. By the early 1960s. isotopes of elements through 103 (lawrencium) had been produced artificially.

Of course in the meantime it has been possible to produce neptunium and plutonium in weighable amounts in the chain-reacting piles. The isotopes which have been produced in this manner are the neptunium isotope of mass 237 and the plutonium isotope of mass 239, the latter being the isotope which is so important in the atomic energy field. With these isotopes it has been possible. using the methods of ordinary chemistry, to greatly extend the knowledge of the chemical properties of these elements.

There are also a number of lighter elements which are now known to be extremely rare or nonexistent in nature. but whose chemical properties have nevertheless been rather well defined as the result of their production by artificial means and the investigation of their properties by the tracer technique. These are the elements with atomic numbers 43, 61, 85 and 87. Many experiments with these elements have been performed with unweighable amounts.

C. Perrier and E. Segrè were able to show in 1937 that the deuteron bombardment of molybdenum produces radioactive isotopes of element 43, and they used these to study the hitherto unknown chemical properties of this element. This is particularly interesting from an historical point of view because this is the first of the artificial elements to be discovered. Their experiments showed that the chemical properties resembled those of the heavier homolog, rhenium, to a much greater extent than they resembled those of manganese, the lighter homolog. They used rhenium as carrier for the radioactivity in order to show that element 43 is precipitated by hydrogen sulphide from alkaline or acid (less than 10 N) solution. They investigated other properties, including the volatility of the oxide and chloride and the conditions for the electrolytic de'position of the metal. R. P. Schuman and also D. C. Lincoln and W. H Sullivan. working on the Plutonium project of the Manhattan District, independently observed the radioactivity (with long half-life) resulting from the lower isomeric state of 43^{99}, formed in the fission of uranium. This is interesting because it is possible now to isolate this isotope in weighable amounts. This particular isotope of element 43 was discovered by Segrb and Seaborg. who produced it from the deuteron and neutron bombardment of molybdenum and found that the upper isomeric state has a half-life of 6.6 hours and the lower isomeric state has a half-life of greater than 40 years. The discoverers, Perrier and Segrb, suggested the name "technetium," symbol Tc, for element 43.

A radioactive form of element 61 was positively identified in the experiments of J. A. Marinsky, L. E. Glendenin and others, on the Plutonium project of the Manhattan District, who found the isotopes, 61^{147} and 61^{149} with half-lives of about 3.7 years and 47 hours respectively, formed in the fission of uranium. This element is a rare earth and the chemical experiments on the tracer scale show that its behaviour is. similar to that of the preceding element neodymium. Experiments involving selective adsorption and elution (removal by dissolution! on ion-exchange resins led to the unambiguous separation of the element from its neighbours. The availability of the isotope 61^{147} in large amounts from fission makes it now possible to isolate the missing element 61 in weighable amounts. Marinsky and Glendenin have suggested the name promethium, symbol Pm. for element 61.

The discovery of radioactive element 8j (isotope 85^{211}), from bismuth plus 32-Mev alpha-particles, by D. R. Corson. K. R. Mackenzie and Segrè, made it possible for these workers to investigate its properties. The general behaviour is that of a metal. with little resemblance to the other halogens. It is precipitated by hydrogen sulphide in 6 *N* hydrochloric acid solution with various carriers, and the sulphide is insoluble in ammonium sulphide. Volatility at comparatively low temperatures is observed; a piece of bombarded bismuth loses most of the activity before melting (275° C.). There is no precipitation upon the addition of silver nitrate to a dilute nitric acid solution using iodide as carrier. These investigators gave the name "astatine," symbol At, to this element.

A radioactive form of element 87 resulting from the alpha branching decay of actinium was discovered by M. Perey in France. This isotope, given the name AcK, has the mass 223 and decays by negative beta-particle emission with a half-life of about 21 minutes. The experiments of Perey showed that this element behaves as expected, like a heavy alkali metal; *e.g.*, it is carried by the compound caesium perchlorate. Perey gave the name "francium," symbol Fr, to this element.

Perhaps the most extensive application of the artificial radioelements in chemical work has been to the study of "exchange reactions." In exchange experiments the atoms of an element in one of its valence forms or types of chemical combination, are labelled by admixture with some radioactive isotope of the element which is the same form or chemical combination. To this system is added the element in another state of valence or form of combination, containing none of the radioactive isotope: the presence of radioactivity in this second chemical form, after it has been separated from the first, shows that an effective exchange of atoms between the two different states of the element has taken place. Experiments of this type give information on chemical bond types, the strength and reactivity of chemical bonds and the effect of solvents on these properties, the structure of ions and compounds, the mechanism of reactions and the mechanism of catalysis. In addition, exchange reactions often offer an excellent and convenient method for the introduction of radioactive atoms into compounds.

Although the subject of exchange reactions is too complicated to make accurate, complete generalizations possible, it seems profitable to make a few rough statements about homogeneous exchange reactions. If we consider exchanges of a given element between two sorts of molecules or ions in which it is held by electron-pair bonds to different numbers or kinds of other atoms, we may say in general that such exchange reactions do not proceed with appreciable rates except in those cases where there are reversible reactions which enable the exchanging atoms to reach equivalent states of chemical combination. For example, there is no exchange of atoms between phosphate and phosphite ions, sulphate and sulphite ions, sulphur and carbon disulphide, iodide ion and iodoform, etc. On the other hand, exchanges have been found between chloride and chlorate ion (caused by the oxidation-reduction equilibrium), between lead nitrate and lead chloride (an extreme example of the ionization exchange mechanism), and between iodide ion and iodine (through the formation of a symmetrical intermediate, I_3^-). When the two exchanging molecules differ only in their net charge, another exchange mechanism—the transfer of an electron from one to the other—may become possible. For example, exchanges have been observed between Fe^{++} and Fe^{+++} and between MnO_4^{--} and MnO_4^-. It is no doubt true that some exchanges occur through a simple transfer of atoms between molecules during a collision; such a mechanism is a special case of exchange through the formation of an intermediate. In many cases, the observation of exchanges of this sort suggests the existence of unstable intermediates which might not be known from other reaction studies.

Probably the most important isotope from the standpoint of future possibilities is the radioactive C^{14}. This isotope, discovered by S. Ruben and M D. Ramen at the University of California, has a half-life of some thousdnds of years and therefore before the advent of the chain-reacting pile was practically unavailable becduse of the difficulty of its production in the large amounts needed to produce substantial radioactivities However, the intense neutron source in the piles makes it possible now to produce this isotope in such quantity and high specific activity as' to place it in a class along with the most available and suitable isotopes. It can be produced in either of two ways, the neutron irradiation of carbon, preferably enriched C^{13}, by the reaction $C^{13}(n,\gamma)C^{14}$, or the neutron irradiation of nitrogen by the reaction $N^{14}(n,p)C^{14}$. Both of these reactions take place with slow neutrons. The reaction with nitrogen is of course preferable from the standpoint of producing C^{14} of the highest specific activity, it being in fact possible to produce isotopically pure C^{14} in this manner. The radiation is of relatively low energy. making it necessary for its detection to employ instruments designed with this in mind, and, in the investigations, to pay close attention to the self-absorption problem.

There is a whole vista of opportunity opened, as a result of the availability of the C^{14} isotope. Organic chemists, biochemists, physiologists and men of medicine have dreamed for years of the day when a radioactive isotope of carbon suitable for tracer investigations should become available. A few of the possibilities which have opened through the availability of this isotope will be indicated below, but of course this field is so vast that it is certain that the best ideas are yet to come.

A great deal has been said in comparison of the potentialities of radioactive C^{14} and the separated stable C^{13} in these fields. Actually these isotopes complement each other and it is fortunate that both are available. There now exists the interesting possibility of tagging uniquely each of two different carbon atoms in a molecule or system and then *simultaneously* observing the course of each of these. Also the separated C^{13} makes possible the production of radioactive C^{14} of higher specific activity from the reaction $C^{13}(n,\gamma)C^{14}$.

Another isotope which has great potentialities is the radioactive H^3 which has a half-life of about 10 years. This isotope can be used in many of the ways indicated for the use of C^{14} if it is present in a molecule in a nonlabile position. The availability of the intense neutron sources makes it possible to produce this isotope in weighable amounts by means of the reaction $Li^6(n,\alpha)H^3$. The radiation consists of extremely low energy beta-particles and therefore its detection demands the use of special instruments, it being necessary to introduce the material in the form of a gas into the inside of the Geiger-Müller counter, ionization chamber or electroscope.

Besides radioactive C^{14} and H^3, such isotopes as the 14.3-day P^{32}, the 87.1-day S^{35}, the 180-day Ca^{45}, the 47-day Fe^{59}, the 250-day Zn^{65}, the 55-day Sr^{89}, the 8-day I^{131} and many others have offered and will offer many opportunities for important research.

The first and most obvious application in organic chemistry for C^{14} would be in an examination of the mechanisms of many isomerizations and rearrangements of organic molecules. There are a number of reactions in which carbon atoms or groups of carbon atoms move from one part of a molecule to another and the question of just how this migration is accomplished has been a subject for discussion among organic chemists for mnny years. By labelling the migrating groups in certain positions it should be possible to determine the precise sequence of events in such a reaction. In many types of rearrangements it is impossible to tell, by ordinary means, which carbon atoms are actually migrating. It is easy to see how a selective labelling of atoms would allow an unequivocal answer to these questions to be obtained.

This type of information is of interest not only for itself and the light it will throw upon the behaviour of organic substances, but it is a necessary preliminary to the synthesis of tagged compounds of biological interest and to the examination by degradation of metabolic products derived from administered labelled materials.

It is in this latter field of biochemistry that the carbon isotopes will have their greatest usefulness. The determination of the intermediary metabolism of the major structural and energy-transforming materials of living organisms such as fats, proteins and carbohydrates, as well as the catalytic or organizing substances such as vitamins, hormones and enzymes. will undoubtedly make great strides as a result of the availability of isotopic carbon and some of the other isotopes as well. Turning to biological systems there is a virtually unlimited field of important work for the organic chemist and workers in all branches of biology.

It is not out of the question that a complete understanding of the photosynthetic mechanism might give men the ability to synthesize food and fuel at will, using this principle. This could give rise to a literal harnessing of the sun's energy. With the aid of C^{14} this might be accomplished. A number of experiments have been performed with the 20.5-minute C^{11}, but this short half-life placed definite limits on the extent of progress which was possible. Nevertheless. Ruben, Kamen and W. Z. Hassid were able to use radioactive C^{11} in a study of photosynthesis in which considerable progress was made. Radioactive carbon dioxide was fed to the unicellular green alga *Chlorella* and also to higher plants under various controlled conditions in the light as well as in the dark. The results obtained by 1947 were quite interesting. The higher plants and the algae absorb carbon dioxide in the dark. This process takes place concurrently with the release of CO_2 by respiration, so that the net effect is an evolution of carbon dioxide. Only by the tracer technique was it possible to demonstrate a simultaneous uptake and evolution of carbon dioxide. The dark uptake of carbon dioxide is likely the first step in photosynthesis and can be represented by the equation $RH + CO_2 \rightleftharpoons RCOOH$. Decarboxylation experiments have shown that the bulk of the radioactive carbon is in the carboxyl group. Attempts to identify the radioactive substances formed in the dark and in the light had been unsuccessful up to 1947. It is of considerable interest to note that formaldehyde, which has played a prominent role in many proposed mechanisms, was not identified from the radioactive carbon dioxide introduced. Experiments with the ultracentrifuge and diffusion methods indicate the average molecular weight of the radioactive molecules to be about 1,000, which explains the failure to identify chemically these molecules with any small molecules.

The radioactive elements, in particular radioactive carbon, will of course receive widespread use in studying animal metabolism. Some examples may be used to illustrate in a general way the manner in which these elements may be used as an aid in the solution of such problems. Thus, in the highly intricate process of carbohydrate metabolism in man, present knowledge has been gained, for the most part, only as a result of painstaking analytical work by classical methods. In general these methods are not capable of high precision, and are not adapted for the determination of highly labile compounds. Thus it is quite likely that many important details of the process under investigation have not been revealed. Almost certainly, the use of radioactive tracers will bring these details to light. Aside from circumventing many analytical difficulties, the use of labelled elements can yield important information not possible by other methods. It is often the case in biological systems that reactions proceed under steady-state conditions. With radioactive tracers it is possible to follow the formation of a compound in the presence of a considerable amount of the previously synthesized compound or to measure synthesis while the net reaction constitutes breakdown. Such measurements will be of great value in determining the mechanisms of biological reactions. For example, B. Hastings and his collaborators at Harvard have used C^{11} in the study of glycogen formation in the liver, and have found that the incorporation of carbon dioxide into organic molecules takes place there. Many carbon dioxide incorporating reactions have been studied with C^{13} by H. G. Wood and C. H. Werkman. The present availability of C^{14} will make possible the elucidation of many mechanisms in the metabolism of carbohydrate and fat. Many biologists believe that artificial radioactivity has given biology and medicine what is probably the most useful tool for research after the discovery of the microscope because almost all of the elements and compounds in biological systems can be tagged and their course through living systems studied.

The most simple and direct use of an element as a tracer is accomplished by its administration as a simple inorganic compound, in which case the distribution of the tagged element in the various structures of the plant or animal is determinerl by measuring the radioactivity of the samples of tissues and body fluids. A large number of experiments of this type have been performed, principally to aid in the understanding of mineral metabolism. For example, the absorption of iron as related to anaemia has been studied by G. H. Whipple and P. F. Hann at the University of Rochester.

Radiophosphorus because of its availability has been the most widely used of all the artificially prepared radioelements as a tracer for metabolic studies in biological systems. The distribution of administered phosphorus in human and animal tissues has been extensively studied. For example, it has been observed that the retention of a single dose of disodium phosphate varied in different tissues in the following decreasing order: bone, muscle, liver, stomach plus small intestines, blood, kidney, heart, lungs and brain. In other experiments there was found to occur a selective accumulation of radiophosphorus in leucaemic tissues. This was important in that it indicated that the leucaemic tissues could be subjected to a greater degree of beta-particle irradiation than would the normal tissues, which in turn indicated the application of radiophosphorus as a potentially valuable therapeutic agent.

The synthesis of the biologically important organic phospholipids has been studied by G. Hevesy and co-workers in Copenhagen, Denmark, and I. L. Chaikoff and co-workers in California. It is compounds like these that are now considered to be vital links in the complex low temperature oxidation mechanisms characteristic of living systems. Chaikoff and associates have shown the importance of the liver in such synthesis and transport; how the turnover of these substances through the liver can be altered by the administration of choline and certain amino acids and how newly synthesized molecules are absent altogether from the blood when the liver is removed. Using surviving tissue slices they have demonstrated the dependence of the synthesis upon the proper functioning of certain respiratory enzyme systems.

The first real insight into the mechanism of the action of insulin on carbohydrate metabolism has come from the studies of J. Sacks at Michigan with P^{32} on the effect of this hormone on the turnover of phosphorus compounds in muscle. All of these studies, of which only a few were mentioned, would have been impossible without the use of a labelling agent.

Extensive metabolic studies have been made with the use of radioactive iodine as an indicator. The pioneering work in this field was done by S. Hertz and his co-workers in Boston, Mass., and J. G. Hamilton and co-workers at California. The thyroid gland, through its synthesis of the iodine-containing hormone, thyroxine, controls the metabolic rate of the entire organism. Nevertheless, the quantities of iodine compounds produced and distributed are so small that even the finest micromethods are hardly adequate fur the task of studying these processes. With the use of radioactive iodine the analytical difficulties can be largely overcome, and in addition, types of measurements can be made which are not possible from chemical analysis.

Among the measurements that have been made with radioactive iodine are the uptake of orally administrred radiviodine by the intact thyroid glands of normal human subjects and by the thyroid glands of patients suffering from various types of thyroid disorder. The course of the uptake may be simply followed by placing a Geiger counter in the vicinity of the throat. The thyroids of patients with hypothyroidism were shown to accumulate iodine at a slow rate, while there was a relatively large uptake of administered iodine in the thyroid glands of patients with nontoxic goitres. In contrast to these behaviour patterns the thyroids of patients with hyperthyroidism were shown to take up administered radioiodine at a remarkably rapid rate, and also to discharge the iodine from the gland in a rapid iashion. It is seen from these studies of the behaviour pattern of the thyroid gland toward an administered dose of radioactive iodine that an aid toward diagnosing the condition of the thyroid gland is available.

A large amount of work on iodine metabolism has been done by Chaikoff, I. Perlman and M. E. Morton at the University of California. They were able to follow in some detail the distribution of organic iodine compounds from the thyroid gland through the blood to peripheral tissues in various states of thyroid activity. They were also able to demonstrate that, to a limited extent, tissues other than the thyroid gland are able to synthesize thyroxine; and by using isolated surviving tissues, they were again able to tie in the synthesis of an organic compound with the energy-producing enzyme systems.

B. C. Smith and E. H. Quimby at Columbia university have used the gamma radiations from intravenously injected $Na^{24}Cl$ to determine the rate of passage of sodium into the extracelluar phase of the tissues in cases of peripheral vascular disease, and thus determined the competency of the circulation, another example of use for diagnosis.

Many more possibilities for the use of radioactive isotopes in biochemical and physiological work might be suggested, but those given above suggest typical possibilities. Obviously, many of these problems arc of profound significance in terms of human weliare.

The study of the mechanism of action of antibiotic substances, many of which act by means not completely understood at present, will he possible. For example, the synthesis of radioactive penicillin or streptomycin mirht give rise to a method for investigating the mechanisms by which these great substances operate. The mechanism of action of antibodies might also be investigated by the use of tracers.

Another possible use of tracers is, of course, in the study of cancer. Here, in addition to the possibilities cited in connection with the use of radioactive indicators in the investigation of mechanisms, there is the therapeutic possibility of effecting the selective deposition of the radioactive material in the cancerous tissue, as has been mentioned in the case of leucaemia. It has occurred to many investigators that it should be possible in the future to synthesize some compound containing a radioactive substance, this compound having the property of being selectively absorbed by the cancerous tissue so that the radioactive rays can act directly at this spot without giving harmful effects on the body's healthy tissue.

Another possibility is that of tagging bacteria with radioactive C^{14}. This does appear to be feasible and to open great possibilities in the study of disease. In fact, Chaikoff and A. Kaplan have made a beginning by tagging the tuberculosis bacillus with radioactive phosphorus.

The therapeutic uses of radioactive substances have already been mentioned and the application of radioactive I^{131} in the work of Hertz and of Hamilton and M. H. Soley, to the treatment of patients suffering from hyperthyroidism has been outlined. Another place where therapeutic value has been established is in the work of J. H. Lawrence and co-workers who have had some success in the application of radioactive P^{32} to the temporary control of the blood diseases, polycythaemia vera and leucaemia. A large number of other therapeutic uses will surely be found. It will be possible to apply alpha-particles, beta-particles and gamma-rays to this purpose and it is worth pointing out that all of these radiations are represented in isotopes which can be produced in quantity so that it is quite likely that the use of radium and its descendents in this type of therapy will soon be superseded by the artificial radioactive elements.

The present availability of the large quantities of radio-activities has opened the possibility oi their use in industry and industrial processes. It will be possible to use radioactive indicators to follow the course of products and impurities in large industrial processes. Applications should be iound in the testing of the efficiency of distillation apparatus, in testing for leaks, and in many other ways. The intense sources of gamma-rays will find application in the field of radiography to look for imperfections in metal products, to study the path of fast moving parts and other applications.

With respect to chemical problems of direct interest to industries, many examples could be cited. Among these may be mentioned studies, with C^{14}, of the mechanism of catalytic cracking, isomerization and alkylation of hydrocarbons which are of profound interest to the oil industry. The future seems to hold unlimited possibilities for the application of radioactive tracers to scientific problems. It is certain that the applications of radioactive tracers which have been made so far arr just the beginning of what is going to become an extremely large and successful field of research.

RADIOACTIVITY, NATURAL. The subject of radioactivity deals with the spontaneous emission'of energy by matter. The phenomenon was first observed in 1896 as a natural occurrence. exhibited to a significant extent only by the elements of greatest atomic weight (uranium. thorium and certain other elements associated with them in nature in very small amount). As detailed below: its early study led to revolutionary changes in man's ideas concerning the structure of matter. Then, when these new ideas had become commonplace through familiarity, it was discovered in 1934 that radioactive varieties of elements not naturally radioactive could be produced by artificial transmutation (see RADIOACTIVITY, ARTIFICIAL). Furthermore, it was soon recognized that this induced radioactivity is of essentially the same character as the natural activity of the heavy radioelements. As a result of this new discovery the subject of radioactivity was enlarged. within a period of a few months, to cover all the elements from hydrogen to uranium, but it was also divided, for strong methodological reasons. according to the categories "natural" and "induced." in spite of its recognized unity. The situation was not changed when radioactive varieties of previously unknown elements, belonging to positions in the periodic table beyond that of uranium, were produced in profusion artificially-, nor when some of the naturally-occurring radioelements were similarly produced: the division remained valid for reasons of history. That division is accepted here: it is justified by the fact that the "classical" study of radioactivity provided the basis for a great proportion of the fundamental developments in physics over a period of more than 30 years, and by the consideration that at the end of that period it also provided the means of transmutation by which the first artificially-produced radioelements were formed. This article, then, attempts to give the history of classical radioactivity, as well as the facts available by the mid-1950s regarding the naturally-occurring radioelements.

History.——At the beginning of the period thus covered, ideas concerning the structure of atoms were entirely speculative. The study of radioactive processes and radiations led, in a few years, to the realization that atoms, in certain cases, are not permanently stable (E. Rutherford and F. Soddy, 1903). In a few more years it led to the conclusion that, so far as mass is concerned, the atom is mostly emptiness—almost the whole of the mass is concentrated in a nucleus, occupying roughly one-billionth (10^{-12}) of the total volume (Rutherford, 1911). It led to artificial transmutation, the modification of an atomic nucleus caused by an external agency, in a few years more (Rutherford. 1919),; and two years before the discovery that such modifications might lead to newly formed nuclei which are artificially radioactive (Irène and Frédéric Joliot-Curie, 1934) the neutron was discovered as a product of transmutation (J. Chadwick, 1932). This last discovery proved basic for any success which theories of nuclear structure later achieved; also, practically. it may be held that its exploitation has already wrought greater changes in world affairs than the manifold exploitation of the discovery of the electron has wrought over, more than twice as many years.

The beginning of the study of radioactivity dates from Feb. 1896, and was an indirect consequence of the discovery of the X-rays made a few months earlier by W. C. Rontgen. It was known that the production of X-rays in a vacuum tube was accompanied by a strong phosphorescence of the glass. and it occurred to several investigators that ordinary substances made phosphorescent by visible light might emit a penetrating radiation similar to X-rays. Following out this idea. A. H. Becquerel exposed among other substances a phosphorescent compound of uranium (uranium potassium sulphate) placed in position on a photographic plate enveloped in black paper. A weak photographic effect was obtained. This was shown to be caused by a penetrating radiation capable of passing through sheets of matter opaque to ordinary light. Further investigation showed that this photographic action was exhibited by all compounds of uranium and by the metal itself, and had nothing to do with phosphorescence. It was shown that if the uranium were kept in darkness its action did not vary appreciably with time.

Becquerel showed that the rays from uranium, like the X-rays, were capable of discharging a body whether positively or negatively electrified. A uranium compound brought close to the charged plate of a gold leaf electroscope causes a rapid collapse of the gold leaves. A modified form of gold leaf electroscope was frequently employed by earlier workers for the purpose of comparing the radioactivity of substances. Rutherford (1899) made a systematic study of the discharging effect produced by the rays from uranium and showed that it was caused by the production of charged carriers or ions in the volume of the gas through which the radiations pass. In an electric field, the positive ions travel to the negative electrode (cathode) and vice versa. thus causing the discharge of the electrified body. If the gas is contained in an ionization chamber and a sufficiently strong field is applied, the ions are all swept to the electrodes before appreciable loss of their number can occur by recombination. The ionization current then reaches a steady maximum value which is not altered by a large increase in voltage. The maximum current through the gas is called the saturation current: its value is proportional to the intensity of the incident radiation. The ions produced in a gas by the rays from uranium and other radioactive substances are identical with those produced by X-rays, and the mechanism of conductivity of the gas is the same in the two cases (see ELECTRICITY, CONDUCTION OF: Conduction *in Gases*).

Radioactive Substances Separable from Uranium and Thorium Minerals.—Some time after Becquerel's discovery, Marie Curie made a systematic examination by the electric method of a large number of chemical elements and their compounds to test whether any possessed the radioactive property of uranium. Only one other element, thorium, was found (1898) to show this effect to a degree comparable with that of uranium—a result independently observed by G. C. Schmidt. Mme. Curie also examined the activity of the various compounds of uranium and found that their radioactivity was an atomic property, *i.e.,* the activity was proportional to the amount of the element uranium present and was independent of its combination with other substances. In testing the activity of the minerals containing uranium, however, she found that the activity was always four or five times as great as that to be expected from their uranium content. If the radioactivity were an atomic phenomenon. this could only be explained by the presence in these minerals of another substance more active than uranium itself. Relying on this hypothesis. Mme. Curie made a chemical examination of uranium minerals in order to try to separate this new radioactive substance. For these experiments. the Austrian government generously provided her with a ton of the residues from the state manufactory of uranium at Joachimsthal (Jachymov). Bohemia. From these residues. which were three to five times as radioactive. weight for weight. as uranium, Mme. Curie separated a substance far more radioactive, which she called polonium in honour of the country of her birth. This substance is usually removed nith the bismuth in the mineral, but by special methods can be separated from it. A further examination (P. and M Curie and G. Bémont, 1898) revealed the presence of a second radioactive substance which is normally separated with the barium; to this second substance the name radium was given. By means of successive fractionations of the chloride, the radium was gradually concentrated, until finally it was obtained nith a specific activity more than a million times greater than that of uranium. The atomic neight was determined as about 225, and a characteristic spark spectrum of bright lines, analogous in many respects to the spectra of the alkaline earths, was observed. From the chemical point of view radium possessed all the characteristic properties of a new element. It had a definite atomic weight, a well-marked and characteristic spectrum and distinct chemical properties. Its comparative ease of separation and great' activity attracted much attention, although similar radioactive properties are possessed by a large number of other substances, equally distinct chemically. F. O. Giesel in the early days took an active part in the preparation of pure radium compounds and was the first to place preparations of pure radium bromide on the market. He found that the separation of radium from the barium mixed with it proceeded much more rapidly if the crystallizations nere carried out using the bromide instead of the chloride. He stated that six or eight crystallizations are sufficient for an almost complete separation.

In addition to polonium and radium, many other radioactive substances have been separated from uranium and thorium minerals with a specific activity comparable with that of radium, although only one of them has been isolated in a pure state. This last is protactinium, discovered independently by O. Hahn and L. Meitner and Soddy and J. A. Cranston in 1918 The others are actinium. discovered by A. Debierne (1899), ionium. discovered by B. B. Boltnood (1907) and radiothorium (1905) and mesothorium (1907), discovered by Hahn.

Besides these substances, in which the duration of the activity is measured by years, many more radioactive bodies have been found which have a transient activity lasting only seconds. minutes or hours. From the scientific point of view. these short-lived radioactive substances are just as important as those which have a much longer life.

Emanations or Radioactive Gases.—In addition to their power of emitting penetrating radiations, the substances thorium, actinium and radium possess another striking and important property. Rutherford first showed (1900) that thorium compounds (especially the oxide) continuously give rise to a radioactive emanation or gas. This emanation can be carried away by a current of air and its properties tested apart from the substance which produces it. The emanations from all three substances possess the property of ionizing gases with which they are mixed. This activity of the emanations is not permanent but disappears according to a definite law with the time, *i.e.*, the activity falls off in a geometrical progression as time increases arithmetically. The three emanations are distinguished by the different rates at which they lose their activity. The emanation of actinium is very short lived, the time for the activity to fall to half value (half-value period) being 3.92 sec. The corresponding time for the thorium emanation is 54.j sec. and for the radium emanation 3.825 days. The property of giving off an emanation is shown in a striking manner by actinium. A compound of actinium is wrapped in a sheet of thin paper and laid on a screen of phosphorescent zinc sulphide. In a dark room the phosphorescence. marked by the characteristic scintillations, is seen to extend on all sides from the active body. A puff of air removes the emanation and with it the greater part of the phosphorescence. Fresh emanation immediately diffuses out and the experiment may be repeated indefinitely. The emanations have all the properties of ordinary gases. although they are intensely radioactive. They can be transferred from point to point by currents of air. They can be separated from the air. or other gas with which they are mixed. by the action of extreme cold. Rutherford and Soddy showed that under ordinary conditions the temperature of condensation of the radium emanation mixed with air is — 150° C.

Rutherford and Soddy also made a systematic examination of the emanating power of thorium compounds under different conditions. The hydroxide emanates most freely, while from thorium nitrate practically none of the emanation escapes into the air. Most preparations of actinium emanate freely. Radium compounds, except in very thin films, retain most of the emanation. The occluded emanation can in all cases be released by solution or by heating. On account of its relatively long period of decay, the emanation of radium can be collected like a gas and stored, when it retains its characteristic properties, in some degree, for a month or more. A more detailed account of the properties of the radium emanation will be given later.

Active Deposits.—The radioactive emanations possess another interesting and important property. The surface of any body exposed in the presence of an emanation acquires a temporary activity. Like the emanations, this induced activity, as it was first termed (M. Curie?1899), decays with time, though at a rate quite different from that of the emanation which causes it. The bodies made active behave as if they were covered by a very thin film of intensely active matter (Rutherford, 1900). This active coating can be partly removed by rubbing the surface, and can be dissolved by strong acids. On evaporating the acid, the active matter remains behind unchanged in amount. The active deposit obtained on a platinum mire or plate can be volatilized at a white heat, and redeposited on the cooler bodies in the neighbourhood. The activity can be concentrated to some extent on the negative electrode in a strong electric field, indicating that the radioactive matter carries a positive charge. This activity produced on inactive bodies is caused by a deposit of nongaseous matter derived from the transformation of the emanations. Each emanation gives a distinctive active deposit which decays at a characteristic rate. The active deposits of radium, thorium and actinium are complex substances, and consist of many distinct products. Several hours after removal from the emanation the active deposit of radium decays to half value in 27 min., that from actinium to half value in 36 min., that from thorium to half value in 10.6 hr.

Radiations from Radioactive **Substances.**—All radioactive substances possess in common the property of emitting radiations that darken a photographic plate and produce electrical conductivity in gases through which they pass. Very active preparations also possess the property of causing marked phosphorescence in some substances. Bodies that phosphoresce under X-rays usually do so under rays from radioactive matter. Barium platinocyanide, the mineral willemite (zinc silicate) and zinc sulphide are the best-known examples.

There are in general three types of radiation emitted by radioactive bodies; these have been named alpha (a), beta (β) and gamma (γ) radiations. Rutheriord in 1899 showed that the radiation from uraniurn is complex, consisting of (a) an easily absorbed radiation, stopped by a sheet of paper or a few centimetres of air, these he called a rays, and (b) a far more penetrating radiation, capable of passing through several millimetres of aluminum, and these he called β rays. Later, P. Villard found (1900) that radium emits an extremely penetrating kind of radiation capable of detection through 20 cm. of iron or several centimetres of lead. To this last the name γ-radiation was subsequently applied.

Alpha Rays.—These rays consist of a stream of material particles which are projected at high speed from radioactive matter. The α particles from all types of radioactive matter are identical in mass and consist of charged atoms of helium projected with velocities of about 10,000 mi. per second. The a particles are expelled from each radioactive substance with a characteristic speed and have a definite distance of travel or range in matter before being stopped. The ranges of the α particles from the different radioactive substances vary between about 2.5 cm. and 8.j cm. in air at standard pressure and temperature. Most of the energy emitted from radioactive bodies is associated with the a rays.

Beta Rays.—Beta rays consist of a stream of electrons which are projected with high velocities, approaching in 'some cases that of light. Contrary to what happens in a emission! a radioactive body emits β particles over a considerable range of velocity.

Gamma Rays.—These rays, which are generally of a very penetrating character, have been shown to be of the same nature as X-rays. The most penetrating of the γ rays accompany the emission of β rays. Differing from the α and β particles, the γ rays are undeflected by a magnetic or an electric field. In general the γ rays from a radioactive body consist of groups of electromagnetic radiations of widely different frequencies.

The three types of radiation from active bodies are analogous in many respects to the radiations produced by the passing of an electric discharge through a vacuum tube at low pressure, but the individual particle energy is on a much higher scale. In order to produce electrons of speed corresponding to those emitted by radium C, a voltage of 3,000,000 would have to be applied to the tube, and to excite X-rays of the frequency of the γ rays of this body 2,500,000 v. would be necessary. Similarly the energy of the α particle from radium C' corresponds to nearly 8,000,000 ev. (electron volts).

Theory of Radioactive Transformations.—Radioactive bodies spontaneously, and over considerable periods of time, emit a great number of α and β particles. In addition, new types of matter, such as emanations and active deposits, appear and these are quite distinct in chemical and physical properties from the parent matter. This radiating power is an atomic property. for it is unaffected by combination of the active element with inactive bodies, and is uninfluenced by the most powerful chemical and physical agencies at the physicist's command.

In order to explain these results, Rutherford and Soddy in 1903 put forward a simple but comprehensive theory. It assumed that the atoms of radioactive matter (unlike the atoms of ordinary elements) are unstable and that each second a definite fraction of the number of atoms present spontaneously breaks up with explosive violence, each atom expelling either an α particle or a β particle with great velocity. Taking as a simple illustration the case in which an α particle is expelled during the explosion. the resulting atom has decreased in mass and possesses chemical and physical properties entirely distinct from those of the parent. Considering the individual process multiplied many billionfold, a new type of matter has thus appeared as a result of the transformation. The atoms of this new matter are again unstable and break up in turn, the process of successive disintegrations of the atom continuing through a number of distinct stages. On this view, for example, the radium emanation is a new substance derived from the transformation of radium. The atoms of the emanation are far more unstable than the atoms of radium and break up at a much quicker rate.

The law of radioactive transformation according to this theory will be considered at this point. It is experimentally observed that, with all simple radioactive substances, the intensity of the radiation decreases in a geometrical progression as time increases arithmetically, *i.e.*, $I/I_0=e^{-\lambda t}$, where I is the intensity of the radiation at any time, t, I_0 the initial intensity, and λ is a constant. Now according to this theory, the intensity of the radiation is proportional to the number of atoms breaking up per second. From this it follows that the atoms of active matter present decrease in a geometrical progression with increasing time, *i.e.*, $N/N_0=e^{-\lambda t}$, where N is the number of atoms present at a time, t, N_0 the initial number, and λ the same constant as before. Differentiating: $dN/dt=-\lambda N$, thus λ represents the fraction of the total number of atoms present which break up per second. The radioactive disintegration constant λ has a definite and characteristic value for each type of matter. For many purposes it is convenient to distinguish the products by stating the time required for one-half the initial number of atoms to decay. This is termed the half-value period of the product and is numerically equal to $\log_e 2/\lambda$. The average life of the atoms of a product before transformation is given by $1/\lambda$. As far as observation has gone, the law of radioactive change is applicable to all radioactive species (radioisotopes) without exception. It appears to be an expression of the law of probability, for the average number breaking up per second is proportional to the number present. From this point of view the number of atoms breaking up per second should have a definite average value, but this number should vary from second to second within certain limits predictable according to the theory of probability. The theory of this effect was first put forward by E. Schweidler (1905) and was later verified by a number of experimenters, including K. W. F. Kohlrausch, S. Meyer, and E. Regener and H. Geiger. This variation in the number of atoms breaking up from moment to moment becomes marked with weak radioactive preparations when, on the average, only a few atoms break up per second. The variations observed are in good agreement with those to be expected from the theory. This effect does not in any way invalidate the law of radioactive change: on an average the number of atoms of any simple kind of matter breaking up per second is proportional to the number present.

Next it is required to calculate how the amount of a radioactive product, which is supplied at a constant rate from a source. varies with the time. As example, the case of the production of emanation by radium will be considered. The rate of transformation of radium is so slow, compared with that of the emanation. that it may be assumed without sensible error that the number of atoms of radium breaking up per second (*i.e.*, the supply of fresh emanation) is on the average constant over the interval required. Suppose that initially radium is completely freed from emanation. In consequence of the steady supply the amount of emanation present increases. but not at a constant rate, for the emanation is in turn breaking up. Let q be the number of atoms of emanation produced by the radium per second and N the number present after an interval t, then $dN/dt=q-\lambda N$, where λ is the disintegration constant of the emanation. It is obvious that a steadv state will ultimately be reached when the number of atoms of emanation supplied is on the average equal to the number of atoms which break up per second. If N_0 be the final steady value, $q=\lambda N_0$. Integrating the previous equation it follows that $N/N_0=1-e^{-\lambda t}$. If a curve is plotted (fig. 1) with N as ordinate and the time as abscissa, it is seen that the recovery curve is complementary to the decay curve of the emanation alone. The abscissae of fig. 1 represent multiples of the time T for half the product to be transformed. The activity of the emanation falls to ½ in the time T. to ¼ in the time 2 T, and so on.

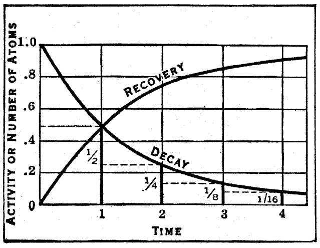

FIG 1—CURVES ILLUSTRATING THE EXPONENTIAL LAW OF DECAY AND RECOVERY OF RADIOACTIVITY

This process of production and disappearance of active matter holds for all the radioactive bodies belonging to a disintegration series. Some special cases of the variation of the amount of active matter with time which have proved of great importance in the analysis of radioactive changes follow.

(a) Suppose that initially the matter A is present and that this changes into B, and B into C; it is required to find the numbers of atoms, P, Q and R, of A, B and C present at any subsequent time t.

Let $\lambda_1, \lambda_2, \lambda_3$ be the decay constants of A, B and C respectively. Suppose n is the number of atoms of A initially present. From the law of radioactive change it follows:

$$P=n\,e^{-\lambda_1 t},$$
$$dQ/dt=\lambda_1 P-\lambda_2 Q, \qquad (1)$$
$$dR/dt=\lambda_2 Q-\lambda_3 R. \qquad (2)$$

Substituting the value of P in terms of n in (1),

$$dQ/dt=\lambda_1 n\,e^{-\lambda_1 t}-\lambda_2 Q;$$

the solution of which is of the form

$$Q=n(ae^{-\lambda_1 t}+be^{-\lambda_2 t}),$$

where a and b are constants. By substitution it is seen that $a=\lambda_1/(\lambda_2-\lambda_1)$. Since $Q=0$ when $t=0$, $b=-\lambda_1/(\lambda_2-\lambda_1)$.

Thus $$Q=\frac{n\lambda_1}{\lambda_2-\lambda_1}(e^{-\lambda_1 t}-e^{-\lambda_2 t}). \qquad (3)$$

Similarly it can be shown that

$$R=n(a\,e^{-\lambda_1 t}+b\,e^{-\lambda_2 t}+c\,e^{-\lambda_3 t}) \qquad (4)$$

where

$$a=\frac{\lambda_1\lambda_2}{(\lambda_1-\lambda_2)(\lambda_1-\lambda_3)},\quad b=\frac{\lambda_1\lambda_2}{(\lambda_2-\lambda_3)(\lambda_2-\lambda_1)},\quad c=\frac{\lambda_1\lambda_2}{(\lambda_3-\lambda_1)(\lambda_3-\lambda_2)}$$

It will be seen from (3) that the value of Q, initially zero, increases to a maximum and then decays according to an exponential law with the period of the more slowly transformed product, whether A or B.

(*b*) A primary source supplies the matter A at a constant rate, and the process has continued so long that the amounts of the products A, B, C have reached steady limiting values. The primary source is then suddenly removed. It is required to find the amounts of A, B and C remaining at any subsequent time t.

In this case of initial equilibrium, the number n_0 of atoms of A supplied per second from the source is equal to the number of atoms which change into B per second, and also from B into C. This requires the relation $n_0=\lambda_1 P_0=\lambda_2 Q_0=\lambda_3 R_0$ where P_0, Q_0, R_0 are the initial numbers of atoms of A, B, C, present and $\lambda_1, \lambda_2, \lambda_3$ are their constants of transformation.

Using the same notation as in case (a), but remembering the new initial conditions, it can easily be shown that the numbers of atoms, P, Q and R, of A, B and C existing at the time t after removal of the source are given by

$$P=\frac{n_0}{\lambda_1}e^{-\lambda_1 t},$$
$$Q=\frac{n_0}{\lambda_2-\lambda_1}\left(e^{-\lambda_1 t}-\frac{\lambda_1}{\lambda_2}e^{-\lambda_2 t}\right),$$
$$R=n_0(ae^{-\lambda_1 t}+be^{-\lambda_2 t}+ce^{-\lambda_3 t}),$$

where

$$a=\frac{\lambda_2}{(\lambda_1-\lambda_2)(\lambda_1-\lambda_3)},\quad b=\frac{\lambda_1}{(\lambda_2-\lambda_3)(\lambda_2-\lambda_1)},\quad c=\frac{\lambda_1\lambda_2}{\lambda_3(\lambda_3-\lambda_1)(\lambda_3-\lambda_2)}.$$

The curves expressing the variation of P, Q, R with time are in this case quite different from those obtained in case (*a*).

(*c*) The matter A is supplied at a constant rate from a primary source. Required to find the numbers of atoms of A, B and C present at any time t later, when initially A, B and C were absent.

This case is closelv related to case (*b*) and the solution can be obtained from general considerations. Initially suppose A, B and C are in equilibrium with the primary source which supplies A at a constant rate. The source is then removed and the amounts of A, B and C remaining vary according to the equations given under (*b*). But the source after removal continues to produce A at the same rate as before. Since initially the product A was in equilibrium with the source and the radioactive processes are in no way changed by the removal of the source, it is clear

that the total amount of A present is unchanged. It is merely divided between two portions. If P_1 is the amount of A present with the source at the time t and P the amount remaining in the part from which the source was removed at $t=0$, then $P_1+P=P_0$, where P_0 is the equilibrium value.
Thus

$$\frac{P_1}{P_0}=1-\frac{P}{P_0}.$$

The ratio P/P_0 can be written down from the solution given in case *(h)*. Similarly, the corresponding values of Q_1/Q_0, R_1/R_0 may be at once derived. It is obvious in these cases that the curve plotted with P_1/P_0 as ordinate and time as abscissa is complementary to the corresponding curve with P/P_0 as ordinate. This simple relation holds for all recovery and decay curves of radioactive products in general.

The variation in the numbers of atoms of successive products with time when the periods of the products are known, have so far been considered. In practice, the variation of the numbers of atoms is deduced from measurements of activity. Using the same notation as before, the activity of any product, such as A, is proportional to its rate of breaking up, *i.e.*, to $\lambda_1 P$, where P is the number of atoms present. If two products are present, the activity is the sum of two corresponding terms, $\lambda_1 P$ and $\lambda_2 Q$—at least if activity is'dctermined by the counting of particles. If it is measured by the ionization method, and the particle from the second product produces K times the ionization produced by the particle from the first product, the activity observed is proportional to $\lambda_1 P+K\lambda_2 Q$. In this way it is possible to compare the theoretical activity curves of a mixture of products with those obtained experimentally.

Analysis of Radioactive Changes.—The analysis of the successive changes occurring in uranium, thorium. radium and actinium proved a difficultmatter. In order to establish the existence of a new product and to fix its position in the scheme of changes, it is necessary to show (a) that the new product has a distinctive period of decay and shows some distinctive physical or chemical properties; (b) that the product under consideration arises directly from the product supposed to precede it in the scheme of changes and is transformed into the product which is regarded as its successor.

In general, it was found that each product showed some distinctive chemical or physical behaviour which allowed its partial or complete separation from a mixture of other products. It must be remembered that in most cases the amount of radioactive matter under examination was too small to be detected by weight, but its presence was inferred from its characteristic radiations and rate of change. In some cases, a separation could be effected by ordinary chemical methods; *e.g.*, thorium X is separated from thorium by precipitation of thorium with ammonia. Thorium X remains in the filtrate and is practically free from thorium. In other cases, a separation was effected by deposition on a metal from the solution of active matter; for example, polonium (radium F) always is deposited on bismuth and may be separated by placing a bismuth plate in a solution containing it. Radium C is separated from radium B by adding nickel filings to a solution of the two in dilute hydrochloric acid; radium C is deposited on the nickel. In other cases a partial separation was effected by electrolysis. or by making use of differences in volatility; *e.g.*, when radium A, B and C are deposited on a platinum plate, on heating the plate, radium B is volatilized first and may be deposited on any cold surface in the neighbourhood. A striking method of separating certain products depends upon the recoil of an atom which breaks up with the expulsion of an α particle. Some of the residual atoms acquire sufficient velocity in consequence to escape from the parent source and be deposited on bodies in the neighbourhood. This is specially marked when the parent source is in the form of a very thin layer on a clean surface. This property was first investigated by S. Russ and W. Makower and by Hahn. Hahn showed that by means of recoil actinium C″ may be obtained pure from the active deposit containing actinium B and C, for actinium C emits α rays and actinium C″ is driven from the plate by the recoil. In a similar way a new product, thorium C″, was isolated, and radium B was separated from radium A and C.

As the analysis of the successive changes proceeded, products were identified which at first were thought not to emit any characteristic radiation, and these were called rayless products. Closer investigation has shown that in these cases. also, a radiation is emitted, a β radiation so easily absorbed that its presence is difficult to detect. The products actinium, mesothorium 1 and radium D belong to this class. It may be worth noting that the presence and properties of an intermediate product emitting a very feeble radiation can be readily inferred if in turn it is transformed into a product emitting a marked radiation. Thus. if in a preparation consisting initially of a pure product emitting an easily-detectable radiation—as in case (a) above—the radiations of a daughter product begin to appear, it can generally be decided whether the rate of growth of the daughter product is correctly described by equation (3) or equation (4) of the previous analysis. If (4) is applicable, even though no other radiation can be detected, it must be assumed that an intermediate product is involved. The disintegration constant of this rayless product can then be determined by accurate comparison of the observed growth curve of its daughter with the predictions of the theory.

In Table I a list is given of the remarkable series of daughter products formed from uranium, thorium and actinium. The system of nomenclature is not ideal; in general, products of average life greater than one year have been given distinctive names

TABLE I.—*Naturally Occurring Radioactive Species*

Radioactive species (parent bodies and daughter products)	Mass no.	Atomic no.	T (half-value period)	Type of change	Mean range of α rays in air (15°C. and 760 mm.)
Uranium-Radium series					
Uranium I	238	92	4.51×10^9 yr.	α	2.69
Uranium Xi	234	90	24.1 days	β	—
Uranium X2	234	91	1.17 min.	β	—
Uranium Z	234	91	6.7 hr.	β	—
Uranium II	234	92	2.50×10^5 yr.	α	3.26
Ionium	230	90	8.0×10^4 yr.	α	3.16
Radium	226	88	1,620 yr.	α	3.29
Radon (emanation)	222	86	3.825 days	α	4.05
Radium .4.	218	84	3.05 min.	α, β	4.66

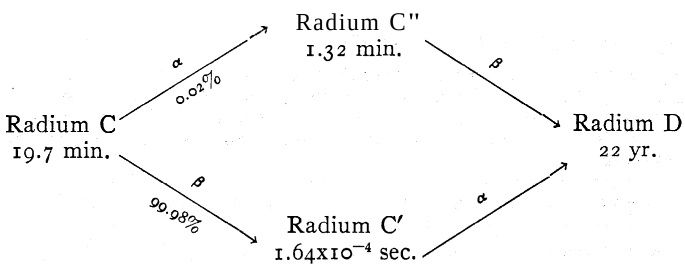
(printed in italics). The successive products following the emanations are in all cases denoted by the letters A. B. C, etc. In some cases intermediate products nere discovered after a system of nomenclature had been accepted, and mere named to indicate as far as possible their positions in the series. As the radioactive emanations are now known to be isotopic, the names radon. thoron and actinon have been suggested as distinctive and indicative of the similarity of these products.

In the table, T is the half-value period of the product. It will be seen that the value of T, which is a measure of the relative stability of atoms, varies between 1.39×10^{10} yr. (thorium) and 3×10^{-7} sec. (thorium C'). The atomic weights of uranium, radium, uranium-lead. thorium, thorium-lead and protactinium have been directly determined by chemical methods, and the atomic numbers of uranium, thorium, and lead by standard X-ray methods. The mass numbers and atomic numbers of the other products are deduced on the assumption that the expulsion of an α particle (helium nucleus) reduces the charge (atomic number) of the radioactive nucleus by two units and the mass number by four units, whereas the expulsion of a β particle raises the atomic number by one unit, but does not change the mass number (see below).

Branch Products.—In the great majority of cases each radioactive product breaks up in one definite way, each atom giving rise to one α particle, or to one β particle and to one atom of the new product. Clear evidence, however, has been obtained that in a few cases the atoms of a single product break up in either of two alternative ways: they may emit either an α particle or a β particle. The two daughter substances thus produced then transform, in general, so as to give a common granddaughter.

The most striking cases of branching occur with the C products of radium, thorium and actinium, each of which breaks up in two distinct ways. In the radium series the scheme of transformation is



where the main branch is by way of a β disintegration to radium C', which emits an α particle and changes into radium D. Only 0.02% of the radium C atoms emit an α particle, forming radium C'', which emits a β particle. Radium C' has an exceedingly short period of transformation which was first measured approximately by J. C. Jacobsen (1926).

In the case of thorium C, two sets of α particles were early observed (Hahn, 1906), one-third of the total number having a range of 4.7 cm. and the more abundant group a range of 8.6 cm. Here (as with radium C) the main branch proceeds by a β ray change to the C' product, which gives rise to the particles of 8.6 cm. range and has an even shorter period than radium C'. The approximate half-value period of thorium C' was first determined by J. V. Dunworth (1939).

In the actinium series, the predominant (99.7%) process is α disintegration leading to the C'' product, only 0.3% proceeding by β disintegration to actinium C'.

The C products in all three series are isotopes of bismuth (see below) and in the radium series there is a second active isotope of this element, radium E. It is interesting to note that branching occurs with this product also. In 1947 E. Broda and N. Feather showed, by the method of recoil, that a β emitting thallium isotope, radium E'', is formed by α emission roughly once in every 3×10^6 disintegrations of radium E. Within a few years rare modes of α disintegration were also established with actinium and actinium K, and rare modes of β disintegration with radium A and actinium A.

One case of branching is of special interest as it differs from all others, and the description already given does not strictly apply to it This occurs in the sequence between uranium X_1 and uranium II. It was shown by Hahn (1921) that two alternative intermediate products, uranium X_2 and uranium Z, occur in this sequence Both these products are β emitters and the branching ratio is such that uranium Z is produced in a small fraction of the transformations only (variously determined as 0.2% to 0.6%). It is probable that uranium X_2 is produced directly from uranium X_1 in all disintegrations and that the formation of uranium Z is by a process of internal nuclear rearrangement which takes place as an alternative to β emission in a small fraction of transformations of uranium X_2. As uranium X_2 and uranium Z give rise to the same substance. uranium II by the same type of change, they must have not only the same atomic number but also the same mass number; their nuclei must therefore contain the same particles but in different configurations. Their discovery constituted the first recognized case of nuclear isomerism. This phenomenon is known to occur widely among the artificially produced radioelements (see RADIOACTIVITY, ARTIFICIAL); in fact long-lived isomers of radium E ($T=2.6\times10^6$ yr.) and actinium C' (T= a j sec.) were produced artificially in 1950–51, though they do not occur as members of the natural series.

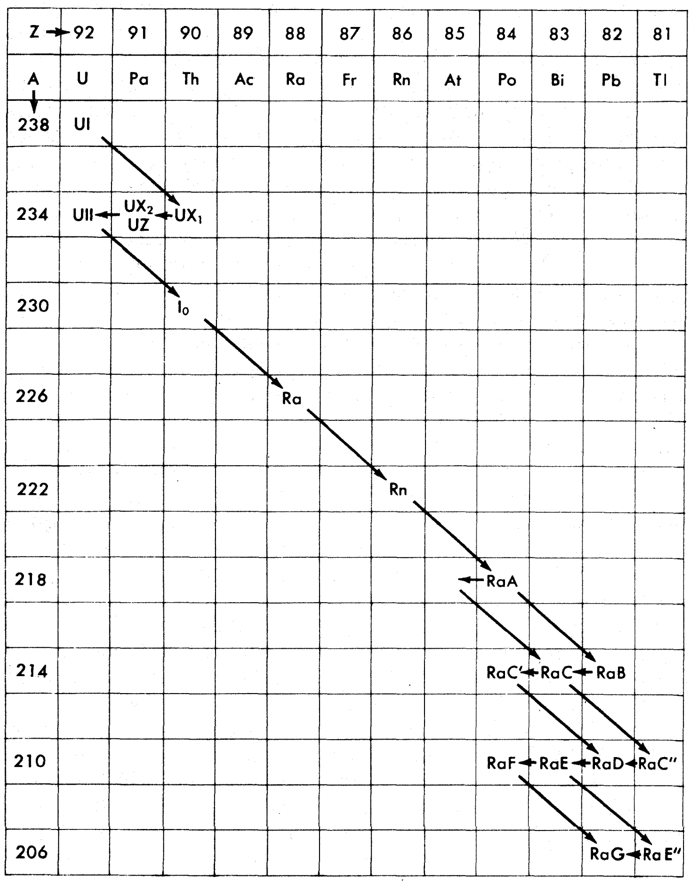
Chemistry of Radioelements (see RADIUM; URANIUM; etc.).—Throughout the classical period of research in natural radioactivity no one was able to obtain the radioactive products of short life in sufficient quantity to examine them by the ordinary chemical methods; but by the use of the radioactive method of analysis it was possible to form some idea of their chemical behaviour. Certain interesting points came to light. Soddy found that the two products radium and mesothorium, although quite dissimilar in radioactive properties, mere chemically so nearly identical that it was impossible by chemical methods to separate one from the other. Other pairings of the same kind had long been suspected. namely. thorium and radiothorium, thorium and ionium and radium D and lead. Soddy named such inseparable species isotopes, since they appeared to belong to the same place in the periodic classification of the elements. (See ISOTOPE.)

Following a detailed chemical study of the active species by Soddy. A. Fleck and G. von Hevesy, an important generalization relating the type of activity to the change in chemical behaviour was announced independently in 1913 by A. S. Russell, K. Fajans and Soddy. This displacement law states that the daughter product after α disintegration belongs to a place in the periodic table two lower than that of the α emitting parent, and the daughter product after β disintegration to a place one higher than that of its β emitting parent. For example, by loss of an α particle from ionium of Group IV, the resulting product, radium, belongs to Group II, and the loss of another α particle gives rise to the emanation which belongs to Group O, and so on. This displacement law soon received a simple explanation. From the work of H. G J. Moseley, the chemical properties of an element are defined by the atomic number, which represents the resultant positive charge of the nucleus. The loss of an α particle of mass 4, carrying two positive charges, lowers the atomic number by two, whereas the emission of a negatively charged β particle raises it by one. Thus, once the atomic number and the mass number of one member of a radioactive series have been determined, these quantities can be deduced for all other members of the series from a knowledge of the radiations emitted in the transformations. It is instructive to arrange the members of the different radioactive series as in figs. 2–4, where the atomic numbers are plotted as abscissae and the mass numbers as ordinates. It will then be seen that the three series exhibit a remarkable similarity after the three bodies of atomic number 90 (ionium, radiothorium and radioactinium).

The active species of the three series, taken together, have atomic numbers which cover the range from 81 to 92, inclusive. Of those elements with atomic numbers between 84 and 92, all isotopes are radioactive; for the common elements thallium (81), lead (82) and bismuth (83), some of the isotopes are radioactive, others are stable. Several active products are isotopic with one another, and this is often indicated by corresponding names; thus all the A products and all the C' products are isotopes of polonium, the C products are isotopes of bismuth. the B products of lead and the C'' products of thallium. The isotopes of lead are of special interest as they include the stable end products of the three series—a statement which will be discussed more fully later.

Transformation of Uranium.— In 1900 Sir William Crookes found that the β ray activity of ordinary uranium could be removed by a single chemical operation and concentrated in an active residue. This represents the separation of the product uranium X_1, of half-value period 24.1 days, which emits β rays and γ rays. A complete analysis of the transformations of uranium at first proved to be a matter of much difficulty. Boltwood showed that the a ray activity of uranium was about twice as great as the equilibrium activities of the other a ray products in the uranium-radium series. indicating that the uranium fraction contained two successive a emitters. This was confirmed by Geiger, who showed that the a rays from natural uranium consist of two groups, equal in number, but with ranges of roughly a.j cm. and 3 cm. The two α ray emitters were named uranium I and uranium II. Assuming these two a emitters to be isotopic, and uranium I to be the ultimate psrent. Fajans concluded. on the basis of the displacement law. that the α disintegration of uranium I must be followed by two β disintegrations to give uranium II. Identifying uranium X_1 as the first of the predicted β emitters. he predicted that the second should have chemical properties analogous to those of tantalum, and promptiy succeeded in isolating it experimentally (1913). This product, uranium X_2, has a half-value period of 1.17 min. and emits energetic β rays. Several years later Hahn found the branch product. uranium Z. also intermediate between uranium X_1 and uranium II. but for present purposes it is sufficient to state that by either branch an α disintegration followed by two β disintegrations leads from uranium I to uranium II. In conformity with this conclusion, the mass numbers of these uranium isotopes are now known to be 238 for uranium I and 234 for uranium II. The growth of uranium II from uranium X_1 through uranium X_2 was first observed by C. H. Collie (19311.

Another β ray substance arising in the transformations of natural uranium was discovered by G. N. Xntonoff (1911). This substance. uranium Y, of half-value period 25.6 hr.. has the same chemical properties as uranium X_1. Its equilibrium activity is only a few per cent of the equilibrium activity of uranium X_1, so that it cannot be in the main line of succession. For some time it was regarded as a branch product, probably of uranium II. and it



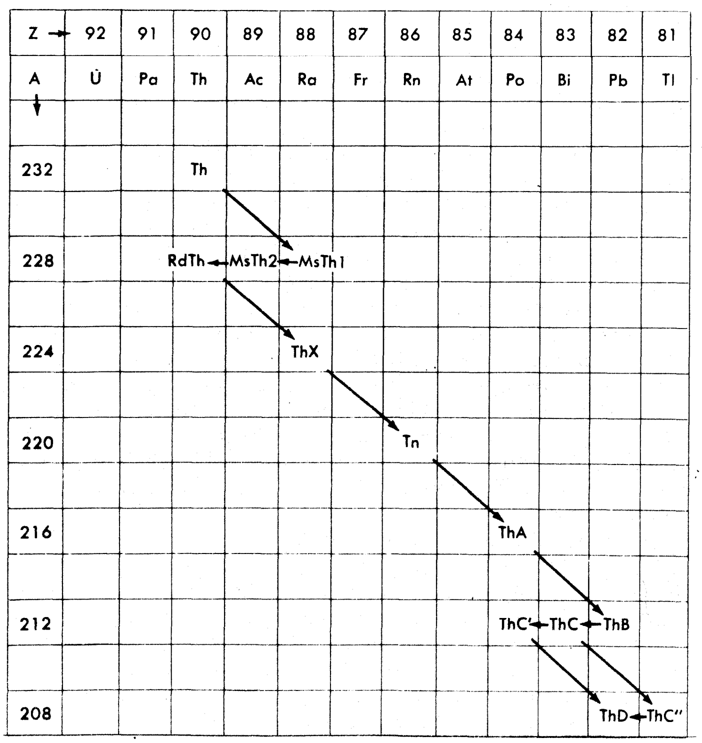


FIG 2–4 — ARRANGEMENT OF RADIOACTIVE SERIES WITH THE ATOMIC NUMBERS PLOTTED AS THE ABSCISSAE AND THE MASS NUMBERS AS ORDINATES THE THREE SERIES EXHIBIT A REMARKABLE SIMILARITY AFTER THE THREE BODIES OF ATOMIC NUMBER 90, VIZ IONIUM RADIOTHORIUM AND RADIO ACTINIUM

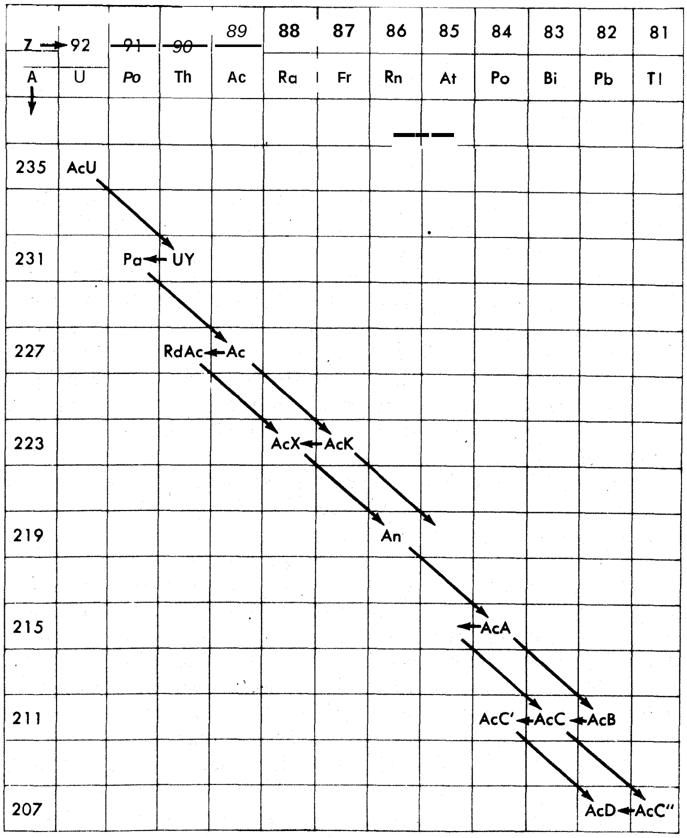

was also believed to be the parent of protactinium and the actinium series. It later became clear that the second assumption is correct, but the first incorrect. Cranium Y is the daughter product of the α emitting uranium isotope of mass number 23j, the so-called actinouranium. A mass-spectrogtaphic analysis of uranium demonstrating the existence of all three isotopes (mass numbers 238, 23j and 234) was first successfully performed by A. O. Nier. In natural uranium the U^{238}/U^{235} ratio is 139, and the U^{238}/U^{234} ratio about 17,000. From these results, and from a measurement of the number of α particles emitted by 1 g. of uranium per second, the periods of uranium I and uranium II were determined, allowance having been made for the weak activity resulting from the actinouranium.

Ionium.—The early work of Boltwood, R. J. Strutt (later Lord Rayleigh) and H. N. McCoy showed conclusively that the amount of radium in old minerals is directly proportional to the amount of uranium. This is what would be expected on the basis of the transformation theory (see above) if radium is a direct descendant of uranium in the disintegration series, and if the mineral had remained undisturbed for a time considerably longer than the half-value period of radium, or of any long-lived product intermediate between uranium and radium in the series. In that case the ratio of the numbers of atoms of radium and uranium present in the mineral would be the same as the ratio of the half-value periods of these two bodies.

In order to obtain direct proof of this genetic relation between uranium and radium, attempts were made, first by Soddy, to detect the growth of radium in samples of uranium from which all trace of previously associated radium had been carefully removed. The presence of radium in solution can most sensitively be detected by bubbling air through the solution into an ionization vessel and looking for ionization caused by the emanation produced. On the basis of a rough knowledge of the half-value periods concerned, Soddy had calculated that if radium were produced from uranium directly, without intermediate product, then the emanation method was sufficiently sensitive to detect the radium formed in one kilogram of uranium nitrate during the course of a week. The experiment showed that the initial rate of production of radium in purified uranium was certainly less than 10^{-4} of the amount calculated on this simple assumption. The next assumption to try out was that a single long-lived product was the direct parent of radium and the direct daughter of uranium. On the basis of this assumption the accumulation of radium in initially purified uranium would proceed at first according to the square of the time—equation (4) above. This result was ultimately obtained by Soddy (1915) in experiments extending over several years.

In the meantime Boltwood (1906) had separated the hypothetical intermediate product from the mineral, that is he had obtained a product in which the accumulation of radium was directly proportional to the time elapsed. In the following year he reached more precise conclusions regarding the chemical properties of the new product and suggested the name ionium, by which it became known. Ionium, which is present to the extent of rather less than two parts in 10^5 in uranium minerals, is now known to be a thorium isotope of mass number 230. This fact explains why it is impossible to separate ionium chemically from any natural thorium (mass number 232) which may be present in a uranium mineral and, since very few uranium minerals contain less than one part in 10^4 of thorium, why it is so difficult to obtain ionium isotopically pure. If such purity is required, the ionium-thorium fraction from a high-grade uranium ore must finally be submitted to physical separation in the mass spectrograph.

Radium. — The amount of radium in an unaltered uranium mineral is always proportional to the amount of uranium in the ratio of 3.43 parts of radium by weight to 10^7 parts of uranium. Its extraction is a tedious task, but it is not complicated by the presence of any long-lived isotope of radium, even though there may be some thorium and thorium products in the mineral. Since the chemical properties of radium are closely related to those of barium, the radium is normally separated with the barium from the other constituents of the mineral. It can then be completely purified from barium by fractional crystallization of the chloride or of the bromide. Mme. Curie and Debierne first isolated (1910) metallic radium by electrolysis of the fused salt, using a mercury cathode. The metal resembles metallic barium, being white in colour and tarnishing rapidly on exposure to the air. It melts at about 700° C. and boils at 1,140° C. The chemical properties of radium and its compounds have been studied by the usual methods. All the evidence, whether from its spectrum or from the solubility of its salts, shows it to be a higher homologue of barium.

In general, the salts of radium are available in quantities of only a few milligrams, possibly mixed with barium. It is therefore most convenient to measure the amount of radium by radioactive methods, rather than by weighing, for then the purity of the radium salt is not significant. The unknown preparation is compared with a sample of radium salt of known radium content which has been standardized directly or indirectly by means of the international radium standards. When the amount of radium present is not less than 1/100 mg. the intensity of the γ radiation (emitted by the active deposit, and mainly by radium C) is used as the basis of measurement. The tube containing the radium is placed at a suitable distance from an ionization chamber which is surrounded by a lead screen at least 3 mm. thick. The effect in the chamber is then caused only by the penetrating γ radiation. By comparison of the ionization current due to the unknown preparation with that produced by a known amount of radium at the same distance, the quantity of radium in the unknown preparation can at once be deduced, provided the radium is in equilibrium with its short-lived products. This last condition is adequately ensured if the radium preparation has been sealed off for at least one month. This method of estimation is simple and direct, and has the great advantage that the radium can be tested in a sealed off glass or metal tube, which is the usual mode of packing. For very weak preparations of radium, use is made of the emanation method, which has already been described. By this method quantities of radium as small as 10^{-12} g. can be measured to within a few per cent. The emanation method has been employed with great success for determining the quantities of radium in minerals and in rocks.

In 1912 a preparation consisting of 21.99 mg. of pure radium chloride, sealed in a thin glass tube, was adopted as the international radium standard and deposited in the Bureau International des Poids et Mesures at Sèvres, near Paris, Fr. At the same time a preparation made by O. Honigschmid, and containing 31.17 mg. of radium chloride, was adopted as a secondary standard and preserved in Vienna, Aus. Arrangements were made for the issue of duplicate standards to all governments who wished to purchase them. These duplicates were prepared in the Radium Institute of Vienna, and compared by the γ ray method with the official secondary standard in Vienna and with the international standard in Paris. In 1934 the original standards were replaced by new standards prepared by Honigschmid from the purest radium chloride, free from any detectable trace of barium. The Paris standard now (1957) contains 22.23 mg. and the Vienna standard 30.75 mg. of initially pure salt. The purchase and sale of radium is generally conducted on the basis of certificates given in terms of the international standard.

Physically, the ideal method of specifying the strength of a long-lived radioactive preparation is in terms of the mean number of disintegrations occurring per second in the sample. Corresponding to a half-value period of 1,620 yr., this number, for one gram of pure radium, is 3.62×10^{10}. This value is for one gram of radium free from its disintegration products; when the radium is in equilibrium with radon and the short-lived active deposit, the number of α disintegrations is four times as large. Originally, the unit one curie was introduced (1910) to specify the amount of radon in equilibrium with one gram of radium. It was later modified to become a unit of activity (disintegration rate) equal to the activity of one gram of pure radium. Because of the experimental uncertainty attaching to this natural unit (about 1%) the curie was later defined by international agreement (1950) as an activity of 3.700×10^{10} disintegrations per second, of whatever type.

From about 1909 to 1939, the wide use of radium for therapeutic purposes and its high cost led to a close search for uranium deposits as a source of this element. The most important uranium deposits in Europe were then those of Joachimsthal (Jáchymov) in the Erzgebirge, originally under control of the Austrian government. The production of this pitchblende mine amounted, at the peak, to about three or four grams of radium per year. When this rate of production failed to meet the demand, low-grade ores. containing on the average only about 2% of uranium oxide. began to be worked in Colorado. From about 1913 until 1922 the greater part of the world supply of uranium was produced in the United States from such ores. but in 1922 rich deposits of pitchblende were found at Katanga in the Belgian Congo. As these deposits were developed, the U.S. and Joachimsthal production practically ceased and Belgian producers obtained a virtual monopoly. This monopoly came to an end after the discovery in 1930 of an extensive occurrence of pitchblende on the shores of Great Bear lake. S.T., Can. From that date until 1939 the Belgian Congo and Canada shared the world market for radium. By the outbreak of World War II in 1939 the total quantity of purified radium in the world probably amounted to more than 1,000 g. After 1945 the growing availability of artificially produced radioelements considerably reduced the demand for radium for medical applications, but the demand for uranium increased for other purposes. To follow this development here would, however, be out of place: it has nothing to do with natural radioactivity.

During World Wars I and II large quantities of radium were used for gun sights, night compasses: instrument dials, etc. The radium was mixed with phosphorescent zinc sulphide to form a paint which is continuously luminous. although as a result of the destruction of the zinc sulphide by the rays, the luminosity gradually decays. Active preparations of mesothorium and radiothorium mere used for similar purposes.

Radon. — Radon (radium emanation) differs from the other products of the uranium series only in that it exists in a gaseous form at ordinary temperatures. It is produced from radium. and is transformed into radium A by α decay. Its half-value period is 3.825 days. If a radium salt is dissolved in an acid solution the radon may be pumped off with the large quantity of hydrogen and oxygen liberated by the action of the radiations on the water. It may then be purified by sparking the mixture and condensation with liquid air. The volume of radon at normal pressure and temperature in equilibrium with one gram of radium is 0.65 cu.mm. This small quantity of gas, together with the active deposit of short life in equilibrium with it, contains initially three-quarters of the total α activity of the radium before its separation. In a pure state, radon is 150,000 times as active weight for weight as pure radium. Notwithstanding the minute volume of radon available, its boiling point has been determined at various pressures. At atmospheric pressure radon boils at $-62°$ C. and freezes at $-71°$ C.; its critical temperature is $+105°$ C. Liquid radon appears colourless when first condensed; at the temperature of liquid air the solid glows with a bright rose colour. The specific gravity of the liquid is 4.4 at $-62°$ C.

Radon has no definite chemical properties and in this respect belongs to the group of inert monatomic gases of which helium and argon are the best-known examples. It is partially soluble in water and readily adsorbed on charcoal.

An intense source of β and γ radiation may be obtained by introducing purified radon into fine capillary tubes. Such radon "needles" have been widely used for therapeutic purposes, while the use of very thin-walled glass tubes provides a powerful line source of α rays. The β and γ activities of such, tubes rise to a maximum about four hours after introduction of the radon, and then decay with the period of radon (3.825 days). A method was developed in 1955 of producing "solid" sources of radon at ordinary temperatures. If a glow discharge is maintained between metallic electrodes in a gas containing radon, it is found that under certain conditions the radon is collected on the negative electrode, in the surface of which it remains occluded. Active sources, which can even be used in a vacuum without significant loss of emanation, can thus be prepared on thin foils of platinum or aluminum. Only when the metal is heated is the radon released. The strength of a radon preparation can be accurately determined by comparison of its γ ray activity with that of a radium standard. since the penetrating γ rays. both from the radium and the radon in equilibrium, arise mainly from the same product, radium C.

Radium Active Deposit of Short Life. — This name may be regarded as applying collectively to the short-lived products radium A, radium B, radium C and radium C' (together with the rare branch products radium C" and astatine 218) which grow into equilibrium with a source of radon in the course of a few hours; in practice, however, it is generally applied to sources of radium B in equilibrium with radium C. radium C' and radium C".

If a negatively charged wire or plate is exposed to radon for one minute and is then withdrawn. it is found to have collected a deposit of radium A. This deposit consists of atoms of radium A which have recoiled from the α disintegration of radon and which. being ionized in the process, have been collected in the electric field. The α activity of such a deposit falls rapidly at first, according to the period of radium A (3.05 min.). and then rises again to a much smaller maximum value as the atoms of radium A change successively into radium B, radium C and radium C'. At that stage the α activity is due predominantly to radium C'. Eventually, this α activity, as well as the β and γ activities due to radium B and radium C, decay together with the period of radium B (26.8 min.). Alternatively, if the negatively charged collector is exposed to radon for an hour or two. obviously the active deposit comes into approximate equilibrium with the radon during the exposure. On withdrawal, the only significant change of activity during the first few minutes then arises from the decay of the α activity due to radium A (about one-half of the total α activity); the β and γ activities decay only slightly in this time. When this α decay is effectively complete, say in 20 min.. the remaining α, β and γ ray activities of the source decay with the 26.8-min, period of radium B. It is to such a source, produced by "long" exposure to radon, that the name active deposit of short life is commonly applied. Most of the classical experiments on α particle scattering and artificial transmutation were made during the years 1909–29 using active-deposit sources of this type.

Radium Active Deposit of Long Life.—Mme. Curie first noticed (1903) that the activity of a body, left in a closed vessel in contact with the emanation from a radium preparation for several months, did not decay completely within the first day after removal. as it would if the dominant decay period were of the order of 27 min.. but that a residual activity (about 5×10^{-5} of the initial amount) remained which did not decrease appreciably over a much longer interval. The relation of this active deposit of long life to the active deposit of short life was worked out by Rutherford and by Meyer and Schweidler in the following two years. On metal plates exposed to radon for a few days only, Rutherford observed the growth of both an α and a β activity of long life. He showed that the β activity reached equilibrium considerably earlier than did the α activity. and he concluded that the dominant decay period of the long-lived active deposit was that of an effectively rayless product. This product and the two products which follow it in the active deposit of long life are still known by the names Rutherford assigned to them — radium D ($T = 22$ yr.), radium E ($T = 5.02$ days) and radium F ($T = 138.3$ days) — furthermore, his identification of radium F with polonium, the first active substance separated from pitchblende by Mme. Curie in 1898, has been fully justified by later research.

For all practical purposes the sequence of disintegrations in each of the two active deposits of radium is the same: two β disintegrations followed by an α disintegration. Thus radium B and radium D are isotopic, radium C and radium E are isotopic. so, also, are radium C' and radium F. There is a further regularity: in the first sequence each disintegration is more energetic than the corresponding disintegration in the second sequence. This fact might suggest that the second products are of less interest than the first, yet in spite of it, and the greater difficulty of obtaining strong sources of the longer lived products, much fundamental work has been done with radium E and radium F. The great advantage of these products is that neither emits γ rays in significant amount. For that reason radium E was for many years the natural choice for those workers who wished to study the problem of β disintegration in its simplest context and. when electrical methods of detecting single α particles superseded the more tiresome method of scintillation counting, the use of radium F avoided the troublesome effects of unwanted background ionization due to β and γ rays. Chadwick's discovery of the neutron was made by using the α particle? of polonium (rather than the more enerretic α particles of radium C′) to bombard beryllium.

The most convenient starting material for the preparation of sources of radium (D+E+F) is provided by the disused glass capillaries and "seeds" in which radon has been sealed for therapeutic use and in which it has finally decayed. The active deposit of long life is found deposited on the inner walls of such containers and may he removed by dissolution in strong acid.

Transformations of Thorium.— The close similarity of the three radioactive series has already been pointed out (*see* figs. 2–4). This similarity is particularly marked between the uranium and thorium series. In the thorium series the sequence of transformations thorium→mesothorium 1→mesothorium 2→radiothorium is closely analogous to the sequence uranium I→uranium X_1→uranium X_2→uranium II in the uranium series, so that thorium and radiothorium are isotopic. as are uranium I and uranium II. On the other hand. since the atomic number of thorium is go, whereas that of uranium is 92, there is one less α disintegration in the sequence from radiothorium to thorium B than there is in the sequence from uranium II to radium B. Thus, from radiothorium onward the thorium series should rather be compared with that part of the uranium series starting from ionium. If this comparison is made. it will be observed that the α disintegrations in the thorium (radiothorium) series are all somewhat more energetic than the corresponding α disintegrations in the uranium (ionium) series. This fact is linked with another: that the mass numbers of the members of the thorium series from radiothorium onward are all two units less than the mass numbers of the corresponding members of the uranium series. In the thorium series. however, there is no counterpart of the radium active deposit of long life; the last α active product is thorium C'.

In a more detailed comparison one difference may be noticed between the series which is of practical consequence. In the uranium series the decay period of uranium II is several million times greater than the decay period of uranium X_1; in the thorium series the period of radiothorium (1.90 yr.) is less than that of mesothorium 1 (6.7 yr.). This fact makes it relatively easy to obtain strong sources of pure radiothorium (by growth and subsequent separation from the mesothorium extracted from thorium minerals in bulk), whereas it is practically impossible to obtain more than insignificant samples of uranium II by the corresponding process (see *Transformation* of *Uranium* above). Since radiothorium is the last product in the thorium series with a period greater than four days, the availability of intense and reasonably long-lived thorium-series sources depends on this favourable circumstance. If a sample of radiothorium is sealed in a glass tube, the whole of the rest of the series will have grown into equilibrium with it in the course of one month: thereafter such a preparation provides a source of the most penetrating γ rays (from thorium C″) available with the natural radioelements. Furthermore, if a negatively charged plate is exposed above an emanating preparation of radiothorium for a period of a few hours, the active deposit collected on the plate provides a source of the most energetic α particles (from thorium C′) naturally available. Much fundamental work has been done with sources of these types. Csing the α particles of thorium C', work on artificial transmutation and nuclear scattering was extended to higher energies (Rutherford and Chadwick, 1925) and the first evidence of resonance scattering by light nuclei was found (S. Devons, 1939). Using the penetrating γ rays. the mode of γ ray absorption by electron-positron pair creation was established (C. D. Anderson and S. H. Neddermeyer, 1933; Chadwick, P. M. S. Blackett and G. P. S. Occhialini. 1934) and the phenomenon of nuclear photodisintegration was discovered (Chadwick and M. Goldhaber. 1934) and further explored (Chadwick. Feather and E. Bretscher, 1937).

Mesothorium 1, the grandparent of radiothorium, is isotopic with radium, and most thorium minerals are of low grade and contain uranium and subsequent products. Commercial mesothorium, therefore. generally has radium as "impurity." If the uranium-thorium ratio in the mineral is 1:10 by weight, nearly one-quarter of the initial activity of the mesothorium concentrate is due to radium (70% of the activity after 20 yr.), assuming equilibrium conditions. By weight, however, in the finally purified mesothorium salt. radium is initially in excess in the ratio 7j:1. Because of these considerations. the only direct method of obtaining mesothorium 1 free from radium is to await its growth in an originally purified sample of thorium. Radiothorium, on the other hand. when it is eventually separated from the commercial mesothorium-radium mixture, carries with it no trace of radium or its products.

Transformations of **Actinouranium.**—It was early recognized that actinium occurs in all unchanged uranium minerals in constant proportion with the uranium: however Boltwood showed that the equilibrium activity of actinium and its products is only a few per cent of the equilibrium activity of the main-sequence products of uranium. At first it was thought that this invariable association could be explained in terms of series branching; later it was found that the correct explanation lay in the fact that the parent members of the two series are isotopic. Actinouranium. the uranium isotope of mass number 23j (see *Transformation* of *Uranium* above), was not discovered until 1935 (A. J. Dempster), but already in 1929 there was strong reason for assuming the existence of this isotope on the basis of F. W. Aston's mass-analysis of the isotopes of uranium lead (see End *Products* of the *Transformations* below). Actinouranium. as its name implies, is the parent of the actinium series as it occurs in nature: it is transformed by a main sequence of four disintegrations (α, β, α, β) into radioactinium. a thorium isotope of mass number 227. The intermediate products in this sequence are uranium Y, protactinium and actinium. Protactinium is an α emitter of relatively long life ($T=3.43\times10^4$ yr.) which occurs in uranium minerals to the extent of about 15% by weight of the radium present. Because of this fact, and because no other long-lived product in any of the three series is isotopic with it, it has been possible to separate protactinium in weighable amounts in a pure form. A. von Grosse determined the atomic weight as 231 in 1935.

From radioactinium onward, and apart from minor branchings, the sequence of transformations in the actinium series is similar to the corresponding sequences in the thorium and uranium series, if the products of the radium active deposit of long life are again disregarded. Mass numbers are one less throughout than those of the corresponding products of the thorium series, and α disintegration energies are greater—except that of the last member of the series. actinium C′. In a broad survey there is nothing of note to be recorded concerning the individual, short-lived products. except that actinium K, the β emitter of half-value period 21 min., originally discovered by M. Perey in 1939 as the daughter product of actinium in a 1.2% mode of α disintegration, was the first isotope of francium (atomic number 87) to be identified. Many other isotopes of this element have since been produced artificially. Actinium K itself also produces a branch product in a rare (0.004%) α mode. This product is an isotope of astatine (atomic number 85), of mass number 219 and half-value period 0.9 min. (E. K. Hyde and A. Ghiorso, 1953). Neither astatine nor francium is represented by a main-sequence product in any of the three naturally occurring radioactive series.

None of the actinium-series products has been used in any of the classical researches involving the radiations from radioactive substances. but in the early years of the exploitation of the fission process the parent body of the series. actinouranium. assumed an importance out of all proportion to its natural abundance. Actinouranium is the only naturally occurring isotope of uranium or thorium which is fissionable using neutrons of thermal energies. It is curious to reflect that this fact assumed such unique importance that an isotope. which had eluded discovery by traditional methods of mass-spectroscopy until 1935. had by 1945 been isolated in kilogram amounts by electromagnetic separation.

End Products of the Transformations.— Once the true nature of the radioactive process was generally recognized and the notion of the transformation series accepted, it became almost necessary to postulate a stable end product (either a known or an unknown element) for each of the three series. From a study of the radium active deposit of slow decay. Rutherford concluded (1905) that radium F (polonium) is the last active constituent of the active deposit and the last member of the uranium series as a whole. He knew the atomic weight of radium (M. Curie, 1903) and had established the fact that polonium was the fifth α emitter in the main sequence from radium onward; he was convinced without formal proof (*see* below) that the α particle is a charged helium atom. On this basis he deduced the atomic weight of the end product to be closely that of lead (in terms of present-day mass numbers. $226-[5\times4]=206$). Pointing out that old uranium minerals invariably contain lead. he suggested that the lead is in fact present as the stable end product of the series. At the same time he gave strong reasons for concluding that the activity separated with lead from uranium minerals: as originally by K. A. Hofmann in 1901, is that due to radium D. These suggestions were made six years before the displacement law mas formulated, but they are seen to be consistent with its provisions. The sequence of transformations from radium D to the assumed end product is β, β, α; thus the two products are isotopic. Moreover, chemically, it soon became clear that radium D is indistinguishable from ordinary lead.

The suggestion that lead is an end product of radioactive transformation was made independently by Boltwood in 1905, and in the following two years he supported this suggestion by chemical analyses showing that the amount of lead present in unaltered uranium minerals of high grade is greater the greater the geological age of the mineral.

During 1914 several determinations were made of the atomic weight of the lead separated from primary uranium minerals (Hönigschmid, T. W. Richards. Maurice Curie). In all cases a value considerably lower than that of ordinary lead (207.21) was found. Based on a wider survey of material. later determinations gave values little different from 206 in some cases (G. P. Baxter and C. M. Alter, 1935; J. P. Marble. 1936). All these results helped to establish the correctness of the previous conclusion that radium G, the daughter product of polonium, is the stable lead isotope of mass number 206.

The analogous decision for the thorium series was not reached so easily. Most thorium minerals contain some uranium, and the end product of this series accumulates three times as rapidly as the end product of thorium. But in 1914 Soddy had already obtained a preliminary value of 208.4 for the atomic weight of the lead in a thorite from Ceylon, and in 1919 Honigschmid obtained a more accurate value of 207.9 with a Norwegian thorite. By that time, however, the displacement law was well established and the sequence of transformations in the main series was fully worked out. and little doubt remained that the end product thorium D was the lead isotope of mass number 208.

Definite proof of the earlier conclusions was finally achieved when the mass spectrograph was applied to the analysis of radiogenic leads of varied origin! and the first direct evidence concerning the identity of the end product of the actinium series was obtained in the same investigation. Thus. for a thorium-lead from Brevig in Norway, Aston found an isotopic constitution 4.6% Pb^{206}, 1.3% Pb^{207} and 94.1% Pb^{208}, and. for a uranium-lead from Morogoro, Tanganyika. 93.1% Pb^{206} and 6.9% Pb^{207}. Since the isotopic constitution of ordinary lead is 1.5% Pb^{204}, 23.6% Pb^{206}, 22.6% Pb^{207} and 52.3% Pb^{208} it was clear that no admixture of ordinary lead could explain the presence of Pb^{207} in uranium-lead, when Pb^{208} was absent. It was thus concluded that, as Pb^{206} is the end product of the yranium series, so Pb^{207} is the end product of the associated actinouranium series, *i.e.*, that actinium D is the lead isotope of mass number 207. This was the first definite assignment of a mass number to any member of that series.

Production of Helium.— In 1902 Rutherford and Soddy suggested that the helium which is invariably found in radioactive minerals is somehow produced in the process of disintegration of radioactive matter. In 1903 Sir William Ramsay and Soddy observed the production of helium by radium and also by radium emanation. Rutherford then adopted the simplifying hypothesis that the production of helium and the emission of α particles are one and the same process, and eventually established the correctness of this view in a masterly series of experiments. In 1906 he showed that the value of e/m (charge/mass) is the same for the α particles from all products, being closely one-half the value of the corresponding constant for the singly charged hydrogen ion.' If the α particle were in fact a positively charged atom of helium it should in consequence be doubly charged. Rutherford and Geiger, therefore, determined the charge carried by the α particle and in 1908 obtained the value 9.3×10^{-10} E.S.U. (electrostatic units). Though Rutherford was convinced that this result implied that the magnitude of the elementary ionic charge was 4.65×10^{-10} E.S.U. (and that the α particle is a doubly charged helium atom), it cannot be pretended that the direct determinations of this quantity at that date gave much support to his view: they ranged from 3.1 to 4.06×10^{-10} E.S.U. In order to convince others, obviously a further proof of the α particle—helium identity was required. This was supplied in the following year when Rutherford and J. T. Royds introduced an intense source of radon into a very thin-walled glass capillary tube, and observed the accumulation of helium in an evacuated vessel surrounding the tube. In a control experiment they showed that the thin glass was quite impervious to ordinary helium under considerable pressure.

As a footnote to this account. it may be remarked that by 1910 R. A. Millikan had already published a preliminary value for the elementary ionic charge of 4.9×10^{-10} E.S.U.—and that the currently accepted value (1957) is 4.80×10^{-10} E.S.U.

The rate of production of helium by radium in equilibrium with its short-lived products was first measured accurately by Sir J. Dewar (1908) and Boltwood and Rutherford (1911). In terms of the international radium standard, one gram of radium in equilibrium with its three subsequent α ray products produces at standard temperature and pressure (S.T.P.) 172 mm.^{3} of helium per year.

Following a suggestion made by Rutherford earlier in the same year. Strutt began a long series of experiments in 1905 with the object of determining the ages of radioactive minerals, from a measurement of the helium contained in them and a knowledge of the amounts of uranium and thorium present. Obviously this method can give merely a lower limit to the age, since there must be some tendency for the helium to escape, except from especially compact and well-crystallized specimens. When the whole of the helium is retained in a high-grade uranium mineral, the effective internal pressure rises, under equilibrium conditions, at the rate of roughly one atmosphere per 1,000,000 yr. Strutt's early work led to estimates of a few hundred million years for the ages of certain Ceylon thorianites containing approximately 70% thorium. but. when the question of the end products of the series had been satisfactorily resolved, it became general to rely rather on determinations of lead/uranium and lead/thorium ratios for estimates of ages of such high-grade minerals. In respect of minerals containing only minute traces of uranium and thorium, however. the helium method was later revived with considerable success. The suggestion originated with A. Holmes (1929) and depended for its success on the development of improved methods of measurement of small quantities of helium (down to 10^{-10} cm.^{3}) by F. A. Paneth and his collaborators. It is possible to estimate ages of a wide variety of igneous rocks over the range 10,000,000 yr. and upward by this method (Holmes and Paneth, 1936; A. C. Lane and W. D. Urry. 1935. 1936).

Heat Emission of Radioactive Matter.— In 1903 it was shown by P. Curie and A. Laborde that a radium compound is always hotter than the surrounding medium, and radiates heat at a constant rate of about 100 g.cal. per hour per gram of radium. The rate of evolution of heat by radium has been measured subsequently by a number of observers. The source of this heat is the energy of the emitted radiations, and is not to be sought in any additional interatomic process. Since the α particles have a large kinetic energy and are easily absorbed by matter, all these particles are stopped by the radium itself or by the envelope surrounding it, and their energy of motion is ultimately transformed into heat. To this contribution must be added the energy supplied by the recoil of the radioactive atom after the expulsion of the α particle, together with that portion of the energy of the β and γ rays absorbed in the envelope.

This view of the heating effect was fully confirmed by measurements of Rutherford and H. R. Robinson (1913) and others. who found that each of the α ray products of radium gave an effect equal to that calculated from the energy of the α particles and the absorbed β and γ rays. Radon and its products, when removed from radium. were responsible for three-quarters of the heating effect of radium in equilibrium. The heating effects of radon, radium A and radium C decayed at the same rates as their activities. Accurate measurements give, for the total heating effect of radium in equilibrium with its short-lived products, and surrounded by sufficient material to absorb all the radiations, a value of 140.1 cal, per hour per gram. Of this 124.4 cal. are due to a particles and recoiling atoms. 6.3 cal. to β particles and 9.4 cal. to γ rays. On account of the great penetrating power of much of the γ radiation, it is difficult to measure its heating effect accurately, but the results show clearly that it is greater than that of the β rays, and that the two together contribute rather more than 11% of the total heating effect of radium in equilibrium with radon and the active deposit of short life.

Experiments on the evolution of heat from radium were early recognized as demonstrating the astonishing amount of energy accompanying the transformation of active matter, especially where α particle. are emitted. For example, one curie of radon in equilibrium with its products emits heat initially at a rate of about 114 cal. per hour. The total amount of heat emitted during its transformation into radium D is about 15,000 cal. The volume of one curie is 0.65 mm.^{3} and its mass 6.5×10^{-6} g. Thus 1 g. of radon emits during its life about 2.3×10^9 cal. of heat. By contrast the combustion of 1 g. of carbon yields 8×10^3 cal., and very few chemical reactions give larger yields.

The distinction between radioactive disintegration and a chemical reaction is that the first involves the nucleus of the atom. whereas the second involves only the outermost electrons. In each case. the energy which is released comes from the rearrangement of the constituent particles. and results in a slight decrease in the mass of the system. The constituent particles in the nucleus are so closely packed, compared with the atomic electrons, that their rearrangement energies are enormously greater and the decrease of mass becomes measurable in favourahle cases. The mass decrease. m, is related to the energy release. E, by the equation $E=mc^2$, where c is the velocity of light. This equation was deduced by Albert Einstein who demonstrated (1905) that, according to the theory of relativity, there is no essential difference between mass and energy. but that energy has mass and mass represents energy. It was first directly confirmed by experiments on artificial transmutation. It appears that in disintegration processes. both natural and artificial, matter is partially converted into energy, a very small change of mass corresponding to a very large release of energy. The most striking example of the enormous amount of energy which can be obtained in this way is provided by the "ideal" fusion process in which helium nuclei are built up from their constitcents with the transformation of roughly 0.75% of the total mass into energy (*see* NUCLEUS).

Nature and Properties of a Rays.—Early experiments showed that the α particle. from whatever radioactive atom it is emitted, is an atom of helium carrying two positive charges. Since helium is the second element of the periodic classification, a doubly charged helium atom is a bare helium nucleus, thus the process of α disintegration consists in the emission of a helium nucleus from the nucleus of a radioactive atom. Only when such an a particle has lost its original energy of emission by passage through matter is it finally neutralized, capturing two electrons and thereafter remaining individually unrecognizable as an ordinary atom of helium gas.

The laws of absorption of a particles in matter were first worked out by W. H. Bragg and R. D. Kleeman (1905). Selecting a narrow pencil of α rays from a thin film of radium of high specific activity, and using a shallow ionization chamber, these investigators found that the curve of ionization per centimetre of path against distance from the source could be analyzed into components of the same shape and of eaual maximum value. representing the contributions due to the radiations from the four α ray products present in equilibrium in the source. For a single α ray product the component curve showed that the ionization per unit path increases with distance from the source to reach a maximum and then falls away rapidly to zero. Empirically. therefore. Bragg and Kleeman were able to define a characteristic range for the a rays from the various products in the series. In order to explain their empirical results they adopted the following assumptions: each product emits α particles of a definite velocity: each α particle travels in an approximately rectilinear path through matter losing energy by ionization at a rate which increases as the velocity decreases: because the number of ions produced by a single α particle is very large the distance traversed in a given medium for complete loss of energy depends only on the initial energy of the particle. Subsequent investigations by more powerful methods entirely confirmed the essential correctness of these assumptions.

The absorption of α particles in matter results essentially from collisions with electrons. As the mass of the α particle is more than 7,000 times the mass of the electron, the energy lost in a single collision is an extremely small fraction of the total energy. This is the reason why a large number of collisions is necessary to stop the a particle completely, and why the stopping distances of all a particles of the same initial velocity are the same. except for small fluctuations. Moreover. since an impact with an electron cannot deflect the a particle appreciably, the a particle will follow a straight path. Collisions with atomic nuclei. which may cause large losses of energy and abrupt changes of direction. are too infrequent to affect the general picture. The fluctuations attending the stopping process were considered theoretically by Niels Bohr in 1915, with results with which later experiments generally agreed. The effect is known as the straggling of the range. In air the mean fluctuation of the ranges around the average value is between 1% and 2% for the various groups of a particles naturally observed. The average value of the range, known as the mean range, is generally used to characterize these groups of a particles. Values of the mean range in air at 15° C. and 760 mm. are given in Table I. Roughly, the mean range is related to the initial velocity of the α particles by Geiger's equation $R=KV^3$, the constant K being determined by the fact that the initial velocity of the a particles of radium C', of mean range 6.91 cm.. is 1.92×10^9 cm.sec.$^{-1}$.

On account of its great energy of motion, the effect caused by a single α particle can be detected in various ways. Crookes first noted (1903) that the α rays produce scintillations when they fall on a screen of phosphorescent zinc sulphide. It was later shown (1908) that each of these scintillations results from the impact of a single a particle. The number of scintillations can be counted with the aid of a suitable microscope, and over a period of about 20 years this method proved of great utility in many investigations. Depending on the human observer, the method was tedious and slow, and it fell into disuse with the introduction of the Geiger-Müller (G-M) counter and the pulse ionization chamber (see below), but the development of the highly sensitive photomultiplier tube later made possible the replacement of visual by electrical recording (S. C. Curran and W. R. Baker, 1944), and scintillation detectors again figured largely in the equipment of laboratories devoted to radioactive research. In place of the thin layers of microcrystals of zinc sulphide or diamond previously employed, a single large crystal of sodium iodide activated with thallium, or a crystal of anthracene, or even a liquid scintillator such as a solution of terphenyl in xylene, may be used as occasion demands. Moreover, with these developments, use of the scintillation method is no longer confined to experiments involving α particles; the modern scintillators are sensitive to β particles and γ rays as well.

In 1910 S. Kinoshita showed that a single α particle produces a detectable effect on a photographic plate. When the a rays fall on a plate at nearly grazing incidence the tracks of the a particles in the developed emulsion are clearly visible under a high-power microscope (M. Reinganum. 1911). With the introduction of special fine-grained emulsions this method became a powerful means of investigation under appropriate conditions.

By the expansion method developed by C. T. R. Wilson (1912), the track of an a particle or a β particle through a moist gas is made visible by condensation on each of the ions produced. The photographs of these tracks bring out in a striking way not only the individual existence of α and β particles, but the main effects produced in their passage through matter.

Rutherford and Geiger first devised an electrical method of detecting single a particles in 1908. The α particles entered. through a small window. a metal tube containing a gas at reduced pressure, and an electric field was applied between the wall of the tube and a central wire electrode. When the applied field was suitably increased the charge communicated to the central wire was large enough to be detected by a sensitive electrometer. A simple counter was later devised by Geiger which responded to single β particles as well as to single a particles. This consisted of a fine needle point (or a small sphere at the end of a wire) placed axially in a metal cylinder. A strong electric field was again required. The modern tube counter of Geiger and W. Müller (1928) has essentially the same arrangement of electrodes as the first counter of Rutherford and Geiger. the thin axial wire being made the anode. This counter is more usually employed, coupled to a simple valve amplifier and electronic scaling unit. for the detection of β particles or of γ radiation. For this application, the conditions are chosen so that the ion-multiplication is very high; then the magnitude of the impulses produced becomes independent of the original ionization. It can also be arranged that the magnitude of the impulse is proportional to the original ionization; then it is possible to distinguish between the impulses produced by α particles and those produced by β particles.

In the counters just described the primary ionization due to the particle is magnified by use of a strong electric field to produce further ionization by collision. An alternative method of detecting a particles is to use a simple ionization chamber and obtain all the magnification electronically. This method was first successfully applied by H. Greinacher (1926) and was further developed by C. E. Wynn-Williams (1927, 1931). From four to six amplification stages may be required and the voltage amplification may be of the order of 10^6 or more. By this method of linear amplification a particles can be counted in the presence of β and γ radiation of much greater intensity.

When α rays fall on a sheet of matter, slow electrons are emitted. These were first studied by J. J. Thomson (1904), and were called by him δ rays (delta rays). Most of the δ rays have an energy corresponding to only a few volts, but a few particles are precent which have much higher energies, some reaching to one two-thousandth of the energy of the a particle (corresponding to tnice its velocity). The δ rays can best be studied by photographing the tracks of α particles in a Wilson cloud chamber containing a gas at low pressure. The swifter δ particles are themselves able to ionize the gas and their tracks are easily visible. Chadwick and K. G. Emeleus and also P. Auger. have shown that the number and velocity of the swifter δ rays agree excellently with the view that they are produced by the collision of a particles with the atomic electrons. The primary process of ionization is the removal of an electron (δ particle,. Secondary ionization is then produced by δ particles which have sufficient energy. In general the primary ionization is about one-half the total ionization observed. For the α particles of radium C', the total ionization in air is about 2.2×10^5 ion pairs per a particle.

The α particle at the moment of expulsion from a radioactive nucleus is doubly charged, and at first it was supposed that it retained this charge until very near the end of its range where the charge was neutralized by the capture of two electrons. Later work, however, by G. H. Henderson and Rutherford showed that the α particle changes its charge several thousand times in its passage through matter. When a rays pass through a sheet of matter in a good vacuum, the issuing rays consist of doubly charged, singly charged and neutral helium atoms. At high speeds the doubly charged particles predominate; at low speeds most of the particles are singly charged or neutral. It seems clear that the a particle in its passage through matter occasionally captures an electron and that this may be removed in a subsequent collision. This process of capture and loss of electrons is repeated many thousand times before the a particle is brought to rest.

Although most a particles travel in an almost rectilinear path through absorbing material, there is in general a small scattering or deflection of the a particles in passing through matter, amounting on the average to a few degrees. This scattering occurs mainly toward the end of the path. In addition, occasionally there is a large-angle scattering. This large-angle scattering is caused by a close collision of an α particle with a single atom of matter. A detailed study of the laws of single scattering of a particles was first made by Geiger and E. Marsden (1913). This investigation confirmed in precise detail predictions based on the nuclear atom model put forward by Rutherford in 1911 (*see* NUCLEUS). Later, Blackett obtained expansion photographs showing close collisions of α particles with the nuclei of light atoms. such as hydrogen. helium, nitrogen and oxygen. In general a forked track is observed, one branch caused by the scattered α particle and the other by the recoiling nucleus.

Relation Between Range of α Rays and Period of Transformation.— It was early observed that there appeared to be a connection between the period of transformation of a product and the velocity of the a particles which it emits. The shorter the period of transformation. the greater is the velocity of expulsion of the a particle. This connection was originally expressed in terms of R, the range of a particles in air, and λ, the constant of transformation. by the relation $\log \lambda = A + B \log R$ (Geiger and J. M. Nuttall, 1911). Herr A and B are constants for the a emitters of any one transformation series. and B is in fact nearly constant for all three series. If the initial velocity, or the initial energy, of the α particles is used instead of the range. a relation of the same general form is obtained.

The Geiger-Nuttall relation. although only approximately fulfilled. was rightly regarded as of fundamental importance. One of the most striking successes of the theory of a disintegration, advanced by G. Gamow and by R. W. Gurney and E. U. Condon in 1928, was that it provided an explanation of this empirical rule.

Theory of α Disintegration.— The difficulty encountered in forming a theory of a disintegration can be illustrated by the case of uranium. Scattering experiments using the a particles of thorium C' (energy nearly 9 Mev) show that there is no appreciable departure from the coulomb potential down to a distance of 3×10^{-12} cm. from the uranium nucleus. At smaller distances, to which these α particles cannot penetrate. there must be large deviations from this potential. to account for the nearly stable binding of α particles in the nucleus. The general shape of the potential field between the nucleus and an a particle is therefore as shown in fig. 5, where the dotted line represents the coulomb potential energy

$$V(r) = \frac{2Ze^2}{r}$$

On the other hand. the α particles emitted spontaneously by

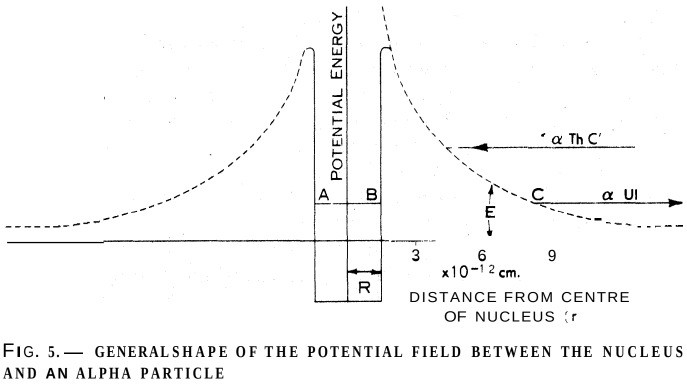

FIG. 5.— GENERALSHAPE OF THE POTENTIAL FIELD BETWEEN THE NUCLEUS AND AN ALPHA PARTICLE

uranium have an energy of only about 4 Mev. As these α particles must come from inside the nucleus, it is impossible to explain, on the basis of classical mechanics, how they can surmount a "potential barrier" requiring at least twice their energy. In quantum mechanics (*q.v.*), however, there is the possibility of "leakage" through the barrier. An adequate description of the theory can only be given in terms of E. Schroedinger's equation for the time variation of the wave function of the α particle, which enables a calculation to be made of the probability of the α particle being found outside the nucleus after a certain time. A semi-classical description can be given by supposing that the α particle inside the nucleus has available energy indicated by the height of the line AB (fig. 5), along which it oscillates making collision with the walls of the barrier. At each collision, the particle has a small but finite chance of penetrating the barrier and escaping, The greater the chance of penetration, the fewer oscillations mill be necessary, on the average. for escape to occur and thus the shorter the period of transformation. This chance depends markedly on the height and thickness of the barrier, or (as the figure indicates), on the available energy of the particle, that is on the energy of disintegration. Thus it can be seen that in a general way a body which emits fast α particles will have a short period, and one which emits slow α particles will have a long period. Detailed calculation leads, in fact, to a relation between the transformation constant and the energy of the α particle which is similar to the Geiger-Nuttall relation. Further, the calculation leads to values of the nuclear radii R (fig. 5) of the radioactive atoms which are. for members of the same series. close to one another and in general agreement with values of the nuclear radius as deduced in other ways.

Long-Range α Particles and Fine-Structure Groups. — For many years it was believed that all α particles emitted by a given product were emitted with exactly the same velocity. The first departures from this rule were found in the cases of thorium C' and radium C'. In thorium C', two weak groups of α particles were found (1916) which have ranges of 9.8 cm. and 11.6 cm., considerably longer than the normal group of 8.6 cm. range. The long-range emission of radium C' is more complicated. consisting of several groups with ranges between 7.7 cm. and 11.5 cm. In each case. the intensities of the long-range groups are very small, being about 10^{-4} to 10^{-6}, or less, of that of the main group. These long-range groups are believed to arise in the following way. The β transformation of the C nucleus sometimes leaves the C' nucleus in an excited state. There are then two possibilities: the nucleus may go to the ground state by emitting a γ radiation. when the normal α disintegration follows. or an α particle only may be emitted. taking away the excess energy of the excited nucleus. The relative probabilities of these two processes are the probabilities of γ emission and of emission of an α particle of high energy. Except when the energy available for α disintegration is very great, the probability of γ emission is generally much the larger of the two. This explains' why long-range particles have been found only with radium C′ and thorium C. On this explanation. the measurement of the energies of long-range groups gives part of the energy level system of the α emitting nucleus, and the energy differences should correspond to the energies of γ rays emitted from that nucleus in alternative modes of de-excitation. This has been borne out by examination of the γ ray spectra relative to the transitions in question.

The more common complexity in α emission involves the so-called fine-structure groups. It was originally observed by S. Rosenblum (1929), who was the first to investigate α particle spectra using a focusing spectrograph. A complexity of this type, of greater or less prominence. was later shown to be an almost universal feature of α disintegration. Among the α emitters of the main sequences. direct or indirect evidence of fine-structure emission was found (by the mid-1950s) for all except the polonium isotopes radium A, thorium A. actinium A, radium C′ and thorium C'. As the name implies, normal α emission in general consists not in the emission of a single group of α particles all of the same energy, hut in the emission of α particles having a sharp-line spectrum of energies in a narrow range. Only because of the narrowness of this energy range (generally less than 5% of the maximum energy in any case) did the effect escape notice for so long. The explanation of the phenomenon is basically simple: here α disintegration always occurs from the normal state, but the product nucleus may be left in its normal state or in some excited state. In the latter event less energy is available for the emitted α particle, and the energy retained is almost immediately released as γ radiation from the product. More difficult considerations are involved in explaining relative intensities in detail. but the rapid decrease in α disintegration probability with decrease in available energy is the main factor limiting the excitation of the product nucleus to its lower energy states. If the lowest excited state of the product nucleus has too high an energy, fine-structure groups will not be observed. This is almost certainly the explanation of the nonobservance of such groups with the five polonium isotopes listed. The products of α disintegration in these cases are isotopes of lead and it is known from other evidence that, particularly for even mass numbers, first excited states of lead isotopes are of unusually high energy.

The predicted correspondence between energy differences among fine-structure groups and energies of γ rays has been confirmed in all cases investigated in detail, only in this connection, and in relation to long-range α particle emission, it should be stated that α particle energies must he "corrected" for the energy of nuclear recoil before an accurate balance is achieved.

Properties of β Rays. — The early experiments showed that β particles which are emitted in radioactive disintegration consist of negative electrons spontaneously liberated in the transformation process. The maximum energy of emission varies widely for different products, from several thousand electron volts up to a few million electron volts. The penetrating power of the rays varies correspondingly: *e.g.*, β rays of radium D are so easily absorbed by matter that they are difficult to detect, while those of radium C can pass through a few millimetres of aluminum before they are finally stopped. At first sight, the laws of absorption of β particles by matter appear different from those relating to α particle absorption, although the process of energy loss is essentially the same. The difference is mainly due to the fact that the electron mass is less than one seven-thousandth of the mass of the α particle, as a result of which β particles are much more easily scattered. Whereas an α particle can be deflected from its straight path only by collision with a nucleus, a β particle can also transfer a large fraction of its energy and momentum to any of the extranuclear electrons which it encounters. Consequently. β particles are frequently deflected from their course and in general pursue tortuous paths in their passage through matter. If they may still be regarded as having a "range" in matter, this range is far from being so well-defined as that of the α particle. Thus the study of the passage of β particles through matter is much more complicated. both in theory and in experiment. than is the same problem for a particles. Although the energy of β particles is in general considerably less than the energy oi the α particles from radioactive bodies, their velocity is generally much higher. For that reason alone, β particles produce fewer ions per unit path than α particles do. and the disparity is increased roughly fourfold due to the difference in charge. An a particle of 3 Mev has a velocity of about 0.04 c (c being the velocity of light) and produces about 4.000 ion pairs per millimetre of its path in air; a β particle of the same energy has a velocity of about 0.99 c and produces only about 4 ion pairs per millimetre of path. Because of this small rate of energy loss a β particle has a much greater range than an a particle of the same energy. Thus, in the example, the aparticle has a range in air of about 1.7 cm., the β particle approximately 13 m. The difference in behaviour between α and β particles is strikingly shown in experiments with the expansion chamber. In contrast to the short, straight and densely ionized tracks of the α particles, those of the β particles are long, show many gradual deflections and occasional forks resulting from close collisions with electrons, and are sparsely populated with ions. In addition to the loss of energy by ionization, there is a loss of energy by radiation, caused by the sudden deceleration of the β particle in nuclear encounters, an effect which is responsible for the emission of X-rays of the continuous spectrum when cathode rays are stopped by a target. The production of γ rays hy β rays in passing through matter was first observed by J. A. Gray (1911).

A great difficulty in the study of the detailed properties of β particles is that the particles emitted by a single radioactive product are not homogeneous, but differ widely in velocity. In the early days, it was found that the absorption of the β rays irom a single product appeared to follow an exponential law, and different groups of β rays were characterized by different absorption coefficients. The exponential law is now known to be the almost fortuitous result of the initial wide-spread energy distribution and the complexity oi the absorption process; a group of homogeneous β rays is not absorbed according to an exponential law. Insofar as absorption methods are still used to analyze the β radiations irom radioactive products. determination of effective foil ranges (Feather, 1938) replaced determinations of exponential absorption coefficients. For energies greater than about 0.7 Mev the foil range increases linearly with the β particle energy.

β Ray Spectrum and the Disintegration Process.—The β particles arising irom the disintegration of a single product are expelled with velocities covering a wide range. This fact was first adequately recognized when the β rays from a product such as radium B or radium C were analyzed in a uniform magnetic field.

Originally, the magnetic spectra so obtained were recorded photographically and many sharp lines were observed, each line representing a group oi particles having a well-defined velocity of emission. Then the more tedious electrical methods of recording were tried (more tedious because a spectrum has to be mapped from point to point, rather than recorded as a whole) and it was found that the lines were superimposed on a continuum. representing particles of all velocities from zero up to a limiting value characteristic of the β ray product concerned. With some products, as later investigations showed, the line spectrum is very complex; with some products it is relatively simple; with radium E, in particular, it is entirely absent. This last fact alone is sufficient to suggest that the line spectrum represents electrons of secondary origin, but it was not definitely known when the question was first decided. In 1914 Rutheriord. Robinson and W. F. Rawlinson showed that a line spectrum could be obtained with a source consisting of a radon-filled capillary tube having a metal sheath sufficiently thick to obliterate all trace oi homogeneity in the electrons emitted from the active deposit in the tube. The line spectrum which was then obtained was quite similar in structure to the natural spectrum, and could have been due only to the effect of y rays from the source in ejecting electrons from the atoms in the surface layers of the metal sheath. It was most likely, therefore, that the natural line spectra observed with unshielded sources were to be similarly explained. as being due to internal conversion of y rays in the radioactive atoms themselves (*see* below). In 1914 also, Chadwick showed by the electrical method, that even when the line spectrum is prominent as with radium (B+C) it represents only a small fraction of the total electron emission of the source. By far the greater iraction belongs to the continuous distribution. Chadmick therefore proposed that the continuous distribution represents the primary β particles. and the line spectrum a secondary effect due to γ radiation, as Rutheriord and his collaborators independently concluded. Later experiments showed that in all cases the disintegration electrons are ejected from the radioactive nucleus mith a continuous distribution of velocities, and that the number of particles in this continuous spectrum corresponds, within the accuracy of experiment, to one particle for each disintegration. The iorm of the distribution was determined for most oi the natural β emitters. The general result is that in the simplest cases the distribution curves are similar, showing a definite maximum and then decreasing to zero at a well-defined upper limit of energy. The form of the distribution in the region of very low energies is difficult to determine accurately; on the other hand, it is the upper limit oi the energy mhich is characteristic of the radioactive product. Radium E and uranium X_2 provide essentially simple spectra, the upper limit of energy in the first case being 1.17 Mev and in the second 2.32 Mev. The value of this end-point energy is an important constant, for in theory it fixes the total energy released in the β disintegration. There is a relation between the maximum energy of β rays emitted by a product and its rate of disintegration. first pointed out by B. W. Sargent (1933), but the relation is not so simple as the Geiger-Nuttall relation in the case of a disintegration.

The distribution curve of the β ray spectrum should be simplest when the product nucleus is formed only in its ground state, as is the case in the absence of γ radiation. In most cases, however, β transformation is more complex and the new nucleus can be formed in any one of a number of excited states; the transitions from these excited states to the ground state account for the y radiation which accompanies such β transformations. In these cases, thereiore, the energy distribution curve of the β ray spectrum will be complex, consisting oi a superposition of a number of continuous spectra, each one of which has a definite upper energy limit and corresponds to a β transformation to a certain quantum level of the resulting nucleus. The successful analysis of a complex β ray distribution into simple or partial spectra provides information on the quantum states of the new nucleus, as in the case of the fine structure of a emission. Because of the nature of the spectra, this analysis is difficult to carry out in practice, but developments of older coincidence methods (W. Bothe and others, 1935, 1937; Feather, 1940) have greatly increased the possible range of experiment.

The process of β decay, in which the transformation of one nucleus into another appears to take place with a release of energy varying between wide limits, is in such strong contrast to the process of a decay, and indeed of all other nuclear phenomena, that for some time the facts were not generally accepted. It was suggested, *e.g.*, that β particles are all liberated initially with identical energies and that the continuous spectrum results irom varied losses of energy suffered by the different particles in escaping irom the atom. This supposition was disproved by direct experiment, in mhich the average energy released per disintegration of radium E was measured calorimetrically. The experiments (C. D. Ellis and W. A. Wooster, 1927; Meitner and W. Orthmann, 1930) gave an average energy of 0.34 Mev, in close agreement with the average value deduced from the observed distribution curve. and far from the upper limit of 1.17 Mev. There can thereiore be no doubt that β particles are emitted from the nucleus with different energies. On the other hand, all phenomena connected with α and γ ray emission show that the radioactive nuclei have well-defined quantum states and that the energies of the initial nucleus and oi the product nucleus have well-defined values. In order to retain the conservation of energy for the process of β decay it is necessary to assume that part of the energy of disintegration is emitted in the iorm of a new arid undetected type of radiation. W. Pauli (1931) suggested that this radiation may consist of particles bearing no electric charge and of small. possibly zero, mass. Such particles. called neutrinos, would have practically no interaction mith matter and thus could not be detected directly. On this assumption the β decay process consists of the simultaneous emission of an electron and a neutrino, mhich share the constant total energy of disintegration between them in arbitrary proportions. The β particle then has its maximum energy when the neutrino is emitted with zero velocity, and the total energy of the disintegration process is equal to the maximum energy of the β rays plus the self-energy of the electron, mc^2, assuming that the neutrino mass is zero. In all cases where a test has been made, this assumption has led to consistent results.

In addition to preserving the conservation oi energy in the β decay process, the assumption of a neutrino resolves other difficulties, for experimental evidencr shows that nuclear angular momentum cannot be conserved unless an additional particle is emitted along with the electron in β decay. The correct relations regarding spin may he restored if a spin of one-half quantum unit is ascribed to the neutrino. At the mid-1950s all attempts to observe effects resulting irom the interaction oi neutrinos with matter had failed. but such a result can be expected from the properties which the neutrino must be assumed to possess. Some experiments, with artificially produced β emitters, in which the energ) anti linear momentum oi the emitted β particle and the associated recoiling nucleus were measured, indicate, however, that linear momentum is not conserved if only these two particles are involver1 in the disintegration. These experiments gave further support to the hypothesis of the neutrino.

A successful theory of the β disintegration process mas first put forward by E. Fermi (1934), on the basis oi the neutrino hypothesis. Fermi supposed that β disintegration consists essentially of the transformation, inside the nucleus, of a neutron into a proton. with the simultaneous emission of an electron and a neutrino. In this way he was able to explain the general shape of the continuous spectrum of primary β rays, and also to deduce a relation between the transformation constant and the maximum energy of β particlrs, analogous to that found empirically by Sargent. Although many details remained to be decided. this theory stood the test of more than 20 years comparison mith experiment, and in the mid-1950s it appeared to provide the only possible description and explanation of β disintegration on the basis of quantum mechanics.

Properties of γ Rays.—The γ rays from radioactivr substances are electromagnetic radiations. A γ radiation may be characterized by its wave length, usually expressed in X units (1 X unit = 10^{-11} cm.), by its irequency ν, or more often by the energy of the quantum $h\nu$, generally stated in electron volts. The spectrum of the γ radiation irom any one product consists of one or more discrete lines which may differ widely in wave length and in intensity. The spectral region occupied by these lines extends upward from the soft X-ray region of a few thousand electron volts quantum energy to the region of a few million electron volts.

The absorption of γ rays by matter is analogous to the absorption of X-rays. but at the higher frequencies the relative importance of the various absorption effects changes. The absorption follows an exponential law with thickness of matter traversed, but, in order that experimentally determined absorption coefficients will be significant, it is essential that the geometrical conditions of the experiment should be such that scattered radiation is prevented from reaching the detector.

The absorption of γ rays in matter is mainly caused by interaction mith the electrons. There are three distinct processes—scattering, photoelectric absorption and the creation of positive and negative electron pairs. The relative importance of these three processes depends upon the irequency oi the radiation and the atomic number of the absorber. The experimental investigation of the three types of interaction is thus complicated by the difficulty of separating their effects.

In the classical theory of scattering, a free electron is assumed to he set in vibration by the electric field of the incident radiation. emitting spherical waves of the same frequency as the incident waves. Thus on the classical theory the scattered radiation has the same wave length as the incident radiation. This theory proved adequate to describe the scattering oi soft X-rays by light elements. However, it was noted by J. A. Gray (1913) that scattered y radiation is more easily absorbed than the incident γ radiation, indicating a change of wave length, but these experiments did not attract much attention. The explanation of the change of wave length on scattering and the calculation of its magnitude, was given by A. H. Compton (1923), together with more direct experimental proof. Compton's argument was that the process of scattering must be regarded, on the quantum theory, as a collision between a photon (quantum of radiation) of energy $h\nu$ and an electron. In such a collision, the electron will, in general, be ejected from the atom and the photon will be deflected from its original direction. In this case, since the photon transfers momentum and energy to the electron, the scattered quantum will have less energy than the incident quantum. Scattering will therefore be accompanied by a change of frequency or wave length. However, if the electron is very tightly bound in the atom, the collision will be effectively with the whole atom and there will be scattered radiation of unmodified frequency. That such scattering occurs is clear from the diffraction and interference effects obtained with crystals; these effects could not occur if the scattered radiation were not coherent. This unmodified scattering becomes less important with increasing energy of the photon; with high-energy y rays it can only be detected with difficulty.

The Compton effect (*q.v.*) is of great importance in the case of high-frequency radiations, such as in general compose the y rays emitted by radioactive substances, ior it means that the radiation becomes degraded to longer nave lengths as it passes through matter. In detail, the effect has been established experimentally by observation both oi the change of irequency as a function of angle of scattering, and also of the simultaneous production of the scattered quantum and the recoil electron. A detailed quantum theory oi the eifect has been given by O. Klein and Y. Nishina (1929) on the basis of P. A. M. Dirac's relativistic theory of the electron.

Absorption of γ rays by the photoelectric effect occurs when the whole energy $h\nu$ of the quantum is transferred to an electron in one or other of the K, L, *M*, etc., levels of the atom. The photoelectron is ejected with kinetic energy $E = h\nu - W_i$, where W_i is the energy required to ionize the atom in the corresponding quantum level. In this case, the quantum oi radiation disappears completely and the residual atom takes up the momentum available according to the conservation law.

For light elements and for γ rays of energy of the order of 1 Mev, absorption occurs almost entirely by Compton scattering. For heavy elements anti radiation of low energy, absorption is due mainly to the photoelectric eifect. In the intermediate range, the two processes are comparable in their effects.

The third mode of absorption—electron-positron pair creation—does not become effective until the energy of ? rays exceeds 1 Mev. Its occurrence mas not recognized until 1934; in what follows its discovery and its general character will be briefly described.

In 1932 experiments by L. H. Gray and G. T. P. Tarrant, C. Y. Chao and others showed that for γ rays of high energy the absorption in heavy elements is not entirely accounted for by Compton scattering, coherent scattering by bound electrons or the photoelectric effect. Some additional effect had to be postulated and it was found that it involved the production in the absorber of secondary radiation of which the main component had a quantum energy of about 0.5 Mev, independent of the energy of the primary radiation. This secondary radiation was nt first attributed to nuclear fluorescence, but a more satisfactory explanation came with the discovery of the positron. The additional absorption process was then shown to he due to creation of positron-electron pairs, and the secondary radiation was explained as the annihilation radiation of the positrons so created.

The explanation of this process is derived from Dirac's relativistic theory of the electron and its requirement of negative energy states as well as positive energy states for the free particle. In order that this theory shall coniorm with reality, the negative energy states must be regarded as in general completely filled (and in that condition unobservable) but an electron in such a state may be raised to a state of positive energy by absorption of a suitable quantum. A quantum of energy greater than 2 mc^2, where mc^2 is the rest energy of the electron, is required. This absorption process will manifest itself in the creation of a pair of particles, a negative electron in a state of positive energy and a positive electron corresponding to the "hole" left in the negative energy states. This process is analogous to the photoelectric effect. It cannot occur in empty space ior, as the quantum is wholly absorbed, energy and momentum cannot both be conserved; it occurs ,in the electric field near a nucleus and the nucleus takes up the extra momentum. The probability of pair production increases with increasing quantum energy of the radiation and is proportional to the square of the nuclear charge number. Z, of the absorbing element. As the probability of Compton scattering is proportional to Z, the number of extranuclear electrons, and decreases with increasing energy, the total absorption coefficient should first decrease and then increase again, as the quantum energy increases. The energy at which the absorption is least should increase with decreasing *Z*. For lead, the minimum absorption coefficient occurs lor γ rays of about 3 Mev, for aluminum, for γ rays of about 20 Mev energy.

γ **Ray Spectra.**—The spectral distribution of y rays has been examined in a few cases by means of diffraction in crystals. The first work oi this kind was done in 1914 by Rutherford and E. N. da C. Andrade who studied the spectrum obtained by transmission through a thin crystal of rock salt using the γ radiations emitted by a fine glass tube filled with radon. A complicated spectrum of sharp lines was observed and the wave lengths of some of the γ rays of radium B and radium C were deduced from the measurements. Later, similar experiments were conducted by M. Frilley and J. Thibaud, using the method of surface reflection at nearly grazing incidence.

These early experiments were carried out with flat unstressed crystals. In 1930 J. W. M. DuMond and H. A. Kirkpatrick gave the theory a focusing spectrograph employing a bent crystal, either in transmission or reflection. The method was first applied to the study of y rays by H. Huluhei and Y. Cauchois in 1934, using a transmission instrument to record the spectrum photographically with an extended source. This method was later developed into one of great precision by DuMond and collaborators (1947). Using an effectively line source of radon and a scintillation counter as detector these workers achieved an accuracy oi 1 part in 4,000 in the wave length of the γ ray of energy 609.4 kev (1 kev = 1000 electron volts) of radium C (1952). The real limitation of the method is one of intensity—it requires sources at least 100 times as intense as any other method for successful application—otherwise it has the great advantage of simplicity of interpretation. With this proviso, it is certainly applicable up to y ray energies of 1.5 Mev.

Nearly all the information on γ ray spectra of the natural products was obtained before the above developments took place, and was in fact derived from a study of the line spectra of electrons to which reference has already been made. In 1921 Ellis continued the work of Rutheriord, Robinson and Rawlinson, comparing the natural line spectra with the excited line spectra representing the electrons ejected from thin foils of heavy elements by γ rays. Ellis obtained conclusive evidence that the more intense lines in the natural spectra occurred in groups, corresponding to similar groups of lines in the excited spectra. For a given product, or for a given foil, the energy differences among the lines in the various groups were constant, being characteristic oi the product or (alternatively) of the material of the foil. Ellis identified these energy differences as the differences between the energies of binding of the extranuclear electrons in the *K*, L, *M*, etc., levels of the atoms concerned, and so attributed each group of lines to a single γ ray, whose quantum energy $h\nu$ was given consistently by the quantities $E_1 + W_K$, $E_2 + W_L$, $E_3 + W_M$, etc.; E_1, E_2, E_3 being the energies corresponding to the electron lines of a given group and W_K, W_L, W_M the electron-binding energies as specified. The excited line spectrum, on this interpretation, represents the ordinary process of photoelectric absorption in the material of the foil, the natural line spectrum a process of internal conversion of the γ ray in the atom of origin. By a detailed comparison of the intensities of corresponding lines in the natural and excited spectra, Ellis and G. H. Aston (1930) first showed that the internal conversion process is more complicated than the external process of photoelectric absorption. It mas later recognized that the original description was inadequate: the process of internal conversion is more correctly described as a direct transfer of energy from the nucleus to the extranuclear system. The excited nucleus may get rid of its energy of excitation either by emission oi a quantum of γ radiation, or hy ejection of an electron from the outer atom. In the latter event, part of the energy of excitation is retained for a short time as energy oi ionization of the atomic level from which the electron was ejected. Subsequently, this energy, also, is emitted as a quantum of fluorescent X radiation, or again alternatively, and in part only, as kinetic energy of an electron ejected from a less tightly bound atomic level, according to another type of internal conversion process first described by Auger in 1926.

In the study of γ ray energies by the method of the natural line spectrum it was originally a matter of practical as well as theoretical importance to know whether the binding energies W_K, etc., effective in the conversion process are those of the initial or the product atom, *i.e.*, whether γ rays are emitted before or after the expulsion of the disintegration particle from the nucleus. This was investigated by Ellis and Wooster (1925), Meitner and others, by various methods. The general conclusion was that, in all cases investigated, whether of α or β disintegration, the y ray follows the emission of the disintegration particle. For example, the γ rays which are ascribed to the disintegration of radium B, of nuclear charge number 82, are actually emitted, following the β disintegration of that body, irom nuclei of charge number 83, and are converted in the electronic levels of atoms of atomic number 83. The associated fluorescent X radiation is that of bismuth ($Z = 83$), not that of lead ($Z = 82$). This general conclusion accords with the modern view concerning the origin of γ radiation introduced in the discussion of α and β ray spectra; *i.e.*, that γ radiation is emitted from the nucleus rather than the outer atom (a question undecided until 1922) and that the necessary excitation of the nucleus is provided at the expense of the energy carried away by an α particle or a β particle in a disintegration process.

For a complete description of any radioactive transformation, in which a parent product X gives rise to a daughter product *Y*, it is necessary to know not only the energies hut also the intensities of all the radiations, both primary and secondary, emitted by *X*. As regards the primary radiations, α or β particles, the detrrmination of relative intensities is comparatively simple ior the α particles, though still difficult for the β particles. Even the determination of energies is not always unambiguous in a complicated case of β-disintegration (see β

Ray Spectrum and the Disintegration Process above). Supposing energies and intensities oi the primary radiations of X to be known, however, there may be 'deduced the relative energies and the intensities of population oi the various energy states in which the nuclei of *Y* are formed. Here it is not necessary that the ground state of Y should be among the states so populated. Formally, the next step is to check that the energies and intensities of the secondary radiations, internal conversion electrons and γ ray quanta, are such as to account precisely for the complete de-excitation of the originally excited Y nuclei. In order to carry out this check, each y ray energy has to be identified as the difference between the energies oi excitation of two nuclear states (and for this purpose states other than those populated in the primary disintegration map have to be postulated), and to the intensity of the y ray has to be added the intensities of the corresponding internal conversion electrons in order to derive the total intensity of the de-exciting transition from the upper to the lower state in question. In most cases the intensities of internal conversion electrons can be determined with good accuracy, but the determination of γ ray quantum intensities is still a matter of considerable experimental difficulty when the spectrum is other than very simple. For this last determination the most reliable method makes use of the Compton effect. The number oi Compton electrons produced in a foil, or in a scintillator, under standard conditions, gives the intensity of the γ ray, when the scattering coefficient is known. When it is realized that ior a y radiation of definite energy the Compton electrons have all energies from zero to a maximum, it will be obvious that this method cannot be one of high resolution without great sacrifice of sensitivity.

Thus a formal account oi the process of achieving a complete description oi a radioactive transformation has been given. In practice the sequence of events is generally quite different: the description is built up and refined as, and when. information on one or another aspect of the transformation becomes available. For some natural products, mainly a emitters, the description is now reasonably complete; ior others, in particular the complex β emitters such as radium C and mesothorium 2, in spite of many detailed investigations, much remained in doubt in the mid-1950s. Only the general basis of the interpretation appears secure in all cases.

Radioactivity of Ordinary Matter.— All matter shows a very weak radioactivity, which in most cases is caused by the presence of extremely small amounts of the well-known radioelements. Thus, in general, one gram oi a common metal will contain an impurity of the natural radioelements of the main series equivalent in activity to about 10^{-14} or 10^{-15} g. of radium. However by the mid-1950s six cases had been definitely established in which the activity is not caused by a contamination of the known radioactive elements but is characteristic of the element itself. The six elements are potassium, rubidium, indium, lanthanum, samarium and lutetium. The activities of potassium and rubidium were discovered by N. R. Campbell and A. Wood in 1907; the others were iound many years later.

Potassium emits a β radiation of maximum energy 1.33 Mev and a small amount oi penetrating y radiation. These two radiations are in no way related. The product of β disintegration is calcium; the γ radiation is emitted following an alternative mode of transformation, by capture of an orbital electron, which decreases the nuclear charge by one unit and so produces argon. This type of transiormation is not represented among the naturally occurring heavy radioelements, but, since its discovery by L. W. Alvarez in 1937, is well known among the artificially produced active species. By separation of the isotopes of potassium it has been shown that both activities are due to the isotope of mass number 40 present in ordinary potassium to the extent of about 1 part in 8,000. The half-value period is 1.2×10^{9} yr.

Rubidium emits an easily absorbed β radiation, but its amount is, weight for weight, greater than that of potassium. The active isotope is that of mass number 87, which has an abundance of 27% in ordinary rubidium. The period of transiormation is 6×10^{10} yr.. and the product is strontium. Strontium has been extracted irom a sample of lithium mica which contained irom 2% to 3% of rubidium. A mass-spectroscopic examination oi this strontium showed that it consisted almost wholly (99.7%) of strontium 87, whereas ordinary strontium contains only 7% of this isotope.

The discovery of the β activity of indium was made by E. A. Martell and W. F. Libby in 1950. In this case the active isotope is indium 115, which constitutes 96% of the natural element. The half-value period is 6×10^{14} yr.

The activity of lanthanum was first detected in 1950. In 1947 a second isotope, lanthanum 138, was found to occur to the extent of 0.09% in ordinary lanthanum, and the activity later observed by R. W. Pringle and collaborators has been ascribed to this isotope. It is transiormed chiefly by electron capture, followed by y emission, giving barium 138 as product, and to a lesser extent by β emission producing cerium 138 The period of transiormation is 7×10^{10} years.

Samarium was shown to be a natural α emitter by von Hevesy, M. Pahl and R. Hosemann in 1933. The α particles have a mean range of 1.13 cm. in standard air and an energy of 2.16 Mev. It was established, by separation of isotopes, that the active isotope is samarium 147 (B. Weaver, 1950); half-value period 1.3×10^{11} yr. Samarium is unique among the stable elements of even atomic number in that there is a gap in the mass spectrum of its isotopes of even mass number: samarium 146 is missing, When this species was produced artificially (D. C. Dunlavey and G. T. Seaborg, 1953) it was shown to be an α emitter of period $j \times 10^{7}$ yr. These two isotopes of samarium, thereiore, of mass numbers 146 and 147, are natural α emitters, but only samarium 147 is of sufficiently long life to be found in significant amount (15%) in terrestrial sources.

The rare (2.5%) isotope oi lutetium of mass number r76 mas discovered in 1936. In 1938 M. Heyden and W. Weielmeier iound natural lutetium to be radioactive and ascribed the activity to this isotope. This ascription was later confirmed. Lutetium 176 emits β particles followed by low-energy y rays. It is probable that the alternative mode of capture disintegration also occurs with intensity of the order of 3%. The half-value period is 4.6×10^{10} yr.

In surveying the results which have been obtained in these difficult investigations of weak natural radioactivities, two generalizations may be noted. The first is that for elements of odd atomic number greater than 7, any isotope of even mass numher is radioactive. Potassium 40, lanthanum 138 and lutetium 1j6 exemplify this rule. The only case in which the rule had not been verified was that of vanadium. Vanadium 50 was discovered in 1949, present to the extent of 0.25% in natural vanadium, but all attempts to detect its radioactivity as oi the mid-1950s had failed. The second generalization is that, if two elements of neighbouring atomic number have isotopes of the same mass number, then at least one oi these isotopes is radioactive. Potassium 40, rubidium 87, indium 115, lanthanum 138 and lutetium 176 represent the unstable members of isobaric pairs of this character. If vanadium 50 is stable, this rule is broken twice: titanium 50 and chromium 50 are certainly stable species. Three other examples of the apparent infringement of the rule remained; they were provided by the neighbouring isobaric pairs cadmium 113 and indium 113, antimony 123 and tellurium 123, rhenium 187 and osmium 187. In spite of various reports. first that osmium and then that rhenium is radioactive, the most thorough investigation (D. Dixon and A. McNair, 1954) can be taken as showing that neither is demonstrably so. It is unlikely, ior example, that the transiormation period of rhenium 187 can be less than 10^{15} yr. Somewhat similar statements can be made in respect of the other two pairs. The theoretical basis for this rule concerning neighbouring isobars lies in the assumption that the mass of the neutrino is zero. By the mid-1950s it seemed so unlikely that this assumption was seriously in error that it was reasonable to suppose that at least four species, then classified as stable on the direct evidence of experiment, are in fact feebly radioactive. Vanadium 50 could be one of these, and probably cadmium 113 another (Feather, 1952).

RADIO ASTRONOMY is a branch of astronomical science. In its first quarter-century it contributed fundamental information to a variety of classical astronomical problems: the statistics of meteors. the structure of the sun's outer envelopes, our galaxy's spiral structure, the temperature of the interstellar gas and the nature of the red shift.

History.— In the United States in 1931, Karl G. Jansky. a Bell Telephone laboratories communications engineer. was exploring atmospheric radio-frequency disturbances which might interfere with transoceanic telephone service. He noticed that while some disturbances were caused by local thunderstorms and some by distant thunderstorms, there was a third noise-component that appeared to be of extraterrestrial origin. With the aid of a rotatable directional antenna he was able to identify this source with a direction closely corresponding to that of the galactic centre. Jansky noticed that this extraterrestrial radiation had the characteristics of noise similar to that generated in metallic conductors. He attributed this cosmic static to the interaction between electrons and ions in interstellar space. Grote Reber, using very modest equipment, demonstrated that the origin of the cosmic radio-frequency radiation was not confined to the region of the galactic centre but was spread along the galactic plane, with a strong secondary maximum in Cpgnus. The radio detection of the sun and the study of its transient phenomena came in the early 1940s After 194j the development in radio astronomy mas impressive. Among the groups in many countries that contributed were the Radiophysics laboratory in Sydney, Aust.; the Jodrell Bank experimental station associated with the University of Manchester, Eng.; the Cavendish laboratory at Cambridge. Eng.; the Leyden (Neth.) university group; the École Kormale Superieure in Paris. Fr.; the National research council at Ottawa. Can.; and in the United States. the department of terrestrial magnetism of the Carnegie institution in Washington; the Naval Research laboratory, Washington; Harvard College observatory: Cornell university, Ithaca, N.Y.; Ohio State university. Columbus; and the National Radio observatory in West Virginia. New installations were being constructed in the mid-1950s by California Institute of Technology, Pasadena. and the University of Michigan, Ann Arbor.

Antennas.—A great variety of receiving antennas has been used in radio-frequency observations. Most modern work is done with antennas of one of the three following types.

(a) Fixed Type.—A parabolic antenna, such as the one employed in Manchester or the "transit" array type built by John D. Kraus at Ohio State university, which consists of helices mounted on a plane rectangle of hard\\-are cloth, often has a high resolution in at least one co-ordinate. but it cannot be aimed and observations must be made when the object crosses the meridian.

(b) Steerable Paraboloid.—This instrument resembles an optical reflector in that the electromagnetic radiation is reflected by a parabolic surface to a focus where a receiving element is placed. A servomechanism moves the reflector (dish) in two co-ordinates to track the diurnal motion of any celestial object. Examples are the jo-ft. dish at the Naval Research laboratory, the 60-ft. antenna at Harvard College observatory, the 2j-m. Leyden instrument and the huge 250-ft. dish planned at Manchester.

(c) *Interferometers.*—These produce fringe systems similar to those produced by optical interferometers. They are particularly useful for observing sources of small angular diameter. For example. if the sun is observed with an ordinary antenna when superposed on the galactic background, it may be barely perceptible at metre wave lengths. The interferometer (which treats the sun as virtually a point source in comparison with the galactic background) corrects automatically for this extended source because the galactic background fills in both maxima and minima of the interference pattern and only the solar pattern is observed.

Multielement forms of the interferometer such as the Mills cross permit accurate measurement of the positions of the discrete radio sources and disturbed areas on the sun.

Features of Cosmic Radio-Frequency Radiation.—Any heated body emits radio-frequency waves in accordance with the usual laws for the emission of radiation. The radiation from an antenna which emits waves at a certain selected frequency has an intensity many times that of a thermal source, however. In the heated body the particles are moving in random directions at random phases. whereas in the antenna the electrons are moving to and fro in unison.

The radio-frequency radiation received from extraterrestrial sources has the character of a random noise superposed on the background of thermal radiation from the surroundings. It is as though an ordinary telescope. its dome and all the terrestrial surroundings were brightly glowing, and the astronomer had to measure sun and stars which appeared as objects only slightly brighter than their background.

Hence. the radio-frequency detection equipment must be able to discriminate between objects with surface brightnesses only slightly greater than those of the surroundings. The intensity of the source can be expressed in terms of the temperature of a black body that would give the same intensity of thermal radio noise, and a standard black body source can be used to calibrate the receiver. The limit of detection corresponds to a difference of about 1" C. between the temperature of the object and that of its surroundings.

Although the radio-frequency radiation emitted by many sources, such as the quiet sun, the moon and certain diffuse nebulae, is of thermal origin, much cosmic static has a definite nonthermal origin, especially the radiation from the neighbourhood of flares and other active regions on the solar surface and the radiation from discrete sources which are regions of small angular size that emit intensely in the radio-frequency region. The nonthermal component often has many times the intensity of the thermal component.

Radio-frequency cosmic radiation differs from optical radiation in one important way. Whereas the wave length of visible light is very small compared with the aperture of the telescope, the wave length of the radio-frequency radiation is often comparable with or even larger than the aperture of the radio telescope. The resolving power. *i.e.*, the ability to distinguish two objects separated by a small angular distance d, depends on the ratio of the wave length λ to the aperture D ($d = 1.2 \lambda/D$). For a 60-in. telescope and a wave length of 5×10^{-5} cm. (an average for visible light), $d = 4 \times 10^{-7}$ radians or 0.08 sec.

With a 60-ft. dish and 21-cm. radiation, the angular resolution is $1\ 38 \times 10^{-2}$ radians or about 0.8°, *i.e.*, somewhat larger than the angular diameter of the moon or sun. With the wave lengths ordinarily employed, most radio telescopes have resolving powers considerably less than that of the human eye. Accordingly, interferometric techniques are applied much oftener than in optical astronomy.

Very high resolution in frequency can be obtained. The profile of the 21-cm. line of neutral hydrogen gas can be studied to yield important information on the motion of the gas and its temperature.

The range of wave length over which observations can be secured also must be considered. The long wave length limit is between 1j and 30 m. It is fixed by the degree of ionization of the ionosphere. The upper limit of the wave length is fixed by the condition that a radio wave can travel through an ionized gas only as long as its frequency is greater than a critical frequency ν_c, in megacycles (mc.) per second, given by

$$\nu_c^2 = 8.06 \times 10^{-5}\ N_E$$

where N_E is the number of electrons per cubic centimetre. Radio waves of frequencies less than ν_c are reflected by the ionosphere. Since the degree of ionospheric ionization, *i.e.*, the number of electrons per cubic centimetre depends on the solar radiation in the far ultra-violet, ν_c will vary from time to time. The atmosphere is opaque for wave lengths shorter than 1.5 mm. There are strong absorptions at 2.5 mm., j mm. and 1.34 cm. The transparency at 8.j mm. is better than the sky in the optical regions. At the high-frequency end of the spectrum the radio astronomer begins to be hampered by nuisances, such as rain, that also plague optical astronomers.

Techniques.—Radio astronomy differs from conventional optical astronomy in that for nearby objects—meteors, the moon and eventually the terrestrial planets—it is possible to direct signals to them and obtain the reflection. The well-publicized radar reflections from the moon are the best-kno n example. On the other hand. if a radar reflection could be obtained from Venus, it would constitute a powerful method for establishing the scale of distances in the solar system. Orbit theory gives the relative positions and distances of all the bodies in the solar system, but the scale can be fixed only when one particular distance (*e.g.*, the distance from the earth to Venus) is found at one particular epoch. The difficulty is that the strength of radar echoes decreases with the fourth poaer of the distance instead of with the square of the distance. as does the light picked up by optical telescopes.

The most striking application of radar techniques has been to the study of meteors. As a meteor passes through the rarefied upper atmosphere of the earth it ionizes a column of gas. A radio wave may be reflected from this column; from the intensity of the reflected beam, and because the intensity depends on the angle between the initial beam and the path of the meteor, it is possible to get the direction of the meteor and eventually its velocity. In this way, extensive data have been obtained on the orbits of meteors and meteor streams. The radar technique possesses one important advantage. Since the radar reflection depends only on the ionization of the air by the meteor, it can be applied during the day as well as during the night. Thus it has been possible to identify several daytime meteor streams that had not been previously observed. The radio observations also substantiated the more reliable optical observations in showing that the orbits of meteors are elliptical, rather than hyperbolic, *i.e.,* meteors belong to the solar system.

Radio observations have yielded important information concerning the lunar surface. Optical observations had shown that the visible surface of the moon underwent a temperature fluctuation with an amplitude of 134° C. during the course of a month as the sun rose and set. Radio waves are emitted not from the visible surface but over a range in depth of several inches. The temperature of these layers as measured from the radio wave intensities fluctuated with an amplitude of only 45°. This evidence showed that the surface layers must have good insulating properties; presumably they consist of finely powdered rocks in a vacuum. Thermal emission also has been observed from Venus.

Jupiter was found to emit in short radio-frequency pulses. The peak energies measured near 22 mc. per second amount to about 10^{-23} watts per cycle per second per square metre. When Jupiter emits in its characteristic frequency, it is the brightest object radio-wise in the sky.

It has been suggested that this radiation is produced by lightning or by volcanic action. Lightning might produce shock waves that could cause oscillations of charged particles in the Jovian atmosphere. Presumably, similar efiects could be produced by volcanoes. but volcanoes would be fixed in place on the planetary surface, whereas the lightning discharges would not. Studies of the durations of the outburst phenomena in conjunction with the visual observations provide, on the one hand, valuable data on the ionosphere of Jupiter and, on the other. the means to correlate recognizable optical features with the radio emission. The sources appear to occur in the same latitudes in the tropical band. Jupiter's great red spot is the strongest producer of radio noise, but not the only one.

It is perhaps significant that radio-frequency radiation is observed from Jupiter and not from Saturn, because in Jupiter, ammonia is beginning to form droplets. whereas in Saturn it is nearly all frozen out. Hence, ammonia may play the same role in Jovian meteorology as water does in terrestrial meteorology.

Solar Radio Observations.— The sun is a most interesting object for radio studies. since simultaneous optical and radio-frequency studies of active regions may be made. First. it is essential to distinguish between the thermal radiation of the undisturbed (quiet) sun and the nonthermal radiation emitted from disturbed regions near sunspots.

The equation for critical frequency (above) shows that at the lower frequencies (longer wave lengths) radiation is obtained only from the outermost solar envelope. the corona. where the kinetic temperature is 1,000,000° C. or more. At higher and higher frequencies it is possible to penetrate deeper and deeper into the corona and finally into the chromosphere. Ultimately, at the shortest wave lengths (highest frequencies) it is possible to reach almost to the optical surface of the sun.

The radio emission from the quiet sun is of thermal origin; its intensity depends on the temperature of the radiating gas and on the total amount of material in the line of sight. By a judicious combination of optical and radio data, a model can be constructed of the solar chromosphere and corona that is more accurate than one obtained by using optical data alone. Furthermore, observations of the occultation of the strong radio source, the Crab nebula, have shown that the outer corona is not spherically symmetrical but has a nonuniform structure.

The nonthermal radio-frequency solar radiation (*i.e.,* the radiation that is caused by charged particles moving in preferential directions somewhat as do the electrons in an antenna) is even more interesting. Several distinct nonthermal radiations exist; some have been correlated with optical activity, notably flares. Generally, nonthermal radiation can be classified as a slowly varying component, noise storm. or as an outburst. The slowly varying component is detected as an excess emission extending from 1 cm. to 1 m.; it may last over a period of weeks and is often circularly polarized. Storms are observed over a range from about 1 to 20 m. One type lasts between an hour and a week, consisting of sudden bursts or pulses of energy lasting from 0.1 to 10 sec. The radiation is virtually all polarized. In another type of storm. each burst or disturbance lasts about 10 sec. The total storm lasts from 30 min. to j hr. and the radiation is often unpolarized. Outbursts correspond to a great intensification of radio-frequency energy. They are often associated with flares, are usually of short duration (1 to 10 min.) and are observed over the entire frequency range from 1 cm. to 30 m. Paul Wild developed a frequency sweeping device that enables the observer to follow these transient events over a wide range of frequencies as a function of the time. Interferometric techniques show that solar radio-frequency noise originates in regions of great solar activity; *i.e.,* near spots. At times of high activity, charged particles in these regions are accelerated to very high energies.

Galactic and Extragalactic Sources.— The radio-frequency radiation from sources outside the solar system can be classified as follows: (1) thermal radiation irom heated gases; (2) nonthermal radiation from the galactic background; (3) nonthermal radiation from discrete sources; (4) 21-cm. radiation irom neutral hydrogen.

Thermal noise has been observed in the great diffuse nebulae, such as Orion, Lagoon and Trifid. An electron moving in one free (hyperbolic) orbit in the neighbourhood of a proton may jump to another with the emission of radio-frequency radiation. The dependence of the intensity of the radiation on the frequency is just what would be expected ior the electron densities and temperatures inferred irom the optical observations. By a judicious combination of optical and radio data, it is possible to correct for the absorption of light in space.

The general galactic background has a much higher intensity than could be attributed to stars radiating as does the disturbed sun. This radiation has been attributed to the emission by accelerated electrons in interstellar space.

Of the discrete sources, the most intense have been identified with optical objects, although some (*e.g.,* the Cassiopeia source) are near the limit of detectability. It is necessary to have not only accurate positions but also accurate sizes. Four groups of discrete sources have been listed, excluding diffuse nebulae: (1) remnants oi supernovae; *e.g.,* the Crab nebula; (2) galactic nebulosities of a new type: (3) peculiar extragalactic nehulac; and (4) normal estragalactic nebulae.

Thr radio angular size and position of the Crab nebula, a supernova of 1054, agrees with the optical position. It was shown to be not a thermal source; the detection of polarized continuous optical radiation suggested that the emitted energy comes from accelerated particles in a magnetic field, rssentially synchrotron radiation.

The Cassiopeia B source in Tycho Brahe's nova of 1572, Cassiopeia A, the Puppis source, and IC 443 are all examples of filamentary nebulae, moving with high velocities, that are strong radio sources; the higher the velocity, the stronger is the radio-frequency radiation. The strong Cygnus source has been identified with colliding galaxies which radiate more energy in the radio region than in the optical region. Among normal appearing galaxies that have unusual radio-frequency radiation is the elliptical galaxy M87 in Virgo. The Andromeda nebula and the Magellanic Clouds more nearly resemble our own galaxy.

The 21-cm. radiation emitted by neutral hydrogen was predicted in 1944 and discovered in 1951. From the shape, intensity and displacement of this line it is possible to obtain data on the motions of the interstellar gas and its temperature. Observations show the gas to be concentrated in the spiral arms and to have a temperature near 100° K.

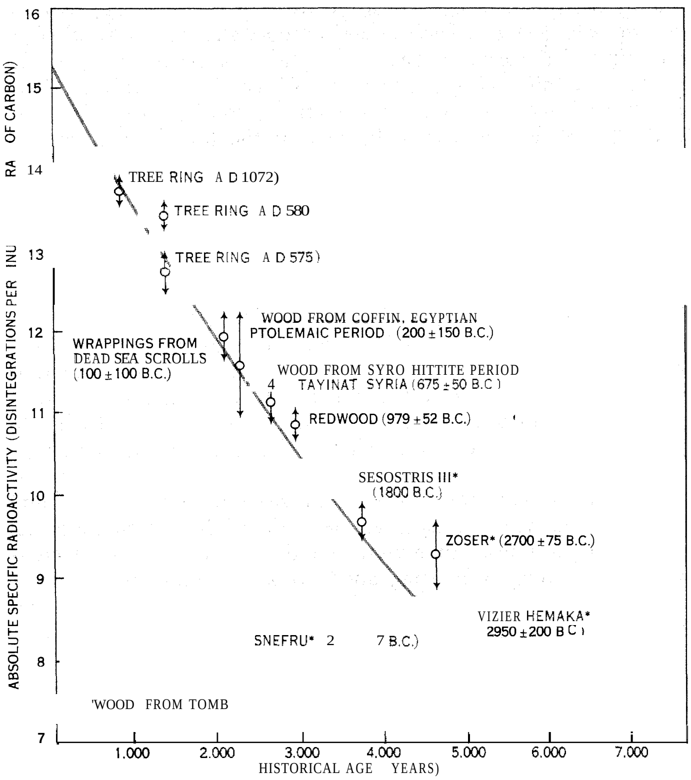
RADIOCARBON DATING. Radiocarbon age dating. developed in the late 1940s at The University of Chicago, is an example of the application of one of the newest sciences (atomic energy) to one of the oldest (archaeology). The technique involves measuring the relative activities of radioactive carbon (C^{14}) in (1) present-day living organic matter and (2) the sample under investigation, and multiplying the logarithm of this ratio by the rate at which the activity of C^{14} decays with time. Careful measurements have shown that the activity of any given preparation of carbon-14 is reduced by exactly one-half during each interval of 5,568 ± 30 years. This value is called the half life of C^{14}.

Radiocarbon is produced in nature by an indirect process involving the interaction of cosmic rays from outer space with the nitrogen in the earth's atmosphere. The competing processes of formation and of decay of C^{14} have been going on for so long that the equilibrium has been established. and the world inventory of C^{14} is estimated at about 70 metric tons. Radiocarbon therefore has been introduced into the biosphere, and all living matter contains a small quantity of radiocarbon which averages 15.3 ± 0.1 disintegrations per minute per gram of contained carbon. This



SAMPLES OF OBJECTS OF KNOWN AGE DATED BY RADIOCARBON METHOD

The curve is calculated from the assay for modern wood and the laboratory measurement of the half life of radiocarbon (5,568 ± 30 years). The individual points show the specific radioactivities of the various samples of known age (the latter given in parentheses). The age of the sample as estimated by the radiocarbon method is shown by the point on the curve corresponding to the indicated specific radioactivity. The range in specific radioactivity for a given sample is the standard deviation based solely on the number of counts taken; it does not include other errors, such as those arising from contamination

activity remains constant throughout the life of the organic matter because of the above-mentioned equilibrium processes.

However, at death the introduction of radiocarbon into the specimen ceases, while the normal decay of the contained radiocarbon continues according to the half life mentioned above. Therefore an archaeological specimen (for example. a mummy,or a tree) which yields 7.65 disintegrations per minute per gram of carbon instead of 15.3 is judged to be 5.568 ± 30 years old. If the material shows only one-fourth the radiocarbon content of living matter, the age of the specimen is 11.136 ± 60 years, etc.

Age dating has revealed that there lived in North America over 9,000 years ago people who were capable of performing the finest basketry work; that the continents of North America and Europe were both glaciated in their northern latitudes 11,000 years ago; and that the calendars of the ancient Babylonians and the Mayas can be correlated with that of the Christians. The accompanying graph indicates the correlation obtained between the ages of various samples as determined by radiocarbon dating and by conventional methods.

Refinements in the technique of measurement have been made by reducing, as far as possible, the effects of spurious radiation, including background activity due to cosmic radiation. and radioactive impurities in the shielding of counters and in the materials of construction of the counter itself. These refinements permit the extension of radiocarbon dating to samples which could be as much as 50,000 years old. Lahoratories at research institutions scattered throughout the world are co-operating in dating archaeological specimens hy this method.

See Willard F. Libby, *Radiocarbon* Dating, 2nd ed. (1955); G. J. Fergusson, "Radiocarbon Dating System," *Nucleonics,* vol. xiii, no. 1 (Jan. 19.55). (W. F. Li.)

RADIOCHEMISTRY: *see* Radioactivity, Artificial: *Application to Chemistry and Medicine.*

RADIO COMPASS, a radio receiving set which permits determination of the line of travel of waves as received from transmitting stations. *See* Navigation; Radio.

RADIOLOGY is the branch of medicine that deals with the employment of X-rays as an aid in the diagnosis of disease and the use of X-rays, gamma rays and other forms of ionizing radiation in the treatment of disease. For details of the physical nature. method of production and technical and industrial applications of the various components of the electromagnetic spectrum. *see* Radioactivity, Artificial; Radioactivity. Natural; and X-Rays.

This article is organized as follows:

I. DIAGNOSTIC RADIOLOGY

A. Apparatus

1. Quality and Intensity of Radiation **Employed.**—Concern with the carious implications of thermonuclear weapons has stirred up a largely unwarranted fear of possible risk from even such small tissue doses as those delivered in X-ray diagnosis. Of course, it is unwise to employ diagnostic radiology (or, for that matter, drugs or surgery) unless there is real need for it. When there is such need, X-ray examinations conducted by qualified radiologists involve risks smaller than those encountered every day at home. at work and on the street, and smaller than the risk of getting along without needed examinations, especially when these may reveal a serious disorder.

In some of the work for which X-rays are used, the quality or penetrating ability of the radiation is expressed in wave length, in frequency or in terms of its absorbability in filters of standard composition and thickness; and its intensity is designated in ionization units, such as the roentgen. In X-ray diagnosis, however, it is the practice to indicate radiation quality and intensity by stating the voltage and current applied to the tube, the current being expressed in milliamperes. abbreviated ma. (1 ma. = 0.001 amp.), and the voltage in peak kilovolts. abbreviated kv. Current is measured by means of a milliammeter inserted between the two halves of the secondary winding of the X-ray transformer at a point where the potential is close to zero; and tube voltage is measured by means of a kilovoltmeter wired across the primary of the X-ray transformer.

Certain aspects of alternating currents and of pulsating unidirectional currents will be reviewed at this point When plotted on a time scale the instantaneous voltage of the current produced by a single-phase, 60-cycle, alternating-current generator, a sine curve is observed. Rising from zero, voltage reaches full potential during the first $\frac{1}{240}$ sec., returns to zero by $\frac{1}{120}$ sec., falls to full negative value by $\frac{1}{80}$ sec. and returns to zero by $\frac{1}{60}$ sec., repeating the pattern indefinitely. That portion of the curve lying between the first and third zero points is called one cycle, and it is the repetition of this cycle 60 times in each second that gives 60-cycle current its name. Obviously the designation of the voltage of such a current requires reference to the factor of time and for such applications as heating, lighting and power the "root mean square" value is employed. This is abbreviated R M.S. and means the square root of the mean of the instantaneous voltages throughout the entire cycle.

A time-voltage plot of the potential applied to the tube of a self-rectified X-ray machine consists of a distorted sine curve in which the peak of the half cycle that is used is lower than that of the half cycle that is suppressed; and in the case of full-wave rectification the plot becomes a series of more or less distorted half cycles, all having the same electrical sign.

In pure sine wave alternating current, R M S. voltage may be computed from maximum instantaneous voltage (MIV) or vice versa by substitution in the equation

$$\text{R.M.S.V} = \frac{\text{MIV}}{\sqrt{2}},$$

but in pulsating unidirectional currents this simple relationship breaks down. The R.M.S. values for such nonsinusoidal currents could be determined by suitably designed meters or by complete analysis of the instantaneous voltages throughout the curve. but this is not commonly done because in the production of X-rays it is the maximum instantaneous voltage of the current passing through the tube that is of particular importance. This voltage is termed the peak voltage. and since in practice it amounts to several thousands of volts it is commonly expressed in kilovolts (1.000 v. = 1 kv.). In most X-ray generators the so-called kilovoltmeter is merely an ordinary A.C. voltmeter wired across the primary winding of the high-tension transformer but calibrated in peak kilovolts by means of direct sphere gap measurements of tube voltage made by the manufacturer during the factory calibration of the machine.

For fluoroscopy and the making of X-ray films, tube current may be as low as 3 ma. or as high as 500 ma. or even higher. and voltage usually ranges from 45 kv. to 90 kv. or even up to 130 kv. The magnitude of the voltage applied to an X-ray tube has tn-o important effects on the radiation that is produced. It determines the wave-length composition of the beam and therefore its penetrating ability, and in addition affects the intensity of all beam components exponentially. For example, a tube voltage of 45 kv. will produce a certain amount of rather soft radiation having a maximum shortness of approximately 0.274 angstroms (Å) (0.274 $\times 10^{-8}$ cm.), a type of radiation so feebly penetrating that it is unsuitable for the fluoroscopy or filming of heavy body parts. Doubling the voltage (to 90 kv.) brings the maximum shortness of the beam down to 0.137 Å, thus providing penetration adequate for the thickest anatomical parts, and in addition this voltage change quadruples the intensity of all the components of the beam.

Contrary to a widely held misconception, there is no specific relationship between the part to be examined and the voltage. current and exposure time that should be employed. Over a considerable range. these factors—voltage, current and exposure time—may be juggled almost at will. provided only that the time intensity product of the radiation reaching the film approaches a constant that has been determined empirically as adequate for recording the tissue densities of the body part that is being examined. The experienced radiologist or X-ray technician uses voltages of approximately 60 kv. and currents of about 25 ma. for thin body parts that can be well immobilized. thus keeping the exposure time within the range where minor time switch errors are of negligible importance and allowing the use of fine-focus tubes: but when the work to be done requires that the exposure time be as short as possible: he sets the time switch for $\frac{1}{60}$ sec. or sometimes even & sec., sets the current at the maximum allowable for the tube (for example, 500 ma.) and then adapts to variation in the thickness and density of body parts by varying voltage.

2. X-Ray Generators.—In their simplest form the X-ray generators used in diagnosis consist of a hot-cathode X-ray tube, a controllable means of heating the cathode. a source of alternating current and a means of regulating the voltage of that current. Circuits of this sort are known as self-rectified because in them the X-ray tube itself acts as a rectifier, passing one half cycle and suppressing the other half cycle of the raw alternating current that is supplied by the transformer. Thousands of sets of this design are in daily use throughout the world, functioning as dental X-ray machines. portable and bedside X-ray machines and in small fluoroscopes. They are adequate where the service is intermittent and the loads range from 3 ma. to 10 ma. at potentials from 40 kv. to 75 kv., but for heavy work full-wave rectification is preferable.

In theory, full-wave-rectified generators differ from the self-rectified sets described above merely by the insertion of four electronic or solid-state rectifiers between the high-voltage terminal of the transformer and the terminals of the X-ray tube. In practice. honever, they are much more complex, including voltage stabilizers for the filament of the X-ray tube, voltage regulators for the primary windings of the high-voltage transformer and the X-ray filament transformer. devices for the automatic selection and limitation of tube voltage and current, circuits for energizing the rotors of rotating anode tubes, meters, fuses, circuit breakers and some means for the precise timing of both short and long exposures. In addition, they allow employment of higher voltages and larger tube currents. All modern generators are completely insulated or "shockproof." regardless of whether they are of the self-rectified or the valve-tube-rectified type.

3. X-Ray Tubes.—The tubes used in X-ray diagnosis consist of a well-exhausted glass-enveloped diode surrounded by a metallic housing that is lined with lead except at a small port through which the useful beam of X-rays emerges. The space between glass insert and housing is filled with insulating oil. In the simplest and smallest sets the tube housing is integral with the transformer housing, but in larger machines the two usually are separate, tube and transformer being connected by means of flexible, shielded, insulating cables. In these modern descendants of William David Coolidge's hot-cathode tube, the cathode stream is focused as a ribbon on a steeply inclined target so that the heat of impact will be distributed as widely as possible and yet the optically effective source of the rays will approach a point. Frequently two filaments are provided—one focusing the electrons sharply for use when great detail is required and small currents are allowable, the other distributing the electrons over a larger target area for use when heavier currents must be employed. Targets are of two general types—those that are stationary and those that rotate or spin during operation. In the stationary anode tube, the target is of swaged tungsten embedded in a massive copper anode which extends out through the glass envelope to conduct the heat of electron bombardment into the insulating oil that surrounds the tube. Sometimes there is a pump or impeller to circulate the oil, and usually there is a blower to expedite removal of heat from the housing.

Rotating anodes turn on precision bearings that are mounted nithin the exhausted glass envelope and therefore must be devoid of ordinary lubricants which would ruin the vacuum. The stator lies outside the envelope, its lines of force passing through the glass to operate the rotor which is attached to the anode stem. Sometimes the anode disk is of massive copper with an embedded belt of tungsten to receive the electron bombardment. but more commonly it is of solid tungsten capable of withstanding a cherry-red heat during heavy loading. For many applications rotating anode tubes are extremely satisfactory. but they have the serious limitations of dissipating target heat almost exclusively by radiation through the glass envelope and lacking the direct conduction through copper that is so efiective in the case of stationary anode tubes.

4. Films, Screens and Cassettes.—X-ray films consist of an acetate cellulose base coated on both sides with an emulsion of

silver halide and gelatin. It is possible to prepare emulsions that are particularly sensitive to X-rays, but since most X-ray films are used in conjunction with calcium tungstate intensifying screens, the emulsions are given maximum sensitivity to the fluorescence of calcium tungstate rather than to X-rays themselves.

For the examination of certain parts—such as the teeth, fingers and toes—plain film without screens is ordinarily used. and in such applications it suffices to wrap the film or otherwise enclose it in a covering such as black paper or cardboard which is opaque to visible light but not to X-rays. For the filming of heavier parts, however, the exposure time can be reduced and the contrast in the image enhanced if films pressed between two intensifying screens are used instead of plain films. These screens must be in intimate contact with the emulsions if sharp detail is to be recorded. Such contact is provided by rigid lightproof containers known as cassettes. The fronts of cassettes are made of bakelite or magnesium to exclude light but admit X-rays, and when phototiming is employed the backs also must be reasonably radiotranslucent. The screen attached to the inside of the cassette front frequently is thin because it must transmit most of the radiation, but the rear screen is thick, absorbs more radiation and fluoresces more actively. In the making of a film—for example, of the chest—the patient stands facing a 14-in. × 17-in. duplitized X-ray film (double emulsion) contained in a double-screen cassette of the sort described above, the X-ray tube being arranged so that its beam of radiation passes through the patient's back in a direction perpendicular to the surface of the film. The X-rays induce a moderately brilliant fluorescent image of the lungs, ribs, heart, etc., on the front screen, produce a slight photographic effect directly on the front and rear layers of film emulsion. and finally induce a brilliant fluorescent image on the rear screen. The light from the two fluorescent images photographs itself onto the emulsion along with the two direct X-ray images. and in the completed film all four images, being superimposed, appear as one.

5. Grids.—X-rays arise on the target of an X-ray tube at the point where it is bombarded by electrons emitted by the cathode. In fine-focus tubes the effective X-ray source may have a diameter as small as 0.3 mm. and in coarse-focus tubes as large as 4 5 mm. All else being equal, X-ray images are sharpest in detail when the radiation source approaches a point and become blurred when the source is large. In the discussion that follows, a point source of radiation will be assumed. for convenience.

From their point of origin X-rays are propagated in straight lines in all directions over a solid angle of 4π. but most of them are absorbed in the lead lining of the housing and the cone of useful radiation that emerges through the port has an apex angle of only approximately 15°. Within the ordinary meaning of the terms, X-rays cannot be reflected or refracted by the substances they encounter on their straight-line course to the X-ray film, but some of them do become scattered. For small. thin parts, scattering is practically negligible, but for heavy parts, such as the skull and trunk of an adult, the radiation that is scattered in the patient's body fogs the image formed by the straight-line or primary radiation to such a degree that finer details become indistinguishable.

Prior to 1917 good X-ray plates of the skull, spine, hip, etc., required that the primary beam be narrowed to a very small diameter to reduce scattering, and 14-in. × 17-in. plates of the entire pelvis of a heavy subject were so badly fogged by scattered radiation as to be of little clinical usefulness (glass plates were used in those days rather than films). However, as early as 1912 Gustav Bucky in Germany laid the groundwork for overcoming this difficulty, and by the early 1920s there became commercially available. first in the U.S. and later in Europe, moving grids designed by the U.S radiologist Hollis Potter. These instruments, knonn as Potter-Bucky grids or, less properly. as Potter-Bucky diaphragms, became an indispensable part of the equipment of all diagnostic radiologists. Such grids. consisting of an assembly of lead strips interspaced with strips of wood. plastic or other radiotranslucent material, are interposed betneen patient and film and are kept in motion while the exposure is being made. The lead strips are aligned as radii of a segment of a theoretical cylinder that has a diameter equal to twice the target-film distance. A small portion of the primary or unscattered radiation that emerges from the patient's body impinges squarely on the edges of the lead strips, where it is absorbed, but most of it passes through the interstices between the strips and thus to the film. The scattered radiation, on the other hand, being no longer aligned with the translucent interstices, impinges for the most part on the sides of the lead strips, where it is absorbed.

In Bucky's original stationary grids, the metallic members were thick and widely spaced, thereby causing disturbing patterns on the film, and Potter's contribution was to conceive and build grids that could be moved during exposure, thus obliterating the pattern of their grid members but not interfering with their ability to absorb scattered radiation. Modern moving girds are fat rather than curved; they are built to extremely precise dimensional tolerances, have great ability to absorb scattered radiation, and reciprocate throughout the exposure instead of starting before the exposure begins and continuing to move in the same direction until the exposure has been completed. Stationary grids were improved even more. In their original form they were virtually useless except as precursors to a great idea, but the work of the Swedish radiologist Eric Lysholm revived interest in them. Excellent European and U.S. units became available, some composed of parallel strips, others having two systems of parallel strips aligned at right angles to one another to form crisscross or honeycomb grids. Grids of this latter type came to be used widely for bedside raying, raying in the operating room, for angiography and for spot filming of the stomach and intestines. In a type of moving grid developed later, transverse members are aligned at less than 90° to the longitudinal members; this retains most of the advantages of honeycomb grids and yet makes it possible to move the grid assembly during exposure and thus leave no pattern of it on the film.

Unlike the moving grids, the stationary ones inevitably leave their own images on films along with the images of the body parts that are being examined. In modern stationary grids, however, these superimposed patterns are regular and faint, detracting little from appearance and nothing from clinical usefulness.

6. Fluoroscope.—A fluoroscope is an apparatus for the direct observation of body tissues by means of X-rays. It consists of a fluoroscopic screen supported in front of the port of an X-ray tube so that a patient may be interposed between the screen and the source of the radiation. A shutter usually is provided to control the area of the beam of radiation emitted by the tube. and a sheet of plywood or other strong but radiolucent material is interposed between tube and patient to provide a surface on which the patient lies when the instrument is tilted from the vertical into the horizontal position. Many crystalline substances will glow when exposed to X-rays. Among the best for clinical fluoroscopy is zinc cadmium sulfide mixed with traces of other materials. A fluoroscopic screen consists of a piece of cardboard coated with a layer of such fluorescent salts and faced nith a sheet of thick lead-bearing plate glass that is highly opaque to X-rays but alrnost perfectly transparent to the greenish light given off by the fluorescing crystals.

B. Techniques

1. Timing the Exposure.—When the intensity of the X-ray beam is low and the exposure time of the order of ten seconds, errors of plus or minus a few tenths of a second are negligible and the simplest of spring-driven time snitches are adequate to time the exposure; but for tube currents of from 100 ma. to 500 ma. and exposure times of the order of $\frac{1}{60}$ sec.. precise timing becomes important and difficult, much of the difficulty being inherent in the pulsating nature of the current applied to the X-ray tube When 60-cycle current is employed, X-rays are emitted by the target not continuously but in brief bursts starting from zero, rising to full intensity and then returning to zero every $\frac{1}{120}$ sec. (each half cycle). Brief exposures therefore must be measured out in half cycles, and it is important that the exposures be initiated and terminated approximately at zero points on the voltage wave. In other words, the timing device and the contactor

must be phased with the generator. Such phasing formerly mas accomplished reasonably well even with heavy conventional magnetic contactors, but it was rendered easier and more precise by the substitution of the electron discharge in heavy-duty thyratrons for mechanically operated metal-to-metal contacts.

In the early 1940s it became possible to time X-ray exposures automatically by means of multiplier phototubes. Phototiming, as it is called, gradually was made available in commercial X-ray machines. In general radiography the phototube and a fluorescent screen are mounted in a box that is impervious to light but has a top that is transparent to X-rays. This box, known as a detector, is located beneath the Potter-Bucky grid where it receives radiation that has passed through the patient's body, the film and the cassette. The detector is calibrated empirically so that when the film has received an amount of exposure that will assure an optimum image, the phototube will have received sufficient fluorescent light to cause it to trigger an electronic switch and thus terminate the X-ray exposure. In photoflubrography (described below) the phototube is mounted in the camera head and, like the lens. "observes" the fluorescent screen. In the case of the filming fluoroscope, which is so important in the examination of the gastrointestinal tract, the phototube scans an image produced on the fluoroscopic screen by radiation that has passed through the patient's body and through the back of the film cassette.

2. Processing X-Ray Films. — When the technician who exposes an X-ray film also develops it, the composition and temperature of the developer and the length of development need not be regulated precisely because modern films have wide latitude and the experienced worker learns to shorten or prolong development until inspection before a safelight indicates that an acceptable image has been obtained. Where the volume of work requires division of labour, however, the situation is different. One set of workers exposes the films to carefully measured amounts of radiation, and another group working in darkrooms develops them in solutions of standard strength and temperature for standard periods of time. Automatic film processing machines found wide acceptance in the years after World War II. Even in small laboratories the simpler hand-operated processing tanks usually included constant-temperature baths. The common practice is to standardize exposures so that development for five minutes at 68° F. in standard-strength developer will yield films of optimum density. For special examinations, such as those conducted in the operating room in conjunction with surgery, the solutions may be warmed in order that developing time may be shortened, the saving in time being considered more important than the inevitable reduction in the quality of the image.

Polaroid film, with its self-processing features, and the process known as xerography, which employs charged selenium plates, hold intriguing possibilities, particularly under emergency conditions where X-ray films and processing solutions might be unobtainable. Unfortunately, however, in their state of development in the early 1960s, both these systems were so much less sensitive than the standard system using films and intensifying screens that they required excessive doses of X-rays to the tissues of the patient.

3. Stereoscopic X-Ray Filming. — Three-dimensional vision is helpful in the radiography of any part of the body and is almost essential in X-ray examinations of the skull and trunk. The two films that are required for stereoscopic filming are made with the film and body part in identical spatial relationship for each but with the X-ray tube shifted slightly between the two exposures. The amount of the shift is determined by the relationship between the distance from the film to the target of the X-ray tube at the time the exposure is made and the optical distance from the film to the eyes of the observer at the time the two films are examined. If these two distances are identical the tube shift should be 66 mm., which is the average interpupillary distance, but if the commoner situation obtains and target-film distance is greater than film-eye distance, then the tube shift must be increased proportionally.

Even without. the aid of instruments some workers become able to view one of the films with one eye, the other with the other eye, and then fuse these two slightly dissimilar, real, flat irnages into a single, virtual, three-dimensional image. It is more convenient, however, and for some persons actually essential to employ a special viewing apparatus.

4. Contrast Media. — The lungs show in X-ray films and in fluoroscopic images by virtue of the sharp difference between the X-ray absorbing power of the air that distends them and that of the pulmonary tissue itself. This difference in absorbing power is called "contrast." The heart, being composed largely of muscle and blood, contrasts strongly with the air-filled lungs adjacent to it but scarcely at all nith the liver beneath; bones are distinguished from surrounding muscle and the various parts of bone from one another by virtue of the calcium phosphate they contain. To a great extent, however, the clinical usefulness of the X-ray examination depends on the employment of artificial contrast media. The most extensively used opaque medium is barium sulfate Stirred into aater and flavoured nith a little chocolate sirup, this insoluble heavy metal salt is employed for examination of the esophagus and stomach; mixed aith powdered resins and water it becomes a barium enema for the examination of the rectum, colon and terminal ileum. An iodized organic compound is used for examination of the gall bladder. urinary tract. blood vessels, spleen and liver. X-ray visualization of the bronchi better than that obtained merely by the contrast of contained air is made possible by the introduction into the bronchial tree of unsaturated vegetable oil partially saturated with iodine. An emulsion of ethyl iodophenylundecylate also is used in bronchography and in the examination of the spinal canal (myelography).

5. Fluoroscopy. — Fluoroscopy has a great advantage over filming in that with it motion can be seen, but there are many offsetting disadvantages, the most important of uhich is the inevitable radiation hazard to operator and patient. In addition, fluoroscopy lacks objectivity because it leaves no permanent record, and the image on the screen is so faint that to see it the room must be well darkened and the eyes of the fluoroscopist fully dark-adapted. The dark-adapted eye employs largely the rod type of vision, nhich is suitable only for rather coarse "seeing." Thus. many of the finer anatomical details that would be seen well by the cone vision used in examining brightly transilluminated X-ray films cannot be seen at all on the fluoroscope. Formerly fluoroscopy was widely employed to detect fractures of the extremities and to aid in their reduction, but it was recognized that this practice is dangerous to patient and physician, as well as being diagnostically inferior to filming. The most important remaining clinical use of fluoroscopy is in the examination of the gastrointestinal tract and the spinal cord, where it is used in conjunction with filming.

Photofluorography.—From the earliest days of radiology, attempts were made to make permanent records of fluoroscopic images by photographing them. but until the late 1930s the maneuver saw little practical application. The advantage of photofluorography lay in its ability to employ small, inexpensive and easily processed photographic roll film instead of large. costly, individual sheets of X-ray film, its disadvantage in the fact that fluoroscopic images were faint and the camera lenses available for recording them slow. As far as the chest is concerned, the disadvantages finally were overcome by developing faster film emulsions, faster screens and refractor lenses large enough to cover a 64-mm. by 70-mm. area on roll film and yet having a speed of f/1.5. Millions of members of military and civilian populations were subjected to small-film chest surveys, but though such photofluorography of the chest is of genuine importance as a public health measure it is not a rival of the older methods as a means for the detailed study of pulmonary diseases.

The substitution of large-aperture reflector lens systems for the f/1.5 refractors improved the quality of chest microfilms and reduced the X-ray dose to the patient.

Electronic *Amplification.*—After 1947 electronic amplification of the fluoroscopic image received increasing attention from numerous U.S. and European workers, but not until the late 1950s was there much clinical application. Methods are of three general types:

1. Employment of X-rays to produce an electron image of the part; acceleration of the electron image by high-voltage fields

aided by electron lenses or mirrors; and conversion of the enhanced electron image into a visible image.

2. Employment of television techniques by the method of Morgan, Moon or Jacobs.

3. Adaptation of developments in solid state physics (*q.v.*).

Developmental problems are numerous and difficult, with the constant necessity of choosing between a desirable increase of image brilliance without too much sacrifice of image resolution.

X-Ray *Motion Pictures*.—Within a year following Wilhelm Conrad Röntgen's announcement of the discovery of X-rays, attempts were made to produce X-ray motion pictures. Scores of publications on the subject appeared thereafter in the public and scientific press. In the so-called direct method a motion-picture positive is made from a sequence of individual X-ray negatives; in the indirect method the positive is printed from a motion-picture negative of the fluoroscopic screen. Both methods required such large doses to the tissues of the subject that they were limited to experimental work with animals; in the case of the indirect method, however, modern image amplifiers have removed this difficulty. For maximum resolution a 16-mm. motion-picture camera records the image directly from the screen of an image amplifier, but where resolution is not too important it may be preferable to televise the image of the amplifier and then photograph the image on the television screen.

C. Applications

1. Teeth.—Intraoral films were early employed for detecting abscesses in the bone about the apexes of the teeth, for locating unerupted or impacted teeth and for discovering retained broken tooth roots. Their field of usefulness was enlarged until they came to play an important part even in the periodic examination and cleaning of the teeth. Small cavities at abutting surfaces, poorly fitting fillings and inlays, recession of the bone from the necks of the teeth and, most important of all, subgingival deposits of salivary calculus—such lesions as these are easily detectable in X-ray films though they may escape all but the most skillful and searching direct inspection.

2. Bones.—For the first few years following Röntgen's discovery, it seemed that X-rays might be used in medicine chiefly as an aid in the diagnosis and reduction of fractures. X-ray films are used not only for the detection of injuries but also for demonstrating the presence of tumours, infections and almost every other form of skeletal disease. In normal bone the cortex shows in X-ray films as a dense amorphous shell and the spongy portion as a honeycombed structure made up of the shadows of the coarse primary trabeculae, on which are superimposed the shadows of the fine secondary trabeculae. Disuse of living bone causes a generalized loss of density known as osteoporosis, but when portions of bone are killed by disease or injury before osteoporosis has occurred, they retain their original density for long periods of time. Some tumours and infections cause localized destruction of bone and others cause the hone to become denser than normal (sclerosis). Certain parts of normal living bone, such as marrow, periosteum and articular cartilage, though not themselves discernible by X-rays, may when diseased produce subtle changes in visible bone adjacent to them, thus leading to their own detection. Rickets, scurvy, syphilis, tuberculosis, Paget's disease (osteitis deformans), benign and malignant tumours and many other skeletal diseases produce changes in the X-ray appearance of bones that are almost always easy to see and frequently so characteristic as to warrant a specific diagnosis.

3. Chest and Heart.—Internists and surgeons must lean heavily on the findings of the radiologist for the detection and management of such pulmonary diseases as tuberculosis, pneumonia and cancer, though of course it is necessary to weigh all the evidence in making the final diagnosis and not depend on X-rays alone. Active fibrocaseous tuberculosis usually produces rather characteristic dense splotches in one or both of the lung apexes, but at certain stages in their course some of the pneumonias and histoplasmosis show X-ray patterns almost identical with those of tuberculosis. Malignant tumours arising in the bronchi usually reveal themselves promptly by causing bronchial obstruction with resulting rather typical areas of lung collapse. Foreign bodies accidentally introduced into the trachea or bronchi frequently are dense enough to show directly in X-ray films; when radiotranslucent they may be detectable with the aid of opaque media or by virtue of changes they produce in the air patterns of the lung. When the diagnosis of pulmonary tuberculosis has been established, repetition of the X-ray examination is one important method for observing the results of treatment.

Radiology may be employed to determine the size and shape of the heart and great vessels, and, with the aid of opaque media, it provides detailed information about the chambers and valves of the heart and the pulmonary vessels, particularly in children suffering from congenital defects.

4. Skull, Brain and Spinal Cord.—The X-ray criteria employed for diagnosing injuries and diseases of bone are most dependable in regions where cortex is thick and well differentiated from spongiosa, as in the long bones of the extremities. Cortex is well developed in the vault of the skull: and fractures, tumours, infection, etc., in the skull are usually reasonably evident. In the face bones, however, where the cortex may be as thin as paper, such lesions may be almost invisible.

Because of the air that they contain, the normal mastoids and the sinuses (frontal, ethmoid, maxillary, sphenoid) show as black shadows sharply silhouetted against bone, and if fluid or benign or malignant tumours are present they too will stand out in contrast with the air. Certain tumours of the pituitary gland cause the sella turcica to enlarge in a characteristic fashion, and in young children a long-continued increase in intracranial pressure may be inferred from a resulting separation of the bones of the skull.

The brain itself is radiotranslucent except for several normal and occasional pathological patches of calcification, and so it is necessary to employ contrast media when the brain is to be examined, the medium of choice being oxygen or air. When such gases are introduced into the subarachnoid space, the procedure is termed encephalography; when they are injected directly into the hollow chambers or ventricles at the centre of the brain it is called ventriculography. In either case, the X-ray examination is done with stereoscopic films, and the object is to study the internal and 'external contours of the brain by virtue of the gas that is in contact with them. Development of cerebral angiography (see Blood *Vessels*, below) greatly expanded the radiologist's ability to diagnose tumours of the brain and small aneurysms of the cerebral vessels.

Opaque media are much more effective than gas for examining the spinal cord and the canal in which it lies, a procedure known as myelography. Under fluoroscopic control, the contrast material in the subarachnoid space is maneuvered into all parts of the spinal canal from the tip of the caudal sac in the lumbosacral region up to (but not into) the cisterna at the base of the brain. The films that are made at all levels and in several positions show the cord itself as a translucent or negative shadow and the surrounding subdural space as a dense shadow by virtue of the opaque medium it contains. Protruding knobs of intervertebral cartilage, spikes or ridges of arthritic osteophytes, tumours of bone, cord or meninges are among the abnormalities that may be detected by myelography; but normal variation is great and differentiation difficult even when the examination is conducted by teams of specially trained neurosurgeons and radiologists.

5. Gall Bladder and Bile Ducts.—In 1923 E. A. Graham introduced a method for the X-ray examination of the gall bladder, known as cholecystography, which came into universal use. An iodized organic compound contrast medium, after being given, by mouth in tablet form, is absorbed from the gastrointestinal tract into the blood and then removed from the blood stream by the liver and combined with the bile. A normal gall bladder, receiving through its cystic duct watery, weakly iodized bile, concentrates it until eventually it becomes thick and its iodine content high. In X-ray films made 10 to 15 hours following administration of the opaque medium, the normal gall bladder casts a dense shadow and any cholesterol stones present stand out as negative shadows against the iodized bile. If the gall bladder is seriously diseased or its cystic duct is occluded, bile will fail to reach the gall bladder or, reaching there, will fail of concentration, either of these events resulting in nonvisualization.

Cholangiography, or examination of the bile ducts, usually is conducted in conjunction with surgery to assure that stones or a tumour obstructing the ducts have not been overlooked. A contrast medium is injected either through a T tube tied into one of the bile ducts or by means of a hypodermic needle introduced through the wall of a duct or of the gall bladder itself. Intravenous cholangiography (*i e.*, with contrast medium injected into a vein) introduced in the late 1950s, met with little success.

6. Urinary Tract.—Pyelograms are X-ray films of the urinary tract made following the introduction of an opaque medium. In the retrograde method, the opaque medium is injected through ureteral catheters introduced with the aid of a cystoscope In the excretion or intravenous method, it is injected intravenously followed by filming at intervals of 5 to 15 minutes.

Most tumours lying in the fleshy part of the kidney outside its collecting system compress, stretch and otherwise distort the calyces and pelves. Tuberculous abscesses are prone to break through into the calyces, allowing the opaque medium to extravasate into diseased tissue. and the infrequent kidney stones that are radiotranslucent may be rendered visible by the opaque medium in the same way that opaque medium reveals cholesterol gallstones Cystograms are films of the urinary bladder made after the direct or excretory filling of that organ with opaque medium. Bladder tumours, diverticula and urethral obstruction by chronic prostatic enlargement produce rather characteristic alterations in the appearance of the cystogram.

7. Female Reproductive Tract.—Sterility of the human female may result from various causes, one of which is occlusion of the fallopian tubes. The best means of demonstrating such occlusion is to make X-ray films following the injection of iodized oil into the uterus. In the normal subject. the oil passes out through both fallopian tubes to spill into the peritoneal cavities, where, 24 hours later, it becomes smeared over the serous surfaces of loops of bowel and appears by X-ray as a slightly opaque, crumpled veil. When no connection exists between the uterine cavity and the peritoneal cavity, the peritoneal spread of the oil does not occur, and when occlusion is due to saclike adhesions about the outer ends of the fallopian tubes, the oil breaks up into droplets and is retained in the watery fluid that fills the sacs, While the purpose of the injection is diagnostic, it is believed that it may sometimes be therapeutic as well, breaking up adhesions if they are not too tough and developing communication where none existed before.

When a pregnant woman is known to have an obstetrically adequate pelvis and a presumably normal fetus. pelvic X-ray examination seldom is called for, but if circumstances require quantitative knowledge as to the dimensions of the birth passages, X-ray examination provides by far the best means of measuring them.

Since X-rays diverge from their point of origin, the X-ray images of anatomical parts that are parallel with the plane of the film are always somewhat larger than the parts themselves; and if the parts are oblique to the film, that too causes distortion of the image. With the aid of a little special equipment and the application of a little simple geometry it is possible to compensate for distortion and translate measurements of film images into the actual dimensions of the maternal or fetal parts they portray, the procedure being known as pelvimetry or fetometry.

8. Blood Vessels.—For many decades injections of opaque heavy metal salts were used for making X-ray films of the blood vessels of anatomical specimens, and later angiography of the living subject became of clinical importance. When vessels of the brain are to be injected, most radiologists prefer to use the contract material in 30% concentration, but for the chambers of the heart and the great vessels leading from them concentrations as high as 70% are necessary. Several films must be made in rapid succession, each exposure being brief. the first in the series phased carefully with the beginning of the injection. Some radiologists use long strips of roll film driven past a window that is transparent to X-rays but opaque to light, while others prefer cut film carried in motor-driven conveyers.

Angiograms are used for the investigation of certain brain tumours; to identify obstructions and abnormal communications involving vessels of the extremities; and, above all else, for the study of the abnormal anatomy of the great vessels in patients with congenital heart disease for whom cardiac or vascular surgery is contemplated.

9. Stomach and Intestine.—X-ray examination is an important. almost indispensable, agent in the diagnosis of gastric and duodenal ulcer; benign and malignant tumours of the esophagus, stomach and bowel; diverticulosis and diverticulitis; ulcerative colitis; regional ileitis; and several other diseases. Barium sulfate is the contrast medium almost invariably employed. Formerly it was fluoroscopic examination that made the diagnosis, with films occupying a position of secondary importance, but many modern radiologists look upon fluoroscopy largely as a means of obtaining small, so-called spot films of various parts of the tract. In spot filming, the fluoroscopist manipulates a small segment of the gastrointestinal tract into position beneath the fluoroscopic screen and adjusts the amount of barium that it contains and the pressure applied to it until he has an optimum view. A film is now brought into position between the patient and the fluoroscopic screen. and, when the X-ray machine setting has been changed from the continuous small current adequate for fluoroscopy to the high voltage and large currents needed for rapid filming, the exposure is initiated with a foot snitch and terminated automatically with a phototube. Ulcers usually deform the outline of the stomach or duodenal bulb and, in addition, frequently excavate craters which, when filled with barium, are highly diagnostic. Cancers appear as soft tissue masses protruding into the lumen of the stomach or bowel and distorting the appearance of the gastric or intestinal mucosa.

II. THERAPEUTIC RADIOLOGY

One of the most remarkable attributes of the X-rays that Röntgen discovered in 1895 was the seemingly innocuous way in which they penetrated human tissue without causing pain: a feeling of heat or any other immediate sensation; but it did not take long for experimenters to learn that in spite of the absence of immediate effect, large doses led presently to redness of the skin, blistering and ulceration. Even small doses, it was found, if repeated often enough were followed by serious skin lesions that. showed up only after a considerable lapse of time. Of course, an agent so capable of damaging normal tissue mas bound to be considered for employment therapeutically if some means could be found to direct its damaging effects specifically against diseased parts.

Something eventually was learned about the fundamental nature of the biological action of radiation, and research on this subject continues, but usefulness did not wait on a complete understanding. Radiation therapy became one of medicine's few means of restraining and in some cases curing cancer.

The radiations employed in therapeutic radiology include X-rays ranging in voltage from about 5 kv. to more than 4,000 kv., radium, artificial radioisotopes, electrons. neutrons and other high-speed particles. Important differences in the physical distribution of the dose determine which of these should be used for a particular application. but biologically speaking it is the similarities rather than the differences that are most obvious throughout the entire range from the low-voltage X-rays used in contact therapy to the high-speed particles of the largest cyclotrons.

For historical and other reasons a discussion of radium and low- and medium-voltage X-ray therapy lends itself particularly well to an exposition of principles that apply throughout the entire radiation range. It is for this reason alone that radium. artificial radioisotopes and X-rays of low (5–100 kv.) and medium (100–400 kv) voltage are emphasized below. This distribution of emphasis should not be misinterpreted as indicating that multi-million-volt X-rays and high-speed particles are clinically unimportant.

The ideas of Heinrich Geissler, J. W. Hittorf, Sir William Crookes and P. E. A. Lenard were important immediate antecedents to those of Rontgen, and in the years after 1895 the stream of those ideas were swelled by innumerable tributaries. Italians such as Enrico Fermi supplied ideas in nuclear physics. Frenchmen such as the Curies, H. Coutard, A. Lacassagne and C. Regaud discovered radium and established the importance of the time factor as a modifier of the reaction of tissue to radiation. German physicists made important contributions, and German physicians such as H. Holthusen studied large masses of clinical material to establish much empirical knowledge. Scandinavians typified by G. Forssell and R. Sievert refined and advanced dosimetry and made large-scale clinical application of facts established in the laboratory.

British contributions were of two sorts. In the closing decades of the 19th century and the opening decades of the 20th such physicists as J. J. Thomson, C. T. R. Wilson, H. G.-J. Moseley and the two Braggs led in the development of X-ray physics. and later such physicians as Ralston Paterson and David Smithers and such radiation physicists as W. V. Mayneord. W. J Meredith and H. ill. Parker increased the precision with which radiation beams might be regulated and directed and advanced knowledge as to the response of normal and diseased tissues to such beams.

In the U.S., W. D. Coolidge conceived and produced X-ray tubes superior to anything available before, and Arthur Holly Compton and his students, employing X-rays to study the nature of matter, discovered in the process new and important facts about the X-rays themselves. Ernest Lawrence's pioneering cyclotron typified a whole group of instruments developed for accelerating particles of various sorts, and the biological experirpents on ionizing radiation that were carried on during World War II under John Lawrence in California and under Robert Stone in Chicago served as patterns for many later similar activities.

A. Dosage

1. Measurement. — The dose employed in X-ray therapy cannot be defined merely by stating the voltage and current at which the X-ray tube is operated. Numerous other factors are involved, including diameter and filtration of the X-ray beam. target-skin distance and the size and location of the lesion being irradiated. The need of dependable dosage guides was recognized more or less clearly from the outset, but their development proved difficult. Tried and found wanting were the measurement of the heat produced by the absorption of X-rays; the intensity of fluorescence; colour changes in several different combinations of chemicals; the blackening of silver bromide paper; the liberation of iodine from a solution of iodoform in chloroform; and an increase in the electrical conductivity of selenium under the action of X-rays.

Ionization Methods. — Rontgen's original papers described the ability of X-rays to ionize air. and in 1896 J. J. Thomson independently discovered the effect and suggested its use by physicists as a means of measuring X-ray intensity. P. Villard in 1908 advocated ionization for measuring the clinical dose, but his idea was not practical at that time because the large, delicate ionization chambers that were serving physicists so well were not suitable for clinical work and no others mere available. Gradually, however, small rugged chambers were developed, and in 1928 at the second International Congress of Radiology in Stockholm. Swed., there was adopted the "r" or roentgen unit, which became the standard throughout the world.

Roentgen Unit. — The roentgen unit was defined in Stockholm as follows:

> The unit of dose is that quantity of roentgen radiation which, when the secondary electrons are fully utilized and the wall effect of the chamber is avoided, produces in 1 c.c of atmospheric air at 0° C and 760 mm mercury pressure such a degree of conductivity that one electrostatic unit of charge is measured under saturation conditions.

This definition sufficed as long as the X-rays to be measured were produced at voltages up to 200 kv., but as r.meters began to be employed in the 1.000-kv. range and for the gamma rays of radium. the following definition was substituted:

> The roentgen shall be the quantity of X or gamma radiation such that the associated corpuscular emission per 0.001293 g. of air produces, in air, ions carrying 1 esu of quantity of electricity of either sign. (The mass of 1 c.c. of dry atmospheric air at 0° C. and 760 mm. of mercury pressure is 0.001293 g.)

Rad.—When the absorbed dose is the chief matter of interest, the roentgen unit has the disadvantage that absorption in air is independent over a considerable wave-length rahge, whereas in water-containing tissues energy absorption per gram increases from approximately 84 ergs for long-wave-length (low-voltage) radiation to about 93 ergs per gram for short-wave-length (high-voltage) radiation. The unit of absorbed dose is the rad, representing the amount of radiation which delivers energy equivalent to 100 ergs to a gram of irradiated tissue.

Roentgen (r) Meters. — The condenser-type r meters in general use in the United States consist of two parts, a chamber-condenser unit and a charging-measuring unit. Three sizes of chamber usually are supplied: a large one that measures up to 25 r; an intermediate size measuring up to 100 r; and a small chamber for measurements up to 250 r. The electrometer that measures the charge has three corresponding scales calibrated from 0 on the left to 25 r, 100 r or 250 r, respectively. on the right.

Chamber-Condenser Unit. — In the 100-r unit the chamber itself is a small plastic thimble that contains one cubic centimetre of air at room temperature and pressure. The inside of the wall of the chamber, which has been rendered conducting by a thin coating of carbon. constitutes one electrode and is connected to the metal sheathing that forms one of the plates of a 60-micro-microfarad condenser. The second electrode is a carbon-coated plastic rod mounted in a block of high-impedance material with its tip protruding into the air in the chamber, its base in electrical contact with the insulated plate of the condenser. Care is taken to exclude air from all parts of the system except the space inside the chamber itself.

Charging and *Measuring* Unit. — The charging and measuring unit consists of a hand-driven plastic disk that generates a static charge by rubbing against a leather pad, plus a quartz fibre electroscope that is calibrated in roentgen units. In using the instrument. the condenser is plugged into the charging unit and the charging wheel is rotated until the fibre stands at 0. The charged condenser is then disconnected from the electrometer and placed for a measured period of time with its chamber in the beam of the X-ray that is to be measured. The X-rays ionize the air in the chamber, causing it to become an electrical conductor, and this in turn allows the charge on the central plate of the condenser to leak to the wall of the chamber and thence to the outer plate of the condenser. When the partially discharged condenser is reconnected to the electrometer, the fibre has moved from the fully charged 0 position on the left toward the discharged 100-r position on the right, the precise amount of loss of charge being read directly in roentgens without computations of any sort.

Roentgen meters of this sort are secondary standards requiring initial checking against large standard chambers and occasional subsequent rechecking. but when they are carefully built and properly calibrated their accuracy is well within the limits necessary for radiation therapy. The required dose varies uidely from as little as 1.200 r in some lymphomas to as much as 5,000 r in most laryngeal carcinomas.

2. Low-Voltage X-Rays. — Until the close of World War I most clinical X-ray apparatus could not be operated at voltages in excess of 100 kv.; while this was more than enough for diagnosis, it limited therapeutic applications to lesions lying at or close to the surface of the body. Regardless of the inciting voltage, the raw beam as it leaves the X-ray tube contains amounts of long-wave-length radiation that are enormously greater than the amounts of short-wave-length rays. Because the long-wave rays are easily absorbed, they are said to be soft, while the short penetrating rays are said to be hard.

If raw radiation from a tube operated at 100 kv. is allowed to fall on a patient's skin, the soft radiation will be strongly absorbed in the superficial layers, so that an exposure time long enough to result in serious skin damage delivers only small amounts of relatively hard radiation to tissues lying a few centimetres beneath the surface. Filtration through three millimetres of aluminum will harden such a beam so that it may be possible to deliver 20% of the surface dose to tissues five centimetres beneath the surface, but it is impractical to deliver doses of therapeutic magnitude to tissues ten centimetres below the surface unless the voltage at the X-ray tube is raised well above 100 kv.

Formerly the degree of reddening of the skin was used as an indication of the dose, but this so-called erythema dose had serious limitations and was abandoned in favour of actual tissue doses expressed in roentgens. Along with the conception of erythema dose went also an undiscriminating attitude toward the employment of radiation for almost any of the cutaneous diseases. Radiation has its place in dermatology, but it is dangerous as well as useful and its employment must be restricted to physicians who are specially trained in its use. Under competent supervision, low-voltage X-rays are indicated in the treatment of such conditions as small- to moderate-size skin carcinomas, large keratoses, obstinate circumscribed neurodermatitis, plantar warts, superficial hemangiomas, ringworm of the scalp, cutaneous lymphomas and Kaposi's sarcomas, but in skin lesions if drugs and other agents will suffice these should be used in preference to X-rays.

Contact Therapy.—Much of the very soft radiation produced at any operating voltage is absorbed in the glass wall of the X-ray tube, and when voltages are reduced below 30 kv. almost none of the rays are hard enough to pass through the glass. For some of the vascular birthmarks, keloids, skin cancers and certain other skin lesions, it is desirable to be able to irradiate superficial tissures heavily with only a minimum dose to deeper structures. This is made possible by special X-ray tubes in which the port for the emergence of the radiation is a thin sheet of beryllium rather than glass. Such tubes are operated at voltages of the order of five peak kilovolts and the circuits are arranged so that it is safe to press the port against the skin of the patient. These three factors—closeness of the target to the skin, low operating voltage and minimum beam filtration—operate to minimize the depth dose and maximize the dose at the surface.

3. Medium-Voltage X-Rays.—By 1915, German scientists had added three concepts and a group of associated techniques which became basic to the radiation therapy of deep-lying lesions. These concepts were: the role of voltage, filtration and the geometry of patient and X-ray beam in determining the dose delivered to deep-lying tissues. The techniques were Walter Friedrich's thimble chamber for measuring the dose in air, body cavities, wax, water, etc., and Friedrich Dessauer's 200-kv. X-ray generators, isodose charts, and employment of wax, water bags and similar material to reduce the patient's body to a straight-sided geometric form to which his isodose charts could be applied. In the next three decades knowledge and experience advanced enormously; but Dessauer's paper, presented in 1921 to the American Roentgen Ray society, lacked little that is really fundamental to an understanding of medium-voltage X-ray therapy as it is now practised.

Increasing the voltage to 200 kv. made it possible to treat deep-seated lesions, most of which had been inaccessible before; but raising it another 50 kv., though desirable, did not prove to be essential. Increasing the voltage still further to 400 kv. brings additional advantages, but most workers agree that they are more than offset by decreased flexibility and considerably greater cost.

There are certain practical advantages in raising the voltage of X-ray therapy machines to 1,000 or even 2,000 kv., but. as in the case of cobalt-60 (see *Artificial Radioisotopes,* below), there is no specific advantage in the shorter-wave-length radiation thus produced. The most important working tool of the radiation therapist continues to be the 250-kv. X-ray generator.

4. Radium.—Opinion as to the clinical importance of radium (*q.v.*) fluctuated widely after the discovery of this element mas announced by the Curies in 1898. Administered internally, it is a slow but lethal poison devoid of any therapeutic value; but confined in airtight needles or capsules, sheathed with a filtering layer of $\frac{1}{2}$ mm. or more of platinum, it constitutes a gamma-ray emitter of established clinical importance. Radium needles or capsules having only thin layers of brass or Monel metal as filters emit large quantities of electrons or beta rays and are of only limited clinical value.

The hardest gamma rays of radium have a hardness or penetrating power approximately equivalent to the hardest of the X-rays produced at 3,000 kv.; but paradoxically the important medical role of radium is to deliver large ionizing doses to superficial tissues while minimizing the effect at a depth. The explanation lies in the geometry of the situation. Gamma rays, like X-rays, diverge from their point source of origin in a solid angle of 4π, so their intensity falls off as the square of the distance from that point of origin. Radium usually is employed in rods of appreciable diameter and length which act as multitudes of point sources re-enforcing one another, but to simplify the explanation that follows, it will be assumed that the radium has been concentrated in a single minute sphere. Since it is possible to bring the source of the gamma rays into almost full contact with surface tissue, it follows that tissues one centimetre distant from that source will receive only about 1% of the dose that is delivered at the surface. and tissues five centimetres distant only about 4% of the dose delivered at one centimetre. (These values ignore losses by absorption and gains by scattering, though both must be taken into consideration in actual practice.)

In a few instances several grams of radium have been concentrated in heavily shielded containers that can be backed off five to ten centimetres from the surface of the patient's body. Such gamma-ray beams filtered through one millimetre of platinum deliver depth doses distinctly better than those obtained with radium at the surface or inserted into the body but are inferior in this respect to well-filtered 250-kv. X-rays from tubes stationed 80 cm., 60 cm. or even 50 cm. away from the surface of the body. These so-called telecurie radium applicators would lose all justification with the availability of megacurie radiocobalt applicators, but heavily filtered interstitial and intracavitary radium employed sometimes alone and sometimes in conjunction with X-rays meanwhile continued to be important.

5. Artificial Radioisotopes.—In addition to the series of naturally occurring radioisotopes of uranium known collectively as radium which emit gamma radiation and have an aggregate half life of 1,590 years. there are available as products of cyclotrons and nuclear reacting piles a great number of artificial radioisotopes of many different elements. In some of these the radiation intensity decays to half its initial value in fractions of microseconds, while others have half lives longer than that of radium. A few of these isotopes had been investigated clinically by the early 1960s, but most of such work remained to be done. Phosphorus-32 administered intravenously as a sodium phosphate in doses of one to two millicuries a week for four to eight weeks is employed for the treatment of chronic leukemia. Iodine-131 administered orally as a solution of sodium iodide in doses of six to eight millicuries, repeated if necessary at trimonthly intervals, is used to reduce excessive activity of the thyroid gland, and occasionally cancer of the thyroid responds favourably to much larger doses. By the second half of the 20th century there was great interest in the clinical possibilities of cobalt-60. Megacurie cobalt applicators possess many of the virtues that are lacking in, and avoid most of the faults that are inescapable in, telecurie radium applicators. The charge of radioactive Co^{60}, though weighing only 12 g. and comprising a rod only 0.7 cm. in diameter and 3 cm. in length. will produce gamma rays of 1.13 and 1.32 Mev with a source intensity more than 200 times that of the same weight of pure radium or 260 times that of radium chloride. The decay of intensity by one-half within 5.3 years requires occasional substitution of new cobalt and the consideration of decay time in computing the output of the applicator, but at most these are only minor inconveniences. Cobalt applicators have certain practical advantages. but, as was anticipated, the radiation they deliver has no specific advantages over that from other sources.

To shield against unwanted gamma radiation, the container is constructed of uranium 13 cm. thick or lead 26 cm. thick; the removal of all beta radiation from the beam requires merely a thin aluminum filter. With such a cobalt source stationed 80 cm. distant from the skin, the surface dose to a 5 cm. by 5 cm. area is approximately 35 r per minute and the dose 10 cm. beneath the surface is 18.2 r per minute.

B. Radiation Physics

The work of calibrating X-ray machines, mapping the doses of the radiation that is purposely delivered to the tissues of a patient's body and protecting patients and radiation workers from unwanted radiation is a subspecialty within the specialty of radiation therapy. Modern treatment centres require the full-time services of considerable numbers of graduate physicists specially trained in this branch of physics. Much oversimplified, dose mapping may be summarized as follows:

The intensity and hardness of the X-ray beam are adjusted by varying the operating voltage and current and the nature and amount of interposed filter. For example, one combination will be found which yields a beam that will have its intensity reduced to one-half by the addition of a testing filter of one millimetre of copper. Such a beam is designated as having a hardness of one millimetre of copper half value layer (mm. Cu. hvl.). Another combination will yield a hardness of 1.5 mm. Cu. hvl., and a third a hardness of. for example, 3 mm. Cu. hvl.

These calibrations depend on r meter measurements of the beam with and without the added test filters, and from time to time the physicist checks them with his meter, but for the day-to-day work beam hardness is adjusted merely by selecting the interposed filter, voltage and current indicated on the calibration charts.

Other tables are prepared showing the dose in roentgens per minute measured at points located, for example, 50 cm. and 80 cm. from the target of the tube.

From roentgen measurements made with the thimble chamber at the surface and inserted into phantoms of wax. water or similar absorbing and scattering material. tables and isodose charts are prepared to show the doses that will be delivered at various points beneath the surface for given beam hardness. tube-skin distance, beam diameter and minute surface intensity.

It is the responsibility of the clinical radiologist to judge as closely as possible the size and location of the lesion, the amount and delivery rate of radiation most likely to be effective. and the tolerance of neighbouring uninvolved tissues. When this has been done the physicist determines the hardness intensity, geometry and aiming of the single or multiple beams best suited to place the radiation in the amounts and at the points stipulated! following which the technician administers the treatment as directed.

The usefulness of the physician-radiologist is enlarged greatly by such assistance from physicists and technicians, but it is necessary that he be competent in their fields as well as his own; legally as well as morally he must be responsible for the whole.

C. Clinical Aspects

The tissues of the body are unaffected by radiation that merely passes through them; it is only absorbed radiation that produces an effect. When there is an effect it is invariably cell injury, and the direct agency in this injury appears to be the ionization invariably associated with absorption.

The relationship between the degree of ionization and the nature and magnitude of the biological response is constant throughout the low- and medium-voltage range. In the multimillion-volt range, direct comparison is difficult because measuring instruments regularly employed for lower-voltage radiation are no longer fully dependable and the type of ionization itself changes slightly. It seems probable, however, that with the change in type of ionization there is an advantageous alteration in the ratio between the intensity of ionization and the magnitude of cell response.

Opinions differ as to whether radiation should be used to treat nonmalignant conditions such as arthritis, bursitis and hypertrophic lymphoid tissue. The former viexi---that such therapy, though possibly ineffective, certainly was innocuous—no longer is tenable, and physicians increasingly believe that X-ray treatment should not be employed where other therapeutic methods are available. On the other hand, the value of radiation in the treatment of cancer is established beyond all argument (see Cancer; Cancer Research). In the radiation therapy of cancer both the effect on the host and the effect on the diseased tissue are important. The body is not totally without natural defenses against cancer, but those defenses usually are not quite adequate and new cancer cells develop more rapidly than old ones are destroyed.

The aim of the radiation therapist is to deliver major damage to cancer cells with minimum damage to the adjacent normal tissue, hoping to tip the scales to such an extent that the natural defenses of the body will regain the upper hand. When too large a dose is given, cancer growth may be increased rather than diminished because the restraining action of a healthy tissue bed has been lost.

Radiosensitivity of tumours is influenced by numerous factors including cell type; tumour size and location; and age and general health of the host. Small tumours located rather superficially in young and otherwise healthy patients respond better than do large deep-seated tumours in debilitated elderly patients. Grouped in order of decreasing sensitivity, the response by cell type is as follows: (1) lymphocytes; (2) granulocytes; (3) epithelial cells, (a) basal cells of secretory glands, (b) basal cells of testes and ovaries: (c) basal cells of skin and intestinal tract, (d) alveolar cells of lungs, bile ducts, and (e) tubules of kidneys; (4) endothelial cells; (5) connective tissue cells; (6) muscle cells; (7) bone cells; (8) nerve cells.

The probability of clinical cure is not proportional to the degree of cell sensitivity, however. For example, the cells of Hodgkin's disease are extremely sensitive to ionizing radiations, but, though patients skillfully treated respond strikingly at first, this favourable response seldom is permanent. On the other hand, cancer of the cervix of the uterus with cells much less sensitive than Hodgkin's tissue can be cured. Skin cancer is curable unless it has been neglected until it has extensively invaded bone or cartilage. Cancer of the larynx. nasopharynx and tongue are particularly suited to radiation therapy because the mutilation incident to surgical extirpation is so disabling. Cancer of the cervix of the uterus responds well to radiation and cancer of the body of the uterus to surgery combined with radiation. Cancers of the stomach and bowel are best treated surgically. In many cases where there can be no expectation of cure, radiation may provide relief from pain and frequently considerable prolongation of the period of usefulness and relative comfort.

RADIOMETER, an instrument for measuring the intensity of radiant energy. The term is applied most often to instruments of the vane type described below, but it can also be applied to the bolometer, pyrheliometer, thermopile and radio balance. For information on these instruments see Heat: Sensitive Radiometers and *Absolute* Radiometers.

It was noticed by A. J. Fresnel that a body delicately suspended in *vacuo* is apparently repelled by radiation. Using this principle. Sir William Crookes constructed an instrument, which he called a radiometer, by pivoting a vertical axle carrying vertical vanes inside an exhausted bulb; one side of each vane was blackened and the other side bright, the black sides all facing the same way round the axle. When rays from the sun or other light source or dark radiation from a warm body fall on the vane, the black sides are repelled more than the bright sides, and the vanes are set into rotation. The more intense the radiation the more rapidly do the vanes rotate. It was Crookes's idea that the instrument might be used to measure the intensity of radiation.

Instead of allowing free rotation of the vane system on a pivot, it may be suspended by a quartz fibre. Radiation falling on the black face of the vane will then cause the system to turn round until the restoring couple, because of the torsion of the suspension, balances the deflecting couple due to the radiometer action. A small mirror, attached to the vane system and reflecting a beam of light on to a scale, enables very small deflections to be observed. Ernst Pringsheim constructed such an instrument in 1883 and used it for spectrographic investigations in the infrared. In 1893 E. F. Nichols improved the radiometer by using mica vanes, one at each end of a horizontal arm suspended on a quartz fibre and each blackened on its front surface. Radiation falling on both vanes would tend to turn them in opposite directions, and if they were correctly adjusted the system would not move under the influence of general stray radiation. The radiation to be measured was allowed to fall on one only of the vanes, and the resulting deflection of a spot of light was observed. With such a radiometer Nichols was able to measure the radiation from individual stars. The radiometer has been applied to measurements of ultraviolet radiation and to that of short Hertzian waves (wave length one to two millimetres).

The explanation of the radiometric action has presented a problem of considerable interest. The question arises whether the rotation of the vanes may be caused by the direct impact of the radiation, somewhat as the rotation of a cup anemometer is caused by the wind. This explanation has been disproved in several ways. If, for example, the vanes are made of transparent material and blackened on the back face, they move toward the direction from which the light comes. The ordinary radiometer effect must be caused, therefore, by stresses set up in the gas. As the pressure of the gas is reduced, the rotation increases to a maximum and then decreases. Even in a very high vacuum, however, a small effect persists. directed away from the light. The magnitude of this residual effect agrees with the value as calculated from the electromagnetic theory of light, which predicts a small pressure because of incident radiation.

The ordinary radiometric action in the presence of gas has been rather definitely shown to be a consequence of the creep of the gas over the unequally heated surface of the vanes near their edges, as was suggested by J. C. Maxwell in 1879. The gas creeps toward the more heated part of the vane's surface and produces there a slight condensation of the gas and an increase in its pressure; the inequalities of pressure thus created give rise to a reverse flow in the surrounding gas, but this flow is hindered by viscosity, so that some inequality of pressure persists and forces the vane back. This phenomenon of gas behaviour, known in other occurrences as thermal transpiration (with "transpiration" used in the pure sense of leaking), is discussed in E. H. Kennard, *Kinetic Theory* of Gases, 1st ed., pp. 333–37 (1938).

RADIO RECEIVER. The two principal parts of a radio system are the transmitter and receiver. The waves radiated from transmitting antennas set up voltages in a receiving antenna, so that the first function of a receiving set is to select the signal desired. This must then be amplified and further modified so that a faithful reproduction of a program can be produced by the loud-speaker. Although a modern broadcast transmitter may have an output of 50 kw., often only a few microwatts from distant stations are available at the receiving antenna, principally because of the spreading out of the radio waves as they are propagated through space. A large amount of amplification is thus required in order to obtain a sound output of one watt, for example.

History. — The first demonstration of the production and reception of radio waves was made by Heinrich Hertz in Germany in 1887. His receiver consisted of an open wire loop with spheres attached to the ends to form a gap. The presence of the waves was "detected" by observing a spark set up in the sphere gap. Hertz was interested only in studying the properties of the waves and expressed no thought of practical application. It remained for Oliver Lodge to develop a system of wireless communication in England in 1894. The receiver included an antenna, tuned circuit, a detector consisting of a glass tube filled with metal filings called a "coherer" and a relay-controlled inker for recording Morse code. Lodge subsequently received several patents on radio apparatus — two of the better-known covering tuned circuits and loop antennas.

There was much activity in wireless telegraphy following Lodge's initial disclosures. Many new and improved types of detectors or "cymoscopes" were invented. These included magnetic types by Guglielmo Marconi, Ernest Rutherford and others; electrolytic by F. K. Vreeland, R. A. Fessenden and Lee De Forest; and a wide variety of crystal detectors using carborundum, galena and iron pyrites.

The first electronic device to appear in radio receivers was the Zehnder trigger tube cymoscope in Germany in 1892. This was a glow tube in which the potential difference between anode and cathode was set to a value of several hundred volts. A discharge could then be initiated by impressing a radio signal between the pair of trigger electrodes with which the tube was provided.

The first thermionic electron tube for radio use was patented by J. A. Fleming in England in 1904. This was a vacuum diode detector tube, known as the Fleming oscillation valve. Its apparent advantage over other types of detectors was the ability to undergo mechanical shocks and static surges without "jarring out." Its inherent insensitivity to weak signals, together with the primitive status of manufacturing, limited its application.

The three-element vacuum tube was invented by De Forest in 1906. A receiver using an audion, as it was called, could deliver more power to an output device than was received from the antenna, so that it was operating in the dual capacity of detector and amplifier. Subsequent work showed that it could be used simply as a radio-frequency (R.F.) or audio-frequency (A.F.) amplifier, or even as a modulator. De Forest manufactured radio sets equipped with audions for several years. The audion was greatly improved by others during World War I and was manufactured in large quantities.

One of the most remarkable applications of the audion was to the feedback, or regenerative, circuit. In this, coupling was introduced between the plate and grid circuits such as to produce an appreciable increase in both the selectivity and sensitivity of the circuit. By providing adequate coupling, such a circuit could be made to oscillate continuously without benefit of external grid signal.

It is difficult to place proper priority for the invention of the feedback circuit. In 1913 Alexander Meissner was granted a patent on an oscillator in Germany and E. H. Armstrong presented a paper describing regenerative circuits. Other names associated with contemporary work were those of C. S. Franklin and H. J. Round in England and De Forest and Irving Langmuir in the United States. A four-way litigation initiated by Meissner, Armstrong, De Forest and Langmuir was decided finally in favour of De Forest by the supreme court of the United States in 1928, and it reaffirmed its action in 1934.

Considerable progress was made in the theory, construction and applications of vacuum tubes and their circuits between 1910 and 1920, much of it in connection with the World War I efforts and long-line carrier-current telephony. The greatest single impetus to be noted in radio history, however, was the introduction of radio broadcasting in 1921. This created a tremendous demand for receivers as transmitters were established throughout the world. The vacuum-tube receiving circuits were battery operated for the first few years, but rectifier-type power packs soon appeared for plate and grid supplies. These were followed almost immediately by the self-contained alternating-current sets, which were made possible by the development of tubes whose cathodes could be operated on alternating current without introducing excessive hum in the output.

The first broadcast signals were amplitude modulated (AM) exclusively, and many types of receiving sets were in use. Some of the commonest were: regenerative, superregenerative, reflex, tuned radio frequency, neutrodyne and superheterodyne. The superheterodyne came to be used almost exclusively for broadcast reception. although a few portable models employ tuned-radio-frequency circuits.

The difficulties of static elimination inherent in AM operation led Armstrong to develop frequency modulation (FM). Although he began work on the problem in 1914. his system was not perfected until 1933 and several more years elapsed before much use was made of it.

Modulated Waves.—It is impractical to transmit audible signals by wireless because the radiated output of an antenna depends upon its size expressed in terms of the wave length of the signal to be transmitted. Since the wave-length range is 3,720 to 37.2 mi. for the ordinary broadcast audio-frequency range of 50 to 5,000 cycles per second, it is only too obvious that not only would the necessary audio-frequency antennas be prohibitively large but there would also be the possibility of a 10.000 to 1, or 40 db., variation in the output over this 100-to-1 frequency range. Furthermore, only one station could be on the air at once in any given locality. since it would be impossible to tune out the unwanted signals. Thus, it is practical to transmit wireless signals only at the high frequencies known as radio frequencies.

The problem was easily solved in radiotelegraphy by the comparatively simple process of keying, or turning on and off, a high-frequency signal. However. it was necessary to devise a different method to transmit a "message" in the form of articulate speech or music. Such a method was found in the utilization of a high-frequency wave as a vehicle, or carrier, for the comparatively low-frequency message. The exact mechanism consists of modifying, or modulating, the carrier signal in some manner by the audio signal, the resultant radiated signal being known as a modulated wave.

Any high-frequency electromotive force, of a form denoted by the formula e = E cos (wt + 0), is completely specified if the amplitude E, angular frequency ω and phase angle θ are given. An audio-frequency signal to be transmitted can be introduced into the given radio signal by causing it to modify any one of these functions. the three methods being known as amplitude. frequency and phase modulation, respectively. A fourth possible method involves breaking up the signal into pulses. However. this discussion will be limited to amplitude and frequency modulation since they are the most commonly used.

Amplitude *Modulation.*—If, in the general equation above, E is set equal to E, + $E_m \cos \omega_m t$, the result is

$$e = (E_c + E_m \cos \omega_m t) \cos \omega_c t = E_c (1 + m_a \cos \omega_m t) \cos \omega_c t$$

in which E_c is the amplitude of the unmodulated carrier voltage; E_m is the amplitude of the modulating signal voltage; ω_m is the angular frequency of the modulating signal voltage; ω_c is the angular frequency of the carrier voltage; and m_a is the amplitude modulation index (E_m/E_c). Applying a trigonometric identity now gives

$$e = E_c \cos \omega_c t + E_s \cos (\omega_c + \omega_m)t + E_s \cos (\omega_c - \omega_m)$$

in which E_s is the amplitude of the side bands $(m_a E_c/2)$, where (w, + ω_m) is the angular frequency of the upper side band and (w, − ω_m) is the angular frequency of the lower side band.

This is the equation commonly used for an amplitude-modulated signal, which consists of a carrier term together with upper and lower side bands for each component of the modulating signal. In order to transmit, at a carrier frequency of 1.000 kc.. music of regular broadcast quality covering a frequency range up to 5 kc., a band width of 10 kc., or 993 to 1.003 kc.. is required. Since this involves a maximum frequency variation of only 0.5% on either side of the carrier frequency, no special difficulty is involved in the design of the equipment.

The process of removing the original signal from the modulated one at the receiver is known as demodulation. As an illustration of this. assume the response curve of some nonlinear device. such as a crystal or vacuum tube operating over the curved portion of its characteristic, to be given by

$$i = a_1 e + a_2 e^2$$

Substitution in the equation for an amplitude-modulated signal and application of trigonometric identities yields, in addition to radio-frequency terms, an audio-frequency response given by

$$2a_2 E_c E_s \cos \omega_m t = a_2 m_a E_c^2 \cos \omega_m t$$

and

$$a_2 E_s^2 \cos 2\omega_m t = \frac{a_2 m_a^2 E_c^2}{4} \cos 2\omega_m t$$

The former corresponds to the original signal to be transmitted; the latter to second harmonic distortion.

Frequency Modulation.—This is accomplished by introducing into the frequency of the signal to be radiated a variation about the carrier frequency that is proportional to the modulating signal. This gives, after some manipulation, for the general equation for a frequency modulated voltage,

$$e = E_c \sin \left(\omega_c t + k_f \frac{E_m}{\omega_m} \sin \omega_m t\right)$$

in which k_f is the ratio of the maximum variation in frequency to the maximum strength of the modulating signal.

This can be expanded to yield a carrier and an infinite number of pairs of side bands whose amplitudes are expressed in terms of Bessel functions (*see* FUNCTIONS, SPECIAL). Although from a practical standpoint it is only necessary to pass a limited number of side bands, the required band width is much greater than that for the AM signal, which requires only one pair of side bands for each component of the modulating signal.

In particular, it has been found possible to transmit a maximum audio frequency of 7.j kc. within a band width of 200 kc., which shows that FM transmission is not practical in the regular band of j50 to 1.500 kc. allocated for AM broadcast A special band of 88 to 108 mc. is used for the stations being spaced 200 kc. apart.

TYPES OF RADIO RECEIVERS

Regenerative Receivers.—One of the first circuits in common usage is shown in fig. 1. In this the single tube acted as both radio-frequency amplifier and detector. The input circuit was tuned by means of the variable air condenser and taps on the vario-

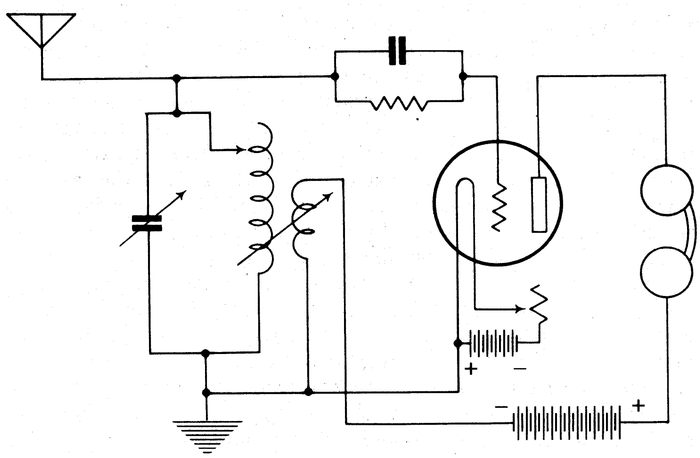

FIG. I.— SINGLE-CIRCUITREGENERATIVE RECEIVER

coupler tuning coil, and the amount of feedback was controlled by rotating the tickler coil. This circuit was especially common in home-built sets, principally because of its simplicity. Other types of regenerative receivers were the two- and three-circuit, tuned plate, Cockaday, etc. Most of them had a tendency to oscillate and to act as a radio transmitter while being tuned. The radiated output would combine with other signals present to produce obnoxious squeals and whistles in neighbouring sets. This, together with a demand for more selective receivers as the number of broadcast transmitters with closer frequency allocations increased, eventually limited the regenerative receiver to long-wave and marine use.

Superregenerative Receiver.—The selectivity and sensitivity of a regenerative receiver increases rapidly with the coupling and resulting approach to the condition for sustained oscillation. Arm-

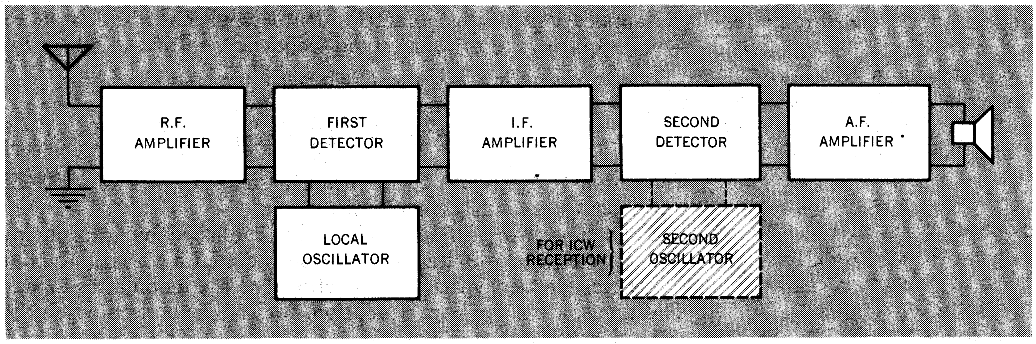

FIG. 2.—BLOCK DIAGRAM FOR SUPERHETERODYNE RECEIVER

strong in 1922 first described a circuit for taking advantage of this by superimposing a supersonic signal upon the received signal in a manner such as to prevent the circuit from oscillating at a high frequency. This principle is used in the superregenerative receiver, which is characterized by extremely high sensitivity. Because of poor quality of output, its use is limited principally to short-wave reception in police and radio amateur sets.

Reflex Receiver.—Reflex action consists of feedback action between the plate circuit of one tube and the grid circuit of the preceding tube. In the reflex receiver, the antenna signal was first amplified by one stage of tuned radio frequency (T.R.F.) and then applied to the grid of the detector tube. The audio-frequency output of the latter was then fed back to the grid of the first tube by means of an audio-frequency transformer, the headset or loud-speaker being connected in the plate circuit of that tube. Thus, the first tube acted simultaneously as a radio-frequency and audio-frequency amplifier, to give sufficient output to operate a small loud-speaker upon occasion. This was an important consideration in the days of high-priced tubes, parts and batteries. Poor selectivity was the principle factor which brought about an early obsolescence.

Tuned-Radio-Frequency (**T.R.F.**) Receiver.—It was found that an increase in both sensitivity and selectivity could be obtained by introducing one or more stages of the tuned-radio-frequency amplification preceding detection. However, the plate-grid capacitances in triodes created a tendency for the circuit to oscillate. Although a limited amount of feedback action was desirable, it was necessary to control it carefully in order to prevent oscillations. Bridge circuits for accomplishing this were developed by C. W. Rice and L. A. Hazeltine. A set utilizing the last was known as the neutrodyne receiver, considered to be the last word in receivers until superseded by the superheterodyne.

Some of the weaknesses inherent in early types of tuned-radio-frequency receivers were separate tuning for each stage and non-uni'form neutralization, sensitivity and selectivity over the broadcast band. The first was removed by gang tuning and the need for neutralization by use of screen-grid tubes, but the problem of varying sensitivity and selectivity remained in tuned-radio-frequency receivers. As a result! this type is used in only a few portable broadcast receivers and certain isolated applications where the selectivity requirements are not too stringent.

Superheterodyne Receiver.—A circuit which gave uniform performance over a wide range of station frequencies was developed by Armstrong while working in France during World War I. This made use of the heterodyne principle, which consists of combining two frequencies to give a different frequency. It had been introduced by Fessenden of the University of Pittsburgh in 1913, to convert radiotelegraph signals into interrupted audio-frequency code signals.

In the Armstrong superheterodyne receiver. or supersonic heterodyne receiver as it was called first in England, the incoming signal is combined with the output of an oscillator to produce a given supersonic frequency, called the intermediate frequency (I.F.). The latter is then amplified by means of one or more tuned stages, demodulated to give the required audio-frequency signal, amplified and finally fed into a loud-speaker. The selection of the particular station to be received is accomplished by adjusting the oscillator frequency so that the difference between it and the carrier frequency of the received station is equal to the intermediate frequency. Since the major part of the amplification is in the intermediate-frequency amplifier, both the selectivity and sensitivity of the set are essentially independent of the original station frequency. The advantages of the superheterodyne receiver were quickly recognized, but since the early sets required eight or ten expensive battery-operated tubes its use was limited to the more expensive models. Within 20 years. however, it had almost completely supplanted other types of broadcast receivers.

The accompanying block diagrams show the principal features of typical modern receivers. Starting at the input terminals, the signal is first amplified with one stage of tuned radio frequency in order to provide initial selectivity and thus to reduce so-called image and cross-modulation effects and mixer tube noise. The tuned-radio-frequency amplifier and local oscillator circuits are gang-tuned with a single control.

The mixer, converter or first detector tube, as it is called, changes the carrier frequency of the signal to the intermediate-frequency value. This was originally taken as 50 kc., but was later increased to 130–175 kc. Later it was further increased to 450–480 kc., with a tendency to standardize at 455 kc. in order to accommodate multiband receivers.

The intermediate-frequency amplifier usually consists of one or two transformer-coupled stages. The primaries and secondaries are permanently tuned, aside from small "trimmers" which are used for alignment purposes. The major portion of the high-frequency gain occurs in the intermediate-frequency amplifier. Remote cutoff pentodes are used to permit automatic gain control.

The function of the second detector is to convert the modulated intermediate-frequency signal into audio frequency. Square-law detection by means of a triode was used originally. This is preferable for weak signals, but since the percentage of second harmonic distortion increases rapidly with signal strength and percentage modulation, linear detection came to be used.

Among the advantages of high-level linear detection are the elimination of one stage of audio-frequency amplification, low harmonic distortion, reduction in tube noise and a lowering in cost of power pack filter because of the higher permissible hum.

The process of linear detection is essentially one of rectification and can be accomplished with either diodes or suitably biased grid-control tubes. Duplex tubes are often used, one part feeding into the audio-frequency amplifier, the other into the automatic volume-control system.

The audio-frequency amplifier may consist of one stage of voltage amplification and a power stage which utilizes two power

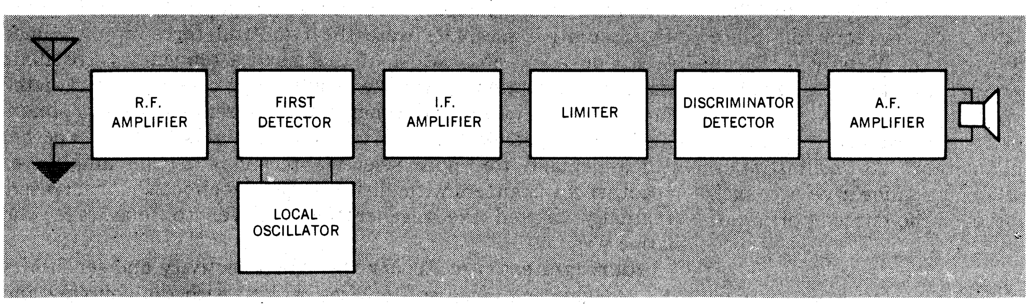

FIG. 3.—BLOCK DIAGRAM FOR FM BROADCAST RECEIVER

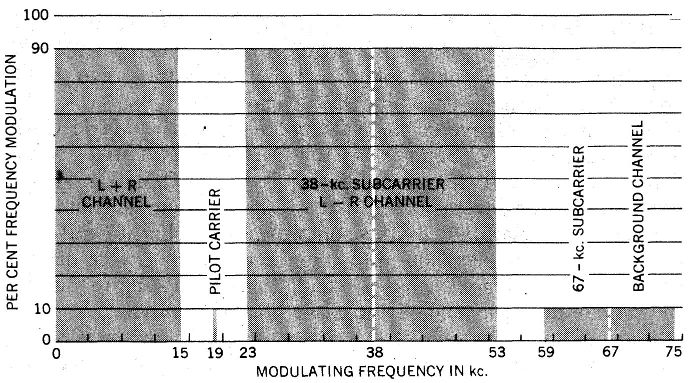

FIG. 4.—FREQUENCY SPECTRUM FOR FM STEREOPHONIC BROADCAST

pentodes in push-pull, when considerable output is demanded.

Automatic volume, or gain, control (AVC) was one of the most important developments in radio receivers. Its principal purpose is to maintain constant detector input. In this way the output of the receiver is unaffected by the strength of incoming signals. In brief, automatic volume control is accomplished by introducing an. extra bias in the remote-cutoff tubes in the tuned-radio-frequency and intermediate-frequency stages, which increases with the carrier input to the second detector. This automatically adjusts the gain of those stages so as to maintain nearly constant detector input as long as the incoming antenna signal exceeds a minimum threshold value.

The output of a receiving set is adjusted to suit the listener by means of a volume control, consisting of a potentiometer in the audio-frequency amplifier.

Since the sensitivity of the ear varies with frequency, some volume controls also include fixed coils or condensers such that the quality of the loud-speaker output will appear to be independent of intensity.

The purpose of the tone control is to allow the listener to vary the relative intensity of the high and low tones. The circuit for doing this often consists of a variable resistance connected in series with a fixed capacitor, its effect being to emphasize the bass notes by de-emphasizing the treble.

Receivers for FM Reception.—The block diagram in fig. 3 is schematic for a typical receiver designed for use in the 88- to 108-mc. FM broadcast band. In commercial sets, however, a converter stage replaces the local oscillator and the first detector mixer. Except that the intermediate frequency is 10.7 mc. instead of 455 kc., a change made necessary by the greater band-width requirements of FM, the functioning of the set is similar for receiving both AM and FM up to and including the I.F. amplifier. The output of the I.F. amplifier, however, instead of feeding into the detector as for AM, first goes through a limiter which levels off the signal to a fixed amplitude of a few volts. This is very effective in eliminating interference as well as noise due to static, ignition systems, etc., since it is estimated that only about 3% of such disturbances are of a frequency-modulation character. This results in a possible gain in the signal-to-noise ratio of as much as 30 db. by the use of FM.

The first step in the demodulation process is to convert the output of the I.F. amplifier into an AM signal. This is done with a frequency-sensitive circuit called the discriminator. A typical arrangement consists essentially of a coupling transformer with tuned primary and secondary. The desired shape of its frequency response curve is obtained by using coupling slightly less than critical. The output of the discriminator is fed into a detector and the resulting audio signal is further amplified and fed into a loudspeaker as in AM reception.

Receivers for Stereophonic Reception.—The U.S. Federal Communications commission on April 19, 1961. approved a multiplex system for broadcasting stereophonic programs in a single band in the regular 88 to 108 mc. FM broadcast spectrum. The approval became effective June 1, 1961. Previously. FM multiplexing had been utilized for several years by at least 200 stations in the U.S. as a means of broadcasting background music on a rental basis to factories, restaurants and other commercial establishments. The approved system for stereophonic broadcast made provision for continuing this special service. although—as in the case of monophonic broadcasting—background music signals are filtered out in home receivers.

The specified FM spectrum for stereophonic broadcasting, including the optional band for transmitting background music, is shown in fig. 4. With appropriate changes in the co-ordinates. this diagram also can be used to represent the upper sideband halves of both the radiated and received signals or. by omitting the background music portion, it can be used to portray the output of the FM limiter-detector stage in a stereophonic home receiver.

The transmitted signal consists of a main carrier that has been frequency-modulated as follows: (1) up to 90% (75 kc. constitute 100% modulation in FM broadcast) by L + R, the sum of the left- and right-hand audio signals; (2) 8% to 10% by a 19-kc. pilot carrier; (3) up to 90% by a 38-kc. subcarrier which has been amplitude-modulated, with carrier suppressed, by L − R, the difference between the left- and right-hand audio signals; and optionally. (4) up to 10% by a 67-kc. subcarrier amplitude-modulated by background music whose upper limit has been set at 8 kc. The standards of periormance are the same as for monophonic FM broadcasting.

The principal functions that must be performed by a stereophonic home receiver are portrayed in fig. 5. The first four sections in this are essentially the same as would be found in a similar diagram for a monophonic receiver? including 10.7 mc. for I.F. amplification. It is principally in the I.F. amplifier that background-music signals are filtered out in both monophonic and stereophonic home receivers; a specially adjusted receiver must be used to detect and amplify the background-music signal.

Starting with the output of the I.F. amplifier in fig. 5, channel A accepts and transmits L + R to the matrixing network, a network whose output is a linear combination of two or more input signals. Channel B_1 accepts the 38-kc. subcarrier that is amplitude-modulated by L − R. Channel B_2 accepts the 19-kc. pilot carrier, doubles its frequency and amplifies it so that it can replace the 38-kc. subcarrier that was suppressed in the transmitter. The outputs of B_1 and B_2 are then applied to an AM detector which delivers L − R to the matrixing network.

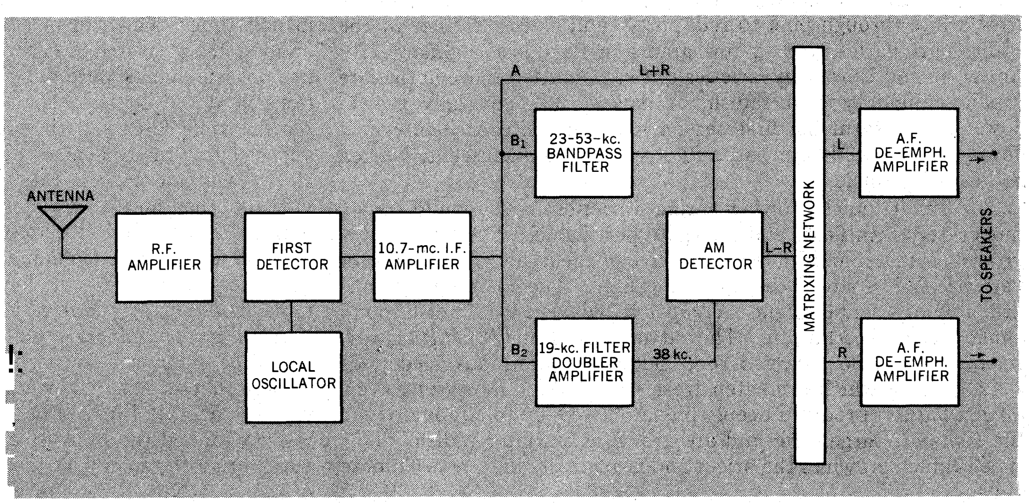

FIG. 5.—FUNCTIONAL DIAGRAM FOR STEREOPHONIC RECEIVER

The output of the matrixing network consists of the sum and difference of its two inputs, to give (L + R) + (L − R) = 2L. and (L + R) − (L − R) = 2R. respectively. After de-emphasis and amplification, these are fed into two loud-speakers so arranged as to give the proper stereophonic effect.

A stereophonic receiver can ordinarily be used for monophonic FM reception, although some interference may be heard if the received signal happens to include a background-music subcarrier that is at some point in the range of 20–53 kc. If a stereophonic signal is picked up by a monophonic receiver. a true monophonic reproduction. consisting of L + R. will be heard; the effect is the same as if two microphones were used in a monophonic broadcast. This is the reason for using L + R in place of either L or R as one of the original modulating signals for stereophonic broadcast. It is necessary to use an adaptor. as well as an additional amplifier and loud-speaker, with a monophonic receiver in order to obtain stereophonic reproduction.

Transistor Receivers. — The development of the transistor made it possible to construct a very small portable radio receiving set. In effect, the transistor permits the use of certain elements whose size is more commensurate with the amounts of useful power associated with the various parts of the receiver. This applies particularly to the replacement of thermionic vacuum tubes by transistors: since the latter require no cathode heating power. This removes the necessity of providing filament transformers and sufficient tube radiating surface to dissipate the cathode power.

RADISH, *Raphanus sativus* (family Cruciferae), an annual or biennial grown for its large. succulent root. The edible part of the root, together with some hypocotyl, form a structure varying in shape, among varieties. from spherical through oblong to long cylindrical or tapered. The outside colour of the root varies from white through pink to red, purple and black; the size of the edible part varies from a few grams in the most popular early American and European varieties to two pounds or more in the late Japanese field type of radish, or daikon. As generally grown, flower stalks form the first season, bearing white or lilac-veined flowers. The seeds are borne in a spongy, nondehiscent, beaked pod called a silicle.

The small, quick-growing spring varieties have a mild: crisp, moderately firm flesh, and are quite perishable. The large, slow-growing summer and winter types have pungent, firm flesh. Winter varieties can be stored through the winter. The common radish is probably of oriental origin. R. *raphanistrum* is a wild radish found along the Mediterranean. The rat-tailed radish (R. *sativus*, var. *caudatus*) has no enlarged root, but bears enormous seed pods 8–12 in. long which are eaten fresh or pickled. R. *sativus* (var. *longipinnatus*) produces deeply pinnate leaves up to two feet long; the roots are large, firm and are grown as a winter radish. This type is much grown in the orient and is generally known as Chinese radish. (V. R. B.)

RADIUM, the most familiar of the natural radioelements, is a metallic element belonging to the alkaline-earth group, of which it is the heaviest. The name, derived from the Latin *radius* ("ray"), originally applied only to the first discovered and most important isotope of the element, that of mass number 226, but is now used as a general name for the element.

Radium was discovered in 1898 by Pierre Curie, Marie Curie and an assistant, G. Bémont, at the Sorbonne in Paris. Mme. Curie had observed that the radioactivity of pitchblende, an ore of uranium, was several times that of the uranium it contained. By chemical separation of the constituents of the mineral, two highly radioactive elements—polonium and radium—were discovered. Prior to this discovery, it had been customary to discard the residue of pitchblende after extraction of uranium.

Radium was found to adhere closely to the common element barium, which it followed in the chemical treatment of the ore, indicating a very close chemical relationship of the two elements. Only after developing a complicated fractional precipitation procedure could the two elements be separated. Then. in 1902, Mme. Curie was able to prepare a pure salt of radium by working up several tons of pitchblende residues. The same general method of extracting radium is used commercially, a tribute to the genius of this pioneer in radiochemistry.

The pure element was first prepared in 1910 by Mme. Curie and A. Debierne; it is a shiny white metal.

The symbol of radium is Ra; atomic number 88; atomic weight 226.05.

Isotopes and Radioactive Properties — Several isotopes of radium, all radioactive, are known. Only Ra^{226} is stable enough to permit its isolation in visible and weighable amounts, and the name "radium" often refers simply to this isotope. Its half life is approximately 1,620 years, and it disintegrates with the emission of alpha particles. It is a member of the uranium, or radium! family of natural radioelements, following ionium in the series. Its immediate transformation product is radon, a noble gas of 3.825-day half life, which in turn changes into a series of shorter-lived radioelements, radium A, B, C, C′ and C″. It is rarely encountered in a radioactively pure form, for immediately after purification from its disintegration products they rapidly grow in again. Radium C emits penetrating gamma rays, so that, although radium itself emits only small numbers of gamma rays of low penetrability, a sample which has been sealed up to prevent loss of the gaseous radon is a source of strong gamma radiation. About a month is required for the gamma activity to reach its maximum, or equilibrium, intensity. The end product of the short-lived descendants of radium is radium D, which is also radioactive, and from this grow radium E and polonium, or radium F. Since the half life of radium D is 20 years it comes to equilibrium slowly in radium preparations.

The half life of radium is so great that it cannot be determined by directly observing the decay, and recourse must be had to indirect methods. Most of these involve the' determination of the specific activity, or the number of disintegrations per unit weight in unit time. This can be done by counting the alpha particles emitted in a measured interval by a sample of known weight. The first measurements were done by visual counting of the scintillations produced by the impact of the particles on a zinc sulfide screen, while later experimenters'have used electrical detection and counting instruments. Since alpha particles are helium nuclei, measurement of the rate of helium generation by radium provides another means of determining the specific activity. The half life also can be calculated from the rate of growth of radium in a sample of purified ionium relative to the amount in equilibrium with the same quantity of ionium in ancient and intact uranium minerals. Finally, from the equilibrium ratio of radium and uranium in such minerals the half life of radium can be calculated if that of uranium is known independently. The specific activity is close to 3.61×10^{10} alpha disintegrations per second per gram, whence the half life is 1,620 years. The disintegration rate of radium formed the basis of a standard unit of radioactivity, the curie, originally a rate of disintegration equal to that of a gram of radium. Now, a curie of any radioelement is by definition that amount undergoing 3.7×10^{10} disintegrations per second.

In the thorium series of radioelements occur two radium isotopes, mesothorium I (Ra^{228}) and thorium X (Ra^{224}), the former a beta emitter of 6.7-year half life and the latter an alpha emitter of 3.64-day half life. One of their descendants, ThC″, emits gamma radiation even more penetrating than that of RaC, and as a result of the complex sequence of half lives the gatnma activity of freshly purified mesothorium increases for about four years and then decays steadily. A fourth isotope, actinium X (Ra^{223}), occurs in the actinium series and is an alpha emitter of 11.7-day half life. *(See* RADIOACTIVITY, NATURAL.)

Several artificial radioactive isotopes of radium are also known. (See NUCLEUS.)

Natural Occurrence.—Although the half life of radium, 1,620 years, is long with respect to human experience. it is infinitesimal in the geological time scale, and any radium present at the time of the formation of the earth has by now completely disappeared. It is only because a new supply of the element is continually being generated by the disintegration of uranium that any is found at the present time, and its distribution in nature is practically identical with that of uranium. There is a constant ratio between radium and uranium, 0.00000034, in all sufficiently old minerals in which radioactive equilibrium has not been disturbed by weathering or leaching. In altered minerals the radium is generally relatively lower because of the greater solubility of its oxide. Springs, rivers, sea water and the ocean sediments contain small amounts of radium. Uranium, and consequently radium, are widely distributed in minute traces in nearly all common rocks, both igneous and sedimentary, the average concentration of radium in the earth's crust being about 1 part per 1,000,000,000,000. The bulk of the earth's radium is so accounted for, but in this form it is, of course, commercially unavailable. Only in uranium minerals is radium present in high enough concentrations to make its extraction feasible, and even the richest ores contain only about $\frac{1}{4}$ g. of radium per ton. Most deposits contain smaller amounts; and some which contain as low as 1% of uranium, or 1 g. of radium in 300 tons, have been exploited for the latter.

Radium was discovered in the mineral pitchblende, an oxide of uranium, which had been mined since about 1840 at Joachimsthal, Czech., for its uranium content. More extensive pitchblende deposits were later found at Katanga in the Belgian Congo and at Great Bear lake and Beaverlodge lake in Canada. Second in importance as a radium source is carnotite, a double vanadate of uranium and potassium found principally as a yellowish impregnation of sandstone in the western United States. Altogether several dozen different radium-containing minerals are known, and deposits of varying extent are found in many other places; some of these have been worked from time to time for radium. The increased importance of uranium, as a source of atomic energy, has resulted in intensive prospecting and the discovery of many more such deposits. *(See* URANIUM.)

Mesothorium is obtained principally from monazite. a mixed phosphate of thorium and rare earths occurring frequently in alluvial sands. *(See* THORIUM.) Thorium *X* and actinium X occur naturally in thorium and uranium minerals. respectively, but are usually obtained from their parents rather than from natural sources.

Industrial Production.—For a number of years following its discovery the only important source of radium was the Joachimsthal mines, operated by the Czechoslovakian government. Later some radium was produced in other European countries. The United States became the first major producer and from 1913 to 1923 was the chief world supplier, with carnotite from the western states being extracted principally at Denver. Colo.. and Pittsburgh, Pa. The rich Belgian Congo pitchblende deposits were discovered in 1913; and the refinery at Oolen, Belg.. began production in 1922. immediately dominating the world market. The extensive Canadian deposits were discovered in 1930; and the refinery at Port Hope. Ont., started producing radium in 1933. In the late 1930s the norld market was divided between the Belgian and Canadian producers on a 60:40 basis by a cartel agreement. After Belgium fell to the German army in 1940, the Congo ores were shipped to the Cnited States and Canada for refining. Following World War II, radium-bearing residues from these ores were shipped to Oolen for extraction of radium.

The following is a typical procedure for the commercial production of radium from pitchblende. The ground ore is digested with a mixture of nitric and sulfuric acids to which a little barium is added to act as a carrier for the radium. The uranium dissolves, and an insoluble residue of radium, barium and lead sulfates and siliceous gangue remains. This is separated by filtration and boiled with sodium hydroxide solution to leach out the lead sulfate and some of the silica. The residue is then autoclaved with sodium carbonate solution to convert the barium and radium sulfates to carbonates, which are dissolved in hydrochloric acid. After filtering off the remaining silica, the barium and radium are again precipitated as sulfates and converted to carbonates to effect a purification. The carbonates are now dissolved in hydrobromic acid and the bromides subjected to an involved fractional crystallization process. Since radium bromide is somewhat less soluble than barium bromide, the crystals are enriched in radium. After ten recrystallizations the ratio of radium to barium in the head crystals is changed from a few parts per 1,000,000 to a few parts per 1,000. At this stage, the bromides from several batches are accumulated, purified again and subjected to further crystallizations until radium of the desired purity, usually 95% or 99%, is obtained. This is sealed into small glass tubes to be measured and sold.

Variations in this process are dictated by differences in the nature and quality of the ores found in different locations. Canadian pitchblende contains considerable native silver, which is recovered by roasting the ore with sodium chloride to convert the silver to its chloride and subsequently leaching the latter out of the sulfate residue with sodium thiosulfate solution. With carnotite. the treatment can be altered by leaching the ground ore with hydrochloric acid to dissolve the radium, uranium and vanadium away from the siliceous matter before adding sulfuric acid. The sulfate precipitate can alternatively be heated with charcoal to reduce the sulfates to sulfides, which dissolve readily in hydrochloric acid. In the fractional crystallization the chlorides are often used instead of the bromides.

Newly developed methods for separating radium from barium involve cation exchange resins and precipitation from homogeneous solution.

Radium was originally interchanged freely among scientific and medical investigators, but when it became an item of commerce it became extremely expensive. However, as new and richer sources have become available. the price has steadily fallen. Typical market prices per gram were $10,000 in 1904, $80,000 in 1912, $120,000 in 1915, $135,000 in 1918. $90,000 in 1920. $70,000 in 1923, $50,000 in 1929, $25,000 in 1936, $20,000 in 1941, $25,000 in 1946. $20,000 in 1950, $16,000 in 1953 and $15,000 in 1957. The total world production in grams was approximately 50 by 1916, 300 by 1925 and 1,000 by 1940. Production was greatly accelerated during and shortly after World War II, but was declining in the early 19jos because of the competition of substitutes.

Chemical Properties.—Of the 88 electrons of the radium atom, the first 86 are strongly bound. whereas the outer two are readily lost leaving a divalent cation of noble gas structure. This property classifies it among the alkaline-earth elements, which include. in order, magnesium, calcium, strontium, barium and radium. There is a general gradation of properties in going from the lighter to the heavier members of the group. and radium continues this trend. It is very similar to barium, all of its known compounds being isomorphous with the corresponding barium compounds and differing so little in properties as to make the separation of the two elements a matter of great difficulty. The chemistry of radium. is. therefore, well understood.

Radium is divalent in all of its compounds. The sulfate. $RaSO_4$, is the most insoluble sulfate known and for this reason is important in the separation of the element from its ores. However, it is only because lead sulfate is also precipitated from the solution of the ore that quantitative precipitation of radium is obtained. for the amount of radium sulfate present is far too low to precipitate by itself. This principle, whereby an element present in quantity too small to permit manipulation by itself is caused to undergo certain chemical reactions by the presence of a larger quantity of a similarly behaving element, is called "carrying" and is important both in the isolation and in the chemical study of radium. The nitrate, $Ra(NO_3)_2$, chloride, $RaCl_2$, and bromide, $RaBr_2$, are soluble in water but highly insoluble in concentrated solutions of the corresponding acids, and are consequently of use in the purification of radium, including its separation from the last traces of barium. The chloride and bromide crystallize as hydrates, $RaCl_2 \cdot 2H_2O$ and $RaBr_2 \cdot 2H_2O$, but form the anhydrous salts on heating. The hydroxide, $Ra(OH)_2$, is the most soluble of the alkaline-earth hydroxides. The carbonate, $RaCO_3$, is insoluble in water but soluble in acids and the sulfide, RaS. is soluble in water.

Metallic radium melts at approximately 700° C. and has high chemical reactivity. It dissolves in water with vigorous evolution of hydrogen and darkens in air with the formation of the nitride. It is prepared by electrolysis from an aqueous solution of the chloride into a cathode of mercury, followed by volatilization of the mercury in a stream of hydrogen.

The optical spectrum of radium is similar to that of the other alkaline-earth elements, consisting of comparatively few relatively strong lines. The ordinary compounds of radium are all colourless but become coloured upon standing as a result of the continual bombardment by radioactive particles. Glass containers of considerable quantities of radium also become coloured, and sizable preparations can be seen to glow in the dark. Those properties are not peculiar to radium but are common to all strongly radioactive substances.

Analytical Methods.—The assay of radium is generally made not by the usual chemical procedures. such as weighing, but by methods based on its radioactivity. Strong samples, such as those for medical and radiographical use, are assayed by their gamma radiation by means of an ionization chamber and electrometer. The sample must be sealed for at least a month before the measurement so that the equilibrium quantity of radium C is present. For calibration of the measuring apparatus, standard preparations of radium have been made. The primary international standard was prepared by Mme. Curie by precise weighing and has been preserved at Sevres, France. Secondary standards, carefully checked against the international standard, are kept in the capitals of the principal nations. In using these standards allowance must be made for theirdecay, which amounts to 0.043% per year. Another assay method is the emanation technique, in which the gaseous radon generated by the radium sample in a measured time is collected in an ionization chamber and the intensity of its radiations measured. This method can be made extremely sensitive by electrically counting the individual alpha particles, and as little as 10^{-14} grams of radium can be so detected.

Uses.—The uses of radium all result from its radiations. The most important of these have been in medicine, principally for the treatment of cancer. For this purpose the element may be used directly. sealed in a tube, or the accumulated radon may be drawn off and compressed into a small capsule which may be used until it has decayed to a low intensity. (See RADIOLOGY.) Large amounts of radium have been employed for industrial radiography, particularly for the inspection of metal castings. Radium is mixed, in small concentrations, with a paste of zinc sulfide to make a luminescent paint for watch, clock and meter dials and signs ahich must be read in the dark. An intimate mixture of radium with beryllium is a moderately intense source of neutrons. Such neutron sources have been used extensively in scientific work and have found practical applications in well logging in geophysical prospecting for petroleum. Radium-bearing slime from uranium processing is used as a marking compound in oil-well casings.

Mention should be made of the hazards of handling radium, which result from the physiological effects of its radiations and which are enhanced by the gaseous nature of its decay product, radon. Before the dangers were recognized and adequate precautions taken a number of radium workers suffered serious injury or death. For physiological effects of radioactive substances see RADIOLOGY.

Mesothorium can be used in a manner similar to radium for all the purposes mentioned, but its greater expense and shorter lifetime limit its applications. It is superior to radium as a luminous paint activator because the intensity of its radiations increases for several years and thus compensates for the fatigue of the zinc sulfide. Except for scientific purposes, the other radium isotopes have no practical value.

For all the uses of radium, substitutes have become available. Artificial radioelements and high-voltage X-ray generators are supplanting radium in radiotherapy and radiography. Fluorescent paints activated by ultraviolet radiation are replacing radium paints in airplane panel meters. Cyclotrons and nuclear chain reactors provide much more intense neutron sources. Nevertheless, the use of radium is still important because of its special properties and its availability as a by-product of uranium.

RADNORSHIRE, an inland county of Wales, bounded north by Montgomery, northeast by Shropshire, east by Hereford, south and southwest by Breconshire and northwest by Cardigan. Its area is 471 sq.mi., and it is consequently the smallest of the six south Wales counties. Pop. (1961) 18,431. The county is a highland region grading eastward to the plain of the Severn. The western section is formed of Ordovician rocks which are succeeded eastward by the Llandovery. Wenlock and Ludlow beds of the Silurian. This region forms part of the central Wales plateau with a general level of nearly 2.000 ft. To the east of the mid-Wales railway that cuts the county diagonally from southwest to northeast the grits and shales of the Lower Palaeozoic rocks are overlain by the Old Red Sandstone which culminates in the rugged mass of Radnor forest (2.166 ft.). The railway follows the lower Ithon valley (a tributary of the Wye) from near Builth Road to Llanbadarn Fawr. The Wye forms the southwest boundary of the county between Newbridge and Three Cocks, and divides Radnor forest from the Epynt mountains of Breconshire. Between Llandrindod and Builth is a disturbed area of Ordovician strata with masses of andesitic and diabasic igneous rocks. The region has also saline, sulphurous and chalybeate springs. East of New Radnor in the eastern section of the county an inlier of Wenlock rocks is surrounded by Ludlow beds; while at Old Radnor a ridge of very ancient rocks appears. The eastern half of the county is characterized by the number of river valleys that open out to the English plain and consequently offer important ways into the county from the east. In the north the Teme opens out to Knighton and Ludlow and forms the northern boundary of the county for a part of its course. The Lugg flows eastward past Presteign, and the Arrow past Kington, while the vale of Wye leads down to Hereford.

History and Early Settlement.-he heavily forested nature of the county in early times made it unsuited for settlement. There are remains on the open higher ground, especially in the north of the county. of tumuli of uncertain date. Evidences of Bronze Age and Megalithic cultures are almost entirely absent. There are, however, a few good examples of hilltop camps, especially at Burfa, and Castle Ring in the parish of Evenjobb. The Roman interests in the region seem to have centred on Castell Collen, a focus of ways among the hills, and on the road running due north from Brecon to Caersws. The post-Roman centuries were naturally times of difficulty in this region and the outstanding memorial of the time is the remains of Offa's Dyke that traversed the county. The best preserved sections are in the hilly districts west of Knighton and Presteign. Church dedications show the influence of the Celtic saint movements of these centuries. Toward the close of the 9th century Maesyfed was absorbed into the middle kingdom of Powys, and in the 10th century it was included in the realm of Elystan Glodrudd, prince of Fferlys, or Feryllwg, who ruled over all land lying between the Wye and Severn. In the reign of William I, the Normans began to penetrate into Maesyfed, where, according to Domesday. the king already laid claim to Radenoure, or Radnor, in the lordship of Melenith (Moelynaidd), which was subsequently bestowed on the Mortimer family. The Domesday records are of interest in that they show evidences of cultural penetrations along the valley ways from the east (English place names west of Offa's Dyke, etc.). Influences from the plain have long been a feature of the social. religious and political life of the county. Later, the Norman invaders forced their way up the Wye valley, the de Braose family, lords of Elvel (Elfael), building fortresses at Painscastle and at Colmyn or Maud's Castle.

The Wye valley long formed one of the debatable districts between Welsh and Normans. After the annexation of Wales by Edward I, the district of Maesyfed remained under the jurisdiction of the Lords Marchers, represented by the families of Mortimer and Todenep.

The valley ways show evidences of compact settlements, in marked contrast to the single iarms of the upland west. The difficult nature of much of the county throughout medieval times, together with the weak Norman hold, meant that the manorial system was very late in establishing itself. The ravages of the Black Death, which were particularly severe in this region, brought manorial conditions to an early end and the county became almost entirely dependent on sheep rearing. The increase in the number of sheep and the development of the wool trade and the great wool markets of the Welsh border — Shrewsbury, Ludlow, Hereford and Gloucester — were features of 14th and 15th century England. There was only one monastic house of consequence in this pastoral county, the Cistercian abbey of St. Mary, founded by Cadwallon ap Madoc in 1143 in "the long valley" of the Clywedog, 6 mi. E. of Rhayader, and from its site commonly called Abbey Cwmhir. Its existing ruins are insignificant, but the proportions of the church, which was 238 ft. long, are still traceable. The churches of Radnorshire are mostly poor and small.

The political instability of the county continued throughout the 15th century and in 1402 Owen Glendower entered the Marches and raided the lands of the young Edward Mortimer, earl of March.

Radnorshire was created a county on the English model by the Act of Union (1536). It was parceled out of the suppressed marches lordships. Together with the rest of moorland Wales the county was conservative and royalist during the 17th century, the local clergy during the Commonwealth coming in for severe criticism under the administration of the Puritan Vavasor Powell (1617–70). The developments in the wool trade and local weaving attracted in the 16th and 17th centuries numbers of continental weavers, mostly religious reiugees, and the county is well known for the strong points of view it took later in religious matters. It was an old stronghold of the Quakers and later of the Baptists.

During the 20th century the rise of Llandrindod as a watering place and the construction of the Birmingham reservoirs in the Elan valley have tended to increase interest in the county. On Oct. 23, 1952, Queen Elizabeth II opened the Claerwen dam which completed the Birmingham water supply plan inaugurated in 1904.

Occupations. — Good hay and cereals are raised in the valleys, oats being by far the chief crop. The extensive upland tracts, which cover more than one-third of the total area of the county, afford pasturage for large flocks of sheep. The quality of the wool of Radnorshire has long been celebrated, and also the delicacy of the Welsh mutton from the small sheep that are bred. Sheep fairs are held at Rhayader.

The Central Wales branch of British railways enters the county at Knighton, traverses it by way of Llandrindod and passes into Brecknock at Builth Road Junction on the Wye. The western section follows the course of the Wye, by way of Builth and Hay. Two small branch lines connect New Radnor and Presteign with other sections.

There is no existing municipal borough, although New Radnor, now a mere village, was incorporated in 1561, and its municipal privileges were not formally abolished until 1883. The chief centres are Presteign, Llandrindod Wells, Knighton and Rhayader, all, except Rhayader, being urban districts. Radnorshire is included in the Wales and Chester circuit, and Presteign ranks as the county town. The whole county together with that of Brecon returns one member to parliament. Ecclesiastically. Radnorshire is divided into 46 parishes, the majority of which lay after 1923 in the diocese of Swansea and Brecon, hut, before that, had been for centuries included in the diocese of St. David's. After a 10% increase in population during World War II the county by the 1950s was as sparsely peopled as ever, with an average of 0.07 persons per acre.

RADOM, a town of Poland in Kielce province. about 64 mi. S. of Warsaw by rail. Pop. (1960) 131.000. Radom has several iron and agricultural machinery works and tanneries. In 1216 it occupied the site of what is now Old Radom. New Radom was founded in 1340 by Casimir the Great, king of Poland. There Jadwiga was elected queen of Poland in 1382; the first act relating to the union of Poland with Lithuania was signed in 1401; the *sejm* (diet) of 1505, where the organic law of Poland was sworn by the king, was also held there. Several great fires, and the Swedish war of 1701–07, ruined the old city. After the third partition of Poland in 1795 Radom fell under Austrian rule; it was in 1815 annexed to Russia and was returned to Poland in 1918. Germany conquered Radom after bitter fighting in Sept. 1939. It was again returned to Poland in 1945.

RADON, atomic weight 222, is the heaviest element of the noble gas group and an important radioelement. Its chemical symbol is Rn and its atomic number is 86. The name radon is used either for the most important isotope, that of mass 222, or for the element as a whole, although for the latter purpose the name emanation (symbol Em) is sometimes preferred. Other isotopes are thoron (Tn, mass number 220) and actinon (An, 219). Thoron was discovered in 1899 by R. B. Owens and E. Rutherford, who observed that some of the radioactivity of thorium preparations can be swept away by a current of gas. Radon was similarly discovered in radium samples by F. E. Dorn in 1900, and actinon was found associated with actinium in 1904 by F. O. Giesel and A. Debierne.

Radon is the immediate product of the decay of radium and undergoes alpha disintegration with a half life of 3.825 days. It yields several short-lived radioelements called the active deposit because of their tendency to adhere to solid objects. Thoron and actinon have similar properties, but because of their short half-life periods, 51.5 and 3.92 seconds respectively, are of less importance than radon. (See RADIOACTIVITY, NATURAL; RADIUM.)

Because of its transient existence, radon is found only in conjunction with a source of radium. The atmosphere contains traces of radon near the ground as a result of seepage from soil and rocks, all of which contain minute quantities of radium. For preparing intense samples a supply of radium is kept in a glass vessel in aqueous solution or in the form of a porous solid from'which the radon can readily effuse. At intervals of a few days the accumulated radon is pumped off. purified, and compressed into a small tube which is then sealed and removed.

Radium C rapidly grows into equilibrium with the radon and, since the former is the source of the intense penetrating gamma rays, the gamma activity is in effect transferred from the radium sample to the tube by this process. The radon can then be used for radiotherapy, radiography or other purposes, until its strength decays to too low a value. "Dead" radon tubes are often saved for the extraction of radium D and polonium.

Radon possesses a particularly stable electronic configuration which gives it a chemical inertness characteristic of the noble gas elements. Thus it is always found in the elementary state, and no true compounds are known. Its properties are similar to those expected by extrapolation from the other noble gas elements, helium, neon, argon, krypton and xenon. It is the most easily condensed and solidified of the group, the boiling point being $-62°$ C. and the freezing point $-71°$ C. It dissolves more readily in water than the other noble gases and is very soluble in a number of organic liquids.

For bibliography, see RADIUM. (T. P. K.)

RADOWITZ, JOSEPH MARIA VON (1797–1853). German statesman, first pursued German unification under the military leadership of Prussia. Born at Blankenburg in the Harz mountains, he became an artillery expert and a friend of the crown prince (who succeeded to the throne as Frederick William IV in 1840). Radowitz combined romantic conservatism with a strong will for military efficiency! and in the war crisis of 1840 he first preached the doctrine of German military union under Prussia, with the emperor of Austria enjoying only a titular supremacy. Radowitz was an isolated figure at the Prussian court and could rely only on personal influence with the king. He occupied only minor posts before the revolution of 1848.

In that year he sat in the Frankfurt parliament, where his combination of military knowledge and strict religious views earned him the name of "the warlike monk." In April 1849 Frederick William IV refused the imperial crown offered by the liberal politicians of Frankfurt. Radowitz then set out to achieve the same aim by conservative methods. that is, by agreement with the German princes instead of with the people. Though still without an official position, he became the principal director of Prussian policy. He founded the Union of Erfurt under Prussian control and was the chief figure at its parliament. This policy provoked Austrian opposition; and in 1850 a crisis blew up. Radowitz had neglected foreign relations. He hated the French republic and was also determined to exclude Russia from the Balkans and the near east Prussia was therefore isolated; and. what was worse, the Prussian Junkers disliked the policy of adventure into which Radowitz was leading them. Frederick William IV was still his only resource.

On Sept. 27, 1850, Radowitz was made Prussian minister of foreign affairs. This seemed to be the prelude to war with Austria. but the other Prussian ministers resisted his policy and at the end of October Frederick William IV agreed to a compromise with Austria, which followed at Olomouc. Radowitz resigned on Nov. 3. He was sent on a mission to London to secure an alliance with Great Britain in exchange for tariff concessions, but the British government refused to involve itself in German affairs. Radowitz seemed to have failed completely, but he had, in fact, anticipated the policy which Bismarck was to carry to success 16 years later. After 1850 Radowitz had no influence on Prussian policy. though he retained the personal friendship of the king. He died, a disappointed man, on Dec. 25, 1853. (A. J. P. T.)

RAE, JOHN (1813–1893). Scottish arctic explorer who surveyed and mapped new coast lines of arctic Canada. was born on Sept. 30, 1813, in the Orkney Islands. He studied medicine at Edinburgh university and was for 10 years resident surgeon at the Hudson's Bay company's station at Moose Factory. In 1846 he voyaged to Repulse bay, and the next spring surveyed 700 mi. of new coast line connecting the earlier surveys of J. C. Ross and W. E. Parry. He then joined Sir John Richardson's expedition in search of Sir John Franklin. During 1851 he traveled some 5.300 mi. and explored and mapped 700 mi. of new coast on the south side of Wollaston and Victoria Lands, a feat which gained him the gold medal of the Royal Geographical society. In 1853 he commanded another expedition which proved King William Land to be an island and elicited the first definite information as to the fate of Franklin. Subsequently he traveled across Iceland. and in Greenland and northern America. He died July 22. 1893, in London. He wrote *A Narrative of an Expedition to the Shores of the Arctic Sea in 1846 and 1847* (1850). (H. G. Kg.)

RAE-BAREILLY (Rae Bareli), a municipal town, *tehsil* (administrative subdivision) and district in the Lucknow division of Uttar Pradesh. India. The town is on the river Sai. 45 mi. S.S.E. of Lucknow. Pop. (1951) 24.958. It has many architectural features. chief of which is a large brick fort. Among other ancient buildings are the palace and tomb of Nawab Jahan Khan, governor in the time of Shah Jahan. and four fine mosques. It is an important trade centre, and cotton cloth is woven. Rae-Bareilly Tehsil (area 375 sq.mi.) had a population in 1951 of 250,065.

Rae-Bareilly District (area 1,758 sq.mi.) is slightly undulating and beautifully wooded. The soil is fertile. the main crops being rice, pulses. wheat, barley, millet and poppy. The principal rivers are the Ganges and the Sai. Pop. (1961) 1,316,753.

RAEBURN, SIR HENRY (1756–1823), the leading Scottish portrait painter after Allan Ramsay, was born at Stockbridge, near Edinburgh, on March 4, 1756. the son of a yarn boiler. He became a scholar of Heriot's hospital and in about 1771 was apprenticed to the goldsmith James Gilliland. He is said to have met the seal-engraver David Deuchar in 1773, and the leading Edinburgh portrait painter David Martin in 1773, but for the most part he was self-taught, progressing from miniature painting to full-scale portraiture. A full-length presentation portrait of George Chalmers of 1776 (Dunfermline town council) is Raeburn's earliest known portrait, and its faulty drawing and incorrect perspective suggest the artist's lack of formal training. By his marriage to Ann Edgar, a rich widow, early in 1780 he achieved financial security and during the next four years considerably improved his artistic skill. In London in 1785 he met Sir Joshua Reynolds, whose works were already familiar to him from Scottish collections and engravings, en route for a prolonged tour of Italy whence he returned to Edinburgh in 1787.

His reappearance was opportune; the rising professional classes of Edinburgh could support a gifted portrait painter and these, with members of the old Highland families, provided him enough sitters. Unlike Ramsay, he never needed to go south in search of patronage. The portrait of "The Archers" (trustees of the late Viscount Novar), of Robert and Ronald Ferguson of Raith, was probably painted soon after his return, and is an ingeniously composed group already showing something of the broad, assured style of his maturity. This concern with elaborate composition was afterward to give place to greater simplicity and directness of presentation. By about 1790 he had painted the outstanding portrait of his wife (Countess Mountbatten collection): a finely characterized work of expressive simplicity, and the double portrait of Sir John and Lady Clerk (Sir Alfred Beit collection), in which the artist experimented with an unusual lighting from behind the sitters' heads (they are in an evening landscape setting) to bring out the character of their faces.

During the years 1790–1800 Raeburn produced some of his most brilliant portraits, such as the dramatic full-length "Sir John Sinclair" (*c.* 1794–95, Viscount Thurso), a romantic composition of a uniformed Highland laird seen against a mountainous landscape background. This foreshadowed the famous "The MacNab" (c. 1803–13, John Dewar and Sons, Ltd.), in which the tonalities became darker and the lighting even more contrasted. It is significant that no drawings by Raeburn survive; he was essentially a painter rather than a draughtsman. This accounts for the weak drawing of the hands in several of his portraits; he is said to have begun his portraits with the brush, without any preliminary drawing on the canvas. After 1800, he concentrated upon the heads and hands of his sitters, reducing to the absolute minimum all accessories and preferring a dark background to set off his subjects. His technique broadened and he used a vigorous, square brushstroke with which boldly to model in the features of his sitters. Although this was often extremely effective, as in the "Lord Newton" (1806–11, earl of Rosebery collection) or "Mrs. James Campbell" (*c.* 1805–12. Colonel Thomas, Glasgow), in his less successful works it became brash and vulgar. Some softening of his brushwork appeared in the last ten years of his career.

In 1810, after the death of John Hoppner, he revisited London with the intention of seeing whether he could establish himself there. but did not pursue this plan. Two years later he was elected president of the Edinburgh Society of Artists, becoming a Royal Academician in 1815. Knighted in 1822, he was appointed His Majesty's limner for Scotland. He died at Edinburgh on July 8, 1823. In many ways Raeburn fulfilled in Scotland the position Reynolds had earlier achieved in London. A popular member of the new cultured Edinburgh society, he rarely associated with fellow artists; he was a man of many interests and a good conversationalist.

RAEDER, ERICH (1876–1960), German naval officer, was born in Silesia, April 24, 1876, and entered the navy on April 1, 1894. He was promoted through the various ranks, becoming a rear admiral in 1922 and on April 1, 1939, admiral of the fleet, the first to hold that rank since Tirpitz. He was commander in chief of the German navy throughout the early part of World War II and until Jan. 30, 1943, serving thereafter, until the end of the war, as inspector general of the navy.

Raeder was an officer of marked ability, whose advice was generally disregarded by Hitler. After the defeat of Germany in 1945, the inter-Allied tribunal at Niirnberg sentenced him to imprisonment, from which he was released in 1956. He died at Kiel, Ger., Nov. 6, 1960.

Raeder was the author of a number of books on naval warfare, including Der *Kreuzerkrieg in den Auslandischen Gewassern* (1922) and *Die Tatigkeit der kleinen Kreuzer Emden und Karlsruhe* (1923). (J. B. Hn.)

RAEDWALD (d. *c.* 620), king of the East Angles, was the son of King Tytili. He became a Christian during a stay in Kent, but on his return to East Anglia he sanctioned the worship both of the Christian and the heathen religions. Very little is known about his reign, which probably began soon after 600. For a time he recognized the overlordship of Aethelberht, king of Kent, but he seems to have shaken off the Kentish yoke. He gained some superiority over the land south of the Humber with the exception of Kent and is counted among the Bretwaldas. Raedwald protected the fugitive Edwin, afterward king of Northumbria, and in his interests he fought a sanguinary battle with the reigning Northumbrian king, Aethelfrith, near the river Idle in the summer or autumn of 616, in which Aethelfrith was defeated and killed. He was followed as king of the East Angles by his son Eorpwald.

See Bede, *Historiae ecclesiasticae,* edited *by C.* Plummer (1896); and J. R. Green, *The Making of England* (1897–99).

RAEMAEKERS, LOUIS (1869–1956), Dutch cartoonist who gained international fame by his anti-German cartoons during World War I, was born at Roermond on April 6, 1869. He at first painted landscapes and portraits. His first political cartoons appeared in 1907 and he joined the *Amsterdam Telegraaf* in 1909. The sincerity and vigour of his wartime cartoons roused enthusiasm in England, France and the United States and after 1916 he lived for some years in England to supply the Allied press more easily. He was also a cartoonist during World War II. He died at Scheveningen near The Hague on July 26, 1956.

RAETIA (in inscriptions; in classical manuscripts usually RHAETIA), in ancient geography, a province of the Roman empire, bounded on the west by the country of the Helvetii, on the east by Noricum, on the north by Vindelicia and on the south by Cisalpine Gaul. It thus comprised the districts occupied in modern times by the Grisons, the greater part of Tirol, and part of Lombardy. The land was very mountainous, and the inhabitants chiefly supported themselves by cattle breeding and cutting timber, little attention being paid to agriculture. Some of the valleys, however, were rich and fertile, and produced corn and wine. Trade was also carried on in pitch, honey, wax and cheese. Little is known of the origin or history of the Raetians, who are described as one of the most powerful and warlike of the Alpine tribes. It is stated by Livy (v. 33) that they were of Etruscan origin At the time when the land became known to the Romans, Celtic tribes were already in possession of it and had amalgamated so completely with the original inhabitants that, generally speaking, the Raetians may be regarded as a Celtic people, although non-Celtic tribes (Lepontii, Euganei) were settled among them They retained their independence until their subjugation in 15 B.C. by Tiberius and Drusus At first Raetia formed a distinct province, but towards the end of the 1st century A.D. Vindelicia was added to it; hence Tacitus *(Germania,* 41) could speak of 'Augusta Vindelicorum (Augsburg) as "a colony of the province of Raetia." The whole province (including Vindelicia) was at first under a military prefect, then under a procurator; it had no standing army quartered in it, but relied on its own native troops and militia for protection In the reign of Marcus Aurelius it was governed by the commander of the *Legio iii. Italica.* Under Diocletian (*q.v.*) it formed part of the diocese of the *vicarius Italiae.* During the last years of the Western empire, the land was in a desolate condition, but its occupation by the Ostrogoths in the time of Theodoric, to some extent revived its prosperity. The chief towns of Raetia were Tridentum (Trent) and Curia (Coire or Chur). It was traversed by two great lines of Roman roads—one leading from Verona and Tridentum across the Brenner to Oenipons (Innsbruck) and thence to Augusta Vindelicorum; the other from Brigantium (Bregenz) on Lake Constance, by Coire and Chiavenna to Como and Milan.

Peaks, *The General Civil and Military Administration of Noricum and Raetia* (1907).

RAETO-ROMANCE DIALECTS are spoken by about 450,000 persons in the Alpine regions of southeastern Switzerland and northern Italy, including the Friuli region. They do not cover a contiguous area; they do not now and never did belong to a single cultural, administrative or linguistic unit; and they are not written in any single standard language. They are also not founded upon the same pre-Latin linguistic substratum, nor do they have the same linguistic superstratum. Apart from being all Romance, that is, Neo-Latin dialects, they owe their being classified together under one name not so much to their similarities, which merely suffice to set them off from all other Romance dialects. as to their geographic location. The term Raeto-Romance (RR) has, therefore, been contested on various grounds; for example: it had little to do with the Latin province called Raetia, which covered a larger surface, though not so dispersed; it had even less to do with a pre-Roman population called Raeti, uhose dialect, imperfectly known, forms the substratum of only a small part of RR; all dialects concerned should be called Ladin in order to avoid Raetic connotations, and RR should be restricted to the dialects of Switzerland; the term RR should be abandoned altogether because all dialects concerned are really Italian: the western of the Lombard group and the eastern of the Venetian group. All these terminological disagreements bedevil the linguistic literature. which must, therefore, be used with proper caution. National animosities and disputes, many still alive, have penetrated (linguistic) research. particularly regarding the districts of northeastern Italy: the Alto Adige (the former Austrian South Tirol) and Friuli.

The RR dialects are spoken in three major areas: (1) In Friuli, the region between the Alps and the head of the Adriatic sea. with the capital at Udine. This idiom is called Friulian. It accounts for over 90% of the total number of speakers of RR. (2) In some valleys of the Alto Adige region, east and west of the city of Bolzano, and in some parts of the Dolomites. This idiom may be called Ladin. (3) In parts of the Swiss canton Grisons (Graubiinden), in particular in the valleys of the two confluents of the Rhine (the Vorderrhein and the Hinterrhein), and of the Inn (the Engadine, Upper and Lower), approximately as far as the Austrian border. These dialects are called Romansh (or, in the native tongue, Grishun) and may be subdivided into Surselvan (Vorderrhein), Sutselvan (Hinterrhein) and Engadinian (Inn)

There is no doubt that at one time the area of RR was much larger. But owing to the absence of documentation it is difficult to learn when a given district changed to another type of speech. Italian or German. In many areas, however, the switch is relatively recent. For example, the Inn valley between Finstermünz, Switz., and Imst, Aus., from the Swiss border haliway to Innsbruck, spoke RR until the 16th century; there were Romance minorities in the Vintschgau as late as the 18th century and in some villages into the 19th; Innsbruck did not become wholly German-speaking until the 13th century, and Vorarlberg, Aus., even later. especially the Montafon (valley of the Ill river'); the Rhine valley past Liechtenstein, and the Wallensee area west of it. were Romance until the 11th century; Chur, the capital of the Grisons, was prevalently of Romance speech until the beginning of the 15th century.

The retreat of RR before Italian and German continues under the impact of the national languages which have greater prestige and currency. Friulian will probably cede to standard Italian, as will all dialects of the state of Italy; whether Ladin will be replaced by German or Italian is not certain: it is spoken within the Italian state: but its nearest and most influential neighbouring language is German (Austrian-Bavarian) of Bolzsno-Merano. Romansh of Switzerland is in a slightly more favourable situation; it is spoken in a country where local dialects, both Germanic (Alamannic) and Romance, are not considered socially inferior but cultivated and cherished. Romansh has also been best describeti of all the RR dialects, has been codified in dictionaries. and grammars, has a literature (including a translation of the New Testament of 1560) and has in fact been the fourth official language of Switzerland since 1938.

Ethnically the area of RR has been mixed and unstable from prehistoric times. Because of its passes it has always served as the crossroads between east and west, and north and south; and because of its inaccessible valleys and heights it has likewise served as a refuge for populations driven in war from more hospitable surrounding regions. Preceding its Latinization it was most likely of Celtic and Raetic speech in its western parts, of Italic (Yenetic) speech in its eastern parts. But it is impossible to dram sure boundaries for these linguistic substrata or to give dates for their Latinization. The political conquest of the district of Friulian, a part of Gallia Cisalpina, occurred around 220 B.C., but the Alpine area of Ladin and Romansh was not conquered until 15 B C., when it became in part the province of Raetia.

All these beautiful but poor mountainous tracts, Raetia, Noricum, Vindelicia. seem to have interested the Romans mainly for logistic reasons, in order to keep open communications with Gallia Transalpina and other northern and western possessions. Hence these regions were neither as intensively nor as extensively Romanized in culture and speech as other parts of the Roman empire which are now Romance-speaking. Furthermore, the Alpine provinces were the first to fall before the onslaught of the Germanic tribes which invaded Roman soil in the 5th century: the Alamanni pushed south across Switzerland about the end of the 5th century; the Baiuwarii crossed the Brenner pass. reaching the upper Isarco valley about 600 and the Bolzano-Merano district around 765. Friuli was the territory through which the invading Ostrogoths and Visigoths moved into Italy; it became eventually a Langobardic possession, but it was no more Germanized by these German tribes than was the rest of Italy. If the Germans had been better organized and if they had pursued a common goal, such as a Germanic state on the soil of the Roman empire, the entire RR area, if not, indeed, large portions of Italy, might have become Germanic in speech. Or if the speakers of the different RR districts had formed a coherent political whole, the various RR idioms might eventually have brought forth a separate standard Romance language. In view of the extremely checkered history of the area throughout the middle ages and into the modern era, the linguistic situation has become difficult to analyze.

The few linguistic traits common to all RR languages are archaisms rather than common innovations. This testifies to a lack of communication among them and the absence of a common culture. The greatest amount of agreement is to be found in the vocabularies of the various dialects; but this is not very significant, since they are all of Latin origin. In phonology the retention of Latin final *-s* over large areas is important both phonemically and morphemically. In the latter respect it causes plural formations with *-s,* thus connecting RR with the western, Gallo-Romance languages. Otherwise the retention of *pl-*, *kl- (cl-)* and *bl-* (rather than palatalization, as prevails in Italian and Rumanian), the palatalization of *ka- (ca-)* and *ga-*, and the diphthongization of vowels in free (that is, syllable-final) position are widespread but far from ubiquitous. Of all the Romance idioms, the RR languages have been least studied because of the scarcity of records of the medieval and even modern period and the absence of any standard literary language or languages. Outside of Switzerland all RR speech is considered mere patois. The description of contemporary speech awaits modern scientific treatment; but it will have to be undertaken soon, lest RR go the way of other now extinct Romance speech forms.

RAFF, JOSEPH JOACHIM (1822–1882). German composer and orchestral conductor. was born near Zurich. Switz., on May 27, 1822, and educated chiefly at Schwyz. He was encouraged and assisted by Liszt and von Bulow, his opera, *Konig Alfred,* being produced at Weimar under Liszt's direction.

Raff lived at Weimar until 1856. In 1859 he married Doris Genast, an actress of high repute, and thenceforward devoted himself with renewed energy to the work of composition, displaying an inexhaustible fertility of invention and great technical skill. He resided chiefly at Wiesbaden till 1877, when he was appointed director of the Hoch-Conservatorium at Frankfurt am Main, an office which he retained until his death on June 25. 1882. Raff's compositions included symphonies, quartets, concertos, sonatas and songs.

RAFFI (pseudonym of HAKOB MELIQ-HAKOBIAN) (1835–1888), the most celebrated Armenian novelist, was born in Phayajuk, in Iranian Azerbaijan. the eldest son of a merchant. After his father's bankruptcy in 1868. he worked as a schoolmaster and a journalist. collaborating nith the Russian-Armenian paper *Mshak* from 1872 to 1884. He died in Tiflis, where he is buried. His principal novels are *Jalaleddin* (1878), *The Fool* (1880; Eng. trans. 1950), *David Bek* (1880). *The Golden Cockerel* (1882), *Sparks* (1883–1890) and *Samuel* (1885). He wrote also a number of short stories and historical articles.

An ardent nationalist, he mas preoccupied with the lot of his fellow Armenians in Persia and Turkey, and his interest in history was that of a writer of the Romantic school. He had a fertile imagination and narrative skill, but the psychology of his characters tends to be shallow, and the construction and style of his nork uneven. (C. J. F. D.)

RAFFIA, a fibrous product obtained from the palm *Raphia pedunculata* of Madagascar. It is prepared from the leaves of the palm, which are cut before they begin to curl. The underpart is removed in strips and dried, after which the strips can be split easily from end to end in any desired width.

Raffia is used in connection with the tongue grafting method of tree or shrub propagation. A tongue cut on the face of the scion (cion) is fitted into a matching notch on the parent stock, and scion and stock are securely bound together with raffia.

Raffia is also widely used in basketry, particularly in the sewing of coiled reed or plaited rush baskets. It may also be woven in the conventional manner by passing it under and over warp strings on a loom.

Raffia can be satisfactorily dyed with vegetable colourings, such as those derived from barks, leaves, berries and flower petals. (E. L. Y.)

RAFFLES, SIR THOMAS STAMFORD (1781–1826), English administrator, founder of Singapore, was born on July 5, 1781, on board a merchantman commanded by his father, Benjamin Raffles, when off Port Morant, Jamaica. He became a clerk in the office of the East India Company, and in 1805 was sent out to Penang as assistant secretary to the first governor. In addition to his duties as secretary he acted as Malay interpreter. and in 1807 he became secretary.

In 1808 his health gave way, and he was ordered for a change to Malacca The East India Company had decided to abandon Malacca, and orders had been issued to dismantle it. Raffles drew up a report explaining the great importance of Malacca, and urging in the strongest manner its retention. Lord Minto was so impressed by the report that he at once gave orders for suspending the evacuation of Malacca. and in 1809 the company decided to reverse its own decision. In June 1810 Raffles, of his own accord, proceeded to Calcutta. where Lord Minto gave him the kindest reception. Raffles remained four months in Calcutta, and gained the complete confidence of the governor-general. He brought Lord Minto round to his opinion that the conquest of the island of Java, then in the hands of the French, was an imperative necessity. To prepare the way for the expedition, Raffles was sent to Malacca as "agent to the Governor-General with the Malay States." He did his work well and thoroughly—even to the extent of discovering that the short and direct route to Batavia by the Caramata passage would be a safe one for the fleet to take.

In August 1811 the expedition, accompanied by Lord Minto, and nith Sir Samuel Auchmuty in command of the troops (11,000 in number, half English and half Indian), occupied Batavia without fighting. On the 25th a battle was fought at Cornelis, a few miles south of Batavia. and resulted in a complete English victory. On Sept. 18 the French commander. General Janssens, formally capitulated at Samarang, and the conquest of the island was completed. Lord Minto's first act was to appoint Raffles lieutenant-governor of Java. From September 1811 until his departure for England in March 1816, Raffles ruled this large island with conspicuous success. He increased the revenue eightfold at the same time that he abolished transit dues, reduced port dues to one-third and removed the fetters imposed on trade and intercourse with the Javanese by Dutch officialdom. In his own words, his administration aimed at being "not only without fear, but without reproach." He had a still greater ambition, which was, in his own words, "to make Java the centre of an Eastern insular Empire," and to establish the closest relations of friendship and alliance with the Javanese, whom he described as "a highly polished people, considerably advanced in science, highly inquisitive and full of penetration." It is interesting to note that when another great Englishman, Rajah Brooke, began his career in Sarawak in 1838, he announced: "I go to carry Sir Stamford Raffles's views in Java over the whole Archipelago."

In November 1817 Raffles quitted England on his return to the East, where the lieutenant-governorship of Fort Marlborough (Sumatra) had been kept in reserve for him. His administration of Sumatra (1818–23) was characterized by the same breadth of view, consistency of purpose and energy in action that had made his government of Java remarkable. He had not, however, done with the Dutch, who, on their recovery of Java, endeavoured to establish a complete control over the Eastern archipelago, and to oust British trade. This design Sir Stamford set himself to baffle, and by a stroke of genius and unrivalled statecraft he stopped for all time the Dutch project of a *mare clausum* by the acquisition and founding of Singapore on Jan. 29, 1819.

In 1824 Raffles returned to England to vindicate his acts to the East India Company. The court exonerated him from the charges made against him, but censured him for "his precipitate and unauthorized emancipation of the Company's slaves," and after his death charged his widow to pay £10,000 for various items, which included the expense of his mission to found Singapore. Harassed by these personal affairs, he still found time to help in the foundation of the zoological society in London. His fine Sumatra collection formed its endowment. He died July 5, 1826.

See Lady Raffles, *Memoir of Sir Thomas Stamford Raffles* (1830); D. C. Boulger, *Life of Sir Stamford Raffles* (1897); Hugh Egerton, *Sir Stamford Raffles* (1899); J. Buckley, *Records of Singapore* (1903).

RAFFLESIA, a genus of plants of the family Rafflesiaceae with six species confined to Malaya. They are all parasitic on the roots of vines (*Vitis*). R. *arnoldi* has the largest flower known (18 in. across, weight 15 lb.) with a smell like decaying flesh. Pollinated by carrion flies, it is the only part of the plant above ground; the remainder is reduced to a funguslike mycelium.

RAFINESQUE, CONSTANTINE SAMUEL (1783–1840), a naturalist and early theorizer about the evolution of species, was born of French-German parents at Galata (Constantinople) on Oct. 22, 1783. He lived in Marseilles and after 1792 in Italy, studying in Leghorn, Genoa and Padua. In 1802 he went with his brother to the United States. He worked in Philadelphia and Germantown, Pa., visited Pres. Thomas Jefferson at Washington, and made many trips in search of natural history specimens. In 1805 he returned to Europe, spending the next ten years in Palermo. Sicily. In 1815 he returned to the United States, where he taught and made botanical collections. In 1819 be became professor of botany, materia medica and modern languages at the Transylvania university, Lexington, Ky., where he founded a botanical garden in 1825. In 1826 he moved to Philadelphia where he lectured at the Franklin institute. He died in poverty in Philadelphia on Sept. 18, 1840.

Rafinesque was a controversial figure in the history of U.S. botany. He was severely criticised by such an authority as Asa Gray (*q.v.*) for careless work and his passion for establishing new genera and species. On the other hand, he was lauded as a genius who had a definite idea about the theory of evolution long before Charles Darwin.

His publications numbered more than 950; the most important among his botanical works are: *Autikon botanikon* (1815–40, facs. ed.. 1942); *Florula ludoviciana* (1817); *Medical Flora,* 2 vol. (1828–30); *New Flora and Botany of North America,* 4 pt. (1836–38); *Flora telluriana,* 4 vol. (1837–38); *American Manual of the Mulberry Trees* (1839) and *Sylva telluriana* (1838, facs. ed., 1942). He also wrote *A Life of Travels and Researches* (1836, facs. ed. 1943).

See T. J. Fitzpatrick, *Rafinesque, a Sketch of his Life with Bibliography* (1911) and F. W. Pennell, *The Life and Wcrk of Rafinesque* (1942). (V. C. As.)

RAGGED ROBIN (*Lychnis floscuculi*), a perennial plant with pink, divided petals, belonging to the pink family, Caryophyllaceae (*q.v.*), native to Europe and Asia, common in Great Britain and naturalized in the eastern United States. It is a slender herb, about $1\frac{1}{2}$ ft. high, and is parasitized by a fungus, *Ustilago antherarum,* which forms its spores in the stamens, whence they are transported from plant to plant by insects.

RAGLAN, FITZROY JAMES HENRY SOMERSET, 1ST BARON (1788–1855), British field marshal, was the eighth and youngest son of Henry, 5th duke of Beaufort, by Elizabeth Boscawen, and was born on Sept. 30, 1788. Lord Fitzroy Somerset was educated at Westminster school, and entered the army in 1804. He served on the staff of Sir Arthur Wellesley in the expedition to Copenhagen (1807), and went with him to Portugal in 1808. During the whole of the Peninsular War he was at his right hand, first as aide-de-camp and then as military secretary. He was the first to mount the breach at Badajoz, and afterward showed great resolution and promptitude in securing one of the gates before the French could organize a fresh defense. During the short period of the Bourbon rule in 1814 and 1815 he was secretary to the English embassy at Paris. On the renewal of the war he again became aide-de-camp and military secretary to the duke of Wellington. About this time he married Emily Harriet, daughter of the 3rd earl of Mornington, and Wellington's niece. At Waterloo he was wounded in the right arm and had to undergo amputation, but on the conclusion of the war resumed his duties as secretary to the embassy at Paris. From 1818 to 1820, and again in 1826–29, he sat in the house of commons as member for Truro. In 1819 he was appointed secretary to the duke of Wellington as master general of the ordnance, and from 1827 until the death of the duke in 1852 was military secretary to him as commander in chief. He was then appointed master general of the ordnance, and was created Baron Raglan.

In 1854 he was promoted general and appointed to the command of the British troops sent to the Crimea (*see* CRIMEAN WAR) in co-operation with a strong French army under Marshal St. Arnaud and afterwards, up to May 1855, under Marshal Canrobert. Here the advantage of his training under the duke of Wellington was seen in the soundness of his generalship, and his diplomatic experience stood him in good stead in dealing with the generals and admirals, British, French and Turkish, associated with him.

For the hardships and sufferings of the British soldiers in the terrible Crimean winter before Sevastopol, owing to failure in the commissariat, both as regards food and clothing, Lord Raglan and his staff were at the time severely censured by the press and the government; but it afterward appeared that the chief neglect rested with the home authorities. He was made a field marshal after Inkermann. During the trying winter of 1854–55 his health was undermined. Disappointment at the failure of the assault of June 18, 1855, finally broke his spirit, and on June 28, 1855, he died.

RAGNAR LODBROK, Scandinavian ruler of the 8th or 9th century, supposed to have invaded England and France. It is nearly certain that such a person existed, but he has become a Scandinavian hero and the myths surrounding him are so extensive that it is difficult to separate the true from the fictional and to determine precisely what took place during his reign. One theory is that there were two men around whom the stories are woven: a prince named Ragnar Lodbrok, who died in 794; and another prince named Raginfrid or Regnier, who actually led the invasions of France and England, which did not take place until the 9th century, but who is known in Scandinavian history and legend as Ragnar Lodbrok also. In any case, the myths about the two men of the same name have become inextricably intertwined.

The story is that Ragnar Lodbrok sailed up the Seine river to Paris, which he captured and which was only redeemed by a ransom of 7,000 lbs. of silver. Later, the story runs, jealous of the reported achievements of his two sons, he planned to outdo them by invading England. He constructed two ships, the largest that had ever been built in Scandinavia, and sailed for Northumberland. He was captured by Aella, the Saxon king of Northumberland, after a valiant fight, and thrown alive into a pit of snakes, which stung him to death. His death song, the Lodbrokar-quida, has become a Scandinavian epic. His sons revenged him by killing Aella, and Northumberland ceased to be a Saxon kingdom and was looted and plundered by the Norsemen.

RAGNAROK, a Scandinavian myth telling of the death of the gods and the destruction of the world. The name is probably derived from the Old Norse words *regin* or rogn ("god") and rok ("reason, origin or history"), although it is sometimes thought that the word comes from the Icelandic ragna ("gods") and rokr ("twilight"). The story is contained in the Icelandic saga *Völuspá*. It tells of the war between the gods, led by Odin, and their evil opponents, led by Loki. The Ragnarok combines three common stories of the destruction of the world: the sinking of the earth into the sea and the devouring of the sun by a monster; a devastating winter; and the destruction of the earth by fire. In addition to the annihilation of the earth, the chief protagonists on each side are killed and there is a period of darkness and chaos. Afterward, however, some of the gods who were not destroyed return to the earth, which has risen from the sea, and with them return a human couple, Lif and Lifthraser (Life and Vitality), who are the progenitors of a new race. This is the story used by Richard Wagner, the German composer, in his opera *Götterdämmerung,* the German word for "twilight of the gods."

RAGUSA, a town and provincial capital of Sicily in the province of Ragusa, 70 mi. S.W. of Syracuse by rail and 32 mi. direct. It consists of an upper and a lower town united into one commune in 1926. Pop. (1951) 40,839. The city has an entirely new quarter, called Littorio. It has some churches with fine Gothic architecture, and is commercially important, a stone impregnated with bitumen being quarried and prepared for use for paving slabs by being exposed to the action of fire. Oil suited to diesel motors is extracted. On the hill occupied by the castle of the lower town (Ragusa Ibla) stood the ancient Hybla Heraea, a Sicel town, under the walls of which Hippocrates of Gela fell in 491 B.C.

During World War II Ragusa was severely bombed by the U.S. and British air forces prior to its occupation.

RAGUSA, Yugoslavia: see DUBROVNIK.

RAGWEED, any North American plant of the genus Ambrosia (family Compositae). The ragweeds are chiefly coarse annuals, with rough hairy stems: mostly lobed or divided leaves, and inconspicuous greenish flowers borne in small heads, the male in terminal spikes and the female in the upper axils of the leaves. The common ragweed (*A. artemisiifolia*), called also Roman wormwood, hogweed and bitterweed, found across the continent, grows from one to seven feet high, with thin, alternate or opposite, much-divided leaves. The great ragweed (*A. trifida*), called also bitterweed and horse cane! native from Quebec to British Columbia and southward to Florida, Arkansas and California, grows from 3 to 17 ft. tall, with opposite, entire or palmately three- to five-lobed leaves. Both the foregoing are annuals and often become pernicious weeds; their pollen, which is shed in great abundance in late summer, is a prolific source of hay fever (*q.v.*). Since these species are annuals, their eradication is easy if they are mowed well before they shed their copious seed. The western ragweed (*A. psilostachya*), found from Illinois to Alberta and southward to California, Texas and Mexico, is similar to the common ragweed, but is a shorter plant, perennial and with thicker leaves.

All the ragweeds; both annual and perennial, can be killed with 2,4-D; after low mowing, the plants are allowed to initiate low new top growth and sprayed with the herbicide.

In England, the tansy ragwort Senecio *jacobaea* (see SENECIO) is sometimes called ragweed. (N. TR.)

RAGWORT (Senecio jacobaea), a common plant in European pastures and wasteland, growing to a height of over 2 ft., with heads of bright yellow flowers. It is allied to the groundsel (*q.v.*) and is one of the five noxious weeds whose removal in Great Britain is enforced by law. This weed, known also as staggerwort, is sparingly naturalized in North America from Newfoundland to Ontario and southward to Pennsylvania. In the United States and Canada various other species of Senecio are called ragwort, *e.g.,* the golden ragwort or swamp squaw weed (*S.* aureus), a conspicuous wild flower of early summer, inhabiting swamps and wet meadows.

RAHAB, the name of two Old Testament figures.

1. Rahab was a Jericho woman who sheltered the spies sent by Joshua (Josh, ii), concealed them under flax on the roof and assisted them to escape by a rope from a window of her house on the town wall. By this act of friendship she secured the safety of her household when the Israelites took Jericho; by arrangement a scarlet cord was to be hung from a window for identification. Thus, she and her family were saved and became converts to the Hebrew religion. The Hebrew text describes her as a harlot (zonalz), and she is so regarded in Talmudic literature. Later Jewish commentators, however, prefer to associate zonah with an alternative root to procure the meaning "one who sells food." Rahab's beauty was proverbial, and from her profession she was reputed to be well informed on public affairs. After her conversion, according to tradition, she married Joshua and became the ancestress of Jeremiah, Huldah and Ezekiel among other prophets.

2. Rahab was the name of the sea monster inhabiting the primeval ocean (Ps. lxxxix, 10; Job ix, 13; xxvi, 12; Is. li, 9; comparable with Tiamat in Assyrian-Babylonian mythology); hence, in a figurative sense, a designation for Egypt (Ps. lxxxvii, 4; Is. xxx, 7).

RAHWAY, a city of Union county, New Jersey, U.S., is 20 mi. S.W. of New York city. Industrial establishments in Rahway produce drugs. chemicals, varnish, machinery, auto accessories, vacuum cleaners, office equipment, books, food products, rubber goods and textile goods. The city is also a residential ,centre. For comparative population figures see table in NEW JERSEY: Population.

The city was settled in the 1680s. During the American Revolution (when it was called Spanktown) it was temporarily an army supply base for General Washington's army and a skirmish was fought there in Jan. 1777. It became a township in 1804 (called Rahway after a local Indian Chief named "Rahwack") and a city in 1858. (W. L. CA.)

RAICHUR, a town and district of Mysore state, India. The town, 351 mi. N.W. of Madras, is a thriving trade centre and has cotton ginning and pressing factories; pop. (1951) 54,032.

The DISTRICT OF RAICHUR has an area of 5.591 sq.mi.; pop. (1951) 953.640. Low-grade iron ore is to be found in the district. Raichur gives its name to the doab or tract between the Kistna and Tungabhadra rivers, which was much fought over by Moslems and Hindus in the 16th century. (S. GL.)

RAIGARH, a town and district of Madhya Pradesh, India. Fine tussore silk is produced in the town; pop. (1951) 29,684. It is 363 mi. from Calcutta, to which it is linked by the Eastern railway.

The DISTRICT OF RAIGARH has an area of 5,150 sq.mi.; pop. (1951) 919.520. About a third of its area and population is accounted for by the absorption in 1948 of the former feudatory state of Raigarh. (S. GL.)

RAIKES, ROBERT (1736–1811), English philanthropist and pioneer of the Sunday school movement, was born at Gloucester on Sept. 4, 1736. His philanthropic work started with the prisoners in the local jail. Later, the lawless behaviour of Gloucester children on Sundays led him to experiment with a Sunday school in Sooty alley, where he engaged a number of paid women teachers to give instruction in reading and the church catechism. The experiment was so successful that in his newspaper, the Gloucester Journal (Nov. 3, 1783), he was able to record that the district had become "quite a heaven upon Sundays, compared with what it used to be."

The Sunday school movement spread to all parts of the country with great rapidity. In 1785 the Sunday School society was formed, and four years later Sunday schools were established in Wales. The Sunday School union (1803) was a direct result of Raikes's work.

Raikes died at Gloucester on April 5, 1811.

RAIL, the common name for marsh birds comprising the family Rallidae, of which there are more than 130 species recognized, world-wide in distribution except in high latitudes. They are somewhat chicken-shaped, aith short rounded wings and large feet with long toes. Rails are secretive in habit and infrequently seen; their loud, harsh calls, how-ever, give away their presence in dense vegetation. Many are excellent game birds; when flushed, they take to wing reluctantly, flying a short distance and then dropping to ground.

In the United States the king rail (*Rallus elegans*), a reddish-brown bird the size of a small chicken; clapper rail (*R. longirostris*), a gray form; and the Virginia rail (*R. limicola*), reddish brown and less than one-half as big, are hunted as game, as is the Carolina rail, or sora (*Porzana carolina*). The little yellow rail (*Coturnicops noveboracensis*) and the six-inch-long black rail (*Laterallus jamaicensis*) are too scarce to be of interest to the hunter.

HUGH M HALLIDAY FROM NATIONAL AUDUBON SOCIETY

VIRGINIA RAIL (RALLUS LIMICOLA)

The land rail, or corn crake (*Crex crex*), is found throughout Europe and western Asia and is a summer visitor to England. Brownish above and yellowish uhite below, it is inconspicuous except in flight, nhen it is recognized by its chestnut wings, barred flank and dangling legs. It nests on the ground and forages for food, chiefly insects, in long grasses. Eight to ten eggs are laid, of a cream colour blotched with red-brown. The young hatchlings are covered with black down. Less abundant but more widely distributed (extending to northern Africa) is the water rail (*Rallus aquaticus*). This is *a* slender bird of much the same habits as the corn crake. It is distinguished by darker plumage and a long, reddish bill.

The Rallidae includes also coots and gallinules (*qq.v.*) and, among a few flightless sorts. *Notornis,* a genus presumed to be extinct till small groups of N. *hochstetteri* were found in 1948 along some alpine lakes of New Zealand. Several rails live on tiny almost barren oceanic islands. (HT. FN.)

RAILWAY, a mode of land transportation the roadway of which consists of one or more tracks. each having two parallel steel rails. Over these rails move freight and passenger carrying vehicles, or cars, with flanged wheels. The cars are usually pulled or pushed by a locomotive, although they may be self-propelled.

TABLE I.—*U.S.-British Railway Terms*

United States	Britain
Baggage car	Luggage van
Boxcar	Goods van or box van
Classification yard	Marshaling yard
Caboose	Brake van
Crosstie or tie	Sleeper
Diaphragm (car)	Corridor connection
Dining car	Restaurant car
Engineer; engineman	Engine driver
Freight car	Goods wagon
Grade crossing	Level crossing
Gondola car	Open wagon
Interlocking plant	Signal box
Journal box	Axle box
Joint bars (rail)	Fishplates
Passenger car	Passenger carriage
Self-propelled car	Rail car
Self-propelled-car train	Train set
Signal tower	Signal cabin
Switching (of cars)	Shunting
Switcher (locomotive)	Shunting engine
Switch or turnout	Points
Tie plate	Baseplate
Truck, swivel car	Bogie

The development of railways is one of the great landmarks in the progress of human civilization. Coming early in the 19th century, railways provided an element that was essential to full realization of the promise of the surging industrial revolution — namely, a reliable, low-cost, high-volume system of land transportation.

It is the principle of flanged steel wheels rolling on steel rails that gives the railway its pre-eminence for heavy-duty transportation. The flanges guide the wheels of locomotives and cars, causing them to follow the line of the rails, and the rolling friction of the wheels on the rails is extremely low. In fact, if a 40-ton railway freight car of the type common in the U S were set rollihg on level track at 60 m.p h.. it would travel five miles or more before coming to a stop. In contrast, a highway truck of similar weight set free on level road at the same speed would roll only about one mile.

Because of this self-guiding characteristic and the low rolling friction, a locomotive of relatively modest horsepower can pull a long train of cars. This, basically, is the reason for the economy of railway transportation, an economy that is clearly evident in terms of manpower and fuel consumption. In 1952, for example. all other forms of transport in the United States used 11 times as much fuel as did the railways — yet the latter produced more than half the total gross ton-miles of transportation. In 1955, U.S. railways produced five times as much transportation per employee as did the intercity truck lines, despite the fact that the railways build and maintain their own roadways, which the highway carriers do not.

In this article, the discussion is divided into these principal sections:

Information on the economic aspects of railway operation may be found in the article INTERSTATE COMMERCE, while a general survey, from a historical viewpoint, of all forms of transport is presented in the article TRANSPORT. Forms of urban and inter-urban rail transport are described in ELECTRIC TRACTION and SUBWAY (UNDERGROUND RAILWAY).

I. HISTORICAL DEVELOPMENT

The railway as we know it originated in England, but the use of wheeled vehicles on rail lines came many years before the advent of mechanical traction. There is a reference to a railway in Europe as early as 1550. Before the end of the 16th century, mining railways were introduced in Britain. particularly in the northeast coal mining area. In the 18th century horse-drawn railways of this kind were to be found not only in England but in Wales and Scotland. Their application was increased with the introduction of cast iron for uheels and for the plateways over which the wagons ran. The earliest atmospheric steam engines, however, were too bulky and heavy for traction purposes.

In 1797 Richard Trevithick made three models, one of which may have represented a proposal for a self-propelled steam engine or locomotive. In Feb. 1804, a locomotive built by Trevithick ran on a tramroad in Wales, but these and subsequent experiments were unsuccessful, probably because the weight of the locomotive broke the rails. In 1808 Trevithick exhibited a locomotive and carriage on a circular track in London, but it was regarded as an amusement and not taken seriously.

Folloaing Trevithick's pioneering, the first practical and successful locomotive was built in 1812 to the instructions of John Blenkinsop, an inspector at Middleton colliery near Leeds. It ran on cast iron rails and had two vertical cylinders driving two shafts geared to a toothed wheel which engaged a rack rail. Three further locomotives were built in 1812 and 1813 and used between the colliery and Leeds, a distance of three and one-half miles.

In 1813, William Hedley built "Puffing Billy," a simple adhesion locomotive (*i.e.,* one that relied on friction between wheels and rails, dispensing with the toothed rack rail). It was used for hauling coal trucks between Wylam colliery and the wharves at Lemington-on-Tyne, a distance of about five miles. In the following year George Stephenson, pioneer railway and locomotive builder, completed his first engine, the "Bliicher." It was put to work at Killingworth colliery.

In 1823, Stephenson was invited by Edward Pease to build and equip a railway from Stockton to Darlington. This was completed in 1825 and ceremonially opened on Sept. 27 of that year. It was the first public railway in the world that employed locomotive traction and that was intended to carry both freight and passengers, and as such it marked the birth of the public service railway. It was not the first public railway, this honour going to the Surrey Iron Railway company, which was created through an act of parliament passed in 1801; it was opened in 1803 between Wandsworth and Croydon, using horses. In 1804 the Oystermouth railway was incorporated and this became the first railway to carry fare-paying passengers (March 1807), horse traction being used.

During the first two years of its existence, steam traction proved unreliable and expensive to maintain on the Stockton and Darlington railway. The first locomotive was "Locomotion" (now preserved at Bank Top station, Darlington). This and similar machines were only suitable for hauling low-speed mineral trains, and their tractive effort and weight were limited by the comparatively weak track. At times the railway reverted to horses, but the situation was improved with the introduction in 1827 of the "Royal George," a six-coupled locomotive designed by Timothy Hackworth. This and other locomotives eliminated the use of horses in rail freight service by 1833.

In 1829 the Liverpool and Manchester railway held a contest to decide upon the best kind of traction to use and it was won by Stephenson's "Rocket" (now preserved at the Science museum, London). The success of the "Rocket" mas due principally to the use of a multiple fire-tube boiler in place of the single-flue boilers previously used. The Liverpool and Manchester railway was opened on Sept. 15, 1830, and it became the first public railway on which all traffic was hauled by steam locomotives. At this time another great stride was made in track construction by Blenkinsop's patent for fish-bellied rolled-iron edge rails (1829). These were much stronger than cast iron rails and enabled heavier locomotives to be used.

A. Railways in the United States

Paralleling this early English development. interest in railways began to develop in the United States, as well as in other countries. One of several horse-drawn tramways built early in the 19th century was Gridley Bryant's Granite railway in Quincy, Mass. Horses supplied power for this three-mile, broad-gauge line, which carried the granite used in building the Bunker Hill monument.

By 1813, the inventor Oliver Evans was proposing a railway between New York and Philadelphia. Two years later, John Stevens received from the New Jersey legislature the first charter for a railway ever granted in America. However, Stevens was ahead of his time: the chartered line, between the Delaware and Raritan rivers, was never built. But in 1825, Stevens built and operated the first locomotive to run on rails in America. It ran on a half-mile circle of track at Stevens' home in Hoboken, N.J.

This was the year that the Stockton and Darlington line opened in England; the success of that pioneering enterprise helped overcome the opposition and apathy toward railways in the United States. On Feb. 28, 1827, the Baltimore and Ohio Railroad company (B. & 0.) was chartered (in the following, abbreviations or names in parentheses are those by which U.S. lines are commonly known). The line began carrying revenue traffic Jan. 7, 1830, and the first 13 mi. of line, from Baltimore to Ellicott's Mills (now Ellicott City) opened on May 24, 1830.

The B. & 0. was the first railway in the U.S. to be chartered as a common carrier of freight and passengers. Moreover, its promoters looked beyond purely local needs. They envisaged a line going all the way to the Ohio river to channel the commerce of the growing middle west through the port of Baltimore. By 1834 the B. & O. had built to Harpers Ferry, Va. (now W.Va.), and on Dec. 24, 1852, it reached the Ohio river at Wheeling. Subsequently the B. & 0. expanded, both through new construction and by acquiring other railways, until it reached Chicago, St. Louis and the Great Lakes.

Almost simultaneously, several other early U.S. railways came into being. Construction of the 5-ft. gauge line from Charleston to Hamburg, S C , by the South Carolina Canal and Rail Road company began in Feb. 1829. On Dec. 25, 1830, this line became the first in the United States to start scheduled passenger operations using a steam locomotive. When the entire line to Hamburg was completed in 1833, it was the longest then operating in the U.S. (136 mi.). Ultimately. the original Charleston-Hamburg route became one segment of the 8,000-mi. Southern Railway system.

Still other railway systems that later grew into giants of the U.S. railaay industry had their beginnings in the decade of the 1830s. The Mohawk and Hudson, first predecessor of the New York Central system, operated its first train between Albany and Schenectady, N.Y., on Aug. 9, 1831. Predecessors of both the Boston and Maine railroad and the New York, New Haven and Hartford Railroad company (New Haven) started regular service in the summer of 1835. Three local lines chartered in Virginia evolved into major rail systems. One was the Richmond and Petersburg, chartered in 1836, oldest element of the Atlantic Coast Line Railroad company. The Portsmouth and Roanoke, pioneer segment of the Seaboard Air Line Railroad company. dates from 1832. The Chesapeake and Ohio Railway company (C. & 0.) had its beginning in the little Louisa railway. chartered in 1836

The Richmond, Fredericksburg & Potomac Railroad company, which operates between Richmond, Va., and Washington, D.C., was incorporated Feb. 25, 1834. It is the oldest American railway that has continued to exist since the beginning under its original name. and without reorganization.

By 1840 there were 2,800 mi. of line in the U.S., and the country had entered its first great era of railway building. Twenty years later, on the eve of the American Civil War, the country had more than 30,000 route miles of track.

With but few exceptions (such as the B. & O.), early railways were purely local in character They mere designed to promote the commercial interest of local communities or areas. As growth progressed, houever, many of the small roads were consolidated, forming through routes that served fairly large territories, and new railway projects became more ambitious. The Pennsylvania Railroad company completed its line from Philadelphia to Pittsburgh in Dec. 1852, using ten inclined planes to climb over the Allegheny mountains. A little more than a year later, it completed an all-rail route.

1. The Westward Movement.—By the 1850s U.S. railways were taking on their historic role as civilizers of the western frontiers. The first locomotive in Chicago, the "Pioneer" of the Chicago and Galena Union, now the Chicago and North Western railway (North Western), made its initial run on Oct. 25, 1848—and Chicago was on the way to its ultimate destiny as the nation's largest rail centre.

Soon railways were pushing west from Chicago. The Chicago and Rock Island, now the Chicago, Rock Island and Pacific Railroad company (Rock Island). was the first railway to link Chicago with the Mississippi river (1854). It also built the first bridge across that river. Other pioneer lines built west from the Mississippi. The first locomotive to operate west of the river made a five-mile run from St. Louis in Dec. 1852. This was on a short railway that became part of the Missouri Pacific Railroad company. The Hannibal and St. Joseph, now part of the Chicago, Burlington and Quincy railroad (Burlington), reached the Missouri river in 1859.

The Civil War slowed, but did not stop, the headlong growth of railways in the U.S. After the close of that conflict, another era of intensive railway building began, and it continued into the early years of the 20th century. It reached its high point during the decade of the 1880s, when some 70,000 route miles were laid. In 1882, the greatest single year of railway building in the U.S., 11,569 mi of track were completed.

Highlighting this era was the completion of several lines—the transcontinentals—which, more than any other factor, helped *make the United States finally a truly united nation. On May 10, 1869, the first transcontinental route was created when the Union Pacific Railroad company, building west from Omaha, Neb., met the Central Pacific, now part of Southern Pacific (S.P.). which was built east from Sacramento, Calif. In 1881 the Atchison, Topeka & Santa Fe railway (Santa Fe) joined rail with the S P. at Deming, N.M., to form the second transcontinental route. Ultimately. there were about nine major routes leading from the middle west or south to the west coast. From Chicago, the Santa Fe and the Chicago, Milwaukee, St. Paul & Pacific (Milwaukee road) run all the way to the west coast over their own rails. The S.P. has its own trackage from New Orleans. La., to Los Angeles, Calif., and on up the coast to Portland, Ore.*

2. *Land Grants.— A feature of the post-Civil War railway building era was government aid to a number of lines through land grants, loans and other types of assistance. About 131,000,000 ac. of public land were granted to 29 railways for about 18,000 mi. of line. These grants (about 8% of the total U.S. railway mileage) made it possible for the railways to push their lines across prairies and mountains that were then almost entirely undeveloped and very sparsely settled.*

Actually, railway aid a-as, on balance. a profitable activity for the U.S. government. For instance. the government received about $167,000.000 in principal and interest from the $65,000.000 it loaned to the Union Pacific and Central Pacific. The original value of the land grants was about $130,000.000, but in return the railways agreed to carry government traffic at reduced rates. By the time this agreement was abrogated in 1955, the railways had paid back to the government. through these reductions, more than $1,000,000,000.

3. *Railway Regulation.— For almost 50 years after their beginnings, railways in the U.S. were subject to little governmental regulation. But after the Civil War, abuses such as rate wars, rate discrimination and financial piracy became more widespread. In these things railways were probably no worse offenders than many other businesses of that era, but since they had by then attained almost a monopoly over domestic transportation, the public could not tolerate these abuses.*

Regulation at first was largely at the state level, but public sentiment resulted in the passage, in 1887, of the Interstate Commerce act, which placed the railways under federal regulation. Later, other acts broadened and extended the areas of federal regulation so that the railways finally had to clear through the Interstate Commerce commission almost all proposals for changes in such matters as financing, equipment standards, signaling and rates.

4. *Labour Relations.— $ailways were one of the first U.S. industries in which employees became unionized. Today there are nearly two dozen "standard railroad labour organizations" which represent employees in various classes or crafts. In 1888 the U.S. congress passed legislation providing, among other things. for special presidential emergency boards to investigate disputes. Through the years, other legislation was added. Labour-management negotiations now are conducted under the complex provisions of the Railway Labor act. Enacted in 1926 and subsequently amended, it provides a national mediation board that has power to mediate disputes, and a national railway adjustment board, composed of management and union representatives. which considers grievances, interpretations and applications of the complicated labour-management working agreements.*

Over the years, relations between railway labour and management in the U.S. have been marked with few industry-wide work stoppages— although there were violent and bloody strikes in 1877 and 1894. A brief nationwide strike also tied up U.S. lines in 1946. (See also LABOUR LAW.)

5. **U.S.** *Developments to World War 11.—By the early years of the 20th century, railway building had slowed in the United States, and the network had reached about its fullest extent. This was a period of improvements in railway plant and equipment; emphasis was on standardization of equipment and operating techniques.*

After a brief period of government control during World War I, the U.S. railways entered an era of further operating refinements but of few spectacular advances, although several technological developments that later had vast impact, among them the diesel locomotive, were being tried. The first inroads of highway competition were being felt. The economic depression, beginning in 1930, dealt the railways a disastrous blow, and many companies went through bankruptcy proceedings. Emerging from this depression decade, U.S. railways faced their supreme challenge, the years of World War II.

6. **U.S.** *Railways in War.— Almost from the first, some military men recognized the value of railways. An early proposal called for a network of railways to be built in the U S. primarily for military purposes. In many other countries, some or all of the railways originally were constructed strictly for military reasons.*

Although some use was made of railways in the Crimean and Mexican wars, the American Civil War was really the first "railway war." Since then, nations in every major war have depended on railways as basic transportation either in the active theatres—as in Europe during the world wars—or to supply men and materials to seaports for overseas shipment, as in the case of the U.S. during those wars.

Experience has shown that railways can move huge quantities of supplies and troops over land with a tremendous economy of fuel and manpower—a vital advantage, of course, during a war emergency. Moreover, railways. while seemingly vulnerable to enemy action, can be more quickly restored to full-capacity operation than any other form of land transport. This was amply demonstrated in World War II and in the Korean mar of 1950–53.

At the very beginning of the American Civil War, railways played a key role. The Confederate victory at the first battle of Bull Run (Manassas) was due in considerable measure to the Manassas Gap railway. which was able to deliver a number of reinforcements to the battlefield just in time to turn the tide. Throughout the war, the Confederacy was able to use its railways to concentrate troops where needed and thus help to overcome its numerical disadvantage. However, the Confederacy was not able to exercise effective organized control of its railways so they could operate to best military advantage.

On the other hand, the Union side was able to organize its military railway operations more effectively. This, along with its better-developed railway network and the fact that most of the U.S. locomotive and car-building plants were in Union territory, played an important part in the final outcome of that conflict.

One of the important lessons learned in the Civil War mas that railway cars must be used only for the movement of troops and supplies— not for storage. By World War I this lesson had been forgotten, however. Cars were loaded and sent on their way with no place to unload them. As a result of this practice, congestion approaching paralysis hit the U.S. railway system in 1917. In order to unravel the tie-up, the U.S. government took over the operation of the railways on Dec. 28, 1917. The lines were restored to private operation March 1, 1920.

No such problem arose in R'orld War II. when the U.S. railways demonstrated how efficiently a well-run system can operate to handle extraordinary traffic movements. In the war year of 1944, freight ton-miles were two and one-half times the level of 1938; passenger-miles had increased fourfold. This tremendous traffic was handled with only relatively modest increases in the supply of locomotives and cars. Moreover, this wartime job mas done at a time when the railways had supplied some 40,000 officers and men for army transportation corps units and another 300,000 employees were in other branches of the armed services.

During the World War II period, U.S. railways carried almost 98% of all military personnel moving in organized groups and more than 90% of all military freight handled by inland transportation. In the Korean war of 1950–53, the railways performed a similar job on a smaller scale while at the same time handling normal civilian transport requirements.

In the Korean war, too, the flexibility of railways under front-line conditions was reaffirmed. Neither the U N or Communist forces could permanently disable the other side's strategic rail lines even under the impact of heavy air strikes.

B. Railway Growth in Canada

The growth of Canadian railways paralleled somewhat that of lines in the United States.

Construction of the first line, between Laprairie and St. Johns, Que., began in 1835; its first train operated on July 21, 1836.

By 1860 there were about 2,000 mi. of railway line in Canada. One of the terms on which British Columbia entered the confederation in 1871 was the construction of a transcontinental route. This line, the Canadian Pacific, was completed in 1885. It is literally the tie that bound Canada into a unified nation.

Two other transcontinental lines reached the Pacific coast in 1914 and 1915. They were the Grand Trunk Pacific, which reached Prince Rupert, B.C., in 1914; and the Canadian Northern, built into Vancouver in 1915. Both of these lines were built with government assistance.

The dislocations of World War I dashed the hopes of internal development that had sparked the construction of these two transcontinentals. They required further government financial help and were finally taken over by the dominion government. In 1923 both the Grand Trunk and the Canadian Northern, along with other railways always owned by the dominion, were unified, forming the present Canadian National railways (C.N.R.).

In normal years the Canadian Pacific operates at a profit; the Canadian National, which has many lines serving as yet sparsely settled areas, usually records a deficit. The C.N.R. also serves as an agency of national policy. As a result it has built a number of lines to open up new territory during the years since World War II.

Other Canadian railways were being built or extended as the dominion entered a period of rapid economic growth. The Quebec. North Shore and Labrador, a 320-mi. ore-carrying line from the iron ore deposits near Schefferville, Que., to the St. Lawrence river at Sept Iles. was opened in 1954. In 1958 the Pacific Great Eastern railway (P.G.E.) completed its line all the way from Vancouver, B.C., to Dawson Creek and Fort St. John, B.C., where it connects with the Alaska highway. Another new line was constructed from the P.G.E. near Prince George, B.C., to Whitehorse, Y.T.

C. United States and Canadian Railways After World War II

For about a century, rail ays were the dominant form of intercity transportation in the United States and Canada. Indeed, their monopoly was almost complete, with the exception of a fair volume of water transport—river, Great Lakes and intercoastal.

But the development of the internal-combustion engine and its application to highway vehicles (starting about the beginning of the 20th century) and the invention of the airplane were to have far-reaching effects on railway transportation. In the period between the two world wars, highway transportation of goods by motor truck and of people in buses and private automobiles was already seriously cutting into railway business, especially on branch and secondary lines.

The demands of war hastened the technological development of these new forms of transportation. and by the late 1940s their inroads had reached critical proportions from the railway point of view. Competing forms of transport were continuing to gain in relative volume at the expense of the railways in the early 1960s. This trend was especially pronounced in the United States, where the growth of highways, aviation facilities and pipelines was particularly intense, but the same trend was noticeable—though in its earlier stages—in most other countries except those that were still in the more primitive stages of economic development.

How did the railways react when confronted with this new competition? Accustomed to competing only with other railways, most found it hard to adjust their thinking—and their operations—to meet the challenge of competitors who could offer the public faster, more flexible or, in some cases, cheaper service; and who in most cases were burdened much less by government regulation. Thus for many years motor trucks, automobiles, buses, waterways, airplanes and pipelines took over increasing volumes of traffic against very little resistance from the rail lines. Only the overall growth of the U.S. economy prevented the railways from suffering a drastic absolute—as well as relative—drop in traffic volume.

Eventually. however, railways began to fight back against their new competitors. They took measures to improve the speed and regularity of their train services; offered passengers and shippers new types of equipment; and adjusted their rates to become more competitive—and to more fully reflect the advantages of railroad transportation for high-volume, long-haul service.

The substitution of diesel for steam locomotives in the U.S. and Canada allowed freight and passenger trains to operate at higher sustained speeds. Moreover, the running gear of modern freight and passenger cars (wheels, springs, journal bearings and brake equipment) allows greatly increased top speeds.

The big problem in freight service continued to be the delays encountered in classification yards and freight terminals through which cars must pass. Much has been done to alleviate yard delays by constructing classification yards that are largely automatic. These new yards can sort out freight cars and make up new trains in much less time than was possible in the past.

Railroads are offering their customers special types of freight cars, designed to permit them to load particular commodities quickly and at minimum expense. Typical are the automobile-parts cars with specially designed racks that allow fast loading of specific automobile components; or the covered hopper cars for bulk handling of commodities such as phosphates, cement or flour. Both special and conventional types of freight cars are becoming larger to take advantage of the economies of high-volume shipment.

Significant, too, was the increase in the use of highway trucks by railways. Under governmental restrictions, U.S. railroads could not (for the most part) operate truck lines except as supplements to or in substitution for railway service. Thus railways used trucks to deliver small-lot (less-than-carload, or L.C.L.) shipments from rail car terminals to consignees in nearby areas, and to pick up L.C.L. freight for subsequent rail movement. In some cases, also, railway-operated trucks substituted for trains in local freight service or on branch lines where the volume of business no longer justified train operations.

1. The "Piggyback" Development.—As early as the 1920s, a U.S. railway was carrying loaded highway trucks on flatcars (although the idea dates back to the 19th century). "Piggyback" combines the flexibility of truck pickup and delivery with the economy of rail movement between cities. Piggyback did not begin to grow rapidly until the later years of the 1950s, but some authorities estimated that piggyback traffic might eventually amount to one-half of the total volume of railway traffic.

Along with piggyback, there was increasing interest among railways and other modes of transport in "container" systems. Clearly, the trend was toward a system of freight transport in which merchandise could be loaded into standard containers or boxes, which then would move either via highway on a truck chassis, via rail on special container cars, in ships especially equipped to handle them, or even by air. A single shipment might use two or more modes of transport in the course of its trip. Railways in the U.S. used containers on a small scale in the 1920s, but not until the early 1960s did the technique meet with widespread acceptance.

Future development of piggyback, and containers, could result in a freight transportation system that was quite highly integrated. Each mode of transport might then perform the type of service for which it is best suited, and a single shipment might be moved by several different modes of transport at minimum extra cost.

2. Passenger Service.—In the United States and Canada, long-haul railway passenger service appeared in the 1960s to have a limited future. A vast network of paved highways and the fantastic growth in automobile ownership had diverted almost 90% of all intercity travel to the public automobile. The remaining travel volume was shared by railways, by buses on the public highways and by the rapidly growing air lines.

The greatest area of usefulness for intercity rail travel in the future appeared to be for trips ranging up to 300 mi. between large centres of population; for overnight sleeping car service between large cities 500 to 1,000 mi. apart; and for some commuter service centring on the larger cities. There also appeared to be a market for a limited volume of long-haul railway service in luxury "cruise" trains.

D. Railways of Mexico and Central America

The railway systems of Mexico and in Central and South American countries are less advanced than those in the U.S. and Canada. Except in Mexico. most countries have a predominance of narrow-gauge lines of relatively light construction.

The Mexican railways, almost all of which are owned by the federal government, have a route mileage of approximately 15.000. Of this approximately 8.400 mi. is operated by the National Railways of Mexico (Ferrocarriles Nacionales de México). The N. de M. was acquired both by purchase and expropriation, beginning in 1937. Prior to that time much of the railway development in Mexico had been by private interests.

Most of the Mexican railway mileage is standard gauge, and there are interchange connections with U.S. railways at several points. As a result, the Mexican railway network may be said to be integrated with those of the C.S. and Canada to a considerable extent. Since World War II a vigorous modernization program has been under way.

The railways of Central America are all narrow gauge and of light construction. Some of them are government owned; others are private railways owned and operated by banana companies. There is little integration: most of the lines are isolated and serve only small areas. Cuba has about 2,900 mi. of public service railnays and another 7,000 mi. of sugar mill railways operated by 175 different mills.

E. South American Railways

South America has about 66,000 route miles of railroad, of which about 62% is narrow gauge. The rest is either standard or wide gauge. Although early development of South American railways, beginning in the middle of the 19th century. was largely by private enterprise, there later was a trend toward government ownership and operation. This was particularly marked in Argentina, where in 1945 only about 31% of the trackage mas state owned; by the 1960s Argentina's 27.600 mi. of line were all under the jurisdiction of the Argentine State railways.

Brazil is a close second to Argentina in total track miles. Of its 23.253 track miles, all but 2,980 are owned by state or federal governments.

There is little integration of railways in the South American countries. This is due partly to the rugged terrain over which many of them operate but even more to the diversity of gauges, as well as equipment standards. Many early South American railways were built by British. French, U.S. and German concerns and this resulted in considerable variation in the types of equipment, methods of operation and even terminology.

Nearly all South American railway systems had improvement programs planned or under way in the 1960s, but most were handicapped by lack of funds.

F. European and Asian Railways

1. Great Britain. — The success of the Stockton and Darlington and the Liverpool and Manchester lines touched off widespread railway construction in Britain. In 1836, the opening of the London and Greenwich railway brought the first public passenger service to London. In 1838, the London and Birmingham railway was opened throughout its length and in 1840 the line from London to Southampton was completed. The Great Western railway's 7-ft. broad-gauge line from London to Bristol was opened to traffic in 1841.

Between 1844 and 1846 parliament authorized the construction of over 400 railways. This represented the height of what was known as the railway mania, and there followed a period of slower development and a growing number of consolidations. Early in the 1900s some systems realized that mergers could create a stronger economic position for them, but because of monopoly fears. acts sanctioning such moves were not passed by parliament.

Amalgamation of Lines — Following World War I, it was evident that large-scale consolidation was a financial necessity, and the government decided upon compulsory amalgamation. As a result of the Railways act of 1921. some 123 separate railway companies amalgamated into four main groups on Jan 1, 1923. The four systems were the London. Midland and Scottish railway; London and North Eastern railway (L. & N E R.); Great Western railway; and Southern railway. Certain minor railways and London's Underground retained their separate existence. The latter were amalgamated with London area bus and tramway systems in 1933 under authority of the London Passenger Transport board, a public body constituted by act of parliament.

The object of creating four large railway systems was to consolidate control and obtain more economical methods of operation. The consolidation also allowed the introduction of a new classification of rates and charges designed to enable the railways to earn a standard revenue.

During the 1920s the railways began to suffer from increased highway competition. To combat this, various new services were introduced. In 1928, an act of parliament authorized the railways to operate both passenger and freight road services, and they acquired extensive financial interests in existing undertakings, principally bus companies.

Despite competition and the general economic depression of the 1930s, the four railway companies mere responsible for some remarkable achievements between 1925 and 1939. In 1928 the L. & N.E.R began the nonstop running of its principal express train between London and Edinburgh, a distance of $392\frac{3}{4}$ mi. The high-speed running of streamlined passenger trains began in 1935 with the introduction of the "Silver Jubilee" between London and Newcastle. It was followed in 1937 with the "Coronation" (London-Edinburgh) and the "Coronation Scot" (London-Glasgow).

At the outbreak of World War II in 1939, the railways were placed under government control. So-ordination and direction nas through the Railway Executive committee appointed by the ministry of transport. During the period 1939–45 the railways operated 260.000 special troop trains and 280,000 matériel trains for the armed services. Over 9,000 incidents of enemy action were recorded on the railways and nearly 400 railway men were killed and 2.444 injured by enemy action. At the end of the war the state of the railways had deteriorated considerably due to lack of maintenance, abnormal wear and tear, shortage of personnel and damage through enemy action.

Railway *Nationalization*.—In 1946 a bill was introduced in parliament for setting up a publicly owned inland transport system. Under the Transport act, which became law on Aug. 6, 1947, the British Transport commission (B.T.C.) was established as the body responsible for taking over the railways, the railway owned docks. road haulage contractors, many road passenger undertakings and the inland waterways. On Jan. 1, 1948, the nationalization of the railways took effect and they became British railways. The Railway Executive committee became the body responsible to the Railway commission for the management and co-ordination of British railways. The latter mere divided. on a geographical basis, into six regions: Eastern, Northeastern, Western, Southern, London Midland and Scottish.

A transport bill which became law on May 6, 1953, provided for greater decentralization of the railways. The Railway Executive committee was abolished and the chief regional managers were made responsible to the commission. The greater degree of autonomy enabled the regional officers more closely to meet the needs of the local traveling public and trading interests.

On Jan. 24, 1955, the B.T.C. announced an extensive and ambitious modernization and re-equipment plan. The plan aimed at producing a really modern system that would be able to meet both current traffic requirements and those of the foreseeable future. It was intended that the main features of the plan would be started within 5 years and completed within 15 years. The main objective was to provide "an equipment, in the widest sense of the nord, of modern design and fit to give reliable and speedy transport service on a large scale." The plan involved an outlay of approximately £1,200,000,000.

The main features of the plan, as far as they affect British railways, may be summarized as follows:

Track and signaling improvements to make higher speeds possible; extension of colour-light signaling, track circuits and the introduction of an automatic warning system on locomotives; the introduction of more power-operated signal towers and the installation, where suitable, of centralized traffic control.

Steam traction to be replaced by electric or diesel traction.

Replacement of much of the existing passenger rolling stock, largely with multiple-unit electric or diesel trains; the remaining passenger stock to be modernized.

Freight services to be drastically remodeled and continuous brakes fitted to all freight cars, which will lead to faster operation; classification yards and freight terminal facilities to be relocated and modernized and the number of classification yards to be greatly reduced; larger cars for certain types of traffic to be introduced.

Expenditures to be directed to other activities including improvements to packet ports, staff welfare, office mechanization, etc.

The modernization plan began to show concrete results in 1958, although no large scale improvements had, by that time, been completed. In 1959 there was a reappraisal of the plan, aimed at accelerating certain portions of it. In 1958 there was a total deficit for the year of £89,000,000, covering all the commission's activities. To meet the situation the government agreed to increase the limit of deficit borrowing from £250,000,000 to £400,-000.000, as well as increasing the general borrowing powers.

British railways run some 23.000 passenger trains each weekday and carry over 1,000,000,000 passengers a year.

In 1957 the B.T.C. (railway merchandise) Charges Scheme came into force, allowing freight charges to be varied below the permitted maximum. This enabled the railway to charge on the basis of loadability, except for consignments of 100 tons or more, for which charges had to be reasonable.

Passenger Service. — Passenger train developments included the widespread introduction of diesel multiple-unit rail-car trains. At the beginning of 1960. 3,000 of these vehicles were in use and by the end of that year the total reached 4.000. Among the principal express trains were the "Elizabethan" (London-Edinburgh, nonstop, summer only) and the "Caledonian" (London-Glasgow). In 1955 a new type of service aimed at the motorist was launched. Called the "Car-Sleeper Limited," it carried automobiles in specially designed cars, their drivers and passengers traveling in sleeping cars. It operated between London and Perth.

British railways expected to rely increasingly on diesel and electric traction, although much traffic in the 1960s was still hauled by steam locomotives. By the end of 1961 the number of steam locomotives was to be reduced to less than 8.000. In 1960 there were 1,400 diesel switch engines and over 800 main-line diesel locomotives in use. Substantial numbers of diesel locomotives, some embodying hydraulic transmission but the majority having electric transmission, mere under construction.

Electric Traction. — Electric traction is used extensively in southeast England, together with suburban lines in various parts of the London area and around Manchester, Liverpool and Newcastle-on-Tyne. All these use direct current and all but one use current collection via a conductor rail mounted alongside the running rail. Electrification of the line connecting Manchester, Sheffield and Wath was completed in 1954. This uses the 1,500-v., D C. overhead conductor wire system. The same system was employed for the electrification of the London-Shenfield line, which was completed in 1949 and extended to Southend in 1956 (this, however, was later converted to A.C. to bring it into conformity with later electrification projects in the same area). The B.T.C. announced in 1956 that future electrification would be on the 25-kv.. 50-cycle, A.C. system. The first application of this form of electric traction was on the Colchester-Clacton-Walton line, some $24\frac{1}{2}$ route miles (inaugurated in 1959). The first trunk route to be electrified using 25-kv. power was to connect London, Manchester and Liverpool.

2. China.—Following creation of the People's Republic of China in 1949, an intensive program of rehabilitating war-damaged lines and constructing new ones was started. Among the new lines were the Chengtu-Chungking railway, opened in 1952, and a line connecting Mongolia and China, opened in 1955. There was some 5-ft. gauge line adjoining Russian territories and also some narrow-gauge mileage; however, the majority of the system was standard gauge. Through passenger train services were being operated between Peiping and Moscow; Peiping and Ulan-Bator; and Peiping and Hanoi.

3. France. — The first railway in France, from St. Étienne to Andrézieux. was officially opened on Oct. 1. 1828. although it was in unofficial use the year before. At first only freight was carried, passenger traffic commencing in 1832. Horse traction was employed until the adoption of steam locomotives in 1832. In 1830 the first section (between Givors and Rive-de-Gier) of the St. Btienne-Lyons railway was opened, and the line was completed in 1832. Both steam and horse traction were used, steam taking over completely in 1844. The first international line from Strasbourg to Basle, Switz., was completed in 1841, by which time France had 350 mi. of railways.

In the 1850s railways construction was at its height and there emerged six principal companies: Nord, Est, Paris-Orléans. Paris-Lyons-Méditerranée, Midi and Ouest. In 1878 the state took over a group of small companies in western France, thus creating the Btat system. By 1902, the railway network had grown to 28,400 miles.

The Ouest railway became state owned in 1908, and following World War I the Alsace-Lorraine railways also became French property. On Jan. 1, 1938. the five remaining privately owned railways were taken over by the government. They — and the existing État system — formed the French National railways (Société Nationale des Chemins de Fer Français [S.N.C.F.]), a joint stock company with 51% of its capital held by the government.

During World War II the S N C.F. suffered extensive damage and by 1944 some 82% of the motive power, 80% of the coaches and 64% of the freight cars had been damaged or destroyed. Extensive damage had been wrought on many other installations, but by mid-1946 nearly all track (24,800 mi.) was restored to use and by mid-1948, 2,491 bridges and viaducts had been rebuilt.

Following the immediate postwar restoration of basic facilities, the S.N.C.F. embarked on the modernization of its system. Initial recovery was aided by the supply of 1,340 steam locomotives from the U.S. and Canada and 48,000 freight cars from North America and Britain.

The principal features in the modernization of the system were the steady abandonment of steam traction, increased use of diesel power and large-scale electrification. Extensive improvements also were made to track and signaling, and large quantities of new rolling stock were introduced.

The initial postwar project was to electrify the main line from Paris to Lyons. and this was completed in 1952. The prewar 1.500-v., D.C system was adopted. Further sections from Lyons subsequently were dealt with. and electrification was being continued to Marseilles. The S.N.C.F. also developed the use of 25-kv. A.C. at the commercial frequency of 50 cycles for rail traction.

4. Germany. — The use of the steam locomotive in Germany began on Dec. 7, 1835, with the opening of a railway between Niirnberg and Furth. Both private companies and states built railways, but after 1876 the privately owned systems were gradually absorbed by the states. By 1909 the total route mileage was 35.625.

In 1920 there was a further change in ownership when the state systems were unified as the German State railways. Their status was changed in 1924 to that of a publicly owned company. but a few years later they again reverted to government ownership.

Following World War II and the partition of Germany, two railway systems emerged. In the German Federal republic (west Germany) there emerged the German Federal railway (Deutsche Bundesbahn or D.B.). while in the German Democratic republic the title of German State railway (Deutsche Reichbahn or D.R.) was retained. In west Germany, apart from the D.B., there were about 250 public railways owned by commercial concerns, municipalities and provincial governments.

After World War II a great deal of reconstruction was necessary and the opportunity was taken to introduce new equipment. There were improvements in track, signaling, communications, locomotives and rolling stock, and steam traction was being replaced by diesel locomotives and electrification.

5. India. — The most complex railway network in Asia, and also the oldest, exists in what was the dominion of India, now split into the republics of India and Pakistan. In 1849, the East Indian Railway company registered. and the first line to be opened was between Bombay and Thana in 1853. This early development was due to British influence, and the various networks gradually extended and increased in size and scope.

The control of the Indian systems comes under the ministry of railways at New Delhi. There are eight railways, which serve different areas of the country: Central, Eastern, Northern. North Eastern, Northeast Frontier. Southern, South Eastern and Western. The Central railway is principally 5-ft. 6-in. gauge, and the Eastern railway is entirely 5-ft. 6-in. gauge, except for 17 mi. of 2-ft. 6-in. gauge. The Northeast Frontier railway is mainly metre gauge, and the North-Eastern railway is entirely of this gauge. The Northern railway is largely 5-ft. 6-in. gauge, as is the South Eastern railway. The Southern railway is mainly metre gauge, and the Western railway has a majority of metre-gauge mileage, with some 5-it. 6-in., 2-ft. 6-in. and 2-ft, gauges. The total mileages for the various gauges of the entire network are: 5 ft. 6 in., 16,246; metre, 15,480; and 2 ft. 6 in. and 2 ft., 2,735.

6. Ireland. — The first railway in Ireland was opened Dec. 17, 1834, between Dublin and Kingstown (now Dún Laoghaire). It was originally constructed to the 4-ft. 84-in. gauge but was converted to the principal Irish gauge of 5 ft. 3 in. in 1857. The first line to be opened in Northern Ireland was the Ulster railway between Belfast and Lisburn in 1839, originally built to a gauge of 6 ft. 2 in., and converted in 1847 to 5 ft. 3 in.

On Jan. 1, 1925, the majority of all lines wholly within the Irish Free State were combined into the Great Southern railways, and on Jan. 1, 1945, this system and the Dublin United Transport company were merged into the Irish Transport company (Córas Iompair Eireann or C.I.E.). The Great Northern Railway board's facilities in the Republic of Ireland were merged with C.I.E. in 1958.

Under the 1948 Transport act (Northern Ireland), the Irish Road Transport board, the Belfast and County Down railway and the Northern Counties committee were all acquired by the Ulster Transport authority (U.T.A.), and in 1958 the portion of the Great Northern railway board in Northern Ireland was merged with the U.T.A.

7. Italy. — The first railway in Italy was between Naples and Portici, opened in 1839. Railway construction in other parts of the country followed, but it was not until the union of the states of Italy took place in 1861 that the idea of a national rail network could be put into practice. In 1885, the major systems were merged into three railways and in 1905–07 these networks, and other smaller lines, were taken over by the state.

During World War II the system suffered considerable damage and extensive reconstruction was necessary. The electrified network, which dates back to 1901, was restored and greatly extended. The majority of the electrification was 3,000-v. D.C., but there was some 3,600-v., $16\frac{2}{3}$-cycle A.C.; this was scheduled to be converted to D.C.

8. Japan. — Japan's first railway was projected in 1869, but construction did not start until 1870 and the first section, between Shimbashi (Tokyo) and Yokohama was not opened until 1872. The years 1885 to 1895 saw the rapid growth of privately built lines in various parts of the country. In 1906 and 1907. under the Railways Nationalization law, the government acquired 17 of the major private lines, boosting the proportion of government-owned mileage from 32% to 91%.

In 1949 the government railways were reorganized into a public corporation, the Japanese National railways (J.N.R.), which in the 1960s operated about 12,600 route miles of line, all of it 3-ft. 6-in. gauge. There were still about 4,600 miles of private railways, most of them short, but some carrying heavy traffic.

Japan's railways, largely built to high standards, carry a very heavy traffic. J.N.R.'s Tokyo-Osaka route (the Tokaido line) in the early 1960s carried the heaviest traffic density on the system (about 60 to 80 passenger trains and 50 to 60 freight trains each way daily). However, the capacity of the double-track, electrified 3-ft. 6-in. gauge line had almost been reached, and a new double-track, standard-gauge line was planned between Tokyo and Osaka, a line that would have no grade crossings and would be built to permit a top speed of 150 m.p.h. for passenger trains.

9. Norway.—Norway's first railway was completed in 1854 between Oslo (then Christiania) and Eidsvoll. Railway construction has always been difficult because of the mountainous nature of the country, the rigorous climate and the relatively small population. Main lines radiate from Oslo to Bergen, Trondheim, the Swedish frontier and Stavanger. A completely isolated section of the system is the electrified Ofoten railway from the Swedish frontier at Riksgransen to Narvik; this carries a heavy iron ore traffic. Some other lines are also electrified, the longest running from Oslo to Stavanger (370 mi.) and the total electrified mileage in 1958 was 951.

10. Pakistan. — The partition of India and Pakistan resulted in the latter having two territories, separated by the widest part of India. As a result Pakistan has two distinct railway systems. Eastern Pakistan is served by the Eastern Bengal railway, which has its headquarters at Chittagong. The majority of its route mileage is metre gauge, with some 5-ft. 6-in. gauge and 2-ft. 6-in. gauge. Western Pakistan is served by the North Western railway, which has its headquarters at Lahore. It is largely 5-ft. 6-in. gauge, with some metre gauge and 2-ft. 6-in. gauge. There is no electrification in Pakistan, but the use of diesel traction was growing in the 1960s.

11. Spain. — The first railway in Spain was the Barcelona-Mataro line, opened Oct. 28, 1848. The topography of the country made subsequent construction slow and expensive. From the many companies in existence there emerged, through a series of consolidations, four major systems. During the civil war of 1936–39, all the railways suffered damage and their position after hostilities was so difficult that the Spanish National railways (Red Nacional de los Ferrocarriles Españoles) was formed in 1941, taking control of 7,580 mi. of 5-ft. 6-in. gauge lines in 1943. There is also an extensive mileage of narrow-gauge track in the country, operated by about 50 privately owned systems.

12. Sweden. — The railways of Sweden were built partly by private companies and partly by the state. The first standard-gauge line was opened in 1856 and the first trunk line from Stockholm to Goteborg was inaugurated in 1862. As early as 1879 the state began taking over private companies and in 1939, the Swedish parliament decided that the majority of lines still privately owned should be taken over by the Swedish State railways. As a result some 95% of the railway network had come under state control by the 1960s.

One of the most important aspects of the system is the heavy traffic in iron ore between mines in Lapland and the ports of Narvik, Norway, and Lulea.

13. **U.S.S.R.**—A gauge of 6 ft. was selected for the first public railway in Russia, which was opened—with horse traction — in 1836. In the following year, steam traction was introduced, with locomotives supplied from Britain. The first line of any length was from Warsaw to the Austrian frontier, opened in 1848, followed by the 400-mi. Moscow-St. Petersburg (now Leningrad) line, opened in 1851; this was of the 5-ft. gauge, which became the standard in Russia. The network spread somewhat slowly at first, gathering momentum from the 1860s onward, until in 1900 there were some 33,000 mi. of line. At the time of the Russian Revolution, route length was 43,800 mi. and there were 25 state-owned and 13 privately owned systems.

Following the revolution, the railways were nationalized and by a series of five-year plans the system was rehabilitated and modernized. World War II resulted in the railways being worked to capacity and, in many areas, being extensively damaged. Postwar reconstruction and modernization included diesel traction, electrification, improved signaling and train control apparatus, and new rolling stock. The railway is the principal form of transportation in Russia and handles approximately 80% of all freight traffic.

The network is split up into 45 railways controlled by railway boards which, in turn, are under the supervision of the ministry of transport and communication.

An important development after World War II was the introduction of dual-gauge passenger coaches which can have the trucks of one gauge exchanged for those of another, using special lifting installations at the break-of-gauge point. This permits the through running of coaches between Russia and east and west Europe.

One of the most notable lines in Russia is the Trans-Siberian railway. 5.787 mi. long, which links Moscow and Vladivostock. Construction commenced in 1891, the work starting simultaneously from the east and west terminals. Originally, passengers could not make the entire journey by rail but had to travel by boat (or, in winter, by sleigh) across Lake Baikal. However, by 1916 a line had been laid around the lake, allowing the entire journey to be made without changing cars.

In 1960 a Trans-Siberian express left Moscow daily, requiring nine days to reach Vladivostock. There also was a through train three times a week between Moscow and Peiping.

G. African Railways

Construction of the first railway on the African continent was started in 1852 in Egypt. It was the Alexandria-Cairo line, the first section of nhich was opened in 1854. It was followed by the opening, in 1860 of a line betueen Durban and the Point in south Africa Development of railway mileage in Africa as a whole was slow until the turn of the century when a number of construction schemes were started. Some other early railway building took place in Tunisia (first line planned in 1875); the Sudan (first tracks of a military line laid in 1897–98); formerly French Equatorial Africa (construction started in 1880); and Tanganyika (construction started in 1891).

1. Union of South Africa. — In South Africa, the discovery of diamonds at the Cape gave considerable impetus to railway construction. By the time the Union was founded in 1910, some 7,570 mi. of track had been laid, of which the majority was state owned. There were three systems, the Central South African railways, the Cape Government railways and the Natal Government railways, all of nhich were merged in 1916. By the 1960s, the South African Railways and Harbours administration had the most extensive network on the African continent. Apart from the operation of the railroads, the administration operates road services, the principal harbours and the South African airways.

2. Central Africa. — The East African Railways and Harbours system was formed in 1948 by the amalgamation of the Kenya and Uganda Railways and Harbours and the Tanganyika Railways and Ports services. Construction of the original Uganda railway was begun at Mombasa in 1895; the site of the present city of Nairobi was reached in 1899 and Kisumu. on Lake Victoria, in 1901. Kampala, the commercial centre of Uganda, was linked with the coast (871 mi.) in 1931 following the completion of a line around the north shore of Lake Victoria and the bridging of the Nile at Jinja. Subsequently, extensions were made to Mityana (1953), Kabagole (1955) and Kasese (1956).

The first line in the Tanganyikan section was completed in 1911, between Tanga and Moshi. The Dar es Salaam line was constructed between 1905 and 1914. A branch from Tabora and Mwanza, on Lake Victoria. was built between 1925 and 1928, after the country came under British mandate. Steam traction predominates, although some diesel locomotives have been introduced.

In 1947 the Southern Rhodesian government purchased the railroad systems in Northern and Southern Rhodesia and the Bechuanaland Protectorate There are connections with the Congo railway, the Beira railway (Mozambique) and the South African railways. The railway was making grouing use of centralized traffic control and it also operated 2,000-h.p. diesel-electric locomotives, some of the most powerful units ever built for 3-ft. 6-in. gauge tracks.

In the Republic of The Congo the principal lines are operated by the Compagnie du Chemin de Fer du Bas-Congo au Katanga (B.C.K.). The first lines to be built were from Sakania to Bukama (1910 to 1918) and Port Francqui to Bukama (1923–28). The Tenke-Dilolo line was started in 1928 and completed in 1931. Another line from Kamina to Kabongo links the B.C.K. with the Compagnie des C. de F. du Congo Supérieur aux Grands Lacs Africains (C.F L.). The C F.L. has 596 route miles of 3-ft. 6-in. gauge track from Albertville to Kabalo and Kabongo and from Kabalo to Kindu. A separate 78-mi. metre-gauge line runs from Ponthierville to Stanleyville.

Other 3-ft. 6-in. gauge systems are to be found in Nigeria, Nyasaland, Sudan. Republic of Congo, Ghana and Angola. The majority of the remaining systems are of metre gauge. In former French West Africa ([1] Senegal to Mali; [2] Guinea; [3] Ivory Coast; and [4] Dahomey) there are four lines of this gauge, totaling 2,542 mi., all operated entirely uith diesel traction. The railway system in Ethiopia is also metre gauge. The building of the main line from Djibouti on the coast of French Somaliland began in 1897 and reached Addis Ababa in 1917.

3. Northern Africa. — Egypt, the scene of the first railroad in Africa, by the 1960s had an extensive standard-gauge system extending to 2.967 mi., with some narrow-gauge mileage as well. There was also a considerable amount of standard-gauge mileage in north Africa. Post-World War II developments included extensive modernization and the virtual replacement of steam traction by diesel and electric power. There were also other lines of narroner gauges in the country, some of which were being converted to standard gauge.

H. Australasian Railways

1. Australia. — The first railway to be operated by steam traction in Australasia was a 2-mi. line from Flinders street, Melbourne, to Sandridge (now Port Melbourne). It was built by the Melbourne and Hobson's Bay Railway company and opened on Sept. 12. 1854. In the following year a second line was opened in New South Wales. Construction was originally in the hands of two private companies, but mhen they experienced financial difficulties they were bought out by the N.S.W. government. The first steam railway in South Australia was opened in 1856. It was 74 mi. long, of 5-ft. 3-in. gauge, and ran between Adelaide and Port Adelaide. Other parts of Australia did not have the benefits of rail transportation until later.

Unfortunately, in the early days of development each state laid down tracks in whatever gauge it considered most suitable to its needs and finances. Only one state, New South Wales, chose the standard 4-ft. 84-in. gauge. Victoria and South Australia selected a broad gauge of 5 ft. 3 in. and Queensland and Western Australia chose the narrow 3-ft. 6-in. gauge. This means that freight often has to be transshipped and passengers transferred from a train of one gauge to that of another.

In later years the Commonwealth Government railways built several standard-gauge lines, the longest being the Trans-Australian railway from Port Pirie, South Australia, to Kalgoorlie, Western Australia, a distance of 1,108 mi. A feature of this line is one track length of 300 mi. without a curve, said to be unique in the world.

After World War II, efforts were made to standardize gauges, but progress was slow. Adding to the gauge problems were those of long distances, sparse population and large concentrations of population in a few large cities.

By 1960, all the principal railway systems were state or government owned, there being only one of any size (the Midland Railway company of Western Australia) which remained in private hands.

The Commonwealth Government railways was unusual in Australia in that it was operating profitably, largely because of the adoption of diesel-electric traction. Piggyback transport (road trailers and semitrailers carried on flat wagons) and container traffic also were introduced on the Trans-Australian route to overcome break-of-gauge delays.

2. New Zealand. — In New Zealand the first railway to be operated with steam traction was opened on Dec. 1, 1863, between Christchurch and Ferrymead. It had a gauge of 5 ft. 3 in.

Following the start of this line, numerous others were built by the different provincial governments. These were of various gauges, but in 1870 an act of the general government stated that all future construction should be of 3-ft. 6-in. gauge. In 1876 the provincial governments were abolished and their railways were taken over by the general government and the lines gradually converted to a uniform 3-ft. 6-in. gauge. Between 1885 and 1908 various private railways also were taken over.

The system was faced with strong competition from air and road transport, and in 1958 it had a working loss of £1,140,000. In the 1960s, emphasis was on increased use of diesel power. the installation of long welded rail, increased use of centralized traffic control and the completion (in 1955) of the $5\frac{1}{4}$-mi. Rimutaka tunnel. An unusual operation was the rail-air freight service between the two islands.

The general trend in Australasia was toward the adoption of more modern equipment (particularly diesel traction), electrification where traffic justified it, and improved passenger and freight rolling stock.

II. TRACK AND ROADWAY

1. Railway Location.—Ideally, a railway should be built in a straight line, over level ground, between large centres of trade and travel. In practice, this ideal is rarely approached. In planning. the location engineer must balance the cost of construction against annual maintenance and operating costs, as well as against the probable tonnage to be carried and the revenue it mill produce.

Thus, railways in areas of dense population and heavy industrial activity have generally been built for heavy duty—with minimum grades and curvature, heavy bridges and perhaps multiple tracks. This mas so in the case of most of the main-line railways of Britain and continental Europe. In sparsely settled country; as in much of the United States during the 19th century. as well as in Canada and South America, railways were built to minimize initial construction costs. As a result, the lines had sharper grades and curves, and were generally of lighter construction. As traffic grew, the main routes were later improved to increase their capacity and reduce operating costs.

2. Gauge.—One of the main cost determinants is the gauge, or distance between the inside faces of the running rails. Generally, the narrower the gauge the less costly is the line to construct and equip. This explains why many of the railways in underdeveloped, sparsely settled countries have been built to narrow gauges. On a narrow-gauge line, curvature can be more severe, less space is required and over-all construction can be lighter. Disadvantages are the limitation of speed because of reduced lateral stability and limitations in the size of locomotives and rolling stock.

Track gauges vary throughout the world from less than 2 ft. to 5 ft. 6 in., and in the past have been as wide as 7 ft.

About 60% of the world's railway mileage is of so-called standard gauge, which measures 4 ft. $8\frac{1}{2}$ in. It is not clear how this odd width originated. One of many suggested possibilities is that it evolved from the wheel spacing of vehicles used on early English wagonways or tramways, which were the predecessors of the modern railway.

Standard gauge got its foothold in North America through the English locomotives imported for some of the earliest U.S. lines. Today, nearly all the railway mileage in North America is standard gauge, although in the early years many lines were built in both wider and narrower sizes.

In Central and South America are to be found extremes ranging from 1 ft. $11\frac{5}{8}$ in. to 5 ft. 6 in. The majority is narrow gauge, although many countries have systems in different gauges—a legacy of unco-ordinated development. Standard gauge, or a width so nearly identical as to allow the through running of vehicles, is found in most of Europe, excepting Finland and Russia (5 ft.), Ireland (5 ft. 3 in.) and Spain and Portugal (5 ft. 6 in.). A considerable mileage of narrow gauges—including metre (39.37 in.), 2 ft. 6 in. and 1 ft. $11\frac{5}{8}$ in.—also exists on the continent of Europe, particularly in Germany, Austria, Spain and Switzerland.

In Africa the principal gauges are 3 ft. 6 in. and 1 m. India and Pakistan both have extensive 5-ft. 6-in. broad-gauge systems, together with a large metre-gauge mileage and narrow-gauge lines

*Predominant ownership is given; most countries have both private and state-owned lines.
†Gauge of the principal mileage; most countries have lines of several gauges.
‡Data are for the late 1950s.

of 2 ft. and 2 ft. 6 in. The lines of the Japanese National railways, which make up most of the mileage in Japan, are all of 3-ft. 6-in. gauge. That country also has a number of short. privately owned railways, some of which are standard gauge, as well as 3 ft. 6 in. The Chinese railways, on the other hand, are laid largely to standard gauge, although there is some 5 ft. and narrow gauge as well. New Zealand employs a gauge of 3 ft. 6 in., but Australia has major networks in three different gauges: 3 ft. 6 in., 4 ft. $8\frac{1}{2}$ in. and 5 ft. 3 in.

The benefits of a uniform gauge were recognized early. It permits free interchange of cars between various railway lines, thus speeding the flow of commerce and, of course, greatly reducing the over-all cost of transporting goods and people. Only because of this virtual uniformity of railway gauge in North America was the railway able to play the dominant role in the settling and development of that continent. Conversely, in areas where uniformity of gauge has not been achieved, such as South America and Australia, development of the railways—and consequently the economic growth of the countries they serve—has been correspondingly slowed.

The principal gauges in use in major countries are shown in Table II. The total route length of all railways throughout the world is 781,000 mi., divided approximately as follows: North America, 36% ; Europe, 34% ; Asia, 12% ; Central and South America, 8% ; Africa, 6% ; Australia and New Zealand, 4%.

3. Rail.—Railway track as we know it originated in the plateways used in English coal mines, consisting of squared timbers on top of which iron plates were fastened. The earliest examples of iron rail were L-shaped, the upright portion keeping the flangeless wagon wheels running on the flat baseplate. From this developed the I-shaped rail which was carried in pedestals or chairs, these in turn being secured to stone blocks or, later, wooden sleepers or crossties. The rails were retained in position in the chairs with the aid of oak keys.

The I-shaped rail led to the bullhead rail, in which the head was of greater area than the foot. The use of this rail in conjunction with chairs attached to wooden ties became the standard for the British railway systems until 1949; the weight of rail for main lines was 95 lb. per yard arid the length 60 ft. After 1949, British railways were converting to a standard flat-bottomed rail weighing 109 lb. per yard.

In the 1830s a French engineer, Charles Vignoles, invented the flat bottomed rail, which was like an inverted T. It was spiked direct to the tie, which made for simple and inexpensive construction. A further refinement was the introduction, in 1847, of the fishplate nhich joined the outer ends of the rails together. This stopped the movement of the rail ends beyond the tie.

The majority of continental railways and those in other areas adopted the flat-bottomed rail from the beginning. The standard rail length in Europe is 30 m. (98 ft. 5 in.) and the weight, for main line use, is 118.8 lb. per meter, or about 109 lb. per yard.

Some of the earliest U.S. railways used iron rails shaped like an inverted U, but since iron had to be imported from England, it was very costly. A more common and much less expensive type of construction involved the use of iron straps fastened to the tops of longitudinal wooden stringers. The main problem with these iron straps mas their often-disastrous tendency to break loose and slash up through the floors of passing cars.

The modern type of track, using the flat-bottomed T rail on wood crossties or sleepers, was tried in the U.S. as early as 1831. The Camden and Amboy Railroad and Transportation company used iron T rails designed by its president, Robert L. Stevens. At first they mere attached, with spikes much like those used today, into wooden plugs inserted in stone blocks. Later, during a shortage of the stone blocks, the rails were spiked direct to wooden ties in order to keep the construction going. The emergency wood ties proved far superior. The track was more flexible; it held up better, gave a smoother ride and was much easier on the rolling stock.

It was not long before most of the railways in the U.S. began using this type of construction, although it did not become standard until about 1850 (as late as 1848 the Galena and Chicago Union railroad laid some strap-iron track). Iron rails were used in the U.S. until 1865. when rails of Bessemer steel made their appearance. By the early 1900s U.S. railways were using open-hearth steel rails, which soon largely supplanted Bessemer steel.

Although present-day rail is, in appearance. similar to the early designs of Stevens and Vignoles, it is actually a highly refined product in terms of both engineering and metallurgy. Much study and research have produced rail designs that minimize internal stresses under the neight of traffic, and thus prolong rail life. After they have been rolled at the steel mills, rails are allowed to cool slowly in special cooling boxes. This controlled cooling minimizes internal shatter cracks which at one time were a major cause of broken rails in track.

Hundreds of different rail cross sections were designed for U.S. and Canadian railways. and most of the larger lines used sections of their own design. Many of these rail sections are still in use, but there developed a strong trend toward standardizing on a few sections. The bulk of the new rail being purchased in the 1960s in North America was of sections weighing 100, 106, 115. 119, 132, 136 or 140 lb. per yard. The American Railway Engineering association was studying the possibility of standardizing on perhaps three or four rails of varying sizes for different traffic conditions. The standard U.S. rail length is 39 ft.

In general, lighter rail sections are used in countries outside the U.S. and Canada. This is partly because in most other countries the railways use lighter rolling stock; in some it is also due to traffic conditions or the need for economy in building the railways. Rail sections varying from 36 to 75 lb. per yard are common in South America. In Japan, 110-lb. rail, or heavier, is used on dense traffic lines, but there is much mileage of lighter rails in service.

Rail Fittings.—As rolling stock became heavier, railways found that under heavy traffic the rails tended to dig into the crossties, thus shortening the life of ties and making it difficult to maintain proper gauge and track alignment. To overcome this difficulty, tie plates are used between the base of the rail and the top of the tie. These plates (they may be up to 14 or 16 in. long on U.S. heavy traffic lines) distribute the load over more of the tie area. In some cases a resilient tie pad of rubber or a similar material is used between the tie plate and the tie.

The standard spike. with offset head, is still the most used fastening. It is driven through holes in the tie plates. In some cases railways have used special types of fastenings, including screw spikes and compression clips. These do an excellent job for critical locations, as on sharp curves or bridges, but they are considered too expensive for general use in the United States. Bolts or clips are used extensively in Europe.

Welded Rail.—One of the most important developments was the welding of rail into long lengths. This continuous welded rail increases travel comfort and saves maintenance. The rail is usually welded into lengths of up to a half-mile. In a few cases these lengths have, in turn, been welded together to produce rails several miles long without a break.

Welded rail was first tried in 1933 by the Delaware and Hudson railroad in the U.S. This line had laid 30-odd miles of continuous rail by 1939. It was not until the decade of the 1950s, however, that U.S. railways began to turn to melded rail in earnest. By 1960 about 1,000 mi. of long rails were being laid annually, and about 1% of all U.S railway mileage consisted of welded rail. In the 1950s. the French railways alone laid over 3,000 mi. of long welded track and it was also being standardized in Britain. Japan and other countries also were adopting melded rail.

Controlling the temperature expansion of long welded rails proved not so difficult as was first thought. It was found that the problem can be minimized by extensive anchorage of the rails against the ties to prevent them from moving when the temperature changes, and by laying the rails when the ambient temperature is close to the mean temperature prevailing in the particular locality. In France and some other countries, beveled expansion joints, in appearance somewhat like switch points, are sometimes provided at the ends of long welded rails.

4. Crossties (Sleepers).—Although timber is still the commonest tie material, both steel and concrete are also used. Steel ties are common in certain European countries, notably Switzerland, and they have also been adopted by a number of African and Asian systems. Concrete ties gained in popularity after initial stressing problems were overcome. Both prestressed and post-stressed types are in use, as well as concrete ties and concrete blocks joined by metal spacing bars. A combination of concrete ties and long nelded rail is said to produce an especially solid form of track.

With concrete ties, the resilience of wood, is, of course, lost. To avoid excessive pounding of both the tie and rolling stock, some form of cushioning pad, of rubber or similar material, is always used between the tie plate and the concrete ties. Bolts or clips are used to fasten the rail to the tie.

Methods of treating wooden ties with preservative chemicals (usually creosote) were improved to a degree that the average life of crossties in the U.S. increased to more than 30 years. Nevertheless, the cost of wooden ties rose steadily, thus creating some interest in ties made of substitute materials. In the early 1960s several U.S. railways, notably the Atlantic Coast Line railroad and the Seaboard Air Line railroad, placed in service experimental sections of track laid with prestressed concrete ties.

5. Roadbed.—Early U.S. railways often were constructed as cheaply as possible. This meant that they usually followed the contour of the ground; earth cuts and fills, where required, were minimized. Railways built in this way often have steep grades and sharp curves, features that greatly increase operating costs and restrict train length and speed. With the advent of modern high-capacity earth-moving machinery (developed primarily for highway construction) railways were able in many cases to eliminate the old adverse grades and curves through line changes. Graders, bulldozers and similar equipment make it practicable to dig deeper cuts through hillsides and to make higher fills where necessary in order to smooth out the profile of the track, and to do this at a

reasonable cost.

Modern equipment also helped railways improve their existing roadbeds, even where major changes were not required. For instance, a number of railways carried out ditching programs, in which the drainage ditches on each side of the right of way were deepened, thus improving drainage and increasing the stability of the roadbed. Where roadbed conditions are unstable, railways often find that it pays to remove the unstable material and replace it with filler material from another location. Stabilizing of the subgrade by injecting concrete grout under pressure is another widely used technique. In planning roadbed improvements, as well as in new construction. railways turned to modern soil engineering techniques (see SOIL MECHANICS).

The first step in building a new railway line, after the route has been surveyed and cleared of brush and trees, is to grade the right of may, much as is done in building a highway. Next. ballast (usually crushed rock, slag or volcanic ash) is applied and the track laid on top of this foundation. When the track has been laid the final ballasting is done and the track is carefully aligned in both the vertical and horizontal planes.

In Canada, where much new railway mileage was built in the years following World War II, track-laying machines are often used. A track-laying machine, mounted on rail cars, feeds ties and rails ahead of the working crew, moving forward over the new track as soon as it is spiked down.

6. Track Maintenance.— Until after World War II, the system of section maintenance—descended from the early days of railways—remained standard in the U.S. and Canada. The typical section was only a few miles in length. It was under the supervision of a section foreman and a gang which might vary in size from 4 to 12 men. They had only a few hand tools. However, because of rapidly rising labour costs. the pressure to develop more economical track maintenance methods became intense.

With modern techniques, a small mechanized force of men can maintain a long stretch of track to high standards. Machines are available to do all the necessary track and maintenance jobs: removing and inserting ties, tamping ballast. spiking rail, tightening joint-bar bolts and leveling and aligning the track. Mechanized forces also can renew rail. either in conventional bolted lengths or with continuous welded lengths; they use cranes to remove the old rail and lay the new. Gauging, spiking and bolt-tightening devices complete the installation.

Ballast-cleaning machines pick up old ballast, sift it, reject oversize or undersize stones, and replace it. Tamping machines consolidate ballast beneath the ties, thus improving running conditions. Scarifiers break up hard, compressed ballast. Complete sections of track—rails and crossties—may be prefabricated at a central shop and then laid on the site by mechanical means.

Rail grinding machines are used to even out irregularities that occur on the running surface of rails. For checking any irregularities in track alignment, other machines are capable of testing for gauge, curvature, etc., while in motion, the results being recorded on moving charts. So-called detector cars. equipped with electronic inspection apparatus, move over main-line tracks periodically to locate any internal flaws in the rails that might cause them to break under the stress of traffic.

Mechanization reduced the number of track and roadway maintenance workers in the U S by about one-half in 15 years following World War II. It constituted a major technological revolution. Improved and more automatic maintenance machines were constantly being developed, and U.S. railways were adopting new construction techniques that promised to reduce the amount of maintenance that the track structure requires. The trend to mechanization of track and roadway work was evident also in many other countries, but in most, mechanization was less advanced. largely because labour costs were not as high as in the United States.

III. LOCOMOTIVES

Although some of the earliest railways used horses for motive power, it was only the development of practical locomotives that permitted railways to become efficient arteries of volume transportation.

Normally the term locomotive refers to a separate unit incorporating nothing more than the machinery to generate (or, in the case of an electric locomotive, to convert) power. However, motive power can also be incorporated in a vehicle equipped with passenger or baggage accommodations, or both Broadly speaking, there are three sources of power for a locomotive: steam, oil and electricity. Steam was the earliest form of propulsion and was in universal use for over 100 years. but after World War II the popularity of the steam locomotive daindled in favour of diesel and electric traction, which are more efficient.

The steam locomotive is a self-sufficient unit, carrying its own water supply for steam generation and either coal, oil or wood for heating the boiler. The diesel locomotive also carries its own fuel oil supply, but because of the characteristics of the diesel engine, direct drive to the wheels is not employed. Instead, mechanical, hydraulic or electric transmission is used; with the last. the diesel engine drives a generator to produce electric power and this, in turn, is fed to traction motors that propel the vehicle.

With electric traction the locomotive is not normally self-sufficient. As the locomotive moves along the track, electric current is picked up from either an overhead conductor wire or a third rail mounted alongside the running rails. The only self-sufficient examples are battery-driven electric locomotives and rail cars, which are not widely used. The only other category of motive power is the turbine locomotive—either the turbo-diesel or the gas turbine. Both use oil fuel and have electric, hydraulic or mechanical transmission.

A. STEAM LOCOMOTIVES

It was George Stephenson's "Rocket"—winner of the Liverpool and Manchester railway's competition of 1829—that ensured a place for the steam locomotive as a means of propulsion and the railway as a means of transport. The success of the "Rocket" was attributed to its multitube boiler and its more efficient system for exhausting the steam and creating a draft in the firebox. basic features that continued to be used in the steam locomotive. The principal characteristics of the "Rocket" were a boiler pressure of 50 pounds per square inch (p.s.i.); cylinders $8 \times 16\frac{1}{2}$ in.; one pair of driving wheels, 4 ft. 83 in. in diameter; and a total weight of about 9,500 lb.

The number of coupled drive wheels soon increased. After the "Rocket," with its single pair of driving wheels, came the four-

coupled locomotive. followed by the six-coupled. The number of coupled wheels grew to a maximum of 14, a locomotive with this remarkable number being built in Russia. Additional wheels of smaller diameter are often provided ahead of and behind the coupled wheels. The pilot wheels ahead of the coupled wheels fulfill various functions, the principal one being to assist in guiding the coupled wheels around curves. The pilot wheels usually consist of two on a single axle or four on two axles. Those to the rear of the coupled wheels normally support the weight of the firebox, enabling it to be larger than if it had to be accommodated between the last pair of coupled wheels. (Common wheel arrangements, and methods of designating them, are shown in Table III.)

Steam locomotive driving wheels are of various diameters, usually larger on passenger locomotives and smaller on freight locomotives. In Europe the average is between 66 and 78 in. for express passenger engines and 54 and 66 in. for freight or mixed-traffic types. Typical locomotives built in the U.S. just before the end of the steam era had drivers ranging from 60 to 84 in. in diameter. At one time it was thought that locomotives with small coupled uheels could not be operated at high speeds, but this later was disproved; for example, 2-10-0's with 5-ft. diameter wheels have been run at 90 m.p.h.

Supplies of coal and water can be carried on the locomotive frame itself (in which case it is called a tank engine) or may be carried in a separate vehicle (the tender) attached to the locomotive; the latter arrangement allows far greater supplies of fuel to be carried. The average capacity of a tender of a European main-line locomotive is 10 tons of coal and 8,000 gal. of water. In Russia and on some African, Asian and Australian systems higher capacities are common. The tender for a typical large U.S. steam locomotive of the World War II period was carried on 14 wheels and had a capacity of 28 tons of coal and 25.000 gal, of water.

1. U.S. Locomotives. — In relatively short order, steam locomotives in the U.S. evolved to the general type that became known as the American Standard. It had horizontal fire-tube boiler, a four-wheel pilot truck to steady and guide the front of the locomotive, and four coupled driving wheels. This 4-4-0 type was used in the U.S. for all kinds of services; it dominated U.S. railroading until well after the American Civil War period. In fact, many 4-4-0's were still in service by the early years of the 20th century.

Nevertheless, to meet the needs of heavy freight traffic, other types of locomotives with more (and usually smaller) drive wheels were developed. Common were the Mogul (2-6-O), the Consolidation (2-8-0) and the Mikado (2-8-2). A type used by a few railroads was the 2-12-2, which had 12 coupled drive wheels. In the late years of steam locomotive development, still greater tractive effort was obtained by using two separate engine units under a common boiler. These articulated locomotives culminated in the Union Pacific's famous "Big Boy," said to be the largest steam locomotive ever built. Used in mountain freight service, "Big Boy" was an articulated 4-8-8-4 type which weighed nearly 600 tons. It could exert 133,575 lb. of tractive force and developed over 6.000 h.p. at 75 m.p.h.

2. Articulated Locomotives. — Articulated designs have also been produced in other countries. One of the best known is the Beyer-Garratt, in which there are two frames, each having its own driving wheels and cylinders, surmounted by water tanks. Separating the two chassis is a further frame carrying the boiler, cab and coal or fuel oil supplies. This type of locomotive is of particular value on tracks which permit only light axle loads, as the weight is spread over a considerable distance. Also, the Garratt can negotiate sharp curves. It is widely used in Africa.

Another form of articulation is the Mallet, in which there is a long rigid frame, below which are two sets of driving wheels each with its own set of cylinders. The rear driving wheels are frame mounted, but the leading ones are pivoted. The name Mallet is taken from the Swiss engineer, Anatole Mallet, who devised the layout for use with compound propulsion.

Simple-expansion steam locomotives can be equipped with two or more cylinders and. especially in Britain, three- and four-cylinder locomotives are common. For double expansion or compounding. more than two cylinders are mandatory. In this system, steam goes first to one or two small cylinders and then to two larger cylinders before being exhausted into the atmosphere; thus it is expanded or used twice, resulting in greater thermal efficiency. In Europe, compound locomotives were most popular in France, where for many years the majority of the designs were of this type.

3. Modern Types. — Typical of modern steam locomotives is the French railways 2-4-1 P class (4-8-2), a four-cylinder compound engine with 794-in. drivers, a boiler pressure of 290 p.s.i. and tractive effort of 45,084 lb. The South African railways class 25 (4-8-4) has two cylinders, 60-in. driving wheels and develops 51,400 lb. of tractive effort. The Indian Government railways class WG (2-8-2) has 614-in. driving wheels and develops 38,890 lb. of tractive effort. The British railways "West Country" class (4-6-2) has three cylinders, 74-in. drivers and can produce 27,720 lb. of tractive effort. Total weights of these engines, with tenders, range from 288,000 to 498,000 lb.

Typical of latter-day U.S. steam passenger locomotives were the Pacific (4-6-2) type and the Hudson or Baltic (4-6-4), which could haul heavy trains at high speeds. The Mountain (4-8-2) and Northern (4-8-4) types were logical further developments in passenger train power. The New York Central's Niagara 4-8-4 represented perhaps the highest state of development in passenger locomotives; this locomotive (also used in high-speed freight service) had a tractive force of 61,500 lb. and developed 4,850 h.p. at 65 m.p.h.

Various refinements gradually improved the reciprocating steam locomotive. Some of these included higher boiler pressures (up to 290 p.s.i. in France and up to 310 p.s.i. for some of the last U.S. locomotives), superheating, feed-water preheating. roller bearings and the use of poppet valves instead of the sliding piston valve. Nevertheless, the thermal efficiency of even the best modern steam locomotives seldom exceeds about 6%. Incomplete combustion, heat losses from the firebox, stack, boiler and cylinders, and other losses dissipate most of the energy of the fuel burned. In terms of modern technology, the reciprocating steam locomotive is obsolete. Yet it has its good points, not the least of which are its simplicity and ability to withstand abuse. See also STEAM.

B. ELECTRIC LOCOMOTIVES

The first challenge to the supremacy of steam came from the electric locomotive. Although efforts to propel railway vehicles using batteries date back to 1835, the first successful application of electric traction was in 1879, when a locomotive designed by Werner von Siemens mas operated at an exhibition in Berlin. In 1881 the first public electric railway commenced operation at Lichterfelde, near Berlin, while in 1883 the first part of Magnus Volk's electric railway at Brighton, Eng., was opened. Another early electric line was the City and South London railway between King William street and Stockwell. This was opened in 1890 and was the first electric underground railway. The initial applications of electric traction were for suburban or metropolitan railways such as those in Berlin, Budapest, Paris and London (see ELECTRIC TRACTION). In 1895 the B. & O. electrified a stretch of track in Baltimore to avoid smoke and noise problems in a tunnel, marking the first use of electrification by a steam railway in the U.S.

One of the first countries to use electric traction for main-line purposes was Italy, where a three-phase, 3,000-v. system was inaugurated in 1902. In the same year, some remarkable experiments were carried out on an experimental line near Berlin, where an electric train achieved a speed of 130.4 m.p.h.

By 1906, a number of electrified lines were operating all over Europe and a start had been made on major electrification schemes. Of these, the most extensive was in Switzerland, where large-scale electrification started at the end of World War I. Other countries that began extensive electrification in the 1920s were Sweden, Germany and Austria. All of these, together with Norway, made use of the same system: 15,000-v., 163-cycle, single-phase A.C. In other countries, direct current was preferred, although Italy electrified a considerable mileage with 3,700-v., 163-cycle, three-phase AC. The use of the overhead conductor wire was almost universal, except for suburban lines and the Southern railway in Britain. By the end of the 1920s nearly every European country had at least a small percentage of electrified track. Electric traction was also introduced in Australia (1919), New Zealand (1923), India (1925), Indonesia (1925) and South Africa (1926).

Following the pioneer B. & O. tunnel electrification, a number of other terminals in the U.S. (such as the New York Central's Grand Central terminal in New York city) and difficult mountain segments of main lines were electrified. Some of these relatively small electrifications were later removed with the advent of the diesel-electric locomotive.

In the 1960s, the only major line-of-road electrifications in the U.S. were on the Pennsylvania railroad (about 671 route miles between New York and Washington, D.C., and between Philadelphia and Harrisburg, Pa.) and on the Milwaukee road in Montana, Idaho and Washington (about 660 mi.). There were also a 134-mi. main-line electrification on the Norfolk and Western railway, and 106 mi. of electrified line on the New York, New Haven and Hartford railroad.

The suburban passenger services of several U.S. and Canadian railways were electrified, including the Canadian National at Montreal, the Long Island and the Erie-Lackawanna railways around New York city, and the Illinois Central at Chicago. Several South American countries have small mileages of electrified track. notably Brazil. About 11% of the route mileage of the Japanese National railways is electrified.

Following World War II, electrification was greatly extended in Europe in a comparatively few years, while there was also expansion in Africa, Asia and Australasia.

1. Advantages and Disadvantages.— Electric traction is generally accepted as the most economical and efficient means of operating a railway, providing that the traffic justifies the capital expenditure and that cheap electricity is available.

Being simply power-converting, rather than power-generating, devices, electric locomotives have several very real advantages. Since they draw on the resources of the central power plant, they can develop power greatly in excess of their nominal ratings to start a heavy train or surmount a steep grade. A typical modern electric locomotive rated at 4,000 h.p. has been observed to develop as much as 10,000 h.p. for a short period under these conditions.

Moreover, electric locomotives are quieter in operation than other types, they produce no smoke or fumes, they accelerate rapidly: and they are completely predictable in performance. Electric locomotives have a high availability factor (that is, they require little time in the shop for maintenance) and, because of their relatively simple construction, the cost of maintaining them is low. It also appears that electric locomotives have a longer economic life than do diesel electrics.

The greatest drawback to electrified operation is the high capital investment and the maintenance expense of the fixed plant—the trolley wires and structures, power substations and associated equipment. A less important disadvantage is the lack of flexibility of electric motive power: it cannot operate where there are no trolley wires.

Electric operation is most suited to railway systems carrying very dense traffic; this is the basic reason why it made rapid headway in many European countries. In Japan, too, further electrification seemed inevitable as a means of more economically handling the extremely heavy traffic that characterizes the Japanese railways.

2. Types of Systems. — Electric traction systems can be broadly divided into those using alternating current (A.C.) and those using direct current (D.C.). With D.C., the most popular line voltages are 1,500 and 3,000, although there is a large mileage in southeast England of 600 v., and several systems in the 600–700 v. range around New York city. The disadvantages of D.C. are that expensive substations are required at frequent intervals and the overhead wire or third rail must be relatively large and heavy. Thus, a very high density of traffic is necessary to justify the cost of this form of electrification.

However, the low-voltage, series-wound D.C. motor is well suited to traction purposes, being simple to construct and easily controlled. Typical of modern locomotives for D.C. operation is the French railways 1,500-v. 9200 series, weighing 82 tons and developing 5,200 h.p. It was on a line equipped with the 1.500-v. D.C. system that, in March 1955, two different types of French locomotives achieved a speed of 205 m.p.h.

Single-phase A.C. at $16\frac{2}{3}$ cycles per second (c.p.s.) is also widely used by a number of European systems. With this system, substations do not need to be so numerous nor does the power transmission equipment need to be so substantial. Its application has been bound up with the lengthy development of the A.C. commutator motor. Initial A.C. electrification was on the three-phase system and the first practical application was on the Burgdorf-Thun railway in Switzerland in 1899, using a line voltage of 750. The first trial with a single-phase supply was on the Seebach-Wettingen line in Switzerland in 1907. The Berne-Lötschberg-Simplon, another Swiss system, was the first railway to be operated on single-phase, 165-cycle A.C., at a line voltage of 15,000, throughout its length (1910–1913) and this type of power was subsequently adopted by the Swiss Federal railways.

In the United States, single-phase A.C. at 25 cycles was used on a number of the main-line electrifications. The Pennsylvania, the New Haven, and the Norfolk and Western (on the former Virginian railway) systems are of this type.

Quite early in the development of electric traction the question of using alternating current at the industrial or commercial frequency (50 c.p.s. in Europe, 60 in the U.S.) was considered. Use of commercial-frequency A.C. means that current can be obtained from the commercial supply network, eliminating the need for the railways to generate and distribute their own power. The overhead contact wire can be much lighter, far fewer substations are necessary, and therefore lines with a lower density of traffic can be electrified on a profitable basis. Initial experiments with 50-cycle A.C. were carried out in Hungary in 1933, using a line voltage of 16.000. In the same year the German State railways decided to experiment on the Hollental branch with this form of electrification, using a line voltage of 20,000.

TABLE IV.—Designations of Wheel Arrangements of Diesel and Electric Locomotives

Symbol	Wheel Arrangement (front to back)	Description
A1A-A1A	○ o ○–○ o ○	Single-unit locomotive with two six-vheel trucks, each with centre idler axle.
B-B	○ ○–○ ○	Single-unit locomotive with two four-wheel trucks, all axles driven.
C-C	○ ○ ○–○ ○ ○	Single-unit locomotive with two six-wheel trucks, all axles driven.
2+(B-B)	○ ○–○ ○ + ○ ○–○ ○	Two-unit locomotive, each with two four-wheel trucks, all axles driven, units joined with articulated connection.
2-C+C-2	o o ○ ○ ○ - ○ ○ ○ o o	Electric locomotive with four-wheel leading and trailing (idler) trucks; six driven axles in two frames with articulated connection between frames.

In 1945, Louis Armand, former president of French railways, set up a commission to study 50-cycle operation on the Hollental line. As a result, French railways pressed forward with the further development of 50-cycle electrification, converting a line between Aix-les-Bains and La Roche-sur-Foron for their first practical experiments. This was so successful that in 1952 it was decided to electrify a network of lines in northeast France using 25,000-v., 50-cycle? single-phase A.C. Subsequently, a number of other countries adopted 50-cycle electrification, including Britain, Turkey, Portugal, Russia, India, the Belgian Congo, China, Japan and Argentina.

With the commercial-frequency A.C. system, there are three ways of taking power to the driving wheels: (1) employ a rotary converter or static rectifier to convert the A.C. supply to D.C. to drive D.C. traction motors; (2) use a phase converter to produce three-phase, variable-frequency current to drive A.C. motors; (3) make direct use of A.C. traction motors. The first method, using mercury-arc, germanium or silicon rectifiers, is the most popular.

The problem of international operation of electric locomotives in Europe was increased by the variety of electrification systems there. It was partially overcome by the construction of multi-voltage and multi-frequency locomotives. A similar problem exists in New York city, where the New Haven railroad operates into Grand Central terminal via the New York Central's 660-v., D.C. electrified system. The New Haven electric locomotives can operate either on 660-v. D.C. or 11,000-v., 25-cycle A.C. The New Haven also operates unique electric-diesel electrics. When in Grand Central terminal these locomotives operate from the 660-v. third rail; at all other times their trection motors are supplied from a standard diesel-electric engine-generator set carried on the locomotive.

Although electrification had made little headway in the U.S. up to mid-century, several factors were at work that showed promise of resulting in further electrification in the future. These included the demand for faster freight trains, the rising costs of diesel fuel, and a trend toward mergers that would tend to increase traffic density on the surviving lines. There was also the possibility of reducing fixed-plant costs through the use of the high-voltage. commercial-frequency system that has proved so successful in Europe and in Japan.

C. Diesel-Electric Locomotives

By the 1960s the diesel-electric locomotive had almost completely superseded the steam locomotive as the standard railway motive power in North America, and it was gaining rapidly in most other parts of the world. As the decade began, the Norfolk and Western railway, the last major C.S. system to continue steam operation, had completed its dieselization and was retiring its great steam locomotives, said by many to have been the most efficient steam motive power ever operated. In short, the railways of the U.S. in just 25 years, completely replaced the steam locomotive—which had been standard for 100 years—with the diesel electric. Actually, most of this change was accomplished in an even shorter period: as late as 1951 U.S. railways had more steam locomotives than diesel-electrics in service.

What caused the diesel electric to supersede the faithful steam locomotive so rapidly? Briefly, the pressure of competition from other modes of transport, and the continuing rise in wage costs, forced the railways to improve their services and to adopt every possible measure to increase operating efficiency. Compared with the steam locomotive, the diesel electric (or simply, the diesel) has a number of major advantages. For instance:

It can operate for long periods with relatively little down time for maintenance. This high availability makes it possible for diesels to operate through on a run 2,000 miles or more in length and then, after brief servicing, to start the return trip. Steam locomotives must be serviced after only a few hours in operation, and thus they are limited to relatively short runs.

The diesel uses less fuel than a steam locomotive (its thermal efficiency is about four times as great).

It can accelerate a train more rapidly and run at higher sustained speeds with less damage to the track structure.

These are the major points at which the diesel excels. It is also superior to the steam locomotive because of its smoother acceleration, greater cleanliness, standardized repair parts and operating flexibility (a number of diesel units can be combined and run by one man under multiple-unit [MU] control). With diesels. too, there is no problem of supplying large quantities of boiler feed water; there is no loss of power capability in cold weather; and there is less stand-by cost, since the locomotive can be completely shut down when not in use.

Because of advantages such as these, most U.S. railways found that diesel locomotives quickly paid for themselves, despite their relatively high initial cost. It is no exaggeration to say that without the diesel locomotive the U.S. railways could not have continued solvent under private operation, as they had up to the beginning of the 1960s.

1. Early Diesel Development.— The earliest patent for an oil-engine using the compression-ignition principle was granted in 1890 to a British pioneer, Akroyd Stuart. A small locomotive incorporating an engine of Stuart's design was built by Hornsby and Sons in 1896. The first patent for a compression-ignition engine was granted to the German engineer Rudolf Diesel in 1894, and the first engine to be built in accordance with his designs was completed in 1897 (see Diesel Engine). The pioneer diesel-engine locomotive of any size was a 1,000-h.p. unit built by the Diesel-Klose-Sulzer company in 1912. It had a four-cylinder, two-stroke engine directly coupled to the driving wheels. This was followed in 1913 by the first diesel-electric rail car to operate in regular service, a Swedish design powered by a 75-h.p. engine coupled to a D.C. generator.

Gasoline-engine vehicles were in existence as early as the first compression-ignition engines. In 1891 two German firms jointly produced a small industrial locomotive with a 4-h.p. gasoline engine, and numerous other examples of gasoline-engine vehicles were produced in several countries following the turn of the century. Rail cars of various kinds, with gasoline engines, continued to be used up to the 1930s. In Europe, however, gasoline was too expensive to use for traction purposes, and its inflammability was a source of danger in the event of an accident.

The earliest ancestors of the modern diesel locomotive in the United States were the gasoline-driven rail cars used by the Union Pacific and other railways on branch-line passenger runs beginning early in the 20th century. The engines used in these cars were neither powerful nor reliable, nor were their mechanical transmissions suitable for such severe service. Next, gasoline-electric rail cars were developed, using larger engines and electric, rather than mechanical, transmissions. These proved more satisfactory, but they still did not fully solve the problem of branch-line passenger service.

After World War I, increased highway competition made the problem of money losing branch lines even more critical in the U.S., and led to renewed interest in gas-electric cars. The Electro-Motive company was formed in 1922 to build gas-electric cars, using engines supplied by the Winton Engine company and electrical equipment by General Electric company. Meanwhile, the American Locomotive company (Alco) had been experimenting with diesel engines, and in 1925 it produced the first commercially successful diesel-electric switching locomotive. This 300-h.p. 60-ton unit was sold to the Central railroad of New Jersey for service at its Bronx terminal in New York city. The locomotive went to work in Oct. 1925 and served continuously until its retirement in 1957 (this pioneer diesel unit is now preserved at the B. &. 0. transportation museum in Baltimore).

A little-remembered next step in North American diesel locomotive development was the delivery, in 1928, of "road" type locomotives to the Canadian National and New York Central railways. The C.N.R.'s locomotive, a 2,660-h.p., two-unit affair, was built by Canadian Locomotive company. Two smaller, single-unit locomotives, one freight, one passenger, were delivered to the New York Central by Alco and General Electric in the same year. These were not especially successful, but the C.N.R.'s two units were separated and continued in service, one until 1939 and the other until after World War II.

Diesel development continued in Europe during this period, also. There were rail car applications in several countries, as well as many examples of higher powered locomotives, notably in Germany and Italy. A Russian engineer, G. V. Lomonosoff, had been pressing the claims of diesel traction since 1910. The Russian government finally agreed to let him put his ideas into practice and in 1925, in conjunction with the German railways, a 1,200-h.p. diesel-electric locomotive was completed. This was followed by a similar unit equipped with mechanical transmission.

Much Eurooean develooment work in the 1920s centred on the transmission of power. Because of its characteristics, the diesel engine is very limited when equipped with direct drive because it cannot rapidly adapt to variable load requirements. Also, it cannot start from rest under load. Experiments were carried out with mechanical, hydraulic, pneumatic, compressed gas, compressed steam and electric transmissions. Gradually it was found that mechanical, hydraulic and electric transmissions were the most satisfactory. In 1928 a diesel-electric train was tested in Britain, and a diesel-hydraulic rail car was placed in service in Northern Ireland in 1933. However, it was in 1932 in Germany that the first really striking results with diesel traction were obtained. A two-car streamlined diesel-electric train, equipped with two 400-h.p. engines, commenced operation between Berlin and Hamburg. This train, the "Flying Hamburger," was soon on a 77-m.p.h. average speed schedule that called for the regular attainment of 100 m.p.h. Other units were built and a network of fast services was introduced all over Germany. In the 1930s diesel rail cars and diesel-engine multi-car train sets were brought into use in most European countries.

A turning point in U.S. diesel development came in 1930, when Electro-Motive company and Winton Engine company were acquired by General Motors corporation. This merger led to the development of a lightweight, two-stroke-cycle diesel engine suitable for general railway application. This was the engine used in the "Pioneer Zephyr" of the Chicago, Burlington and Quincy railway. Delivered in April 1934, this was the first train in the U.S. to use diesel-electric power successfully in main-line service. Together with the Union Pacific's "M-10000," later renamed the "City of Salina," the "Pioneer Zephyr" also inaugurated the modern era of streamlined lightweight passenger trains. The "Pioneer Zephyr" remained in service for more than 25 years and then was preserved in the Museum of Science and Industry, Chicago.

The "Pioneer Zephyr," the "M-10000" (which used gasoline as fuel) and a few other early diesel-powered passenger trains were actually modernized versions of the old gas-electric cars. They were articulated trains in which a single truck supported the adjacent ends of adjoining cars. This meant that cars could not be added or removed easily to meet traffic demands. In most cases the new trains mere so popular that the traffic soon outgrew them, and eventually most of them had to be relegated to lighter-traffic runs.

Logically, the next step was to build a nonarticulated diesel locomotive that could be used to pull any train. In 1935 Electro-Motive division delivered one 1,800-h.p unit to the B. & O and two to the Santa Fe. The latter two units, operated as a single 3,600-h p. locomotive, were used to begin the first high-speed passenger service between Chicago and Los Angeles, May 12. 1936. They covered the 2,226-mi. run, pulling the "Super Chief," in $39\frac{3}{4}$ hr.

After 1935, the diesel began to play an increasingly important role in passenger train operations in the U.S.. as well as in yard switching work, but it was not until 1939 that the first road freight diesel, a four-unit Electro-Motive demonstrator, mas built. This 5,400-h.p. locomotive could be split and operated as two 2,700-h.p. locomotives. The original demonstrator was eventually sold to the Southern railway. Meanwhile, the Santa Fe, in 1940, had become the first railway to operate diesel locomotives in regular freight service.

By the end of World War II the diesel locomotive had become a proven, standardized type of motive power, and it rapidly began to supersede the steam locomotive in North America. In 1943 there were nearly 40.000 steam locomotives and only 2,100 diesel units in service in the U.S. Less than 20 years later there were but a handful of steam locomotives in regular operation (mostly on short-line railways) and about 28,000 diesel-electric units. Because of its greater efficiency, this smaller number of units proved fully capable of performing as much or more transportation work than the larger steam locomotive fleet it replaced.

After World War II, the use of diesel traction greatly increased also in Europe, Africa, Asia and Australasia. Practically every major system in these areas used the diesel engine in some form, and there were some systems—especially in Africa—that became completely dieselized.

2. Elements of the Diesel Locomotive.—Although the diesel engine has been vastly improved in power and performance, the basic principles remain the same: drawing air into the cylinder, compressing it so that its temperature is raised and then injecting a small quantity of oil into the cylinder. The oil ignites without a spark because of the high temperature. The diesel engine may operate on the two-stroke or four-stroke cycle and may have cylinders arranged in line, in V formation, horizontally opposed or in vertical formation. Rated operating speeds are from 350 to 2,000 r.p.m. and rated output may be from 10 to 2,400 h.p.

In the United States, early road units, and most yard switchers, use diesels ranging from 600 to 1,200 h.p. Road units now commonly have 1,800-. 2.000-, or 2,400-h.p. engines. Most builders use V-type engines, although the in-line type is used on smaller locomotives (up to 1,200 h p.).

Electric transmission is the most popular, and is nearly universal in North America. With electric transmission, the diesel engine is directly connected to a main generator that converts the mechanical energy produced by the engine into electrical energy. Through the appropriate control equipment, this in turn is used to drive the traction motors. The traction electrical system operates at a nominal 600 v.. but there is great variation in the voltage under operating conditions. The traction motors are of the series-wound type, each geared to the axle it drives. Most locomotives have a traction motor on each axle, although some passenger locomotives or units designed for light branch-line service may have six-wheel trucks with the centre axle an idler.

Hydraulic transmission employs the principle of a centrifugal pump or impeller driving a turbine in a chamber filled with oil or a similar fluid. The pump. which is driven by the diesel engine, converts the engine power to kinetic energy in the oil impinging on the turbine blades. The faster the blades move. the less the relative impinging speed of the oil and the faster the locomotive moves.

Mechanical transmission is the simplest type and is mainly employed in the lower power range. Basically it is a clutch and gearbox similar to those used in automobiles. A hydraulic coupling, in some cases, is used in place of a friction clutch.

3. Types of Diesel Motive Power.—There are four broad classes of equipment using diesel prime movers:

The light rail car or rail bus (up to 180 h.p.) usually is four-wheeled and employs mechanical transmission; it often is powered by a standard motorbus engine or a horizontal or pancake engine. The vehicle may haul a light trailer car.

The rail car in the low horsepower range (up to 1,000 h.p.) usually is equipped with mechanical transmission; higher powered versions may have hydraulic or electric transmission. Nearly all rail cars are capable of hauling trailer vehicles, while the most powerful types are designed essentially for hauling additional vehicles, although they also have passenger or baggage space.

Train sets (500 to 2,000 h.p.) are formations of more than one vehicle, usually designed to be worked from a single set of controls. They include one or more powered vehicles in their formation and usually have hydraulic or electric transmission.

Locomotives (10 to 3,300 h.p.) may have mechanical, hydraulic or electric transmission, depending on power output and purpose. They frequently are designed to work in MU formations. In the lower power range (to 600 h.p.) the usual duties are switching and light freight traffic. Medium-power locomotives (600–1,200 h.p.) may be used for freight haulage, passenger work or heavy switching purposes. Locomotives over 1,200 h.p. are normally required for main-line duties in Europe and North America. The 1,500–2,000 h.p. range is the most popular class for express train haulage, and for freight service in North America.

4. Diesel Operations in the **U.S.**—In North America, diesel locomotives are built in three distinct types designed for switching, freight and passenger service. Freight and passenger types are very similar in appearance, but passenger units are usually geared to a higher top speed and are equipped with an automatic steam boiler for train heating.

Road locomotives may be of either the streamlined or cab type, an outgrowth of the early streamlined articulated train designs, or of the purely functional hood type. In the former the body conforms closely to the cross-sectional dimensions of modern passenger cars. In hood units the covering for the engine, generator and other components is smaller and is not streamlined. Yard engines are always of the hood type in the U.S. and Canada (with the exception of a few early box cab yard switchers).

The so-called road switcher or general-purpose diesel has become almost standard in the U.S. and Canada. This hood-type unit is usually geared for medium top speeds and has an offset cab located between a short hood (which may contain a steam generator) and a longer hood covering the diesel engine, generator and control equipment. The road switcher can be used in either passenger or freight service interchangeably, and it can also be assigned to yard switching service as needed. Because of this versatility, the number of locomotives required may often be substantially reduced when road switchers are used.

5. Operating Methods.—It became almost universal practice in North America to equip diesels for MU control. This permits setting up a "building block" system in which two or more units can be combined and operated as a single locomotive from one control cab. This can be done on short notice to cope with fluctuations in traffic, for example, or to obtain extra power for a mountain grade. The electrical systems of the different builders' locomotives are sufficiently standardized so that it is possible to operate units of mixed makes together in a locomotive "consist."

In the early days of dieselization, railways tended to emulate the operating methods they had used with steam locomotives, but to take advantage of the diesel's special characteristics they soon found it necessary to change their techniques, and often their physical facilities. For one thing, the diesel closed many division-point roundhouses, since it could run across a whole continent, if necessary, without requiring any maintenance attention. Moreover, many railways found it necessary to pay increased attention to the scheduling of motive power operations. Rather than having locomotives assigned to a maintenance terminal on a first-in, first-out basis, some roads found it desirable to operate as many units as possible on definite cycles. Such a cycle may take a locomotive to all parts of the line, hauling a succession of different regular trains, before it returns to the maintenance point after perhaps 15 days on the road.

D. Special Locomotive Types

Although the diesel locomotive with electric drive is the present standard type in North America and over much of the rest of the world, railways are constantly experimenting with other types of locomotives. For example, on several occasions experiments have

been made to adapt the steam turbine for rail traction purposes. One of the first examples was built in Sweden in 1921. Other prototypes followed in Europe and there were also experimental turbine-electric locomotives, none of which met with success.

The first gas-turbine locomotive was developed in Switzerland and completed in 1941. Another Swiss-built gas-turbine locomotive developing 2,500 h.p. was supplied to British railways in 1949. The first British-built gas-turbine locomotive developed 3,500 h.p. and was completed in 1951 (it was later converted to 25,000-v., 50-cycle A.C. operation).

Shortly after World War II the Union Pacific railroad (UP.) acquired a total of 25 gas-turbine electric locomotives of 4.500 h.p. each to be used on main-line heavy-duty freight service between Omaha, Neb., and Ogden, Utah. Although the gas-turbine is not as efficient as the diesel engine, the U.P. found that the turbine locomotives can develop high sustained speeds with heavy trains, and that they cost less to maintain than diesel-electric iocomotives of comparable power. The original 25 units were subsequently supplemented by thirty 8,500-h.p. units.

Union Pacific also experimented with a coal-fired, gas-turbine electric locomotive. Work on a coal-burning gas-turbine locomotive began in the U.S. after World War II, and research and testing solved many of the problems inherent in using coal in a gas turbine. The coal-burning turbine was considered to have significant possibilities for railways which, like the U.P., serve areas rich in coal.

Also employing a turbine is the turbo-diesel or free-piston gasifier locomotive. In this design the turbine is driven by power gas from a free-piston diesel compressor. Pioneer work with this type of engine for rail traction purposes commenced in Sweden in 1933.

In 1955 another Swedish locomotive was produced, much. larger than the original example. It had a power-gas producer that worked on a two-stroke-cycle diesel principle (the power gas is exhaust gas leaving the producer under high pressure at a temperature of 900" F.). The locomotive was driven, via a reduction gear, by the turbine, fed by the power gas. It developed an output of 1,300 h.p. and used 20% less fuel than the equivalent diesel-hydraulic or diesel-electric locomotive.

E. Self-Propelled Rail Cars

Although the gas-electric and gas-mechanical cars of the 1920s and earlier evolved into the diesel-electric locomotive, they were not too successful in their intended role. In the U.S. especially, there was still a need for a self-propelled rail car that could be used on light-traffic lines.

In 1949 the Budd company introduced a modern self-propelled coach that it called the rail diesel car (R.D.C.). The 85-it. stainless steel car was powered by a pair of 300 h.p., 6-cylinder, in-line diesels, each of which drove one axle through a torque converter. The engines were mounted under the floor, leaving almost the entire car body available as revenue space. The car had a control compartment at each end, could be operated in MU trains with other R.D.C.'s, and was air-conditioned.

The R.D.C. found favour with many railways in the U.S. and other countries. Some, notably the Western Pacific and the B. & O. in the U.S., and the Commonwealth Government railways in Australia, began using these self-propelled diesel cars on long-distance runs.

Self-propelled cars have been widely used for many years for electrified commuter service serving larger cities, as well as on local subway and rapid-transit systems. Modern MU cars, as they are called, can accelerate and decelerate rapidly because of their lightweight construction and improved motors and control equipment. (See Electric Traction.)

In its Chicago-area commuter operations, the Chicago and North Western railway began using nonpowered cars equipped with MU control equipment, and a control cab, in conjunction with standard diesel-electric locomotives. By having one of these control cars at the rear of a train, it is possible to operate the train in either direction at normal speed, without turning the locomotive or cars at either end of a run.

IV. RAILWAY CARS

The ancestors of modern freight and passenger cars were the wagons and stage coaches of the early 19th century. Some of the earliest railway cars were, indeed, merely road vehicles fitted with flanged wheels.

After the first crude beginnings, railway car design took diverging courses in North America and Europe, partly because of differing economic conditions on the two continents and partly because of differing technological developments. Early railway cars on both continents were largely of two-axle design. but passenger car builders soon began building cars with three and then with four axles, the latter arranged in two four-wheel swivel trucks or bogies. Swivel trucks produce smoother riding qualities and allow the weight of heavy cars to be distributed over more axles—an important consideration, especially on some of the early, lightly built rail lines.

In North America, the two-truck design soon became the standard for freight as well as passenger cars. Over the years, American freight cars have become much larger than their European counterparts. A typical modern American boxcar is about $50\frac{1}{2}$ ft. long, weighs 53,000 lb. empty. and has a capacity of 100,000 lb. of lading and a cubic capacity of 4.860 cu.ft.

To a remarkable extent, the characteristics of rolling stock reflect the background of the early railway builders in each country. Thus, the cars used in Africa and most Asian countries reflect European origins; South American equipment favours North American or European practice, depending on who built the first lines. In Japan most freight cars are of the four-wheel type, but in Australia eight-wheel truck-type cars are more common. After World War II, there was a trend in European countries toward larger, eight-wheeled freight cars. but European railways are often handicapped by close clearances and sharp curves on factory loading tracks.

A. Freight Cars

Three basic types of freight cars have developed: the open-top car, the boxcar and the flatcar. Apart from these examples, many additional designs have been introduced to suit particular types of freight. In Europe, the freight vehicle usually runs on four wheels. Capacity varies: British cars are the smallest, having an average capacity of 12 long tons, although vehicles taking 16, 20 and $24\frac{1}{2}$ long tons are in use. On the continent capacities vary from 16 metric tons to 30 metric tons. In Russia, however, much larger two-truck vehicles are generally employed, having capacities of up to 90 metric tons. Two-truck cars having a capacity of up to 30 or 40 long tons are also used to a great extent in Africa, Australia and most Asian countries.

After World War II a number of new freight car designs evolved in Europe. These included double-deck vehicles for transporting automobiles; open cars with sliding roofs; pressurized tank cars for the transport of dry solids in bulk; boxcars with wide side doors for the easy movement of loads packed on pallets; and hydraulically operated tipping cars.

European railways also made great strides in the use of demountable containers carried on flatcars. These were first introduced in the 1920s to enable the railways to offer a door-to-door service and there came to be many examples in service for the transport of all kinds of merchandise from liquids to highly perishable commodities such as frozen food.

Of the approximately 2,500,000 freight cars operating on U.S., Canadian and Mexican railways, about 800,000 are boxcars—the standard house car with closed sides, a roof, and sliding doors on each side. Cars of 40- and 50-ft. lengths are common, but the trend is to larger units. American railways use an equally large number of open-top cars—so-called gondola and hopper cars, the latter having hoppers with doors for unloading through the bottom. Other common American freight car types include flatcars, tank cars and refrigerator and livestock cars.

Many thousands of cars are equipped with special internal fittings designed to accommodate specific products without the need for dunnage (*i.e.*, bracing or blocking of the load). Typical of these are the automobile parts cars, which are often designed to carry a certain automobile component, such as bodies, frames or engines, of just a single manufacturer. The internal loading equipment in these cars must be changed whenever the automobile manufacturer changes the design of his product.

Among other special types of boxcars are those with "long-travel" cushioned draft gear to prevent damage to fragile commodities; heated cars to protect commodities such as potatoes during winter; extra-long flatcars with two- or three-deck automobile racks, and so on.

As the 1960s began, still other types of specialized freight cars were becoming more and more important. Especially notable was the growing use of piggyback cars designed for efficient loading and hauling of highway trailers. A wide variety of piggyback cars was in use, ranging from converted standard 40-ft. flatcars to 85-ft. cars especially planned to carry two large or three small highway trailers or containers.

For the railways, the growing variety of specialized freight cars complicated the problem of keeping all shippers supplied with cars of the proper types. On the other hand, specialized cars usually ran more miles and earned more revenue than standard cars, and thus were a worthwhile investment. To supply special freight cars more efficiently, the private car companies played an increasing role. These companies buy the equipment and either operate it or lease it to shippers and often to the railroads themselves, a practice long followed in the U.S. with tank and refrigerator cars.

B. Passenger Cars

Cars with two four-wheel trucks were used in the United States almost from the beginning, but the two-truck coach was not introduced into Britain until 1874 and on the European continent until 1880. At about the same time the flexible gangway or corridor connection was adopted for main-line cars, enabling passengers to have access to any part of a moving train. Early American cars had open platforms at each end; it was not until around 1900 that closed-vestibule cars came into general use.

Sleeping cars were operated in the U.S. as early as 1837, and the first Pullman sleeper was placed in service in 1859; sleeping cars were introduced in Britain in 1879.

In Europe there was a gradual trend toward longer and lighter passenger vehicles. The standard British coach measures 67 ft. in length, while continental designs are up to 86 ft. 6 in. long. The introduction of steel, first for coach frames and later for frames and bodies, added to the weight of vehicles. An all-steel continental coach might weigh up to 45 metric tons, or 55 metric tons for a sleeping car. However, it was found possible to reduce these weights without loss of strength by using lightweight steels, stainless steels and light alloys. For example a modern lightweight steel coach of the Swiss Federal railways is 73 ft. long, seats 80 passengers and has a tare weight of only 26 metric tons. In contrast, typical U.S. passenger cars weigh from about 60 to 80 short tons, or even more.

Experiments have been carried out with ultra-lightweight trains. The Spanish railways operate a number of lightweight sets, called Talgo trains, consisting of several short coach units, each resting at one end on a single axle. At the other end the weight is carried on a pivot which forms part of the next vehicle, and the leading coach is supported on the diesel locomotive. The train is thus made up of a series of jointed units and, having a very low centre of gravity, it can traverse curves at high speed.

The interior accommodations of passenger cars vary widely. In Europe the six- or eight-seat compartment with the corridor along one side of the coach is still favoured, although the use of coaches with a centre aisle has increased, particularly for suburban service. Reclining coach seats were adopted by a number of systems for long journeys.

United States passenger cars use the centre-aisle arrangement almost exclusively, except for some sleeping cars. Besides the coach, with its two rows of seats, the modern U.S. passenger train may include several types of sleeping cars for overnight travel, a dining car and a lounge or observation car. In addition, "head-end" cars—for mail, express and baggage—are operated in most U.S. and Canadian passenger trains.

A typical modern sleeping car has six bedrooms (each with two beds) in the centre of the car, with six roomettes (each with a single bed) at each end. Thus the total capacity of the car is about 24 persons. This relatively low capacity produces low revenue, making necessary rather high fares to cover the cost of operating the car. The high fares, in turn, discourage patronage in competition with the much faster airlines. This is the basic problem of sleeping-car service under modern conditions.

As one answer to this problem, the Budd company in the U.S. developed the "slumbercoach," a sleeping car similar to the European compartment coach. It has eight small double rooms and 24 single rooms. The total capacity of 40 makes possible rates only slightly above the standard coach fare. In use on a few lines in the U.S., slumbercoaches proved highly successful.

The dome car, developed in the U.S. after World War II, enables passengers to ride under a raised, glassed-in roof section from which they have a wide-range view of the countryside. Below the dome section may be sleeping rooms, a lounge section or coach seats. Although costly to build and operate, dome cars without doubt helped attract patronage. They became widely used on railways having scenic routes in the western U.S. and Canada. The same type of service was adopted in other countries as well, notably in France and Italy.

With growing industrialization many countries began building their own rolling stock, whereas previously they had obtained their cars from European or American builders. Many of the cars in service have been designed to suit climatic and other special conditions of the countries in which they operate. *Narrow-gauge railways also impose restrictions as to weight and size. Even so, a 3-ft. 6-in. gauge coach of the South African railways, for example, may be up to 63 ft. 5 in. long and weigh up to $43\frac{3}{4}$ long tons. In Australia the trend has been to longer coaches, many of which follow the American pattern in design and appearance.

C. Standardization of Running Gear

Although U.S. and Canadian railways build many different types of cars to suit their own needs or whims, most of the cars may operate interchangeably among railways. Through the work of the mechanical division of the Association of American railroads (and its predecessors) the elements of the running gear—wheels, trucks, draft gear, couplers and brakes—have been standardized. Not only does this permit any car to operate over almost any railway on the North American continent, but it also allows any railway to repair or maintain any car it is using, regardless of who owns the car.

This mechanical standardization was an important factor in the growth of the American railway industry, yet it does impose some problems. Any improved type of coupler or brake, for example, must be compatible with existing older equipment if it is to be used on cars operated in interchange service. However, despite this limitation, mechanical progress has been steady. Roller bearings almost entirely replaced the traditional plain journal bearings on passenger cars and locomotives, and came into increasing use on freight cars. Several improved types of automatic couplers were adopted; an improved freight air brake, the type AB, became universal, and wheels were constantly improved. Truck or bogie spring systems were made more effective against vertical shocks and oscillations in moving cars, and the draft gear used in freight cars was refined to provide more cushioning against longitudinal jolts.

As a result of these changes, the mechanical standards of freight cars approached more and more those of passenger cars. This was a necessity, because longer trains were being operated at higher speeds, and it became even more urgently necessary to prevent damage to merchandise in transit.

1. Couplers.—European couplers originally consisted of nothing more than chains linking the vehicles, with solid buffers to help absorb the shock when one vehicle came in contact with another. Later, spring buffers were introduced, along with screw couplings that permit two vehicles to be brought together so that buffer faces are just touching; this helps to ensure smooth starting and stopping.

During their first half-century, U.S. railways used a crude link-and-pin coupler that was extremely dangerous to employees who had to couple cars. Beginning in 1882, American railways began to convert to the knuckle-type automatic coupler. This basic design, built heavier for today's larger cars and much improved in detail, is still the North American standard. Knuckle couplers are also used in many other countries, notably Japan, Russia and Australia. In fact, the majority of non-European railways use automatic couplers of one pattern or another.

In Britain, automatic centre couplings were tried out on the Great Northern railway in 1898. Later, automatic couplings were used on the main-line passenger coaches of the London and North Eastern and the Southern railways. In 1948 British railways adopted this type of coupler for all their main-line coaches. and experiments later began on an automatic coupler for freight cars.

Multiple-connection automatic couplings have been adopted by a number of railuays, principally for diesel rail-car trains or MU electric trains. This type of coupling incorporates connections for the continuous brakes, heating and electrical controls, as well as joining the vehicles together.

Instead of buffers, U.S. cars have draft gear, directly behind and attached to the couplers, which may employ spring, friction, rubber or hydraulic elements to help absorb coupling and operating jolts. The standard draft gear is mounted in a pocket 24- or 36-in. long, but a number of long-travel draft gears and cushioned centre sills have been developed to give greater protection to fragile commodities.

2. Brakes.—Two continuous braking systems are in general use —the vacuum brake and the compressed-air brake. Of the two, the more popular is the air brake, patented in 1869 by George Westinghouse and made compulsory in the U.S. by the Railroad Safety Appliance act of 1893. The vacuum brake is used principally in Britain, where continuous brakes have been compulsory on passenger vehicles since 1889. With either system, every vehicle is connected by a brake pipe; therefore, application of the brake on the locomotive applies brakes throughout the train.

Although virtually all passenger rolling stock throughout the world is equipped with continuous brakes, this is not the case with freight cars. The majority of British freight cars, for example, do not have continuous brakes, although steps have been taken to remedy this situation. In other countries the bulk of the freight stock is fitted with continuous brakes.

The brake itself takes the form of a single or double shoe which presses against the wheel tread. The disk brake also has been widely used on U.S. and Canadian passenger trains (see also BRAKE).

3. Dual-Gauge Vehicles.—Vehicles capable of running on more than one gauge are in use in Europe. The Spanish Transfesa company operates freight cars that can be used on the 5-ft. 6-in. broad gauge of Spain and on the standard 4-ft. 84-in. gauge of other European countries. Special apparatus at frontier yards enables wheel sets of one gauge to be exchanged quickly for those of the other. Similar arrangements, on a larger scale, are to be found at certain Russian frontier stations, so that 5-ft. gauge Russian passenger coaches can receive standard-gauge trucks and operate into east and west European countries.

In some countries special cars are used to carry cars of a different gauge in piggyback fashion. In Australia, for example, complete trains of specially adapted flatcars are in use to carry, in turn, entire trains of a narrower gauge, thus obviating the need for transshipment of freight.

V. CAR AND LOCOMOTIVE MAINTENANCE

The design, construction and maintenance of rolling stock is a responsibility of a railway's mechanical department. In steam locomotive days, some of the larger railways (both in the U.S. and elsewhere) built their own locomotives, as well as many of their own cars. However, U.S. railways did not build new diesel locomotives, although there was a trend toward building cars in railway shops rather than having them built by the commercial car manufacturers.

In terms of money spent for wages, materials and the operation of shops, rolling stock maintenance is a vast operation. In normal years U.S. railways, for example, spend about 18% of their income for this purpose.

Railway shops perform all the operations and contain much of the machinery common to a heavy manufacturing industry. Moreover, railway shop production was being organized more and more around assembly-line techniques. just as in other industries.

1. Locomotive Shops.—In contrast to the steam locomotive back shops that railways formerly required on each operating division, the dieselized railway usually needs only one heavy repair shop. Here the locomotives are more or less completely dismantled and their major components—engines, electrical equipment, running gear—are either completely overhauled or renewed. Under normal conditions, a diesel locomotive is given heavy repairs or rebuilding only after a period of perhaps five to seven years. Between these major overhaulings, a locomotive receives maintenance attention usually on the basis of mileage; that is, certain routine maintenance work is performed at specified mileage intervals (in the U.S., certain inspection and maintenance work is prescribed by the Interstate Commerce commission).

In addition, of course, locomotives also are given certain routine inspections at the end of each run. Although many railways still use converted roundhouses for much diesel maintenance, others have found that specially built diesel shops are more efficient.

2. Car Shops.—Freight car maintenance may be classified as running repairs, intermediate repairs and heavy repairs or rebuilding (the exact definition of each varies among railways). As trains enter terminal yards they are inspected for running gear or other defects. Any cars requiring attention are switched out of the train and sent to the "rip track," a shop equipped to do light repair work such as wheel changing, air-brake repairs and minor repairs to the car bodies.

If a car has been severely damaged, it may be sent to a heavy repair shop. Often, railroads rebuild an entire series of cars. This is most likely to occur after the cars have seen 15 or 20 years of service. The rebuilt cars may be equipped with entirely new bodies and emerge from the assembly-line car shop the virtual equivalent of new cars.

VI. BRIDGES, BUILDINGS AND TUNNELS

The fixed plant of a railway consists of much more than just the track itself. In the U.S. alone, about 4.000 mi. of line are on bridges. In mountainous country, tunnels must be built to avoid excessive grades or excessively roundabout routes. Where mountain railways are not in tunnels they must often be protected by snow sheds against drifting and avalanches. In addition, railway engineering departments are concerned with constructing and maintaining thousands of different buildings ranging from small watchman's shanties to huge passenger terminals.

1. Bridges.—The designer of a railway bridge faces some challenging problems. He must allow for the forces that result from the concentrated impact as a train moves onto the bridge, the pounding of wheels, the sidesway of the train, the drag or push effect as a train is braked or started on the bridge. These factors mean that a railway or rail-highway bridge must be designed more stringently than a highway bridge. The heavier construction of a railway bridge designed for main-line traffic, as compared with a highway bridge of similar length, is usually quite evident even to a casual observer.

As trains and locomotives became heavier, bridges had to be strengthened accordingly. In the past, newer, heavier steam locomotives usually caused the need for stronger bridges, but modern diesel-electric locomotives are less damaging to bridges than large steam locomotives. However, as freight loads became heavier and train speeds higher, railways still had to design and build their bridges to high standards.

Besides the need to strengthen bridges, there was another major objective in much modern railway bridge construction: reducing maintenance costs. This became evident in the widespread trend toward replacing timber trestles with concrete slab structures or with concrete or steel-pipe culverts. Prestressed concrete slab bridges came into use on an increasing scale. All-welded steel bridges, although remaining relatively rare on railways, became more common, as did the use of high-strength bolts rather than rivets for field assembly of bridge spans.

Under the spur of rising labour costs, U.S. railways sought ways to mechanize the maintenance of bridges and other structures. Typical of solutions to the problem were the bridge sprayer machines used to apply protective coatings, as well as special types of derrick equipment for replacing bridge ties and stringers. *(See* also BRIDGES.)

2. Buildings. — Railway buildings in the 20th century became fewer and more functional. The newer types of motive power, for instance, required only a few maintenance shops. Car shops, too, were being consolidated into fewer but usually more modern structures. In North America, the declining importance of passenger traffic resulted in the elimination of many passenger stations, and some local freight stations were removed, too, since with paved highways almost everywhere, it became more economical to concentrate freight terminal operations at a few large stations.

Only a few really modern passenger stations have ever been built in the U.S. One is the Los Angeles Union Passenger terminal; one of the latest is the New Orleans Union Passenger terminal, completed in 1954. Grand Central terminal in New York city, completed in 1913, is perhaps the best-known railway station in the world: approximately 150,000 passengers use it daily. In contrast, however, approximately 580,000 use the Tokyo station of the Japanese National railways daily.

Europe, however, has a number of large, modern passenger stations. One of the most striking is Rome Termini, the construction of which started in 1938, although it was not completed until 1951. Of prewar construction is the Central station, Milan, one of the largest in Europe. Opened in 1931, it has 22 platforms, of which 18 are 1,051 ft. long.

3. Tunnels. — Although it is a highly expensive form of construction, tunneling provides the most economical means for railways to traverse mountainous terrain and to gain access to the heart of a crowded city. However, railway tunnels confront the construction engineer with some unique problems, particularly in matters of ventilation on nonelectrified lines. Some examples of famous tunnels and methods of construction may be found in the articles TUNNEL and SUBWAY (UNDERGROUND RAILWAY).

VII. COMMUNICATIONS AND SIGNALING

A. COMMUNICATIONS

Modern railways have operating and service problems as complex as those of a major manufacturing concern — in some respects even more so. The railway's plant and its operations may be spread out over thousands of miles of line serving hundreds of communities. Quick communication between stations is usually essential in the operation of trains. It is also required in order to give service information to the public and to carry on the vast amount of routine correspondence and accounting data that a railway enterprise generates.

1. Telegraph and Telephone. — Railways were among the first to adopt the electric telegraph and the telephone. The railway telegraph dates back to 1837, when it was tried on the London and Birmingham line. In the U.S., the telegraph was first used for dispatching trains in 1851; the telephone was first tested in 1877.

Modern railways are among the larger operators of electrical and electronic communications facilities. For example, the dial telephone network of the S.P. system covers the entire western area of the U.S. It allows personnel anywhere on the railway and its affiliates to dial direct to offices anywhere on the 14,000-mi. rail system serving 12 states. Other railways have similarly extensive telephone systems.

The Morse telegraph, originally used in North America for all railway business messages as well as train dispatching, eventually was relegated to use only on some secondary and branch lines, and train dispatching was done almost entirely by telephone, or by centralized traffic control signaling.

For message communication other than that. involved in dispatching of trains, most U.S. railways came to rely heavily on the printing telegraph (Teletype) as well as the telephone. Many railways installed teleprinter networks to connect all stations, engine houses, yard offices and general offices.

The teleprinter is used for many purposes beyond the exchange of routine messages. One of the more noteworthy developments is the transmission of the complete train "consist" (or list of cars in the train) by teleprinter from the origination point of a train to the next terminal on its route. By having the exact train consist, the destination terminal can plan switching operations well in advance of a train's arrival.

Simultaneously, the same train consist list may be transmitted to the railway's general headquarters, where it can be used to inform customers of the whereabouts of their shipments. The consist can also go to the car records office, which records the movements of individual cars, and to the accounting department.

More and more, railways in the 1960s moved toward the concept of integrated data processing, which requires a data-processing centre usually located at company headquarters. Operations and accounting data of many types may be fed into this centre direct from outlying points on the railway. Often, one or more large electronic computers may be included in the complement of business machines.

Central data processing requires a large number of communications circuits. The capacity of a single pair of telegraph lines may be increased many times by superimposing on it a number of electronic "carrier" circuits, each operating in a different frequency range. But modern demands for circuits in some cases even exceeded the capacity available through carrier equipment. Thus, some railways turned to broad-band radio beams (microwave) to supply the many channels needed for direct telephone dialing systems and teleprinter and data processing circuits.

2. Radio. — In 1959 the Pacific Great Eastern railway, between Vancouver and Dawson Creek-Fort St. John, B.C., became the first railway to use microwave radio for all line-side communications, doing away almost entirely with line wires. Other major North American carriers, notably the Santa Fe, S.P. and U.P., also installed extensive microwave systems. Microwave has the additional advantage of minimizing communication failures in areas subject to heavy sleet and snowfalls, which might bring down conventional open-line wires.

American railways also began to use very high-frequency (VHF) radio on a large scale after World War II. In freight operations VHF permits communication between the locomotive and caboose of a long train, between two trains, and between the train dispatcher and wayside stations and trains.

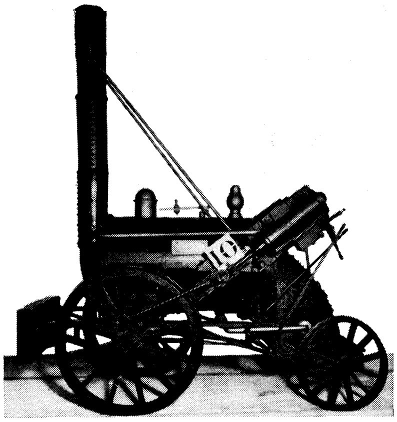
In terminals, radio greatly speeds yard switching work, because it allows the yardmaster to keep in close touch with the yard engines. Through VHF radio, too, widely separated elements of mechanized track maintenance crews can maintain contact with each other and with oncoming trains. Supervisory personnel use radio in their automobiles to keep in touch with activities under their jurisdiction.

To some extent, train radio took over some of the communication functions formerly reserved for the locomotive whistle. Enginemen commonly use standard combinations of long and short whistle sounds to communicate with the rest of the train crew and with wayside stations. On U.S. passenger trains, an intra-train air whistle system allows the conductor or trainmen to signal the engineman.

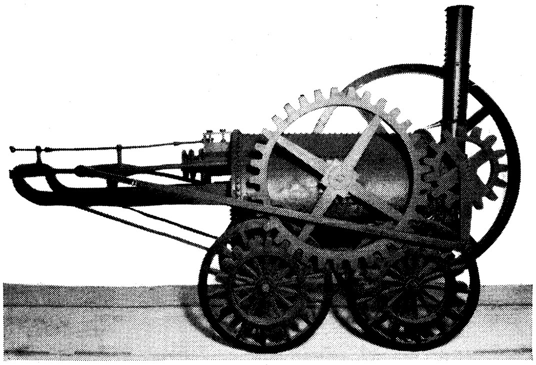
B. SIGNALS

Railway signals are a form of communication designed to inform the train crew (in particular, the engine crew) of track conditions ahead and to instruct it in the operation of the train.

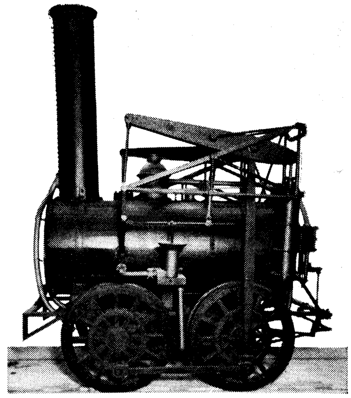
The earliest form of signaling consisted of a lamp by night or a flag during daylight. The first movable signal was a revolving board, introduced in the 1830s and followed in 1841 with the semaphore signal, which provided "stop," "proceed with caution" and "all clear" indications. Among the widely used early types of signals in the United States was the highball signal, consisting of a large ball, hoisted to the top of a pole, to inform the engineman that the train might proceed.



The "Rocket," built by George Stephenson. It was the winner of the 1829 trials by the Liverpool and Manchester railway, England



Richard Trevithick's "New Castle," 1803, the first locomotive in the world to do actual work



The "Stourbridge Lion," built in England and shipped to the U.S. where it was placed in operation in 1829

The "Best Friend of Charleston," first locomotive built in the U.S. for regular service on a railway. It began scheduled passenger service in 1830 from Charleston, S.C., over a route which eventually became part of the Southern Railway system

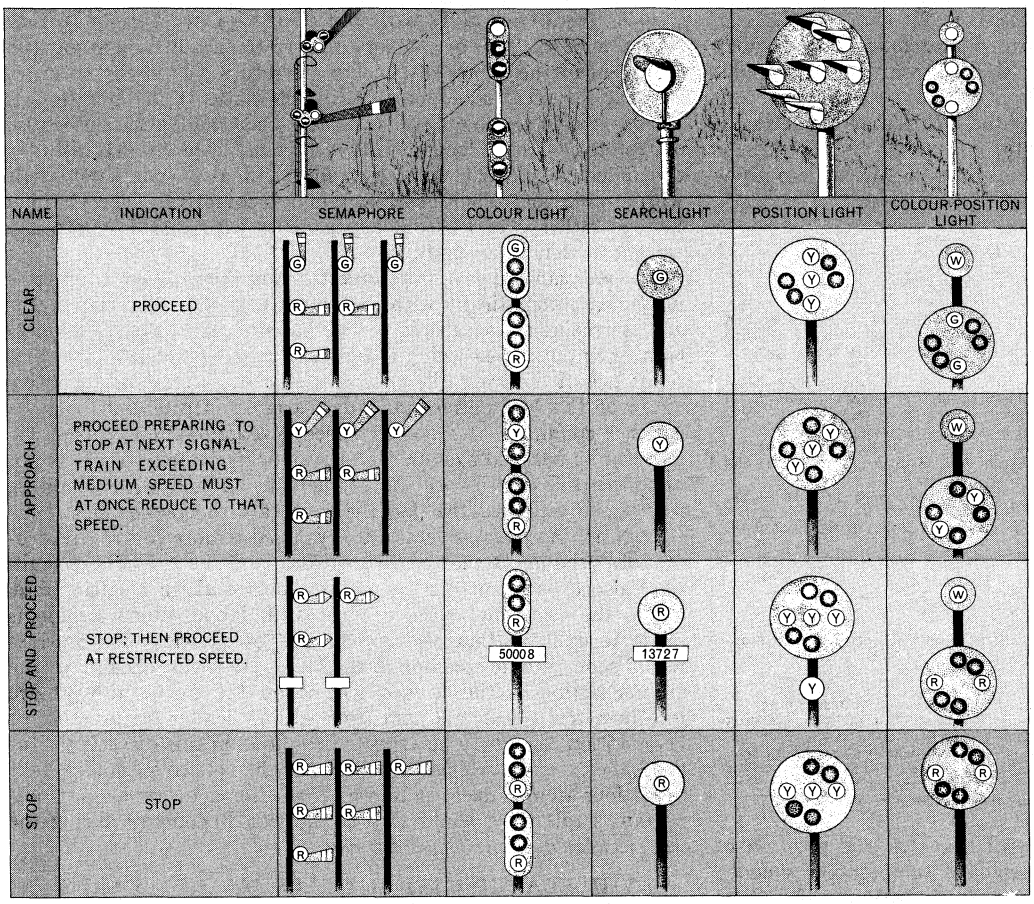

FIG. 2.— STANDARD AMERICAN SIGNAL INDICATIONS AND ASPECTS

Lamp colours: G, green; Y, yellow; R, red; W, white. The three columns under "Semaphore" show how the same indication may be given with one, two or three signal heads on the same mast (any of the other types of signal may also be combined in the same fashion); two- and three-head signals ordinarily are used at junctions, passing sidings, e t ~ . A stop-and-proceed signal is designated by a number plate on the mast below the signal head, by a marker light, by a pointed semaphore blade or by a combination of these features

The first attempts at interlocking switches and signals were made in France in 1855 and in Britain in 1856. Interlocking at crossings and junctions prevents the signalman from displaying a clear signal for one route when clearance has already been given for a conflicting route.

Another forward stdp was the introduction of train operation on the distance interval or block system. The electric tablet machine (1878) for the safe operation of traffic over a single track was another note orthy development.

The next major step forward was the application of power to signaling. Experience gained with large power interlocking frames having mechanical interlocking between levers led to the development of all-electric interlocking. This, in turn, led to relay interlocking in which interlocking and controls are effected by electrical relays.

A development in the design of the signal itself was the introduction of the colour-light type in addition to the semaphore pattern. The colour-light signal uses a separate bulb and lens for each aspect. By the 1960s it was being generally superseded in the U.S. by the searchlight type, which uses only a single lens and bulb, the different colours being displayed by means of roundels or colour filters that are rotated in front of the lamp. Two other types of signals are used in the U.S.: the position light, in which rows of yellow lights duplicate the positions of semaphore arms, and the colour-position signal, which uses coloured lights arranged in rows.

Most lines in Europe are controlled from wayside signal towers, or cabins at stations, in conjunction with fixed signals. Block signaling is usual, the track being divided into sections, and a train is not permitted to enter a section until the train ahead has left it. This manual block system was once much used in the United States also, and is still found there on some lines. Electric interlocking improves this system by making it impossible for the "line clear" indication to be given for a section already occupied by a train.

Of more recent introduction is automatic block signaling. This uses track circuits which are short-circuited by the axles oi a train, putting the signals in the rear of the train (and. on single track, in front of it as well) at the danger aspect. A track circuit is made by the two rails of a section of track, insulated at their ends. Electric current, fed into the section at one end, flo s to a relay at the opposite end and the wheels of any vehicle will then short-circuit the current supply and energize the relay.

Signaling on African, Asian and Australian systems usually follows European practice in areas of heavy traffic. On lines of lighter traffic, control is often via the telegraph or telephone.

In the early years of U.S. railways. it was common to program operations on the basis of a strict timetable, which set up all the places where trains were to meet. If one train were delayed, others would also be held up, since it was impossible to change the meeting points.

By using the telegraph it became possible for the dispatcher to issue orders to keep trains moving in unusual circumstances, or to operate extra trains when required. This "timetable-train order" system is still used on about 100,000 mi. of lighter-traffic line in the U.S. and on much Canadian mileage. It is widely supplemented by automatic block signals, which provide an additional safety factor.

TABLE V.—Standard U.S. Locomotive Whistle Signals

Sound	Meaning
□	Apply brakes; stop
—	Release brakes; proceed
	Flagman protect rear of train
— — — —	Flagman return from west or south*
— — — — —	Flagman return from east or north*
• •	Engineman's answer to any signal not otherwise provided for
, • •	When standing: will back up. When running: will stop at next passenger station
• • • •	Call for signals (usually to request towerman or operator to clear a signal so train can proceed)
— • •	Another section of this train is following
— — • —	Approaching public crossing at grade
————	Approaching station, junction or railway crossing at grade
— — •	Approaching a meeting or waiting point

*Followed by one or more short sounds to designate which track is meant, when train is in multiple-track territory

The earliest function of signaling was to advise the engineman when it was unsafe to proceed and to indicate where a train should stop. In contrast, the aim of modern signaling is to keep trains running to the best advantage. Route-setting is one of the developments that helps accomplish this. With it, a complete route can be set up by operating push buttons on an electrical control panel. Equipment of this kind allows a large area to be controlled from one point, thus reducing the number of signal towers and personnel required.

1. **Centralized Traffic Control.—A** logical extension **of** the

route interlocking principle is centralized traffic control (C.T.C.). This is a system in which trains are operated entirely through remote control of the switches and signals from a central point by an operator, who sees the track layout in miniature on his control panel. Lights on the panel show the location and progress of all trains at all times. By pushing buttons and turning levers, the operator directs the movement of trains over distances from a few miles to several hundred miles.

Table VI.—*British* **Locomotive** *Whistle Signals*

Sound	Meaning
—	Approaching signals at "danger" or to indicate when ready to proceed on same track (on main or fast lines)
— —	As above, when on slow, or freight, track next to main line
— — —	As above, when on track next to slow or freight line (one additional long iound is given for each additional line farther away from the main line)
— •	On main line and requiring to proceed to the left
— • •	On main line and requiring to proceed to the right
— — •	On slow or freight line and requiring to proceed to the left
— — • •	On slow or freight line and requiring to proceed to the right
• • • • •	Requiring to pass between slow line or loop and main line
▪ ▪ ▪ ▪	Requiring to cross from main to main
(crow)* —	Requiring to pass between bay and platform lines
• • ▪	Train ready to leave siding
• • ▪ ▪	Shunt from sidinns to main line
▪ ▪	To or from locomotive
(three crows)	Express train requiring fresh locomotive at next stopping place
(crow) — (crow)	Fire on trackside
— • ▪ ▪	Locomotive requires water
	Locomotive clear of switch which requires turning
(crow) ▪	Train or locomotive shunted clear of switch leading from one running line to another
▪ ▪ ▪	Train or locomotive shunted clear of all running lines
(2 crows)	Preparing to start train assisted by locomotive in rear

'Crow: the traditional "cock crow" indication, thus: — ▪ — ▪ —

In C.T.C., track circuiting is essential so that the position of every train is known. Switches and signals are operated by coded electrical circuits which reduce the wiring required. C.T.C. is being used on an increasing scale in Africa, Asia and New Zealand as well as in certain European countries. Over long distances, C.T.C. substantially increases track capacity by making more effective use of the line.

Since C.T.C. eliminates any need for written train orders or manual operation of block signals, it permits closing of telegraph or signal stations — another major economy. On lines of light traffic, most of the benefits of C.T.C. can be obtained at less cost by having the signals controlled from the central office and the switch points operated manually by the train crews.

2. New Forms of Signaling. — Completely automatic signaling, activated by electronic program machines, had been introduced by the 1960s on some of London Transport's subway lines. The program machine has a plastic band incorporating a complete timetable translated into a series of punched holes. The line of holes is positioned for each train by a photoelectric cell. A comb with steel "feelers" scans the line of holes, causing a series of electrical contacts to be closed; these in turn carry out all signal, switch and interlocking movements.

In Germany, experiments were being conducted with train control by radio signals to the enginemen, instead of by fixed wayside signals Signal indications are given on a panel in the self-propelled car or locomotive and are accompanied by tone signals. Orders are acknowledged by a train recognition signal and the position of the train on the line is visually presented to the control operator on a track panel. In addition, all locomotives and self-propelled cars are linked to the controller by radio telephones.

3. Automatic Train Controls. — Automatic train control (A.T.C.) provides the engineman in the locomotive cab with audible (and sometimes visual) information on track conditions. Should a restrictive indication be ignored, the brakes are applied automatically to stop the train. Several U.S. railways use automatic speed control, a refined form of A.T.C. A miniature signal in the cab repeats the wayside signal aspects (or it may take the place of wayside signals). Should train speed exceed that indicated by the aspect being displayed, the brakes are automatically applied to reduce the speed below the permissible level.

4. Automation of Train Operations. — Only a slight further extension of this type of control is needed to permit fully automatic operation of the train — dispensing entirely with the engine crew. From a technical standpoint, fully-automatic train operation is entirely feasible, and experiments have been made with automatic or remote control of locomotives and trains. The French railways controlled an electric train by radio and also conducted trials with a radio-controlled diesel s itching locomotive. The German Federal railways carried out experiments with a radio-controlled electric switching locomotive.

The Russian railways were investigating the problem of operating trains automatically with the object of saving electric current and increasing track capacity. The basis of the system is an electronic computer into which is fed data relating to the weight and resistance of the train, the characteristics of the line, the tractive effort of the locomotive and any variable information such as weather conditions, temporary speed restrictions, etc. The system can be adapted to both diesel and electric traction. It is not intended to dispense with the engineman, but his work would be reduced to watching the line ahead in case of emergencies.

In North America, several railways tried remote control of locomotives used in classification yard work, and the New Haven railroad also experimented with remote control of an electric train. While the experiments were successful, labour-union problems made it unlikely that widespread use of crewless locomotives would soon become common in the U.S. However, because of the guiding action of the flanged wheels on the rails, railways are ideally suited to fully automatic operation. Under the pressure of competition, they may be expected to move in this direction. Indeed, the extent to which railways would be able to automate their operations seemed likely to be a major factor determining how important a role they would play in the world economy during the last decades of the 20th century.

VIII. CLASSIFICATION (MARSHALING) YARDS

A freight train starting on its run usually consists of cars moving to a number of different destinations. Somewhere en route, the cars going to each destination must be sorted out and transferred to other trains going to the proper terminals. This is done in classification or marshaling yards. In the years following World War II, railways made much progress in improving the efficiency of these yards — mainly through the use of automatic equipment.

Most large classification yards have a hump over which cars are pushed. The cars then roll down the hump by gravity and each is routed into a classification track corresponding to its destination. The principle is similar to that of sorting letters into pigeonholes at a postoffice.

The speed of a car rolling down the hump siding can be controlled by retarders — electric or electropneumatic clamps that grip the wheels of the car as it passes over them. The degree of retardation can be controlled automatically by an electronic computer which takes into account such factors as the weight, speed and rolling friction of the car. Equipment of this kind enables more cars to be handled, reduces human error, lessens the risk of damage to cars and their loads, and reduces delays.

However, modern improvements involve more than just the automatic humping of cars. The modern electronic yard is usually blanketed with a local radio network, as well as telephone, teleprinter and pneumatic tube communication circuits. Television may be used to scan trains entering or leaving the yard. Infrared detectors scan the wheels of incoming trains to pick out any journal bearing that may be overheated. Repair shops adjacent to the yard are mechanized to speed the repair of cars found to be in bad order as they move over the hump. In a fully modern hump yard it is not unusual to classify a train and have the cars moving in outbound trains in less than two hours.

Because modern classification yards can sort cars with such efficiency, they eliminate the need to do this work at other, smaller, intermediate yards. Thus, one modern hump yard may permit curtailing or closing a dozen or more other yards. Most of the modern yards built in North America have paid for themselves in operating savings in three or four years, and this takes no account of the benefits of improved service to shippers.

IX. CO-OPERATION AMONG RAILWAYS

In both North America and Europe, close working relations among different (and often competing) railway systems developed almost from the earliest years. It was found desirable, for instance, that connecting railways agree on such basic elements as the gauge of track and the type of couplings to be used on cars. This mas done to such an extent that a shipper can send a carload of his goods from almost any railway point in North America to any other point, including, via car ferries, Cuba; and a passenger may buy, at his local railway agency, a ticket for a trip that may cover thousands of miles in the cars of many different railways.

1. North American Organizations. — The principal element for co-ordination among North American lines is the Association of American Railroads (A.A.R.), with headquarters in Washington, D.C. Members of the A.A.R. include about 185 of the principal railways in the U.S., Canada, Mexico and Cuba. The American Short Line Railroad association is a similar organization serving 275 smaller lines. In addition, railways and the companies that supply them with materials and equipment work together through numerous regional groups and trade associations.

Through its several divisions and their numerous working committees, the A.A.R. co-ordinates the operations of the individual companies that make up the North American rail network. Among results of this joint activity (by the A.A.R. and its various predecessor groups) are standard items of car equipment, such as couplers, brakes and safety appliances; standard time; standard train operating rules; standard rules governing the interchange of cars among railways; and rules covering the collection and division of revenues for interline movements of freight and passengers.

Through its research centre at Chicago, the A.A.R. also carries on technological research and testing; this is in addition to the testing and research work done by many individual railway companies. The A.A.R. also represents the U.S. railway industry in connection with legislative proposals in congress that may affect the railways, and it carries on an extensive public relations program for the industry as a whole.

Although the Canadian and several U.S. railways operate their own sleeping cars, most cars of this type are operated by the Pullman company, which is jointly owned by the principal railway companies. A similar jointly owned company, the Railway Express Agency, Inc., handles most express package traffic. This agency uses both railways and other types of transport; it has an active air express division.

A number of companies also own large fleets of freight cars but do not actually operate any railway line. These so-called private car lines were formed usually to meet the need for certain specialized types of equipment that could be better supplied in this way than by the individual railways.

Railways also co-operate throughout the western hemisphere through the Pan American Railway Congress association, which has its headquarters at Buenos Aires, Arg. It operates much like the International Railway Congress association (which has world-wide membership), that is, through the exchange of technical information among railways in the different North and South American countries.

2. European Organizations. — In Europe, too, the gradual spread of railway routes led to the need for some form of co-operation and uniform regulations relating to the movement of equipment. From this need came the Convention Internationale sur le Transport des Marchandises, or International Convention for the Transport of Freight (C.I.M.), which was established in 1890.

Later came the Convention Internationale sur le Transport des Voyageurs, or International Convention for the Transport of Passengers (C.I.V.). These were followed by the Regolamento Internazionale Veicoli, or International Wagon union (R.I.V.), and Regolamento Internazionale Carrozzi, or International Carriage and Brake Van union (R.I.C.). They succeeded earlier arrangements concerning the international movement and interchange of passenger and freight vehicles. From these arrangements also came annual passenger and freight train timetable conferences.

In 1885 the International Railway Congress association was formed for the purpose of exchanging technical information between administrations, and in 1922 the Union Internationale des Chemins de Fer, or International Union of Railways (U.I.C.), was created. Its original aim was to improve international services. During the interwar years it was also concerned with technical measures and joint regulations for improving international traffic.

After World War II, European railway co-operation made great strides in many different spheres and, in particular, the scope of the U.I.C. was considerably enlarged. From the U.I.C. sprang a number of other organizations that made important contributions to the economy and progress of the European railway systems.

The Europ freight car pool came into being in 1953. Previously, freight cars entering another country had to be returned to the owning system as quickly as possible after unloading, subject to efforts being made to find a return load. Europ cars are not bound by this requirement, which saves millions of empty car miles a year.

Interfrigo was created in 1949 with the object of developing the international transport of perishable traffic at controlled temperatures. It is owned jointly by 11 railway systems, and there are agreements with nonmember administrations. Interfrigo has a fleet of 900 vehicles and, in addition, operates in international traffic some 10,000 refrigerated vehicles belonging to members and their subsidiaries.

The Office for Research and Experiments (O.R.E.) was created by the U.I.C. in 1949. Its purpose is to conduct research and tests for the benefit of members. Unlike the Association of American Railroads, O.R.E. does not have its own research establishment. Instead, it uses the laboratories and testing plants of its members. Financing is handled by a common fund, the cost being divided among the 29 members in proportion to the operated track mileage of each.

Eurofirma is a financing company that was established in 1955 with about 16 administrations as members. It finances the purchase of locomotives and rolling stock.

Trans-Europ express (T.E.E.) services are operated jointly by the Dutch, Swiss, German, French and Italian railways. They consist of a network of international express trains linking important cities in eight countries. Operations commenced in 1956. The trains are owned by the different administrations but must conform to accepted standards of comfort, speed, etc. The first trains were all diesel-powered, but in 1959 the Swiss ordered trains capable of running on four different electric traction systems for operating T.E.E. services.

Although it is a private company, the Compagnie Internationale des Wagon-Lits (C.I.W.L.) occupies a unique position in the field of international passenger services in Europe. It has been engaged in the operation of sleeping cars on international services since 1876. It also operates dining cars, Pullman cars, buffet and light refreshment facilities, restaurants at stations and airports, a motel, and restaurant and cabin facilities on river steamers. The company is registered in Brussels and has its operational and administrative headquarters in Paris. Its activities, although concerned principally with Europe, also extend to Africa and the middle east.

X. CONCLUSION

The railways can look back over a proud history. They were a vital element in the industrial revolution. They helped make Britain an industrial power, played similar roles in countries such as France and Germany, and went on to do much the same in Russia. Railways literally built the United States and Canada, and they remained the economic backbone of most of the major world powers.

But the railways in a number of countries — especially in Britain and the United States — were in serious trouble by the 1960s: they were steadily losing traffic to other modes of transport. In most countries, the railways had long since come under state control. and the remaining privately owned lines were finding it difficult to operate at a profit. Railway mileage mas shrinking in many countries. Did this foretell the end of this great form of transportation?

Technology was evolving so rapidly that it was probably unwise to say that this could not happen. However, as of the 1960s, it seemed unlikely. No other form of transportation had yet been developed to the point where it could challenge the railway as an all-around carrier.

Railways still otier two major advantages: (1) At distances of more than 100 or 200 mi.. they can haul any kind of freight. as well as passengers, at a true cost lower than any other form of transportation on land or air; (2) They are all-purpose land carriers. Pipelines may carry liquids and some solids economically: airplanes may produce savings on very high-value commodities; trucks offer speed and flexibility for relatively short hauls; overland conveyor belts may prove of value for certain bulk commodities. But only railways can carry anything, almost anywhere —and do it with little regard for weather conditions.

In sum. the railway is one of the earliest and greatest material achievements of the industrial era. It seemed likely to continue serving man's evolving civilization for many years to come.

TUBE: *see* SUBWAY (UNDERGROUND RAILWAY).

RAIMONDI, MARCANTONIO (called MARCANTONIO) (*c.* 1480–*c.* 1534), Italian engraver, outstanding Italian master of engraving of the Renaissance and the first who practised it to reproduce designs of other artists rather than his own. He received his training in the workshop of the famous goldsmith and painter Francesco Raibolini, called Francia. There, according to Vasari, "he made waist buckles and many other things in *niello* . . . being in truth most excellent in that craft."

The real fame of Raimondi was to be founded on his attainments in that particular development of the goldsmith's art which consists of engraving designs on metal plates for printing. About 80 engravings can be attributed to the first six years of his career (1505–11). They include many subjects from mythology and some of religious character. Figures, drapery and composition bespeak the influence of Francia, but the landscape backgrounds and the expression of form by light and shadow indicate German traditions as well. Perhaps for commercial reasons or to improve his style, he produced a series of counterfeits of copper engravings from Albrecht Durer's woodcuts. There are 69 of these: 17 from the "Life of the Virgin," 37 of the woodcut "Little Passion" and a few others. The "Life of the Virgin" was copied in 1506 and signed with Durer's signature. Durer, traveling in Italy in the same year, complained to the Venetian senate and Raimondi added his own signature to the copies he subsequently completed in 1510 of Durer's "Little Passion." Raimondi profited greatly by these studies of Durer's energetic line and his use of crosshatching in modeling. He was to make brilliant use of these under another influence. Until this time he had lived only in Bologna, with the exception of a visit or visits to Venice.

Soon he was attracted to the circle that surrounded Raphael in Rome. Where or when he met Raphael is uncertain. His passage to Rome by way of Florence was supposedly marked by an engraving (1510) known as "The Climbers" (*Les Grimpeurs*), in which he reproduced part of the design of Michelangelo's cartoon of soldiers surprised while bathing, he added behind the figures a landscape imitated from the young Dutch engraver Lucas van Leyden. The piece in which he is recorded to have first tried his hand after a work of Raphael is the "Lucretia." From that time until he disappears in the sack of Rome in 1527, Raimondi was almost exclusively engaged in engraving the designs of Raphael or of his immediate pupils. Raphael, the story goes, was so delighted with the print of the "Lucretia" that he later personally trained and helped Raimondi.

A printing establishment was set up under the charge of Raphael's colour grinder, Baviera, and profits in its early days were shared by the engraver and the printer. The sale soon became very great; pupils gathered about Raimondi, of whom the two most distinguished were Marco Dente, known as Marco da Ravenna, and Agostino De Musis, known as Agostino Veneziano. During the last 10 years of Raphael's life and for several years following his death, the group produced a great number of engravings after the master's works. They did not usually copy his finished paintings, but worked up (with the addition of simple backgrounds and accessories) his sketches, which often gave the composition in a ditierent form from the finished work, and are all the more interesting on that account.

Raimondi's best engravings (*e.g.,* "Massacre of the Innocents") were done during the first years after he had attached himself to Raphael. In them he entered into the genius of his master and lost little of the chastened science and rhythmical purity of Raphael's contours. In the parts where he was left to himself (the rounding and shading, the background and landscape) he managed his burin with all the skill and freedom he had gained by the imitation of northern models, while dispensing with the northern emphasis and redundance of detail. Raimondi's engravings after the works of Raphael's later years were colder and more ostentatious. Still more so, as is natural, were those which he and his pupils produced after the designs of the followers of Raphael and Michelangelo, such as Giulio Romano, Polidoro Baccio or Bandinelli.

Raimondi's association with Giulio Romano (*q.v.*), was the cause of his first great disaster in life. He engraved a series of obscene designs by that painter in illustration of the *Sonnetti lussoriosi* of Pietro Aretino which caused his arrest. Marcantonio's ruin was completed by the calamities attendant on the sack of Rome, by the German troops of the emperor Charles V of Spain in 1527. He had to pay a heavy ransom to escape the Spaniards, and fled, to quote Vasari, "all but a beggar." It is said he took refuge in his native city of Bologna, but he never again emerged from obscurity. All that is known with certainty is that in 1534 he was dead.

RAIN: *see* METEOROLOGY; RAINFALL.

RAINALDI, CARLO (1611–1691), Roman baroque architect, noted particularly for his works of the 1660s, was born in Rome in 1611 and died there in 1691. He collaborated with his father, Girolamo Rainaldi (1577–1655), a distinguished architect who transplanted to Rome the north Italian mannerist tradition of Pellegrino Tibaldi. After his father's death, Rainaldi evolved a monumental grand manner, without entirely discarding his paternal heritage.

The final building of his masterpiece, Sta. Maria in Campitelli (1663–67), showed a north Italian rather than a Roman pedigree. The use of many freestanding columns gave the building a scenographic quality which had neither past nor future in Rome but influenced late baroque north Italian church design. Nor was the facade, closely set with columns, rooted in the Roman tradition. Again, its basic motif—two enormous aediculae, one set into the other—was current in northern Italy.

Rainaldi's last important work was the grand façade uniting the old apse of Sta. Maria Maggiore with the chapels of Sixtus V and Paul V (1673). Thenceforth his practice was confined to a number of smaller enterprises. (RF. W.)

RAINBOW, a name for a set of coloured arcs seen against the sky whenever falling water droplets (from a rain cloud or in a spray of a waterfall or fountain) are illuminated by a strong light source (the sun or the moon).

The bows appear as concentric arcs, with the common centre on the line connecting the eye of the observer and the light source. Most frequently only one bow is clearly visible. It appears on the opposite side from the source; its angular radius of the red border is about 42°. Other colours of the spectrum can be seen inside of this border, ending with the violet. Occasionally another, secondary rainbow is observed above the primary rainbow. Its angular radius is about 54°, and the sequence of the colours is reversed: the red is inside and the violet on the outer border of the bow. The space between these two bows seems to be relatively dark. The centre of these bows is, angularly, as far below the horizon as the source (the sun) is above. Hence, usually less than a semicircle of these coloured arcs is visible. However, if the droplets are illuminated by a reflected source from a large water surface, the rainbow will appear as arcs of circles, with the centre above the horizon. Such a reflected rainbow will intersect the ordinary rainbow at the horizon.

Inside of the outer border of the primary rainbow, additional coloured bows can be sometimes seen, called (improperly) supernumerary bows. The appearance of these bows depends primarily upon the size of the droplets; thus it varies quite considerably. When superposed on the ordinary rainbow, these supernumerary bows cause eventually a broadening or disappearance of any particular colour in the rainbow, which then results in a great variety in the brightness and purity, as well as in the angular width of coloured bows. In particular, if the water droplets are very small (of a diameter of 0.1 mm. or less), the superposition of the ordinary and supernumerary bows leads to an almost white rainbow, sometimes known as Ulloa's ring or a fogbow.

The rainbow was first correctly explained by M. A. de Dominis in 1611. The primary bow is formed by two refractions and one internal reflection in the water droplets, the secondary bow by one more additional internal reflection. This explanation was further developed and experimentally confirmed by Descartes (1637). The explanation of the colours in the rainbow was given later by Sir Isaac Newton. The supernumerary rainbows were explained much later by Thomas Young (1803) as the interference effect of two ray systems in the inner space of the bows; the mathematical theory was given by Sir George Biddell Airy (1838).

The original explanation of the rainbow by De Dominis and by Descartes is based on tracing the path of a light ray falling on

n	Minimum deviation (D)	
	Red (.656μ)*	Violet (.397μ)
Primary rainbow	137°.6 ($\pi-42°.4$)†	139°.4 ($\pi-40°.6$)
Secondary rainbow	230° ($\pi+50°.4$)	233°.6 ($\pi+53°.6$)
Tertiary rainbow	317°.5 ($2\pi-42°.5$)	322°.1 ($2\pi-37°.9$)
Quarternary rainbow	402°.8 ($2\pi+42°.8$)	408°.6 ($2\pi+48°.6$)

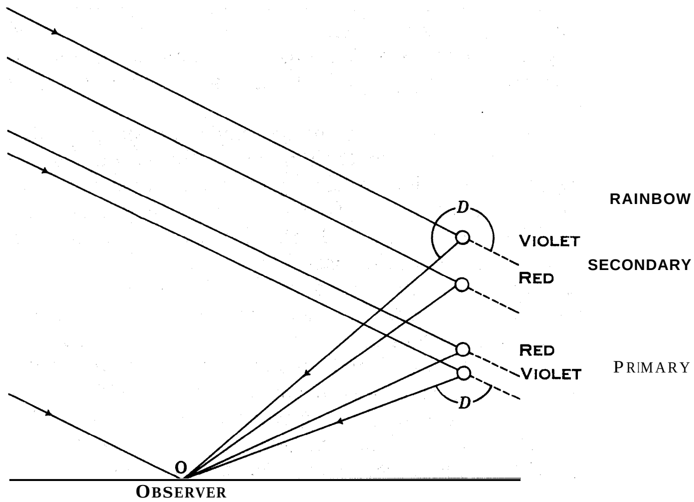
*$\mu=10^{-4}$ cm. †$\pi=180°$.

a transparent sphere with the use of the laws of geometrical optics. From the law of refraction and reflection it is easy to determine the deviation of the emerging ray from its original direction of incidence.

The angle of this deviation depends upon the angle of incidence, the number of internal reflections n and the index of refraction of the medium inside the sphere. For a particular angle of incidence the deviation has a minimum, given in the table.

The light emerging from the sphere reaches a high intensity around the direction of minimum deviation; the intensity then gradually decreases as the deviation increases. There are, however, no rays, hence no intensity on the other side of this direction (for smaller deviations). The observer will then see the highest intensity looking against the rays having minimum deviation, called sometimes Descartes rays. The Descartes rays from all individual droplets will form a cone with the vertex in the observer's eye and with the axis in the direction from or toward the source—the sun.

The light emerging from the droplets after one internal reflection will have the greatest intensity in the directions forming such a cone with the angle of 42°.4 in the red and of 40°.6 in the violet. The observer will see bright arcs of all spectral colours from the red over yellow, green, blue to violet. Since the angle for the red is greater, the red arcs will form the outer border, the violet arcs the inner one. The display fits the description of a primary rainbow. Similarly the secondary rainbow can be explained as consisting of Descartes rays from two internal reflections; the



SCHEMATIC DIAGRAM OF THE ORIGIN OF THE PRIMARY AND SECONDARY RAINBOW. *D* IS THE ANGLE OF MINIMUM DEVIATION OF EMERGING RAYS

angle between the axis of the corresponding cones and the rays is 50°.4 for the red and 53°.6 for the violet. The secondary bows appear above the primary, and the sequence of the colours is reversed. (*See* fig.) The rays from the droplets above the primary and below the secondary bow would have to have the deviations smaller than the corresponding Descartes rays if they were to reach the observer's eye. This explains the dark space between these two bows. The tertiary and quarternary bows are quite faint and thus difficult to see against the bright sky in the vicinity of the sun.

The rays incident on the sphere on either side of the Descartes rays emerge only on one side of the minimum deviation. In this region the two systems of rays are crossing each other. Their superposition leads necessarily to interference patterns, with alternative maxima and minima of intensity in different directions. For a particular colour the positions of these maxima and minima are strongly dependent upon the size of the sphere, being closer for larger diameters of the sphere. The main maximum is usually close to the primary rainbow.

The superposition of the secondary maxima and minima are responsible for the great variation in the brightness and in the width of individual coloured arcs in the rainbow. If, for example, the secondary maximum in the red falls in the direction of the green arc in the primary rainbow, the mixture of these two colours produces an additional yellow arc; in the rainbow the yellow arc has enlarged width compared to that of other colours. For smaller droplets the secondary maximum in the red may be shifted beyond the blue or violet of the primary rainbow, thus giving rise to a supernumerary bow.

RAINFALL or snowfall usually occurs from fairly thick cloud systems fed by ascending moist air. In its ascent the air expands as a result of the decreasing pressure with height and cools adiabatically (see Adiabatic Processes in Atmosphere). Water-vapour saturation is reached and maintained, accompanied by the production of great quantities of liquid water droplets or ice crystals.

In such active clouds the physical processes required for growth of the cloud droplets or crystals to raindrops or snowflakes are accomplished easily. Meteorological evidence indicates that the ascending motion is far more important than the minutia of precipitation physics in determining when and where the precipitation will occur. Radiation, conduction and mixing are relatively inefficient atmospheric cooling processes. producing the less spectacular forms of condensation, such as dew, frost, fog and drizzle. Air cooled by lifting may be internally stable and require forced lifting, such as produced by mountains. or it may be potentially unstable and require only an initial impulse to establish free convection.

Raindrops have limited fall velocities and may be deposited some distance downwind from their point of formation, but, in general, rates of precipitation are closely related to rates of ascent. Rapid and extensive lifting by free convection in unstable air masses produces the intense rainfalls associated with showers and, in the warmer, more humid air masses. thundersho~vers.

Lifting processes are represented by air gliding upward over mountain slopes or over wedges of cooler air, free convection, underrunning by cooler wedges of air and large-scale net horizontal inflow of air at lower levels. The last is the most effective natural lifting process, since large masses of air are forced upward. Any or all of the lifting processes may operate on stable or unstable air within the life cycle of one major rainstorm. Orographic lifting of stable air gliding upward over gently sloping cooler wedges of air produces the typical winter rains. which are uniformly light, steady and extensive. The flash floods of the southern United States represent the other extreme, in that highly unstable and very moist maritime air is lifted by the combined effects of horizontal convergence, upglide over cooler continental air and orographic lifting.

Forced lifting of maritime westerlies produces more than 100 in. of rainfall a year on many windward points on western mountain ranges, leaving some leeward continental areas with ten inches or less per year. Rainfall is greatest on windward coastal slopes. near warm tropical waters and in areas of marked cyclonic activity. Rainfall is least near the centre of continents, in colder higher latitudes, leeward of mountain ranges and within areas of persistent anticyclonic activity.

Mt. Waialeale, Hawaii, with a 20-year average of 460 in. from tropical easterlies, is the wettest known point. The nearest competitor is Cherrapunji. Assam, with an annual average of 426 in. from the moist tropical monsoon. Less than 10 in. and more than 60 in. per year represent approximate extremes of rainfall for all of the continents. Rainfall is slight in the central regions of the subtropical anticyclones, which are therefore the desert regions of the earth. In parts of the desert no appreciable rain has ever been observed.

Over most of Europe. South America, eastern North America and central Africa the annual rainfall exceeds 20 in., while over most of Asia. excluding India. Tibet and China. the annual rainfall is less than 20 in.. being less than 10 in. in a long tongue extending from Arabia across to northeast Mongolia. The central regions of Australia, most of northern and a part of southwest Africa. portions of the intermontane area of the United States, portions of the west central coast and southern east coast of South America also have less than ten inches of rain in the year. Portions of the west coast of Africa, between the equator and 10° N., a strip of the west coast of India, parts of Assam, a coastal strip of Burma, windward mountain slopes in the temperate latitudes of North and South America and many isolated tropical stations average more than 100 in. of rain in the year. Rainfall intensities greater than 1 in. in five minutes. 4 in. in one hour or 20 in. per day are quite rare, but these intensities on occasion have been more than doubled for the respective durations.

The measurement of rainfall over an area by means of a network of rain gauges is often unsatisfactory because large variations in the amount of rainfall occur between adjacent gauges. This defect can be partly remedied by the use of a 3 to 10 cm. radar, which can give an areal picture of relative rainfall intensities at any moment as far as 200 mi. away. This is possible because the amount of radar reflection from raindrops is very sensitive to their size and number. (See Radar Meteorology.)

Average annual rainfall plus melted snow water is given in the table for some of the chief cities of the world. Data for other places will be found in standard textbooks on climatology. Detailed rainfall data for specific areas is best obtained by inquiry directed to any of the more prominent national meteorological services.

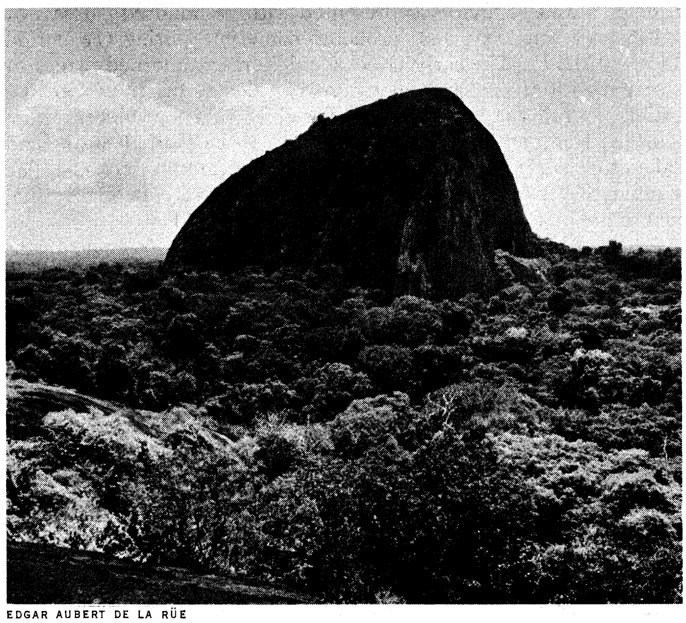
RAIN FOREST. The name rain forest is commonly applied to the luxurious evergreen forest typical of wet tropical lowlands (tropical rain forest). Some authors have chosen to broaden the term to include certain forest types found in subtropical and temperate climates. Factors favourable to the development of the true tropical rain forest are annual rainfall amounts in excess of 80 in. (nith no pronounced dry season) and mean temperatures between 68" and 8j° F.

The term rain forest was first employed in 1898 by A. F. W. Schimper, who described the formation as "Evergreen, hygrophilous in character, at least 30 m. high, but usually much taller, rich in thick-stemmed lianas and in woody as well as herbaceous epiphytes." This definition came to be the one most commonly accepted by ecologists.

A characteristic feature of the climax tropical rain forest is the storied or stratified layering of the dense tree canopy. The crowns of the trees usually form three distinguishable stories, but occasionally they form only two. The trees themselves are remarkably uniform in general appearance even though the number of separate species may be large (often as many as 100 distinct species of trees per acre); trunks are usually straight and slender, bases often flanged by plank buttresses; foliage consists most frequently of large. leathery, dark-green leaves with entire or nearly entire margins; flowers are usually inconspicuous. As P. W. Richards stated, "So uniform is the foliage that the non-botanical observer might easily be excused for supposing that the forest was predominantly composed of species of laurel" (P. W. Richards, Tropical Rain Forest, Cambridge University Press, 1952).

Contrary to popular belief, the tropical rain forest is not an impenetrable jungle of undergrowth, creepers and rotted vegetation. Such a description applies only along edges of clearings or banks of waterways, where the strong tropical sunlight can penetrate to the forest floor. In most cases, herbaceous ground flora is sparse and the soil bare or only thinly covered by dead leaves. An abundance of climbers is characteristic of the forest, however, in addition to almost unbelievable numbers of epiphytes, which grow on trunks, branches and even the leaves of the trees. The latter group of flora include some of the most exotic flowering plants found in any plant community.

The tropical rain forest forms an irregular belt around the earth, bisected unequally by the equator and interrupted by seas,



EDGAR AUBERT DE LA RÜE

EQUATORIAL RAIN FOREST NEAR THE SOUTHERN BORDER OF FRENCH GUIANA. A GRANITE INSELBERG, LIKOUTOU, RISES FROM THE FOREST TO A HEIGHT OF 1.650 FT.

mountains and, in a few cases, "tongues" of dry subtropical climates which here and there extend into equatorial regions. Ecologists recognize three distinct formations of tropical rain forest. These correspond to the three primary regions of the earth which possess equatorial rainy climates, and may be described as follows:

American rain forest: tropical portions of Central and South America from the Gran Chaco on the south to southern Mexico on the north.

Indo-Malayan rain forest: this formation extends from Ceylon and western India to Thailand, Indochina, the Philippines and through the Malay archipelago to New Guinea. In Australia the rain forest occupies a narrow strip along the northeastern coast.

African rain forest: this formation is quite irregular; the largest portion lies within the Congo basin and along the coast of the Gulf of Guinea.

Related Types. — The changes in vegetation with increasing altitude within the tropical rain forest are as marked as in the forests of temperate latitudes. As greater altitudes are reached, the typical forest of the equatorial lowland begins to change character: trees are lower, the number of species becomes less, and finally the typical tropical flora is replaced by a mountain vegetation, where many of the species are temperate. Richards refers to this formation type as the "montane rain forest." The altitude at which this transition occurs varies markedly from region to region depending upon temperature, rainfall, exposure to winds, soil and perhaps other factors. The base of the montane rain forest in some areas occurs at altitudes as low as 800 ft.; in others it is as high as 4,000 ft.

In eastern Australia, southeast Asia and on the east coast of South America, the evergreen rain forest extends far into subtropical latitudes. These forests differ from the true tropical rain forest and should be considered a distinct formation type — subtropical rain forest. The species of trees decrease in number with increasing distance from the equator, and subtropical and temperate species occur together in increasing proportion. Features such as buttressing and cauliflory tend to disappear. Nevertheless, the forest retains much of the true tropical aspect.

One of the important subtypes of the tropical rain forest is the mangrove swamp forest found along tropical seacoasts. The marine muds of coastal tidal zones provide ideal conditions for mangrove formations. These formations, however, may also occur far inland along brackish estuaries. Standing upon stilt roots which lift the main trunk of the tree above high-water level, the mangrove forest at low water presents an impenetrable tangle of roots and knees. Mangroves are of considerable economic importance because of their role in reclaiming land from the sea and also because they are an important source of firewood, timber and tanbark. Mangrove vegetation extends to about 32° N. and even farther from the equator in the southern hemisphere, but it reaches its greatest luxuriance where the tropical rain forest is the climax forest formation.

The term temperate rain forest is reserved to describe certain subantarctic broadleaf evergreen forests of southeastern Australia, New Zealand and southern Chile which are dominated by such temperate trees as *Nothofagus*. Rainy temperate forests of other regions, such as those of the coasts of Washington and Oregon, are occasionally referred to as rain forests, but such a usage of the term has not gained general acceptance among ecologists.

See Paul Westmacott Richards, *The Tropical Rain Forest* (1952); A. F. W. Schimper, *Plant-Geography Upon a Physiological Basis* (1903). (W. C. Js.)

RAINIS, JOZSEF, pseudonym of JAN PLIEKSANS (1865–1929), Latvian poet and dramatist, was born on Sept. 12, 1865, at Tadenava, in the district of Illukst, Courland. He was educated at the Riga *Gymnasium,* and from 1884 to 1888 studied law at St. Petersburg (Leningrad). He then practised as a barrister at Mitau, Courland. From 1891 to 1895 he edited in Riga a democratic Latvian paper, *Dienas Lapa* ("Daily Paper"). He was arrested by the Russian government on political grounds and remained in exile, first at Pskov and then at Viatka, until 1903. Among Latvian poets he may be considered the chief exponent of democracy. He translated plays from Shakespeare. Goethe and Schiller. His principal historical tragedies are *Uguns un nakts* ("Fire and Night"), *Put vejini* ("Blow Breeze") and *Daugava* ("The Dvina"). *The Sons of Jacob* was translated into English and was produced on May 22, 1925, at the New Scala theatre, London, by the International Theatre society. For several years Rainis was director of the Latvian National theatre and in 1920 he became a member of the Latvian *saeima* (parliament).

Rainis died at Riga on Sept. 13, 1929.

RAINPROOF FABRICS. Rainproof fabrics can be divided into two general classes — apparel fabrics and nonapparel fabrics. Included in the first group are fabrics used in raincoats, slickers, umbrellas, etc. Among those in the second group are fabrics employed in making tents, tarpaulins, etc. Rainproof fabrics may be actually waterproof or merely water repellent. Waterproof fabrics are impervious to water, the interstices or pores in the cloth being completely covered or filled by the waterproofing agent or sufficiently stopped up that water will not pass through them at the maximum pressure to which the fabric is exposed under conditions of use.

Water-repellent fabrics, on the other hand, are not impervious to water, the repellent effect being obtained not by closing or materially reducing the size of the interstices or pores, but by treating the cloth with a compound which increases the surface tension between the fibres and the water and thus makes it more difficult for the water to penetrate into and through the fabric.

Thus, a raincoat made from a lightweight water-repellent fabric may withstand a light shower but not a heavy, driving rain. The degree of water repellency depends on the type and twist of yarn, weight and closeness of weave and efficacy of the water-repellent compound. In general, heavy, closely woven fabrics are more water repellent than are light, loosely woven fabrics.

Other important applications of waterproof and water-repellent fabrics, in addition to those mentioned above, include shower-bath curtains, spotproof table covers and sheetings for hospital use. Fabrics which are both waterproof and chemical resistant find use in such applications as protective clothing for workers engaged in the handling of chemicals. Fabrics which are both waterproof and gasproof or airtight are employed as a protection against noxious gases. (W. W. CH.; X.)

RAIN TREE (Samanea saman), a tropical South American tree, so called from the fact that the ejection of juice by cicadas (*q.v.*) upon it causes it to appear to be always raining under its branches.

Andira inermis, which belongs to the same family (Leguminosae), is also called rain tree for the same reason.

RAINY LAKE lies 150 mi. W. of Lake Superior, partially on the international boundary between Ontario and Minnesota. The lake is 1,108 ft. above sea level and covers an area of 345 sq.mi. It is 56 mi. long and has an average width of 5 mi. (maximum, 27 mi.). There are over 500 islands in it. The shores, characteristic of lakes on the Canadian shield, are irregular and deeply indented. Drainage is westward through Rainy river to Lake of the Woods.

Fort Frances, Ont., and International Falls, Minn., on the river at the lake's southwestern extremity, manufacture pulp.

(W. G. DN.)

RAIPUR, a municipal town, a tehsil and district in Madhya Pradesh, India. The town (pop. [1951] 89,804) lies 188 mi. E. of Nagpur. The former Rajkumar college, where the sons of the chiefs of the Chhattisgarh and Orissa states were educated, has been thrown open to the public and there are four colleges in Raipur all affiliated to the university of Saugar, viz., the Chhattisgarh college, the College of Science, the Law college and the New Arts college. In the late 1950s the erection of a steel plant at Bilai in the neighbouring Durg district was projected, with a mines and metallurgy college to be established.

Raipur tehsil (area 1,115 sq.mi.) had a population (1951) of 384,269.

RAIPUR DISTRICT (pop. [1951] 1,640,006) covers an area of 8,214 sq.mi. and occupies the south and centre of the Chhattisgarh rice plain. It includes a large area of forest.

RAIS (or RETZ), **GILLES DE** (1404–1440), marshal of France, the central figure of a 15th-century cause *célèbre,* was born at Machecoul in Sept. or Oct. 1404. He joined the Montforts, supporting John V of Brittany against the house of Penthièvre. He helped to release Duke John from Oliver of Blois, count of Penthièvre, and was rewarded by extensive grants of land. In 1426 he raised seven companies of men-at-arms and, under Richemont (Richmond) (see ARTHCR III of Brittany), began active warfare against the English. He accompanied Joan of Arc to Orléans, fighting by her side there and afterward at Jargeau and Patay. He had advocated further measures against the English on the Loire before carrying out the coronation of Charles VII at Reims. On July 17. 1429, he was made marshal of France at Reims. He was a munificent patron of literature and of music. He ran into financial difficulties and began to sell his estates for small sums, but in 1436 his kinsfolk appealed to Charles VII, who proclaimed further sales to be illegal. John V refused to acknowledge the king's right to promulgate such a decree in Brittany. Gilles hoped to redeem his fortunes by alchemy and also spent large sums on necromancers, seeking to guarantee himself from evil consequences by extravagant charity and splendid celebration of the rites of the church. The abominable practices of which he was really guilty seem to have escaped the notice of his equals or superiors, though suspected by the peasantry. His servants kidnapped children. generally boys, whom he tortured and murdered. In 1440 he came into conflict with the church by an act of violence which involved sacrilege and infringement of clerical immunity and in the autumn he was arrested and cited before the bishop of Nantes on various charges, the chief of which were heresy and murder. With the latter count the ecclesiastical court was incompetent to deal, and Gilles refused to accept its jurisdiction (Oct. 8).

A parallel inquiry was made by Pierre de l'Hôpital, president of the Breton parliament, by whose sentence he was hanged (not burned alive as is sometimes stated) on Oct. 26, 1440, with two of his accomplices. In view of his confessions his guilt seems certain, but the irregularities of the proceedings, the fact that his chief accomplices went unpunished, together with the financial interest of John V in his ruin, have left a certain mystery over the trial. His name is connected with the tale of Bluebeard (*q.v.*).

RAISIN, the dried fruit of certain varieties of grape (*q.v.*). Raisin grapes were grown as early as 2000 B.C. in Persia and Egypt. Dried grapes are mentioned in the Bible (Num. vi, 3) during the time of Moses. David was presented with "a hundred clusters of raisins" (I Sam. xxv, 18), probably sometime during the period 1110–1070 B C. The early Greeks and Romans adorned places of worship with raisins, and they were awarded as prizes in sporting events. Until the 20th century the chief raisin producers were Turkey, Iran and Greece; by mid-century the United States had taken the lead in production, with Australia ranking second. The United States raisin industry is located entirely in California, where the first raisin grapes were planted in 1851.

The word raisin is a contraction of the French raisin *sec,* meaning dried grape. However, by common usage only a few varieties of grapes are said to yield raisins upon drying. The three most important varieties of raisin grapes are the Thompson seedless, a pale yellow seedless grape, also known as sultana (Australia), white or oval kishmish (Turkey, Iran), sultanina (California); the muscat or Alexandria, a large-seeded variety also known as gordo blanco (Australia), white hanepoot (South Africa); the black corinth, a very small, black seedless type, also called zante currant, staphis (Greece) and panariti. Other varieties of local importance are the round kishmish, rosaki, dattier, monukka and cape currant.

The trade name applied to a raisin may also signify the method of drying (natural, golden-bleached, sulfur-bleached, lexia), the form in which marketed (seeded, loose, layers), the principal place of origin (Vostizza, Smyrna, Malaga), the size grades or the quality grades. Natural raisins are dried in the sun in their natural condition; they are grayish-black or grayish-brown with the natural bloom intact and with a rather tough skin. Golden-bleached raisins are produced from Thompson seedless grapes dipped in 0.5% lye, exposed to fumes of burning sulfur for two to four hours and dried in a tunnel dehydrator. They are lemon-yellow to golden-yellow in colour, used chiefly in baked goods. Sulfur-bleached raisins are pretreated the same as golden-bleached, but are dried by exposure to direct sunlight. The grapes are spread on trays and left in the sun for three to four hours. The trays are then stacked and the drying is continued for several weeks in the shade. The finished product appears waxy, and cream to faintly reddish-yellow. Soda-dipped or soda-bleached raisins are from Thompson seedless grapes hot-dipped in dilute lye but not sulfured, then dried in the sun or in a dehydrator. If dried rapidly they are light amber to medium brown, moderately tender and mild-flavoured. Oil-dipped and lexias are dipped in a dilute solution of lye upon which a thin film of olive oil is floated; they are dried on trays in direct sunlight, are medium to dark brown, tender and mild in flavour.

The values below represent a composite of several reports on the nutrient content of Thompson seedless raisins containing about 17% moisture: carbohydrate 68%–71%, protein 2%–3%, fat 0.5%–3%, 1,300–1,600 calories per pound; milligrams in 100-g. portions: calcium 55–78, phosphorus 33–130, iron 1.5–3.3, potassium 700–900, sodium 52–87; vitamin **A,** 50 I.U. per 100 g., small amounts of vitamins B_1, B_2, B_6, niacin, biotin and a trace of vitamin C. Natural fruit acids contribute to the pleasant tartness of this delicacy. (Jo. E. B.)

RAJAH, a Hindu title for a chief, or prince, derived from the same root as the Latin *rex.* Other forms are rao, rana and rawal, while chiefs of high rank are styled maharaja, maharao and maharana. The Hindustani form is rai, and the title of the Hindu emperor of Vijayanagar in south India was raya.

RAJAHMUNDRY, a city in the East Godavari district of Andhra Pradesh, India. Pop. (1961) 130,030. It is on the left bank of the river Godavari, at the head of the delta, 360 mi. N. of Madras, and has a station on the Southern railway, which is there carried across the river by a bridge of 56 spans.

Tradition divides the merit of founding Rajahmundry between the Orissa and Chalukya princes. In 1470 it was wrested from Orissa by the Mohammedans, but early in the 16th century it was retaken by Krishna Raja. It continued under Hindu rule till 1572, when it yielded to the Mohammedans of the Deccan under Rafat Khan. It passed into the possession of the French in 1753, but they were driven out by the British in 1758.

RAJASTHAN, a state of India in its northwestern part, occupying most of the Rajputana region (*q.v.*) and formed by the union of most of the princely states of the old Rajputana agency. It is bounded on the north by Punjab state and Pakistan, on the east by Uttar Pradesh and Madhya Pradesh, on the south by Bombay state and on the west by Pakistan. Area of Rajasthan, 132,-150 sq.mi.; pop. (1961) 20,146,173. The capital is Jaipur, pop. (1961) 402,760; other important towns are Jodhpur, Bikaner, Udaipur, Kotah and Alwar. The union was formed on March 25, 1948, by the former princely states of Bundi, Dungarpur, Jhalawar, Kishangarh, Kotah, Tonk, Udaipur (*qq.v.*), Banswara, Kushalgarh (chiefship), Partabgarh and Shahpura; on March 30, 1949, Bikaner, Jaipur, Jaisalmer and Jodhpur (*qq.v.*) were absorbed; the short-lived Matsya union (founded March 18, 1948)—Alwar, Bharatpur (*qq.v.*), Dholpur and Karauli states—was absorbed on May 15, 1949; and in Jan. 1950 part of Sirohi was added.

Largely desert in the west, the soil becomes more fertile toward the east. Grain, oilseeds, fruit and vegetables are cultivated, mainly in the east; camels, cattle and sheep are tended in the desert region. Marble, sandstone and limestone are found in abundance, and a large quantity of salt is processed, mainly from the famous salt lake at Sambhar. Weaving, dyeing and printing of cotton cloth, manufacture of carpets and other woollen fabrics, pottery, enamelling and work in ivory, lac and stone, and in brass and other metals, are the important industries.

The administration of the merged states was integrated, and the union divided into five divisions. The *rajpramukh* (the maharaja of Jaipur from 1949) governs on the advice of a ministry and there is a state assembly of 160 members. The government resettled 400,000 refugees and initiated measures to develop the water resources of the union. On April 1, 1950, the federal financial integration of the union was completed and certain items of expenditure transferred to the central government.— (S. GL.)

RĀJASTHĀNĪ LANGUAGE is a group of Indo-Aryan dialects bordered by Western Hindi on the one side and by Gujarati and Sindhi on the other—an area roughly that of Rājpūtānā and adjoining parts of central India.

Rājasthānī has many dialects which can be assigned to four main groups: northeastern, southern, western and east-central. The northeastern form, Mēwātī, approximates most closely Western Hindi. It is a transitional dialect and sometimes classified with Hindi. The southern, Mālvī, spoken in Mālwā and neighbouring areas, shares characteristics with Western Hindi to the east and with Gujarati to the west. The western. Māṛwāṛī, spoken in Māṛwāṛ and neighbouring districts. is geographically more extensive than all the other dialects combined. Jaipuri, the language of Jaipur, is the standard east-central dialect. It has affinities with Gujarātī, whereas Māṛwāṛī resembles Sindhi. None of the Rājasthānī dialects is recognized in the Indian constitution. *See* also GUJARATI LANGUAGE; HINDUSTANI LANGUAGE.

Phonology.—With few exceptions, the Rājasthānī system agrees with other modern Indo-Aryan languages (*q.v.*). Long *ā* is sometimes pronounced like *au* in English "Paul," *ē* and *ai* like a in "hat" and *nu* like o in "hot." In the west and south especially, *s* is replaced by h—in northern Gujarati and in a number of the Bhil dialects. An original aspirate h and the aspiration of aspirated consonants are often lost; *ch* is replaced by *s*. In contrast with Western Hindi, Rājasthānī (like Gujarati and Sindhi) retains the cerebrals *ḷ* and n. Otherwise Rājasthānī shares a common ancestry with Gujarātī in Śaurasēnī Apabhraṁśa.

Morphology.—Rājasthānī has two genders: masculine and feminine. There are sporadic instances of the neuter, less in the subdialects toward the midland, more to the west and south to the borders of Gujariiti, which has three genders. A special agent form of noun is used instead of the oblique form with the postposition *ne*, though this construction is often encountered in Mēwātī and Mālvī.

A strong adjective agrees in gender, number and case with its noun; weak adjectives remain unchanged. The pronouns correspond generally with those of Hindi. In common with Gujarātī, Rājasthānī uses the inclusive pronoun *ap* "we." In conjugation a passive stem is formed with the suffix ij; Sindhi and Lahndā have a similar formation. The simple present indicative often functions as a subjunctive. The simple future stem is made by means of the suffix *s* (or h); a periphrastic future is formed by adding *gō*, *16* or *lā* to the subjunctive, of which *gō* and *lō* agree in gender and number with the subject, while *lā* never changes. Compound tenses are formed from participles plus auxiliaries. (See *Linguistic Survey* of *India*, vol. ix, pt. ii. 1908.)

The literature of Rajputana, chiefly in manuscript form, includes a number of bardic chronicles. In Māṛwāṛ, premodern literature falls into two categories: *Ḍiṅgal* (composed in Māṛwāṛī) and *Piṅgal* (composed in Braj Bhāshā). Modern literary activity is sparse.

RAJGARH, a town and district of Madhya Pradesh, India. The town had a population of 7,408 in 1951.

RAJGARH DISTRICT (area. 2,383 sq.mi.; pop. [1961] 517,837) is comprised in part by the former princely state of the same name (area 926 sq.mi.; pop., 1941, 148,609) and some adjacent territory formerly under princely jurisdiction, all absorbed into Madhya Bharat on June 15, 1948. Madhya Bharat was merged into Madhya Pradesh on Nov. 1, 1956. The ruler of Rajgarh was a Ponwar Rajput. His state and Narsingarh resulted from a partition in the 17th century. Rajgarh later became tributary to Scindia, but fell under the general settlement of Malwa (*q.v.*) in 1818.

RAJGIR HILLS, a range of hills in the south of the Patna district of Bihar, India. They form part of a range extending northeast for 40 mi, from the neighbourhood of Bodh Gaya; at one place they rise to 1,272 ft., but elsewhere they seldom exceed 1,000 ft. in height. The hills in Patna district consist of two parallel ridges. In the valley between, south of the village of Rajgir, was built the old city of Rajagriha, "the royal residence." Legend ascribes it to Jarasandha, king of Magadha (south Bihar), who had his capital at Giribraja, "the city of hills." The outer fortifications can be traced on the crests of the hills for more than 25 mi.; they are 17½ ft. thick, built of massive undressed stones without mortar. These ruined walls are generally ascribed to the 6th century B.C. The remains of New Rajagriha, the reputed capital of Bimbisara (*c*. 520–490 B.C.), lie two-thirds of a mile north of the valley.

The Rajgir hills are associated with the life of Buddha, who often taught there. Chhatagiri is the old Gridhrakuta, or vulture's peak, which was one of his favourite resorts. One of the towers on the Baibhar hill (Vaibhargiri) has been identified as the Pipara stone house in which Buddha lived. The Sattapanni, the cave in which after his death the council of his disciples was held to record the tenets of the faith, has been identified with different sites on this hill and with the Soubhandar cave at its foot; the latter is now believed to have been excavated by Jains in the 3rd or 4th century A.D. A brick mound, topped by a Jain shrine, stands in the centre of the valley. Rajgir is a place of pilgrimage. There are modern Jain temples on the hills around the valley. There are also hot springs in the valleys surrounded by Hindu shrines.

RAJKOT, chief city of Bombay state, India, and former headquarters of the old Western India States agency and the two Kathiawar subagencies; pop. (1961) 194,510. It is an important rail centre for north-central Saurashtra, and is the seat of Dharmendrasinhji college, Kotak Institute of Science (Gujarat university) and a museum.

The former princely state of RAJKOT, a taluka (subdivision) (area 344 sq.mi.; pop., 1951, 181,619), was within the Western Kathiawar subagency of the combined Baroda, Western India and Gujarat administration before absorption into Saurashtra on Feb. 1, 1948. Saurashtra was absorbed into Bombay state Nov. 1, 1956.

RAJMAHAL, a former capital of Bengal, now a village in the district of Santal Parganas, Bihar state, India, situated on the right bank of the Ganges, where that river makes a turn to the south. Pop. (1951) 4,896. Rajmahal was chosen for his capital by Man Singh. Akbar's governor, in 1595–96, but in 1608 the seat of government was transferred to Dacca. It was again made the capital by the prince Shah Shuja in 1639, and was a second time superseded by Dacca 20 years later.

Even in 166j Manucci found that it had fallen into ruin, being full of dilapidated palaces, great fallen mansions and neglected gardens. Rajmahal has given its name to a range of hills, comprising an area of about 2,000 sq.mi., which rise to a height of about 2,000 ft. They are inhabited by an aboriginal race known as Maler (the Malli of Megasthenes) or Sauria Paharias; *i.e.*, "hillmen." The valleys are inhabited and cultivated by the Santals, a different aboriginal race.

RAJPRAMUKH (Hindi *raj[a]* "prince" + *pramukh* "chief official." "president," etc.). the title given to those Indian princes who were appointed in place of governors in certain constituent states of the dominion — later republic — of India where it was thought expedient to retain some of the traditional polity of princely jurisdiction and to employ the administrative ability of the princes. The states concerned are Hyderabad and Mysore, large territories capable of continued provincial autonomy within the federal framework; and five unions of former princely states —Madhya Bharat. the Patiala and East Punjab states union, Rajasthan. Saurashtra and Travancore-Cochin. The *rajpramukhs* of Hyderabad and Mysore are those princes recognized by the president of the republic as respectively nizam and maharaja of the two states; in the states unions the *rajpramukh* is elected for life by a council of the rulers of the covenanting states. and is usually the ruler of the most important of them. He is assisted by one or more *up-rajpramukhs* or vice-presidents. The *rajpramukh* and *up-rajpramukhs* are answerable to the state and republican legislatures and to the president of India, and retain none of the autocratic powers of the old princes; their position is rather that of a constitutional monarch. Vindhya Pradesh was set up as a *rajpramukh* state when India became independent, but after certain legislative difficulties, was administered centrally through a chief commissioner from Jan. 1, 1950. Kashmir (*q.v.*), under dispute between India and Pakistan after the political partition of the subcontinent. was regarded in the 1950 Indian constitution as a *rajpramukh* state within the republic.

See Ministry of States, *White Paper on Indian States* (Delhi, 1950).

RAJPUT (Sanskrit *raja-putra,* "son of a king": also known as *Thakur*, "Lord," and *Chhatri*), a generic term for a number of land-owning and military endogamous subcastes and hypergamous lineages spread over India, mainly in Rajputana and other parts of central and northern India. They have been described as the main obstacle to complete Moslem domination of Hindu India during the years of Islamic supremacy. Traditionally regarded as the descendants of the Rajanya warriors of the Rig-Vedic era and putative successors of the ancient Kshatriyas, the Rajput groups vary greatly in status from princely lineages such as the Sesodiya and Kachwaha down to lowly cultivators. They are divided into three major lines: the Solar line, the Lunar line and the "Fire-descended" line. Most authorities agree that they are of mixed origin. V. A. Smith *(Oxford History of India,* Oxford University Press! 1919) described them as "essentially an occupational caste composed of all clans following the Hindu ritual who actually undertook the act of government." E. A. H. Blunt (The *Caste System* of *Northern India,* Oxford University Press, 1932) concluded that in ancient India "a Hindu or Hinduized ruler *de facto* obtained recognition as a Rajput *de jure*." Sir Denzil Ibbetson regarded Punjab Rajputs simply as the royal families of a common Jat and Rajput stock. The fact that Rajputs are of mixed origin and that entry into Rajput rank could be obtained by political or military success probably accounts for the fact that today this caste title has become the goal of many *jatis* wishing to rise in status. Patrician lineages in tribal groups tend to sever commensal and marital relations with their natal groups and establish themselves as endogamous subcastes of Rajputs, often inventing an origin myth to justify their new position. Another ladder of entry into Rajput groups is provided by the custom of hypergamous marriage, which has led to much stratification into status levels of which the higher will take wives from, but not give wives to, the lower. The Rajputs are a proud caste with high traditions of courage and honour. Their social structure is feudal in character, and they are less constrained by caste restrictions on behaviour and diet than most castes.

See James Tod, *Annals and Antiquities of Rajasthan* (1829–32; Oxford ed., 1920). (H. N. C. S.)

RAJPUTANA, a region of the northwestern part of the Indian subcontinent, formerly occupied by the Rajputana states agency and now largely falling within Rajasthan (*q.v.*), a constituent state of the republic of India. The Rajputana agency's area was 132,559 sq.mi. and its population (1941) 13,670,208 (13,282,105 in areas subsequently taken into Rajasthan), compared with Rajasthan's area of 130,207 sq.mi. and population (1951) of 15,290,797. The difference of area arises from the incorporation into Bombay of the states of Danta, Idar, Palanpur and Vijayanagar and part of Sirohi. The former agency had headquarters at Abu in Sirohi state and was divided into four subagencies — the Jaipur, Western Rajputana, Eastern Rajputana, and the Mewar and Southern Rajputana states agencies. All the Rajputana states were under Rajput rulers except Tonk (Moslem), Bharatpur and Dholpur (Jat).

Physical Features. — The Aravalli range of mountains intersects the country from southwest to northeast. About three-fifths of Rajputana lies northwest of the range and comprises the Rajasthan districts of Bikaner. Jaisalmer and Jodhpur. With the exception of the parts of Jodhpur which lie immediately below the Aravallis, this area is sandy, ill-watered and unproductive, improving gradually from a desert in the northwest and west to comparatively fertile land in the east. The country to the east and southeast of the Aravallis includes fertile lands, hill ranges and long stretches of forest, where fuel and fodder are abundant. The chief rivers are the Luni, the Chambal and the Banas. The Chambal rises in the highlands of the Vindhyas and discharges itself into the Jumna after a course of 560 mi. There are several important artificial lakes, constructed for storing water. The only basin of any extent is the Sambhar salt lake, of about 50 mi. in circuit.

From the geological point of view, the country may be divided into three regions — the central and largest, comprising the whole width of the Aravalli system, formed of very old submetamorphic and gneissic rocks; an eastern region, with a sharply defined boundary, along which the most ancient formations are abruptly replaced by the great basin of the Vindhyan strata or are overlaid by the still more extensive spread of the Deccan trap, forming the plateau of Malwa; and a western region, of ill-defined margin, in which, besides some rocks of undetermined age, it is more or less known or suspected that Tertiary and Secondary strata stretch across from Sind, beneath the sands of the desert, toward the flanks of the Aravallis. Rajputana produces a variety of metals. Ore of cobalt and zinc blende are peculiar to it. Copper and lead are found in several parts of the Aravalli range and of the minor ridges in Alwar and Shaikhawati, and iron ores abound in several areas. Alum and blue vitriol (sulphate of copper) are manufactured from decomposed schists at Khetri in Shaikhawati.

The climate over the whole of Rajputana is very dry and hot during the summer — Sri Ganganagar, where 122° F. has been recorded, is the hottest place in India — whereas in the winter it is much colder in the north than in the lower districts, with hard frost and ice on the Bikaner borders. The rainfall is unequally distributed.

Social Structure. — The territory became known as Rajputana because it was politically possessed by the Rajputs (*q.v.*). The whole number of this race was only about 620,000 at the beginning of the 20th century, and nowhere did they form a majority of the whole population in a state; but they are strongest, numerically, in the northern areas and in Udaipur. The Brahmans rank first; with them may be classed the Bhats, the keepers of secular tradition and of the genealogies. Next come the mercantile castes, mostly belonging to the Jain sect; these are followed by the powerful cultivating tribes, such as the Jats and Gujars, and then come the so-called aboriginal tribes, chief of whom are the Minas, Bhils and Meos. Rajasthani (and its dialects) is the chief language, being spoken by more than 70% of the population.

History.— Before the invasion of upper India by the Mohammedans. Rajputana was subject for the most part to two or three powerful tribal dynasties. Chief of these were the Rathors, who ruled at Kanauj; the Chauhans of Ajmer; the Solankis of Anhilwara, in Gujarat; the Gehlots with the Sisodhyia sept, which remained in Mewar or Cdaipur; and the Kachwaha clan, which remained in Jaipur. These tribal dynasties of Rajputs were gradually supplanted by the Moslem invaders of the 11th century and weakened by internal feuds. The clans were finally either conquered, overawed or conciliated by Jalal ud-Din Mohammed Akhar—all except the distant Sisodhyia clan, which, however, submitted to Jahangir in 1616. The Marathas, having been called in by the Rathors to aid them, took possession of Ajmer about 1756; thenceforward Rajputana became involved in the general disorganization of India. By the end of the 18th century nearly the whole of Rajputana had been virtually subdued by the Marathas. On the outbreak of the Pindari War in 1817, the British government offered its protection. The Pindaris were put down, Amir Khan submitting and signing a treaty which constituted him the first ruler of the existing state of Tonk. By the end of 1818 similar treaties had been executed by the other Rajput states with the paramount power. The political history of Rajputana then became comparatively uneventful. The great storm of the mutiny of 1857 was short, as most of the rajahs remained loyal. For later political history of the region *see* AJMER and RAJASTHAN.

Rajputana is of great archaeological interest, possessing some fine religious buildings in ruins and others in excellent preservation. Among the latter are the mosques at Ajmer and the temples on Abu. But the most characteristic features of architecture in the country are shown in the forts and palaces of the chiefs.

RAJSHAHI (formerly RAMPUR BOALIA), a municipality, district and division of East Pakistan. The municipality of Rajshahi (pop., 1951, 39.662 mun.), on a branch of the Eastern Bengal railway (whose main line crosses the district from north to south), is the divisional and district headquarters and a steamer station on the Ganges.

The municipality is the seat of Rajshahi university, founded in 1953 to affiliate about 20 colleges formerly connected with Dacca university, and of the Varendra Research society's museum.

RAJSHAHI DISTRICT (pop., 1951, 2,214,172) comprises a marshy alluvial plain seamed with old river beds, but to the north and west a slightly elevated area is found in the Barind. Rice is the staple crop; pulses. oilseeds and jute are also grown. Indigo cultivation has disappeared and the silk industry is moribund. The hemp grown on a small tract in the north supplies all the ganja (see HEMP) consumed in this region. District area 3,639 sq.mi.

RAJSHAHI DIVISION comprises Rajshahi, Bogra, Dinajpur, Jessore, Khulna. Kushtia, Pabna and Rangpur districts (total area, 21,958 sq.mi.); *i.e.,* East Pakistan west of the line of the Jamuna (Brahmaputra) and Madhumati rivers. Pop. (1951) 14,064,239.

RAKOCZY, the name of a noble Magyar family, settled from early times in the county of Zemplen (from 1919 in Slovakia).

SIGISMUND RAKOCZY (1544–1608) was one of the foremost supporters of Stephen Bocskay (*q.v.*) in his rising against Jesuit encroachment in northern Hungary, and succeeded him for a brief period in 1607 as prince of Transylvania, resigning the throne in 1608 in favour of Gabriel Bathory.

GEORGE RAKOCZY I (1591–1648), the youngest son of Sigismund, was like him a staunch Protestant. He took a leading part in the rebellion of Gabriel Bethlen (*q.v.*) against Bathory, and was made commandant of Kassa (Kosice). After Bethlen's death Rakoczy was elected prince of Transylvania by the diet of Segesvar (Sighisoara) on Nov. 26, 1630. Following Bethlen's national Hungarian policy he declared war in 1644 with Sweden as ally on Emperor Ferdinand III on behalf of the oppressed Protestants of northern Hungary. By the Peace of Linz (1644) he secured the return of some territory to Transylvania and the confirmation of Hungarian religious liberties. His capital Gyula Fehervar (Alba Iulia) became a great Protestant centre.

GEORGE RAKOCZY II (1621–1660) was the eldest son of George I and Susannah Lorantffy. In 1643 he married Sophia Bathory, who embraced Calvinism for the purpose. Succeeding his father in 1648 as prince of Transylvania George II sought like him alliances with the neighbouring hospodars of Moldavia and Wallachia. Hoping to realize his father's abortive Polish ambitions he joined in 16 j6 with Gustavus Adolphus of Sweden in attacking Poland; an expedition undertaken in defiance of the Turks, to whom Transylvania still owed tribute. Rakoczy was forced to retreat on humiliating terms. He was deposed by the diet on Turkish orders in 1657, but was reinstated a year later; whereupon the Turks invaded Transylvania in force. Rakoczy died at Nagyvarad (Oradea Mare) of wounds received at the battle of Gyula (May 1660).

FRANCIS RAKOCZY I (1645–1676) never succeeded to his father's throne. His mother, disregarding his father's last wishes, procured in 1662 his conversion to Catholicism to which she had herself reverted. He kept a splendid court on the family estates at Sarospatak and Makovica. In March 1666 Francis married Helen Zrinyi (Zrinski). a Catholic and Hungarian patriot. Francis joined in 1670 the Zrinyi-Frankopan conspiracy, led by his wife's father Peter, who was executed in 1671. Rakoczy escaped death through the influence of his mother with the Jesuits, on the payment of a ransom. He died in 1676 at Makovica.

FRANCIS RAKOCZY II (1676–1735), losing his father in infancy, was brought up, together with his sister Juliana, by their mother Helen Zrinyi in an atmosphere of fervent Magyar patriotism. Her marriage in 1682 to Imre Thokoly, leader of the Hungarian Protestants and organizer with Turkish assistance of abortive anti-Habsburg risings, did much to dissipate the family fortunes. Defeated, Thokoly went into exile, leaving his wife to organize alone the defense of Munkacs (Mukachevo, Ruthenia). After its surrender in 1688 the boy Francis, violently torn from his mother and sister, was taken to Vienna to be brought up in Austrian ways, and put in the charge of Cardinal Leopold Kollonic, sworn enemy of Magyar patriotism. The cardinal placed him in the Jesuit college of Neuhaus (Bohemia). Francis however resisted and continued his studies at Prague. His emancipation from the cardinal was helped by the marriage of his sister to a Belgian nobleman in Austrian service, Ferdinand d'Aspremont-Linden, count of Reckheim. The couple encouraged Francis in his marriage to Charlotte Amelia of Hesse-Rheinfels, solemnized at Cologne in 1694.

Rakoczy now settled on his Hungarian estates. His birth, wealth and brilliant personal qualities made him the natural leader of the Magyar nation, a role in which he was encouraged by other magnates. On the eve of the War of the Spanish Succession they sought help for the Hungarian cause from Louis XIV. Their intermediary Longueval. a Belgian captain in the Austrian service, betraying his trust, Rakoczy was arrested and imprisoned at Wiener-Neustadt, where his grandfather Peter Zrinyi had met his fate. Escaping certain death with his wife's help by leaving his cell in the disguise of a dragoon officer, he took refuge in Poland where he remained for two years. In 1703 he was actually offered the crown of that country, but returned instead to Hungary, putting himself at the head of the peasant revolt, known as the Kuruc (crusader) rising. He had some initial success, but the Magyar gentry stood aloof and the battle of Blenheim destroyed hopes of help from France. On June 13, 1704, the Kuruc army of 7,000 was routed by the imperialists at Koronczo and later at Nagyszombat. Want of arms, money, native officers and infantry made any permanent success in the open field impossible, yet Rakoczy drilled his little army into some degree of efficiency, and even after the rout of Pudmerice (Aug. 11, 1705) disposed of 100,000 men.

Meanwhile the Transylvanians were looking to Rakoczy to restore their independence; he was elected prince on July 6, 1704, and he set up a council of state of 24 members. The following year he was made dux of a Hungarian confederation. His efforts to secure toleration for his Calvinist followers alienated the Holy See, and peace negotiations with the emperor during 1705 came to nothing, the latter refusing to acknowledge the independence of Transylvania. France would not recognize the rebels officially unless they formally proclaimed the deposition of the Habsburgs, a desperate measure actually adopted by the diet of Onod on June 13, 1707. In spite of this Louis XIV sent no effective help. Efforts to secure the tsar's help against Austria failing and his peasant armies suffering further heavy defeats, Rakoczy left his country forever on Feb. 21, 1711, a few months before the signing of the Peace of Szatmar. After two years in Poland. Rakoczy took refuge in France in 1713 on the invitation of Louis XIV. After a time at court he withdrew as an oblate to the Camaldule monks of Grosbois (his marriage had proved unhappy) but in 1717 accepted a Turkish offer to help organize an army in Turkey against the Austrians (he was to have a new principality as prize). Before Rakoczy reached Constantinople Sultan Ahmed III had determined on peace-making and had no use for his services. Exiled in 1719 to Rodosto (Tekirdag), near Istanbul, Rakoczy remained there till his death on Good Friday, 1735. His remains were solemnly transferred to Hungary in 1906.

His two sons lacked character. The Turks for a time played with the elder, Joseph, and in 1737 he was recognized by the sultan as prince of Transylvania, but died the following year, thus bringing the history of the Rakoczy family to a close.

See *Histoire des révolutions de Hongrie,* containing memoirs of Francis Rakoczy II (The Hague, 1739); Émile Horn, *François Rakoczi II* (Paris, 1906). (B. Br.)

RAKOVSKY, CHRISTIAN GHEORGHYEVICH (1873–?), Soviet politician and diplomat, of Bulgarian descent and Rumanian nationality, was born on Aug. 13, 1873, at Kotel, Bulgaria. His father's home in the Dobruja passed after the Russo-Turkish war to Rumania, and the family became Rumanian. Rakovsky's Bulgarian ancestors, especially his grandfather, had organized risings against the Turkish rule, and the revolutionary traditions of the family were revived in Christian Rakovsky. In 1890 on account of his socialist activities all appointments in Bulgarian schools were closed to him. He therefore went to Geneva, where he joined the international social democratic student movement, and came in contact with G. V. Plekhanov and other Russian social democrats; and also to Germany, where he met Karl Liebknecht. He graduated as a doctor of medicine at Montpellier, and wrote his thesis on *The Etiology of Criminality and Degeneration* (1897). Returning to Bulgaria, he recommenced revolutionary activities, and in *Russia* in *the East* (1898) denounced tsarist politics. In 1900 he served as an officer in the Rumanian army. During the peasant riots of 1907 he was expelled from Rumania, his title to Rumanian citizenship not being considered adequate, and his civil rights were only restored in 1912.

After Rumania entered World War I, Rakovsky was arrested and imprisoned in various places, and finally at Jassy, where he was released by the Russians on May 1, 1917. After the Soviets came into power in November he became a member of the central executive committee of the Union, and in 1919 he became a member of the central committee of the Communist party. Rakovsky was well known as a writer on political and economic subjects under the pen name of "Insarov," and a number of his books were written and published in Russia *(Modern France,* 1900; *Metternich and His Time,* etc.).

Rakovsky's diplomatic career began with his appointment as head of the delegation entrusted with the peace negotiations with the Ukrainian central *rada.* In 1919 he was appointed president of the soviet of people's commissars of the Ukraine, and in 1922 represented the U.S.S.R. at the conference of Genoa. In 1924 he was the Soviet chargé d'affaires in London, and in 1926–27 Soviet ambassador to France. His support of Trotsky led, in 1928, to his expulsion from the Communist party and exile to Stalingrad. He was readmitted in 1934, and was a departmental chief in the commissariat of health until 1937, when he was dismissed. He was among the 21 members of the "Right Trotskyist bloc" arrested in February and tried in March 1938. Rakovsky was sentenced to 20 years' imprisonment.

RALEIGH, SIR WALTER (*c.* **1552–1618**), British explorer, was born about 1552, the son of Walter Raleigh, of Farhell, and Catherine, daughter of Sir Philip Champernown of Modbury. He was born at the farmhouse of Hayes near Budleigh Salterton Bay. In 1568 he was entered as a commoner of Oriel College, Oxford. In 1569 he followed his cousin Henry Champernown, who took over a body of English volunteers to serve with the French Huguenots and was perhaps present at the battle of Jarnac (Mar. 13, 1569) Nothing is known with certainty of his life until February, 1575, when he was resident in the Temple. In June 1578 his half-brother Sir Humphrey Gilbert obtained a patent for six years authorizing him to take possession of "any remote barbarous and heathen lands not possessed by any Christian prince or people." During 1578 Gilbert led a piratical expedition against the Spaniards. Raleigh accompanied his half-brother as captain of the "Falcon," and was perhaps with him in an unsuccessful voyage in 1579. In 1580 Raleigh was twice arrested for duels, and he attached himself to the earl of Leicester, and to the earl of Oxford. Late in 1580 he was serving as captain of a company of foot in Munster. He took an active part in suppressing the rebellion of the Desmonds; he advocated a ruthless policy against the Irish, and recommended assassination as a means of getting rid of their leaders.

In December 1581 he was sent home with despatches and his great fortune dates from his arrival at court, where he was already known through his correspondence with Walsingham. He had corresponded with Walsingham for some time. It is possible that Raleigh did throw his mantle on the ground to help the queen to walk dry-shod over a puddle, and that he scribbled verses with a diamond on a pane of glass to attract her attention. His tall and handsome person, his caressing manners and his quick wit certainly pleased the queen, and the stories in Sir Robert Naunton's *Fragmenta Regalia* and in Fuller's *Worthies* represent at least the mythical truth as to his rise into favour. The rewards showered on him were out of all proportion to his services in Ireland. In February 1583 he accompanied the duke of Anjou to Flanders. In 1583 he received the grant of Durham House, Strand, and in the same year the queen's influence secured him two beneficial leases from All Souls, Oxford, which he sold to his advantage, and a patent to grant licences to "vintners"—that is, tavern keepers, which he subleased. In 1584 he had a licence for exporting woollen cloths. He was knighted in 1584. In 1585 he succeeded the earl of Bedford as Warden of the Stannaries. He made good use of his powers in the mining districts of the west. He reduced the old customs to order, and showed himself fair to the workers. In 1586 he was given 40,000 ac. of the forfeited lands of the Desmonds, on the Blackwater in Ireland. He endeavoured to establish English colonies, and introduced tobacco into England. In 1587 he received a grant of part of Babington's forfeited land.

Raleigh was now at the height of his favour; Queen Elizabeth always had several favourites at once, lest any one might be supposed to influence her. She treated Raleigh exclusively as a court favourite, but never gave him any great office, nor admitted him to the council. Even his post of captain of the Guard, given in 1587, was mainly ornamental. The patent given to his half-brother Sir Humphrey Gilbert ran out in 1584. To avert this loss Raleigh, partly out of his own pocket, provided the means for the expedition to Newfoundland in 1583, in which Gilbert died. The patent was renewed in Raleigh's favour in March 1584.

Raleigh now began the series of ventures in the colonization of Virginia. His patent gave him and his heirs the proprietary right over all territory they occupied on payment of one-fifth of the produce of all mines of precious metals to the crown. In April 1584 Raleigh sent out two captains, Philip Amadas and Arthur Barlowe, on a voyage of exploration. They sailed by the Canaries to Florida, and followed the coast of North America as far as the inlet between Albemarle and Pamlico sounds in modern North Carolina. The name of Virginia was given to a vast and undefined territory, but none of Raleigh's captains or settlers reached the state of Virginia. In the same year he became M.P. for Devonshire. His first body of settlers, sent out in 1585 under Sir Richard Grenville, landed on what is now Roanoke Island in North Carolina. The settlers got on bad terms with the natives, and deserted the colony when Drake visited the coast in 1586. Attempts at colonization at the same place in 1586 and 1587 failed *(see* North Carolina), and in 1589 Raleigh resigned his rights to a company of merchants, preserving to himself a rent, and a fifth of whatever gold might be discovered.

After 1587 Sir Walter Raleigh's position as favourite was challenged by the earl of Essex. *(See* Essex, 2nd Earl of.) In 1588 he was in eclipse. He was in Ireland for part of the year with Sir R. Grenville, and as vice-admiral of Devon looked after the coast-defences and militia levy of the county. In 1589 he was again in Ireland, visiting Edmund Spenser at Kilcolrnan. It was by Raleigh's help that Spenser obtained a pension, and royal aid to publish the first three books of the *Faerie Queen.* In 1589 Raleigh accompanied the expedition to the coast of Portugal which failed to raise a revolt against Philip II. In 1591 he was at the last moment forbidden to take part in the voyage to the Azores, being replaced by his cousin Sir R. Grenville. In 1592 he was again at sea with an expedition to intercept the Spanish trade, but was recalled by the queen, having seduced one of her maids of honour, Elizabeth Throgmorton. Raleigh denied the stories in a letter to Robert Cecil. On his return he was put into the Tower, and if he was not already married was married there. To placate the queen he made a fantastic display of despair at the loss of her favour. The maids of honour could not marry without the queen's consent, which Elizabeth was always reluctant to give and would be particularly unwilling to give when the husband was an old favourite of her own. Raleigh proved a good husband and his wife was devoted to him through life. He superintended the distribution of the booty from the Portuguese carrack "Madre de Dios." He had provided large sums for the expedition, but the queen left him barely enough to cover his expenses.

Raleigh now retired to an estate at Sherborne in Dorsetshire, which he had extorted from the bishop of Salisbury by unscrupulous use of the royal influence. A son was born to him here in 1593. But a retired life did not suit Raleigh, and in 1595 he sailed on a voyage of exploration to the coast of South America. The object was undoubtedly to find gold mines, and Raleigh had heard the wild stories of El Dorado. His account of his voyage, *The Discoverie of Guiana,* published on his return, is brilliant, but contains much manifest romance and was received with incredulity. He was now the most unpopular man in England for his greed, arrogance and scepticism in religion. In 1590 he was named with Marlowe and others as an atheist. The share he took in the capture of Cadiz in 1596, where he was wounded, was followed by a return to favour, and he was apparently reconciled to Essex, whom he accompanied to the Azores in 1597. This co-operation led to a renewal of the quarrel, and Raleigh became still more unpopular. In 1600 he obtained the governorship of Jersey, and in 1601 took a part in suppressing the rebellion of Essex, at whose execution he presided as captain of the Guard. In 1600 he sat as member for Penzance in Elizabeth's last parliament. He was a steady friend of religious toleration, and a bold critic of the fiscal and agrarian legislation of the time.

James I., who regarded Essex as his partisan, had been prejudiced, and Raleigh's desire for war with Spain was against James's peace policy. Raleigh sold his Irish estates to Richard Boyle in 1602. He was expelled from Durham House, which was reclaimed by the bishop, dismissed from the captaincy of the Guard, deprived of his monopolies and of the government of Jersey. He was concerned in the complication of conspiracies of the first months of James's reign, and was committed to the Tower on July 19, 1603. Here he tried to stab himself, but only inflicted a small wound. His trial at Winchester, November 1603, was conducted with outrageous unfairness, and his gallant bearing in face of the brutality of the Attorney-General, Sir Edward Coke, turned public opinion in his favour. Raleigh was probably cognizant of the conspiracies, though the evidence against him was insufficient to prove his guilt. Much was kept back by the council, and the jury was influenced by knowing that the council thought him guilty.

The sentence of death passed on Raleigh was not carried out, but he was sent to the Tower, where he remained till March 19, 1616. His estate of Sherborne, which he had transferred to his son, was taken by the king. A sum of £8,000 offered in compensation was only paid in part. Raleigh's confinement was easy, and he turned to chemical experiments and literature. He had been known as a minor poet, and in prison he composed the only volume of his vast *History of the World* published. He invented an elixir, a very formidable quack stimulant. Hope of release never deserted him, and he secured his freedom in a way discreditable to all concerned. He promised the king to find a gold mine in Guiana without entrenching on a Spanish possession. It must have been obvious that this was impossible, and the Spanish ambassador, Gondomar, warned the king that the Spaniards had settlements on the coast. The king, who was in need of money, replied that if Raleigh was guilty of piracy he should be executed on his return. Raleigh gave promises he obviously knew he could not keep and sailed on March 17, 1617, relying on the chapter of accidents, and on vague intrigues he had entered into in Savoy and France. The ill-equipped expedition reached the mouth of the Orinoco on Dec. 31, 1617. Raleigh was ill with fever, and remained at Trinidad. He sent five small vessels up the Orinoco under Lawrence Keymis, with whom went his son Walter and a nephew. The expedition found a Spanish settlement on the way to the supposed mine, and a fight ensued in which Sir Walter's son and several Spaniards were killed. Keymis returned to Sir Walter with the news of his son's death and his own utter ruin, and killed himself as a result of Raleigh's reproaches. After a miserable scene of recriminations and mutiny, the expedition returned home. Raleigh was arrested, and in pursuance of the king's promise to Gondomar was executed under his old sentence on Oct. 29, 1618.

BIBLIOGRAPHY.—An edition of his *Works* in eight volumes was published in London in 1829. It contains a *Life* by Oldys and Birch, written with all the knowledge then available. A *Life of Sir Walter Raleigh* (1806, 2nd ed) was much used by Southey in his biography of Sir Walter Raleigh in vol iv of *The British Admirals* in the *Cabinet Cyclopaedia* (1837) Two biographies appeared simultaneously, *Life of Sir Walter Raleigh* by J. A. Saint John, and *Life of Sir Walter Raleigh* by E Edwards (1868) E. Edwards's work is in two volumes, of uhich the second contains the correspondence, and is still the best authority. Smaller lives, which in some cases contain new matter, are those by E W Gosse, "Raleigh" in *English Worthies* (1886); *W.* Stebbing, *Sir W Raleigh* (1891 and 1899); Martin Hume, *Sir Walter Raleigh* (1897): *H.* de Selincourt, *Great Ralagh* (1908); and M Waldman, *Sir Walter Raleigh* (1928). For special episodes *ree* Sir John Pope Hennessy, *Sir Walter Raleigh in Ireland* (1883), and *T* N. Brushfield, *Raleghana* (Ashburton, 1896). Two separate editions of Raleigh's poems have been published, *Poems, with biography and critical introduction* by Sir *F.* Brydges (1813), and *Poems of Raleigh with those oj Sir H. Wotton, etc.,* edited by J Hannah (1892). S. R Gardiner made a careful examination of the events of Raleigh's life after 1603 in his *History of England from the Accession of James I to the Outbreak oj the Civil War* (1883–84).

RALEIGH, SIR WALTER (1861–1922), English man of letters, born on Sept. 6. 1861. in London. was educated at University college. London, and King's college, Cambridge. He was professor of modern literature at University college. Liverpool, and professor of English literature at Glasgow In 1904 he was appointed professor of English literature at Oxford. He was knighted in 1911. and elected to a fellowship at Merton college in 1914. He died on May 13. 1922

Raleigh was a good critic and a stimulating teacher. He was not bound by the accepted judgments on individual writers, but brought a fresh and original mind to bear on literature. He did as much as any man of his time to break with what may be called the "dry-as-dust" school. His publications include *The English Novel* (1894). *Style* (1897), *Wordsworth* (1903), *The English Voyagers* (1904). *Shakespeare* (1907), *Six Essays on Johnson* (1910), *Romance* (1917) and many essays on literary subjects.

RALEIGH, the capital of North Carolina, U.S., located 23 mi. S.E. of Durham, has four major characteristics: politics, education, trade and manufacturing. Politically, as the state capital (and the seat of Wake county), the city is much like other state capitals of similar size The general assembly meets there regularly every odd-numbered year. The state capitol, completed in 1840, stands in the middle of a 4 ac. square and is considered a gem of Greek Revival architecture. Capitol square is surrounded by various state buildings (Labor, Library, Agriculture, Revenue, Education, Justice. Highway and others), all of which have been held to a height not exceeding five or six stories so as not to dwarf the capitol. Various state institutions are in or near Raleigh, including the hospital for the insane (1856), the prison (1869) and schools for the deaf and blind.

The city has four senior colleges: the State College of Agriculture and Engineering (1887); Shaw university (Baptist, 1865); St. Augustine's college (Protestant Episcopal, 1867); and Meredith (Baptist. 1891); and two junior colleges for women, St. Mary's (Protestant Episcopal. 1842) and Peace (Presbyterian, 1872). Within a 30-mi. radius are the University of North Carolina, Duke university, North Carolina College at Durham and the Southeastern Baptist Theological seminary. To take advantage of this concentration of institutions of higher learning, there has been established near Raleigh the Research triangle, a centre of industrial research. The large number of colleges and universities in the area has resulted in a heavy percentage of college graduates and a high level of cultural interest and activity. The North Carolina Museum of Art in Raleigh is one of the finest institutions of the kind in the area.

Raleigh has long been the major retail shopping centre for eastern North Carolina but in the middle part of the 20th century,. due largely to rapid transportation, the volume of trade grew enormously. The city also developed as a wholesale distributing centre, especially for chain food stores.

Industrial volume was small up to the beginning of World War II, but thereafter the city attracted a considerable number of factories producing a wide variety of products. It also became the home office or regional headquarters of a number of insurance companies. In a short period Raleigh changed from a small, slowgoing southern town to a modern, bustling, rapidly expanding city. Its population in 1960 was 93,931; for comparative population figures see table in NORTH CAROLINA: Population. The population of the standard metropolitan statistical area (Wake county) was 169,082 in 1960.

Raleigh was laid off from a tract of forest soon after the American Revolution (in 1792) when North Carolina, like several other of the original states, moved its capital westward from the seaboard. It was named for Sir Walter Raleigh and was incorporated in 1793. During the Civil War Gen. William T. Sherman's army entered the city without opposition in April 1865, and occupied it for the remainder of the war. During the late 19th and early 20th centuries Raleigh shared in the industrial development of the state but its major growth did not take place until during and after World War II. The city has a council-manager form of government, in effect since 1947. Pres. Andrew Johnson was born in Raleigh. (C. CR.)

RALPH (d. 1122), archbishop of Canterbury, called Ralph de Turbine, or Ralph d'Escures from his father's estate of Escures, near Séez in Normandy, entered the abbey of St. Martin at Séez in 1079, and ten years later became abbot of this house. After Anselm's death in April 1109 Ralph acted as administrator of the see of Canterbury until April 1114, when he himself was chosen archbishop at Windsor. Claiming authority in Wales and Scotland, he refused to consecrate Thurstan as archbishop of York because the latter prelate declined to profess obedience to the archbishop of Canterbury. This step involved him in a quarrel with the papacy, and he visited Rome, but was unable to obtain an interview with pope Paschal II, who had left the city. In spite of peremptory orders from Paschal's successors, Gelasius II and Calixtus II, the archbishop still refused to consecrate Thurstan, and the dispute was unsettled when he died on Oct. 20, 1122.

RAM. A male sheep, one kept for breeding purposes in domestication and not castrated, as opposed to the castrated wether. (See SHEEP.) For the ram as one of the signs of the zodiac, see ARIES. The word may be connected with O.Nor. *ramme,* "strong," or with Skt. ram, "to sport." The butting propensities of the ram have given rise to the many transferred senses of the word, chief and earliest of which is that of a battering implement used before the days of cannon for beating in the gates and breaching the walls of fortified places. (See ENGINES OF WAR.) Many technical uses of the term have been developed from this, *e.g.,* the weight of a pile-driving machine, the piston of a hydraulic press and other machines or portions of machines worked by water power. (See POWER TRANSMISSION.) The ancient war vessels were fitted with a beak projecting from the bows, and used to ram or crush in the sides of an opposing vessel. For the development of this in the modern battleship, see SHIP.

RAMADAN (the "Scorcher"), the fifth month of the Moslem year. Already sacred to the pre-Islamic Arabs, it became in Islam the holy month of fasting, selected because it was in this month that "the Koran was sent down as a guidance for the people" (Koran ii, 181). Tradition has it that the *lailat* al-qadr, the "Night of Power" (or "of the Decree"), in which the first revelation occurred is to be identified with the 27th of Ramadan. During this night the angels and spirits descend to earth and "it is peace until the rising of the dawn" (xcvii, 3, 5). Ramadan parallels Yom Kippur in its religious function; it, too, constitutes a period of atonement. But whereas the Jewish festival imposes a strict fast of 24 consecutive hours, the Moslem ordinance prescribes abstention from food, drink, sexual intercourse (indeed. any avoidable change of the body's composition) from the moment when "so much of the dawn appears that a white thread may be distinguished from a black" until with nightfall the two become indistinguishable once more (ii, 183), this abstention to be continued throughout the 29 days of Ramadan. Only the very young and the very old, the sick, pregnant and nursing women and persons on an extended journey may be excused.

Beginning and end of Ramadan are announced when one trustworthy witness testifies before the authorities that the new moon has been sighted; a cloudy sky therefore may delay or prolong the fast. The five daily prayers continue in Ramadan but the addition of the supererogatory prayers, or *tarawih,* at night is considered meritorious, particularly during the last ten days, which are regarded as especially sacred.

In the Koran the development of the Ramadan fast (one of the five "pillars" or absolute requirements of Islam) may be followed from the injunction to fast on Ashura, the Day of Atonement of the Jews (later identified with the tenth of Muharram, the first month of the Moslem calendar), to the command to fast "a certain number of days" during Ramadan (ii, 180) and finally to the month-long fast. The last may have been structured on the Christian Quadragesima (Lent) or comparable Manichaean practices. Fasting has come to be regarded as a most important religious act, and it is observed by many who will neglect their daily prayers. Psychologically a part of it is the Lesser festival or the Festival of Breaking Fast on the first three days of Shawwal when the strain of Ramadan is released.

See BAIRAM.

See G. E. von Grunebaum, *Muhammadan* Festivals (1951).

(G. E. V. G.)

RAMADI, a town in Iraq in 33° 30' N.. 43° 30' E. about 80 mi by road from Baghdad. Pop. (1957) 17,747. The town lies on both sides of the Euphrates, which is there crossed by a bridge of boats, and in the 20th century became of some importance as an airport and as the point at which the overland mail leaves the cultivated area and starts its journey over the desert.

RAMAKRISHNA (1836–1886), perhaps the best-known Hindu saint of modern times. While his background and training were intensely Hindu, his teaching was spiritual in character and universal in quality. While religion appealed to him temperamentally, he felt to the full the difficulties of faith and the force of modern criticism. He brought peace of mind to many doubters and dissenters in India and outside India. In a world giddy with material power and achievements, callous to human suffering and misery and indifferent to the higher life of spirit, he presented an ideal of holiness and compassion.

Ramakrishna was born in the village of Kamarpukur in Hooghly district. Bengal, on Feb. 20. 1836. His father. Khudiram Chattopadhyaya, was an orthodox Brahman. respected in his village for his integrity and ability as a teacher. His mother, Chandramani Devi. was a simple woman of character and piety. Of his parents, Ramakrishna said: "My mother was the personification of rectitude and gentleness. She did not know much about the ways of the world; innocent of the art of concealment, she would say what was in her mind. People loved her for her openheartedness. My father, an orthodox Brahman, never accepted gifts from the Sudras [lowest varna or caste]. He spent much of his time in worship and meditation and in repeating God's name and chanting his glories. Whenever in his daily prayers he invoked the goddess Gayatri, his chest flushed and tears rolled down his cheeks. He spent his leisure hours making garlands for the family deity, Raghuvir." Ramakrishna, who was originally named Gadadhar Chatterji, was the youngest child of a family of three sons and two daughters. From the beginning, he was attracted by the lives of religious heroes and did not pay much attentidn to the subjects usually taught in schools.

When he was seven years old he had his first experience of spiritual ecstasy. It is said that, on a summer day, as he was walking along a narrow path between paddy fields he saw a beautiful dark thundercloud. As it spread, rapidly enveloping the whole sky, a flight of snow-white cranes attracted his attention. The beauty of the scene overwhelmed him and he fell to the ground unconscious. Some villagers who happened to be in the vicinity took him back to his home. Ramakrishna said later that in that state he had experienced great joy.

When Ramakrishna was seven years old his father died, and this event plunged him into grief. He became more helpful to his mother in the discharge of her household duties. When he mas 13 his eldest brother Ramkumar left for Calcutta to improve the financial position of the family. Ramkumar was appointed a priest in the Kali temple at Dakhineswar 6 mi. north of Calcutta. The temple was founded by Rani Rasmani, a Sudra by caste. Ramakrishna's orthodoxy was so strict that he protested against his brother taking service in the temple and refused to take any cooked food on the day when the temple was opened and thousands were sumptuously fed. He left the temple and returned to Calcutta, leaving his brother there. But brotherly love prevailed and Ramakrishna returned to the temple and stayed there cooking his own food. A few months later his brother fell ill and Ramakrishna took charge of his duties and served as a priest in the temple His worship was quite different from that of the professional priests. He performed the duties of the office with ardent devotion and sincerity. His worship intensified his yearning for a vision of Kali, who for him was the mother of the universe. He would sit in the temple for hours, praying and weeping till he lost all consciousness of the outer world. While meditating he would lay aside his cloth and Brahmanical thread. Explaining his conduct, he said to Hriday, his boyhood friend and now his attendant: "Don't you know that when one thinks of God one should be freed from all ties. From our very birth we have the eight fetters of hatred, shame, lineage, pride of good conduct. fear, secretiveness, caste and grief. The sacred thread reminds me that I am a Brahmin and therefore superior to others. When calling on the Mother one has to set aside all such ideas."

When he was 23, to get him back to the world, his people married him to a girl of five, Saradamani Devi. (Such an early marriage is only a betrothal, the marriage being consummated years later when both the boy and the girl are mature.) The marriage did not tone down his fervent devotion but enhanced it. He became restless and excited and panted for a vision of Kali. "I felt as if my heart were being squeezed like a wet towel. I mas overpowered with a great restlessness and a fear that it might not be my lot to realise her in this life. I would not bear separation from her any longer. Life seemed to be not worth living. Suddenly my glance fell on the sword that was kept in the Mother's temple. I determined to put an end to my life. When I jumped up like a madman and seized it, suddenly the Blessed Mother revealed herself. The buildings with their different parts, the temple and everything else vanished from my sight, leaving no trace whatsoever, and in their stead I saw a limitless, infinite, effulgent ocean of consciousness. As far as the eye could see, the shining billows were madly rushing at me from all sides with a terrific noise. to swallow me up! I was panting for breath. I was caught in the rush and collapsed unconscious. What was happening in the outside world I did not know; but within me there was a steady flow of undiluted bliss, altogether new. and I felt the presence of the Divine Mother." With his visions and trances, he was not able to attend to the temple service.

A Brahman lady, who was slightly over 50 years of age and well versed in scriptural lore, helped him in his spiritual life. Ramakrishna described to her his experiences, which many people regarded as symptoms of madness. She replied: "My son, everyone in this world is mad. Some are mad for money, some for creature comforts, some for name and fame, and you are mad for God." Under her instructions Ramakrishna completed the spiritual exercises associated with the worship of Sakti and Vishnu.

About 1864, there came to Dakhineswar a wandering Vaishnava monk whose chosen deity was Rama. Ramakrishna took to the worship of Rama and realized that Rama was the spirit of the universe. He also practised the worship of Krishna and had a vision of him. He practised Vaishnava love to the highest point, where the human soul loves God as a devoted wife loves her husband. Its great example is the love of Radha for Krishna. To realise this ideal Ramakrishna dressed himself as a woman and behaved like one. He saw the beautiful form of Krishna in a trance and was satisfied. "After this vision," he said, "I realise that Bhagavan, bhakta, and Bhagavata — God, devotee and scripture — are in reality one and the same."

Ramakrishna next came under the influence of Totapuri, who initiated him into the truths of Advaita Vedanta and taught him the way to *nirvikalpa samadhi,* where a state of consciousness is reached which goes beyond all dualities of subject and object. Totapuri advised him to renounce the world. Ramakrishna had no objection to renouncing the world, but stipulated that his admission into the monastic order should be kept a secret, as he did not wish to hurt the feelings of his old mother who had been living with him for some years at Dakhineswar. Totapuri agreed. When Ramakrishna tried to withdraw his mind from all objects of the empirical world, he found it difficult to take his mind away from Kali, the divine mother of the universe. "In spite of all my attempts I could not altogether cross the realm of name and form and bring my mind to the unconditioned state. I had no difficulty in taking the mind from all the objects of the world. But the radiant and too familiar figure of the blissful Mother, the embodiment of the essence of pure consciousness, appeared before me as a living reality. Her bewitching smile prevented me from passing into the great Beyond." When Ramakrishna explained his difficulty to Totapuri. the latter took a piece of glass, stuck it between his eyebrows and said. "Concentrate the mind on this point." Ramakrishna did so. "My spirit at once soared beyond the relative plane and I lost myself in ecstasy."

Ramakrishna, after attaining the experience of *advaita* or nonduality, remained, however, in relative consciousness and found no incompatibility between the Absolute and personal God. "When I think of the Supreme Being as inactive — neither creating nor preserving nor destroying — I call him Brahman or Purusa or the superpersonal God. When I think of him as active — creating, preserving and destroying — I call him Sakti or *maya*[1] or *prakrti*[2], the personal God. But the distinction between them does not mean a difference. The Personal and the Superpersonal are the same thing, like milk and its whiteness, the diamond and its lustre, the snake and its wriggling motion. It is impossible to conceive of the one without the other. The Divine Mother and Brahman are one."

The realization of absolute Brahman convinced Ramakrishna that the gods of the different religions are but different ways of looking at the Supreme and that the ultimate reality could not be adequately expressed in human language. All religions led their adherents by different paths to the same goal. He wished to explore the non-Indian religions from the inside.

Toward the end of 1866 he started practising the disciplines of Islam under the guidance of a Moslem teacher. He dressed as a Moslem and repeated the name of Allah. He gave up visiting Hindu temples. He had a vision of God as Allah and lapsed into the ocean of the Absolute.

In 1874 Ramakrishna became eager to learn the truth of the Christian religion. One day his eyes became fixed on a painting of the Madonna and the Child. The figures in the picture took on life and the rays of light emanating from them entered his soul. He saw Jesus in a vision and for three days he could think of nothing, speak of nothing except Jesus and His love. Thus he had visions of Rama, Krishna, Siva, Kali, Allah and Jesus and these experiences became a part of his life. He came to the conclusion that all religions are one though each of them stresses a different aspect of the undivided life of spirit. He said: "I have practised all religions, Hinduism, Islam. Christianity, and I have also followed the paths of the different Hindu sects. I have found that it is the same God toward whom all are directing their steps, though along different paths. . . . He who is called Krishna is also called Siva, and bears the name of the Primal energy, Jesus and Allah as well—the same Rama with a thousand names. A lake has several *ghats*. At one the Hindus take water in pitchers and call it *jal;* at another the Muslims take water in leather bags and call it *pani;* at a third the Christians call it water. Can me imagine that it is not *jal* but only *pani* or water? The substance is one under different names, and everyone is seeking the same sub-

[1]Power of self-expression of the personal God. [2]Nature.

stance; only climate, temperament and name create differences. Let each man follow his own path. If he sincerely and ardently wishes to know God, peace be unto him! He will surely realize him."

Lost in his spiritual efforts, Ramakrishna forgot completely that he had a wife. She had by then grown up, and went to him in 1872. Ramakrishna received her kindly and said that the old Ramakrishna was no more, that he could no longer look upon any woman as his wife, and that he saw in her the divine mother She begged him to let her stay with him and serve him to the best of her ability and asked that he should teach her the way to perfection. She stayed within the temple compound and practised whatever Ramakrishna taught her. The first lesson she received from him was: "God is everyone's beloved, just as the moon is dear to every child. Everyone has the same right to pray to him. Out of his grace he reveals himself to all who call upon him. You too will see him if you but pray to him." Saradamani Devi said of her husband: "I have no words to describe my wonderful exaltation of spirit as I watched him in his different moods. Under the influence of divine emotion, he would sometimes become perfectly motionless in ecstasy. This would continue throughout the night. There was such an extraordinary divine presence in him that now and then I would shake with fear and wonder how the night would pass. Months went by in this way. Then one day he discovered that I had to keep awake the whole night lest, during my sleep, he should go into ecstasy—for it might happen at any moment—and so he asked me to sleep in the music room."

Those who have the personal experience of the Supreme, according to the Indian tradition, return to the worldly life, live, move and act in it for the welfare of humanity. Many earnest seekers, the leaders of the different religious movements, approached Ramakrishna for spiritual instruction and guidance, and were impressed by the purity of his character, his childlike simplicity and perfect unselfishness. All who approached him benefited a great deal and acknowledged him as their guru or spiritual preceptor. He explained profound truths in homely parables and pithy sayings. To Ramchandra Datta, who was sceptical about God, Ramakrishna said: "God really exists, you don't see the stars in the daytime, but that doesn't mean that the stars do not exist. There is butter in milk. But can anybody see it by merely looking at the milk? To get butter you must churn milk in a quiet and cool place. You cannot realise God by a mere wish, you must go through some mental disciplines."

One of the pupils asked him: "Why are there so many divergent opinions about the nature of God?" Ramakrishna answered: "Really they are not contradictory. As a man realises him, so does he express himself. If somehow one attains him, then one finds no contradiction. . . . Kabir (Kabitpanthis) used to say, 'The formless Absolute is my Father, and God with form is my Mother.' " When the question was raised whether the rites and ceremonies were not the mere husk of religion, Ramakrishna said: "Yes, but without the husk, paddy will not grow in the field. You eat rice but you sow paddy." To the question, "When shall I be free?", his answer was "When 'I' shall cease to be. The sun can give heat and light to the whole world, but it can do nothing when the clouds are in the sky and shut out its rays. Similarly so long as egoism is in the soul, God cannot shine upon the heart." Man cannot be content with a conceptual knouledge of God, he must burn to possess him: "The vulture soars high up in the air, but all the while he is looking down into the chamel-pits in search of putrid carcasses. So the book-read pandits speak glibly and volubly about divine knowledge, but it is all mere talk, for all the while their mind is thinking about how to get money, respect, honour, power, etc., the vain guerdon of their learning." He who is really great is meek and humble: "A tree, laden with fruit always bends low. So if thou wantest to be great, be low and meek." The responsibilities of the truly spiritual are heavy: "If a white cloth is stained with a small speck the blackness appears very ugly indeed by the contrast; so the smallest fault of a holy man becomes painfully prominent by his surrounding purity."

Ramakrishna spent the remaining years of his life in the unselfish service and spiritual education of his fellow men. His work, along with the trances he had experienced frequently, affected his health and early in 1885 he suffered from throat trouble which developed into cancer. He died of it on Aug. 16, 1886. As his famous disciple Swami Vivekananda said: "It was no new truths that Ramakrishna came to preach, though his advent brought old truths to light. In other words, he was the embodiment of all the past religious thought of India."

RAMALHO ORTIGÃO, JOSÉ DUARTE: see Ortigão, Jose Duarte Ramalho.

RAMAN, SIR CHANDRASEKHARA VENKATA (1888–), Indian physicist, received the Nobel prize for physics in 1930 for his work on the diffusion of light. Raman discovered that the light scattered by any medium contains frequencies differing from that of the incident light by amounts which are characteristic of the scattering medium. These characteristic Raman frequencies are equal to the infrared frequencies of the substance and are caused by energy interchanges between the incident light and the scattering substance. However, some frequencies appear in the Raman spectrum which are "forbidden" in the infrared, and vice versa, so that studies of infrared and Raman spectra complement as well as confirm one another.

Less well known than the Raman effect (*q.v.*), but perhaps more important. was Raman's influence in stimulating interest in, and securing support for. scientific research in India. He contributed to the building up of nearly every research organization in India; he founded the Indian *Journal* of Physics and the Indian Academy of Sciences; he trained hundreds of students and sent them to important posts in universities, colleges and government work throughout India and Burma.

Raman was born at Trichinopoly (Tiruchirapalli), Nov. 7, 1888. He graduated from Presidency college in Madras and received a master's degree in 1907. He had already completed researches in optics and acoustics; but since there was at that time no opportunity for a scientific career in India, he entered the finance department of the Indian government, securing his position by competitive examination at the age of 19.

Continuing his researches in his spare time, he finally came to the attention of the authorities of the University of Calcutta, who offered him a professorship of physics in 1917. Raman was knighted in 1929. In 1933 he moved to the Indian Institute of Science at Bangalore as head of the department of physics. In 1947 Raman was named director of the Raman Research institute at Bangalore.

RAMAN EFFECT. When a beam of monochromatic light passes through a transparent substance, a certain amount of light is scattered from the path of the original beam with altered wave length. This effect was discovered by Sir Chandrasekhara Venkata Raman (*q.v.*) in 1928 and is known by his name. The effect may be observed visually in favourable cases by directing a spectroscope toward a sufficient volume of a substance, such as a large bulb containing benzene, illuminated transversely by the light of a mercury arc lamp. Additional lines are then seen in the spectrum of the scattered light, which are not present in the spectrum of the incident beam. The effect is, however, more conveniently studied by photographing the spectrum of the scattered light, since the record thus obtained is permanent and can be examined at leisure and accurately measured.

In general, there is also a strong scattering of the incident beam without change of wave length. This records itself as a line or lines in the same position as in the incident light; while the Raman lines appear, for the most part, shifted with respect to them toward greater wave lengths. Lines shifted toward shorter wave lengths may also be recorded in the spectra, but these are usually much weaker than those shifted toward greater wave lengths. As many sets of Raman lines appear in the spectrum of the scattered light as there are monochromatic radiations in the incident beam of an intensity sufficient to give an observable effect.

The changes of wave length observed in the Raman effect owe their origin to the movements of the molecules of the scattering material. The translatory movements give rise to shifts of wave length which are usually small and irregular and therefore unobservable. The rotations of the molecules in gases give more readily observable effects, viz., a set of closely spaced but nevertheless discrete Raman lines located on either side of the incident line. In liquids, only a continuous wing or band is usually observed in the same region, indicating that the rotations in a dense fluid are hindered by molecular collisions. The internal vibrations of the molecules. on the other hand. give rise in all cases to large shifts of wave length. The Raman lines attributed to them appear well separated from the parent line and are therefore easily identified and measured.

A proper interpretation of the effect can only be based on the quantum theory (*see* QUANTUM MECHANICS), though certain classical analogies (namely, combinational tones in acoustics and frequency modulation in radio) may be invoked to aid its comprehension. The simplest view of the phenomenon is that it results from the exchange of energy between the light quanta and the molecules of the substance on which they impinge. If the energy $h\nu$ of the light quantum is in part taken over by the molecule in the form of vibrational or rotational energy $h\nu_m$, the residue $h\nu - h\nu_m$ appears as scattered radiation of lower frequency $\nu - \nu_m$. If, on the other hand, the molecule parts with energy $h\nu_m$ to the light quantum, the latter has its energy increased to $h\nu + h\nu_m$ and appears as scattered radiation of increased irequency $\nu + \nu_m$. In either case, the difference between the irequencies of the incident and scattered radiations is ν_m, which is a characteristic frequency of the molecule. The correctness of this explanation is proved by the fact that the positions and strengths of the lines recorded in the spectra are correctly predicted by considerations based on it. In particular, the lines oi frequency $\nu + \nu_m$ and $\nu - \nu_m$ are not recorded with equal strength, but have an intensity ratio $e^{-h\nu_m/kT}$ which is a function of the temperature T and also depends on the energy-quantum $h\nu_m$ which is transierred in the process of light scattering.

A thorough understanding of the subject of Raman spectra would involve further considerations regarding the optical properties of molecules as well as the dynamical theory of their rotations and vibrations. It should, however, be remarked that molecular rotations and vibrations do not in every case give Raman lines. Methane gas (CH_4), for instance, does not give an observable effect, because oi the rotation of its molecules. The molecules of benzene (C_6H_6) have no fewer than 20 distinct frequencies of possible vibration, but less than half this number are observed as frequency shifts in its Raman spectrum. Such cases of nonactivity have, however, been satisfactorily explained. The symmetry of form and structure of the molecule and the symmetry of the particular modes of vibration play an important role in the more complete theory. The vibration frequencies are themselves determined by the atomic masses and the interatomic forces which hold the atoms together in the molecule.

The applications of the Raman effect have been many and varied. Several of them depend on the fact that the nature oi the spectrum is characteristic of the molecule and indicative oi its structure. For example, X-ray measurements and other data indicate that in nitrous oxide (N_2O) the atoms are aligned, but the Raman spectrum shows that the arrangement of these atoms is asymmetrical rather than symmetrical, that is, N-N-O not N-O-N. Further, the study of the spectra may he used as a basis of qualitative identification or quantitative estimation where the usual methods of chemical analysis are too laborious or fail altogether. Raman spectroscopy has also been used to follow chemical or physicochemical processes of a progressive nature occurring in the substance under study. Electrolytic dissociation, molecular association, polymerization and chemical reactions have been studied by its aid with notable success.

Raman effect studies have also aided theoretical chemistry by providing numerical data regarding the nature and magnitude of the interatomic forces in molecules and molecular complexes. They have also enabled disputed questions regarding the symmetry or structure of molecules to be decisively settled. The substitution of atomic isotopes (for instance, deuterium for hydrogen) in molecules of known structure resulting in a change of the vibration frequencies has been employed extensively in such studies. In addition, the rotational and vibrational frequencies of molecules determined from the Raman spectra are fundamental requisites for elucidating their optical and thermodynamic behaviours.

The study of the Raman spectra of crystals and especially of the simpler ones, such as diamond, rock salt and quartz, is of exceptional interest because the facts observed throw light on the nature and properties of the solid state of matter. Theory indicates that a perfect crystal free from internal imperfections and inclusions should scatter no light except that which appears with changes of irequency due to internal vibrations in the solid These vibrations are found to be oi a fundamentally different nature in the lower and upper parts of the frequency range. In the former part of the range, the vibrations resemble those in an elastic solid which would result from longitudinal and transverse waves travelling in opposite directions and forming stationary wave patterns within its volume. In the upper part of the frequency range, there is a different kind of disturbance, namely atomic vibrations on a fine scale which represent periodic changes in the structure of the crystal. These vibrations are restricted at any one time to volume elements of extremely small dimensions. Raman effect studies have shown that the spectral characters of the two types of vibration are wholly different. The elastic vibrations have a continuous spectrum of frequencies; the atomic vibrations appear as a set of sharply defined lines in the infrared region of the spectrum. Their frequencies are determined by the geometry of the crystal structure as well as by the atomic masses and the interatomic forces.

BIBLIOGRAPHY.—The discovery of the Raman effect was first announced by Sir C. V. Raman in the *Indian Journal of Physics,* ii, 387 (Calcutta, 1928). Since then, an extensive literature has grown up around the subject. A useful summary of the work done up to 1942 is found in an article by G. Glockler in the *Reviews of Modern Physics,* xv, 111 (New York, 1943). The following treatises published in English. besides others in French and German, deal fully with particular aspects of the subject: J. H. Hibben, *The Raman Effect and Its Chemical Applications* (New York, 1939); S Bhagavantam, *Scattering of Light and the Raman Effect* (Brooklyn, 1942); G. Herzberg, *Infrared and Raman Spectra of Polyatomic Molecules* (New York, 1945).

(C. V. R.)

RAMANUJAN, SRINNASA (1887–1920), Indian mathematician who worked on the theory of numbers. mas born at Erode, southern India, on Dec. 22. 1887 His full name was Srinivasa Ramanuja Ayengar. He was educated at the town high school and at the Government college at Kumbakonam. He obtained a scholarship from the University of Madras, but after his marriage. in 1909, became a clerk in the Madras Port trust. Correspondence with G. H. Hardy of Cambridge led to his obtaining a further scholarship from Madras university. and a grant from Trinity college, Cambridge. In spite of religious difficulties arising from the fact that he was a Brahmin he came to England in April 1914, where Hardy. by private teaching. helped to provide the necessary mathematical background for his original work. His mathematical work is on the theory of numbers. theory of partitions and the theory of continued fractions. He became ill in 1917, returned to India in 1919, when he resumed some of his mathematical work, but died on April 26. 1920, at Kumbakonam. He was elected a fellow of the Royal society in 1918 and a fellow of Trinity college later in the same year.

Ramanujan's notebooks were published in 1957.

See G. H. Hardy, P. V. Seshu Aiyar and B. M. Wilson (eds.), ***Collected Papers of Srinivasa Ramanujan*** (1927); G. H. Hardy, ***Ramanujan*** (1940). (O. OE.)

RAMANUJAS, followers of Ramanuja, a southern Brahmin of the 12th century. Sri Vaishnavas, as they are usually called, worship Vishnu (Narayana) with his consort Sri or Lakshmi (the goddess of beauty and fortune), or their incarnations Rama with Sita and Krishna with Rukmini. Ramanuja's doctrine is essentially based on the tenets of an old Vaishnava sect, the Bhagavatas or Pancharatras, who worshipped the Supreme Being under the name of Vasudeva (later identified with Krishna, as the son of Vasudeva). They established shrines at Srirangam near Trichinopoly. Mailkote in Mysore, Dvaraka (the city of Krishna) on the Kathiawar coast, and Jagannath in Orissa; all of them were decorated with Vishnu's emblems, the tulasi plant and salagram stone. While Sankara's mendicant followers were prohibited to touch fire and had to subsist entirely on the charity of Brahman householders. Ramanuja, on the contrary, not only allowed his followers to use fire, but strictly forbade their eating any food cooked, or even seen, by a stranger. On the speculative side, Ramanuja met Sankara's strictly monistic theory by another, recognizing Vishnu as identical with Brahma, the Supreme Spirit animating the material world as well as the individual souls which have become estranged from God through unbelief, and can only attain again conscious union with him through devotion or love (bhakti). His tenets are expounded in various works, especially in his commentaries on the Vedantasutras and the Bhagavadgita. The followers of Ramanuja split into two sects, a northern one, recognizing the Vedas as their chief authority, and a southern one, basing their tenets on the Nalayir, a Tamil work of the Upanishad order.

RAMBAUD, ALFRED NICOLAS (1842–1905), French historian, was born at Besançon on July 2, 1842. After studying at the École normale supérieure, he completed his studies in Germany. He was appointed *répétiteur* at the École des Hautes Etudes on its foundation in 1868. His earlier historical work was done in Byzantine and Russian history. Probably his study of Russia was motived partly by his sense of the desirability of a Franco-Russian entente. Rambaud was *chef de cabinet* to Jules Ferry (1879–81), and in 1883 became professor of contemporary history at the Sorbonne.

He now wrote his *Histoire de la civilisation française* (2 vol., 1885, 1887; 9th ed., 1901) and his *Histoire de la civilisation contemporaine en France* (1888; new ed. entirely revised, 1906), and undertook the general editorship of the *Histoire générale du IV^{e} siècle jusqu'à nos jours.* The plan of this great work had been drawn up with the aid of Ernest Lavisse, but the entire supervision of its execution was carried out by Rambaud. Rambaud held the position of minister of Public Instruction from 1896 to 1898, and sought to carry on the educational work of Jules Ferry. He died in Paris on Nov. 10, 1905.

See the notices by E. Lavisse in the *Revue de Paris* for January 15th, 1906, and G. Monod in the *Revue historique* (vol. xc., pp. 344–348).

RAMBOUILLET, CATHERINE DE VIVONNE, MARQUISE DE (1588–1665), French *salonnière,* was the daughter and heiress of Jean de Vivonne, marquis of Pisani, and Giulia Savelli. She was married at twelve to Charles d'Angennes, vidame of Le Mans, and afterwards marquis of Rambouillet. The young ,marquise found the coarseness and intrigue that then reigned in the French court little to her taste, and after the birth of her eldest daughter, Julie d'Angennes, in 1607, she began to gather round her the circle afterwards so famous. She established herself at the Hôtel Pisani, called later the Hôtel de Rambouillet. Almost all the more remarkable personages in French society and French literature frequented it, especially during the second quarter of the 17th century. Madame de Rambouillet's natural abilities had been carefully trained, but were not extraordinary. She had genuine kindness and a lack of prejudice that enabled her to entertain on the same footing princes and princesses of the blood royal, and men of letters, while among her intimate friends was the beautiful Angélique Paulet. The respect paid to ability in her salon effected a great advancement in the position of French men of letters. The almost uniform excellence of the memoirs and letters of the period may be traced largely to the development of conversation as a fine art at the Hôtel de Rambouillet, and the consequent establishment of a standard of clear and adequate expression. Mme. de Rambouillet was known as the "incomparable Arthénice," the name being an anagram for Catherine, devised by Malherbe and Racan. Among the famous incidents in the story of the Hôtel are the sonnet war between the Uranistes and the Jobistes—partisans of two famous sonnets by Voiture and Benserade—and the composition by all the famous poets of the day of the *Guirlande de Julie,* a collection of poems on different flowers, addressed in 1641 to Julie d'Angennes, afterwards duchesse de Montausier. Julie herself was responsible for a good deal of the preciosity for which the Hôtel was later ridiculed.

The *Prkcieuses,* who are usually associated with Molière's avowed caricatures and with the extravagances of Mlle. de Scudéry, but whose name, it must be remembered, Madame de Sévigné herself was proud to bear—insisted on a ceremonious gallantry from their suitors and friends, though it seems from the account given by Tallemant des Réaux that practical jokes of a mild kind were by no means excluded from the Hôtel de Rambouillet. They especially favoured an elaborate and quintessenced kind of colloquial and literary expression, imitated from Marini and Gongora, and then fashionable throughout Europe. Molière's attack was probably levelled not at the Hôtel de Rambouillet itself, but at the numerous coteries which in the course of years had sprung up in imitation of it. But the satire did in truth touch the originators as well as the imitators,—the former more closely perhaps than they perceived. The Hôtel de Rambouillet continued open till the death of its mistress, on Dec. 2, 1665, but the troubles of the Fronde diminished its influence.

The chief original authorities respecting Madame de Rambouillet and her set are Tallemant des Réaux in his *Historiettes,* and Antoine Baudeau de Somaize in his *Grand Dictionnaire des Précieuses* (1660). Many modern writers have treated the subject, notably Victor Cousin, *La Société française au xvii^{e} siècle* (2 vols., 1856), and C. L. Livet, *Précieux et Précieuses . . .* (1859). There is an admirable edition (1875) of the *Guirlande de Julie* by O. Uzanne.

RAMBOUILLET, a town of France, capital of an arrondissement in the department of Seine-et-Oise, 30 mi. S.W. of Paris on the railway to Chartres. Pop. (1946) 7,169. Rambouillet derives its interest from the associations connected with the ancient chbteau. Originally a royal domain, the lands of Rambouillet passed in the 14th century to the D'Angennes family, who held them for 300 years and built the chbteau. Francis I died there in 1547; and Charles IX and Catherine de Medici found a refuge there in the Wars of Religion, as Henry III did after them. The title became a marquisate in 1612, and a dukedom under Louis XIV. It was here that in 1830 Charles X signed his abdication. The shooting of the famous coverts of Rambouillet was resewed for French presidents of the republic.

RAMEAU, JEAN PHILIPPE (1683–1764), French musical theorist and composer, was born at Dijon, the son of an organist, on Oct. 23, 1683. His father wished him to study law, but the boy's head was full of music, which he could only pursue in haphazard fashion. In 1701 his father sent him to Milan to break off a foolish love-match. But he learned little in Italy, and soon returned in company with a wandering theatrical manager, for whom he played the second violin. He next settled in Paris, where he published his *Premier livre de pièces de clavecin,* in 1706. He succeeded his father as organist of Notre Dame, Dijon, in 1709, and in 1714 removed to Lyons, where he was organist at the Jacobins. In 1715 he was organist at Clermont-Ferrand and working on his *Trait6 de l'harmonie.* There he remained until 1722. He studied the writings of Zarlino, Descartes and other theorists.

Rameau's keen insight into the constitution of certain chords, which in early life he had studied only by ear, enabled him to propound a series of hypotheses, many of which are now accepted. While the older contrapuntists were perfectly satisfied with the laws which regulated the melodious involutions of their vocal and instrumental parts, Rameau demonstrated the possibility of building up a natural harmony upon a fundamental bass, and of using that harmony as an authority for the enactment of whatever laws might be considered necessary for the guidance either of the contrapuntist or the less ambitious general composer. And in this he first explained the distinction between two styles, which have been called the "horizontal and vertical systems," the "horizontal system" being that by which the older contrapuntists regulated the onward motion of their several parts, and the "vertical system" being that which is built up perpendicularly from the bass. From fundamental harmonies he passed to inverted chords, to which he was the first to call attention; and the value of this discovery fully compensates for his erroneous theory concerning the chords of the eleventh and the great (Angl. "added") sixth. *(See* HARMONY.)

Rameau first set forth his new theory in his *Traité de l'harmonie* (Paris, 1722), and followed it up in his *Nouveau systkme* (1726), *Génération harmonique* (1737), *Dkmonstration* (1750) and *Nouvelles réflexions* (1752). After his return to Paris in 1722 he produced some light dramatic pieces, and then showed his real powers in his opera, *Hippolyte et Aricie,* founded on Racine's *Phkdre* and produced at the Académie in 1733.

Rameau wrote more than 20 operas, the most successful of which were *Dardanus, Castor et Pollux, Les Indes galantes* and *La princesse de Navarre.* Honours were showered upon him. He died in Paris on Sept. 12, 1764. Rameau was undoubtedly the greatest French musician of his day.

BIBLIOGRAPHY.—Biographies by Charles Poisset (1864), Nisard (1867), Pougin (1876) and L. de la Laurencie (1908); also Chabanon, *Eloge* (1764); Paul-Marie Masson, *L'Opéra de Rameau* (1926). His *Oeuvres complètes,* ed. by Saint-Saens (1894 *et seq.),* had reached the 18th volume in 1924.

RAMESES or RAMESSES (Gen. xlvii, 11; Ex. xii, 37: Num. xxxiii, 3), or, with a slight change in the vowel points, RAAMSES (Ex. i, 11), the name of a district and town in Lower Egypt, is notable as affording the mainstay of the current theory that King Rameses II was the Pharaoh of the oppression and his successor Merneptah the Pharaoh of the exodus. The first three passages cited above are all by the priestly (postexile) author and go together. Jacob is settled by his son Joseph in the land of Rameses and from the same Rameses the exodus naturally takes place. The older narrative speaks not of the land of Rameses but of the land of Goshen; it seems probable, therefore. that the later author interprets an obsolete term by one current in his own day. just as the Septuagint in Gen. xlvi, 28, names instead of Goshen Heroopolis and the land of Rameses. Heroopolis lay on the canal connecting the Nile and the Red sea, and not far from the head of the latter, so that the land of Rameses must be sought in Wadi Tumilat, near the line of the modern fresh-water canal. In Ex. i, 11, again. the store-cities or arsenals which the Hebrews built for Pharaoh are specified as Pithom and Raamses, to which the Septuagint adds Heliopolis. Pithom also takes us to the Wadi Tumilat. It is possible that these names were added by a writer who knew what fortified places were in his own time to be seen in Wadi Tumilat, for the form of the story of the Hebrews in Egypt is throughout deficient in precise geographical data The postexile or priestly author indeed gives a detailed route for the exodus (which is lacking in the older story), but he, we know, was a student of geography and might supplement tradition by what he could gather from traders as to the caravan routes.

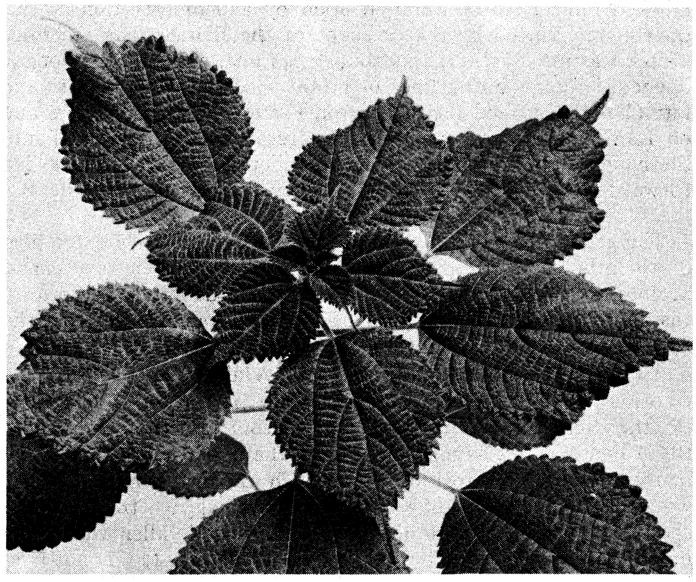
It appears, however, from remains and inscriptions that Rameses II did build in Wadi Tumilat, especially at Tell Maskhuta, which Lepsius therefore identified with the Raamses of Exodus. But E. Naville's excavations found that the ruins were those of Pithom and that Pithom was identical with the later Heroopolis. F. Petrie found sculptures of the age of Rameses II at Tel Rotab, in the Wadi Tumilat west of Pithom, and concludes that this was Rameses. The biblical city is probably one of those named Prameses, "House of Ramesses," in the Egyptian texts.

RAMESWARAM, a town in Ramanathapuram district, Madras state, India, on Rameswaram Island, in Palk strait. 93 mi. S E. of Madura, with which it is connected by a railway bridge. Pop. (1951) 5,419. Its great temple commemorates Rama's crossing over to Ceylon by Rama's or Adam's bridge (*q.v.*).

RAMIE. Ramie is a textile fibre of the soft or bast fibre group, which occur as longitudinal strands in the inner bark of dicotyledonous (broadleaf) plants. The individual cells of the fibre bundles are botanically true fibres—elongated and thick walled with characteristic pitting. These cells are tenaciously gummed one to the other to form the cablelike strands which become commercial fibre when once freed from other bark tissues. The ramie or "China grass" plant is a many-stemmed shrub, *Boehmeria nivea,* of the nettle family (Urticaceae). The variety *tenacissima* is called Rhea. Slender stems as much as eight feet long bear heart-shaped leaves with a whitish underside along the upper third of the stalk. At their base the stems may be nearly an inch thick and contain there the most abundant fibre. The ramie plant is perennial, new stems arising from the crown after the old are cut. A planting should endure for several years. with about three harvests annually. The species prefers warm humid climate and rich soils and should be fertilized generously to maintain good stands.

Ramie has been under cultivation from time immemorial. It was grown in ancient Egypt. where it was used to wrap mummies. Presumably it is native to China and Formosa and is mentioned in Chinese literature as early as 2200 B.C. Since 1855 it has been planted sporadically in the southern United States. Several attempts at European culture have been unsuccessful.

Fibres.—The fibres themselves are strong (eight times more so than cotton), durable and of fine texture and good colour. The cells are among the longest of natural fibres—up to one foot long but only $\frac{1}{750}$ in. in diameter. Ramie is superior in many respects to flax, hemp and jute. Its chief liability, however. has been the difficulty of freeing the fibre bundles from the gummy ensheathing tissues and inability to adapt the crop to large-scale mechanized handling. Production lagged behind major fibres, running only about 20,000 or 25,000 tons annually, produced mostly in China, with exports largely to Japan and Europe. In the United States it has continued as a minor crop in Florida, Louisiana, Texas and California.



WALTER SINGER

RAMIE (BOEHMERIA NIVEA) LEAVES

Retting.—Retting is the process of freeing stem fibres by bacterial decomposition (rotting). The thin-walled cells of softer tissue decompose more readily than thick-walled resistant fibres. Immersing the stems or exposing moistened stems to air usually fails to decompose the cementing gums of ramie, so that the fibre must be separated by pounding and scraping and even then contains up to one-fourth its weight as resin. Eventually the resin or gum must be dissolved chemically. The fibres then become flexible and smooth—so smooth, in fact, that spinning becomes difficult on machinery developed for other fibres. In the far east harvest is by hand a stalk at a time. Each stem can be selected for proper maturity. The limited production in the U.S. is harvested by machine. Much ramie is homespun in the east, with little final cleaning. This gives a coarse, although enduring, fabric. Adhesive gums can be removed by procedures such as boiling in lye, or sometimes an acid treatment, bleaching or induced retting. Degummed fibre is washed, then "softened" with glycerin, waxes or soaps. Spinning is usually on machinery designed for silk or other fibre. Most ramie fabric includes a percentage of some other fibre, such as wool or cotton. It has been used in fire hose, fishing nets. propeller-shaft packing, hats, upholstery and various fabrics. Clothing made of ramie cloth wears well and is said to be mothproof. (R. W. SY.)

RAMILLIES, a village of Belgium, in the province of Brabant, 13 miles N. by E. of Namur, between the sources of the Little Gheete and of the Mehaigne. Pop. (1955 est.) 606. It is famous for the victory of the Allies under the duke of Marlborough over the French commanded by Marshal Villeroi on May 12–23, 1706, in the War of the Spanish Succession (*q.v.*). The position of the French on the high ground about Ramillies was marked by the villages of Autréglise (Anderkirch) on the left, Offuz on the left centre, Ramillies on the right centre and Taviers on the right close to the river Mehaigne. In front of the last was a smaller village, Franquenay, which was held as an advanced post. Between these *points d'appui* the ground was mostly open upland, and the position as a whole was defective in so far that the villages were barely within cannon shot of each other. It was particularly strong on the flanks, which were protected by the marshy beds of the Mehaigne and the Little Gheete. Ramillies stands almost on the watershed of these adjacent valleys, and here Marlborough decided to deliver his main attack. The forces were about equal and were at first equally distributed along the whole line of each army. Marlborough's local concentration of force at the spot where the attack was to be pressed home was made not before, but after the action had opened. Villeroi's left wing of cavalry and infantry was secure — and at the same time immobilized — behind the upper course of the Little Gheete, and the French commander allowed himself to be imposed upon by a demonstration in this quarter, convinced by the presence of the British that a serious attack was intended. It was about 1:30 P.M. when the cannonade opened. Soon the first lines of infantry of the Allied centre and left (Dutch) opened the attacks on Franquenay and Taviers and on Ramillies, and, when after a severe struggle Taviers fell into the hands of the Dutch, their commander, Marshal Overkirk, led forward the whole of the left-wing cavalry and fiercely engaged the French cavalry opposed to it.

The ground was open, both parties had placed the greater part of their horse on this side and it was only after a severe and prolonged engagement that the Allies were definitely victorious, thanks to the arrival of a force of cavalry brought over from the Allied right wing. Meanwhile the principal attack on Ramillies had been successfully pressed home. While Villeroi was trying to bring up supports from the left to take part in the cavalry battle, the French in Ramillies were driven out into the open, where the Allied cavalry, having now gained the upper hand, rode down many battalions. Most of the French cavalry from the other wing, having to force its way through the baggage trains of the army arrived too late, and once Ramillies had fallen the whole line of the Allies gradually took up the offensive. It was not long before the French line was rolled up from right to left, and the retreat of the French was only effected in considerable confusion. Then followed for once a relentless pursuit carried on by the British cavalry to Louvain, 20 mi. from the field of battle.

RAMMED EARTH (PISÉ DE TERRE) is a building material resulting from the application of compaction to certain soils. Of the forms of earth building used by civilizations of varying technical development, rammed earth is the most durable. Since World War II it has been especially studied as an economic technique for underdeveloped regions. Its use is limited to soils with high sand and low clay contents, 70%:30% being a usual proportion, with the sand graded to various particle sizes. The mix, with about 10% water added, is compacted in molds by iron-headed rammers weighing 5 to 20 lb. (See SOIL MECHANICS.)

The mold may be a box for individual wall blocks or a long wooden form, about 2 ft. high, consisting of two sides separated by spacer bolts, which is placed on the wall. The soil is rammed into this in about 3-in layers. the form being removed when it is filled and again superimposed. Special angle, 'T' and stopped-end forms are used for corners, junctions and openings. Roller-mounted forms, pneumatic rammers and hydraulic, mass-production block presses are available.

The moisture content at compaction is critical to the ultimate strength and shrinkage of the wall, the optimum falling between narrow limits. Compressive strengths vary from 100 lb. per square inch to 500 lb. per square inch, while densities average 130 lb. per cubic foot and increase with sand content. Minimum wall thicknesses are usually 12 in.; this mass results in a high thermal capacity, the wall thus acting as a thermal flywheel. The time lag in its temperature changes maintains uniform internal conditions in climates with large day-night temperature variations. The wall surface is often given increased weather resistance with plaster, bitumen or linseed-oil treatment. Strength and weather resistance can be increased by small additions of soil stabilizers. Portland cement and bitumen are the most commonly used.

(T. A. M.)

RAM MOHAN ROY (1772–1833), the founder of Brahmo Samaj (*q.v.*) in India, was not only a great religious leader and social reformer but also a far-seeing statesman who indicated the lines of progress for India under British rule. Hence he is sometimes called the father of modern India. He was born in 1772 in a village in Burdwan district in Bengal. During the first 30 years of his life he seems to have traveled widely outside his province and mastered several languages — Sanskrit, Persian, Arabic, Hebrew, Greek and English, in addition to Bengali, his mother tongue. In 1803 he secured an appointment under the East India company, served its administration in various capacities until he retired in 1815 and settled in Calcutta. There he began his great agitation against the rite of suttee (*q.v.*) and vigorously kept it up until suttee was abolished by law by Lord William Bentinck in 1829.

During 1815–19 Ram Mohan published his translations of the Upanishads and his papers on Hindu theism. His object in these and similar writings was to wean his countrymen from what he regarded as the corruptions of medieval Hinduism and the evils of Hindu society, *viz.,* idol worship, animal sacrifices, polygamy and the caste system, and to draw their attention to the original purity of the teachings of Vedanta (see INDIAN PHILOSOPHY: The Vedanta). It was for achieving this object that he also later founded the Brahmo Samaj (1828).

Ram Mohan next turned his attention to the problem of education, and in a famous letter to Lord Amherst (1823) made a vigorous plea for scientific and English education for India in preference to the traditional Sanskrit education. He was as great a champion of political freedom as he was of scientific education; his memorial for the repeal of the Press ordinance of 1823 has been hailed as the Areopagitica of Indian history. Ram Mohan's letters show that he greatly admired the progress of freedom in Europe and hoped that India through its British connection would grow in knowledge and freedom and ultimately claim equal partnership with Britain.

In 1830 he went to England on behalf of the titular emperor of Delhi to plead his cause before the British government. He fell ill there and died at Bristol on Sept. 27, 1833. (D. S. SA.)

RAMNAD (RAMANATHAPURAM), a town and district of Madras. India. The town (pop. [1951] 24.053) is at the base of the peninsula that juts out toward Rameswaram Island. in Palk strait. It was the seat of the head of the Maravar caste: his title was setupathi, "lord of Ramasetu" or Rama's causeway (Adam's bridge, the chain of shoals across Palk strait).

RAMNAD DISTRICT (area 4,849 sq.mi.; population [1961] 2,420,-943) is a desolate tract crossed by the Southern railway branch running from Madura to the Palk strait ferry. Fishing is carried on.

RAMÓN Y CAJAL, SANTIAGO (1852–1934), Spanish histologist and with Camillo Golgi (*q.v.*) joint winner of the 1906 Nobel prize for medicine in recognition of their work on the structure of the nervous system, was born May 1, 1852, at Petilla de Aragon. He was a wild youth and so backward in his studies that his father, a struggling country surgeon, took him away from school and apprenticed him first to a barber and then to a cobbler. He was eventually allowed to enter the medical school of Saragossa (Zaragoza) and after obtaining his medical licence in 1873 served for a year as an army surgeon in Cuba.

In 1875 he was appointed an assistant in the Saragossa medical faculty and having at last found his natural bent he devoted himself to the study of anatomy. In 1877 he was promoted extraordinary professor and two years later he became director of the medical museum of Saragossa university. In 1883 he went to the University of Valencia as professor of descriptive anatomy and in 1887 to the University of Barcelona as professor of histology and pathological anatomy.

From 1892 until his retirement in 1922 he held the chair of histology and pathological anatomy at the University of Madrid. He died on Oct. 17, 1934.

Ramón y Cajal won world-wide fame by his researches on neuroanatomy. Having adapted Golgi's silver-stain method of staining nervous tissue, he began to explore the then unknown world of the cerebellum and the cerebrum and to publish the results of his researches in a flood of books and papers. One of his most fundamental achievements was the establishment of the neuron or nerve cell as the basic unit of the nervous system. Among his best-known writings are the great Manual de *histologia* normal y *técnica micrográfica* (1889; Eng. trans., 1933), Textura del sistema nervioso del hombre y de *los* vertebrados (1897–1904) and Estudios *sobre* la degeneracidn y regeneracidn del *sistema nervioso* (1913–14; Eng. trans. 1928). He was also the author of a fascinating autobiography, *Recuerdos de mi vida* (1901; Eng. trans., 1937), and of the earlier *Charlas de Cafe'* (1920), containing anecdotes and thoughts on a wide variety of subjects.

See D. F. Cannon, Explorer of the Human Brain: The Life of Santiago Ramdn y *Cajal* (1949). (W. J. Bp.)

RAMPION (*Campanula rapunculus*), a biennial plant of the Campanulaceae family, native to Europe, that is sometimes cultivated as a vegetable for its first-year roots and radical leaves for use as a salad. The white roots are about a foot in length and spindle shaped. Horned rampion is the common name applied to species of the genus *Phyteuma* of the same family. Several of these are used as rock-garden plants. (J. M. Bl.)

RAMPOLLA, COUNT MARIANO DEL TINDARO (1843–1913), Italian cardinal: was born on Aug. 17, 1843, at Polizzi, in the Sicilian diocese of Cefalù. Having completed his studies in the Capranica college, at Rome, and having taken holy orders, he studied diplomacy at the College of Ecclesiastical Nobles and in 1875 was appointed councilor to the papal nunciature at Madrid. Two years later he was recalled to Rome and received high office. After another brief stay in Madrid as nuncio he was created cardinal and became papal secretary of state. New to the Sacred College and free from traditional preconceptions, he was admirably fitted to carry out the papal policy under Leo XIII. (*See* Papacy.) Rightly or wrongly, he was held personally responsible for the rapprochement with France and Russia and the opposition to the Powers of the Triple Alliance; and this attitude had its effect on his career when Leo XIII died. Rampolla was not selected as pope, owing to the veto of Austria, and resigned his office as secretary of state. He died in Rome on Dec. 17, 1913.

RAMPUR, a town and district in the northwestern part of Uttar Pradesh. India, between Moradabad, Naini Tal. Bareilly and Budaun districts. The town (pop. [1951] 134,277), on the left bank of the Kosi river, is a centre for damask, light steelwork, pottery and sugar manufacture. It is the seat of Raza college. connected with Agra university.

Rampur District (area 895 sq.mi.; pop. [1951] 543,324) corresponds with the former princely state of Rampur (Gwalior residency). After the achievement of independence by India. Rampur was at first centrally administered from Delhi through a commissioner, but on Dec. 1. 1949, it was merged into Cttar Pradesh. The former ruler. the nawab. was a Rohilla Pathan, representing the family that established its power over this area in the 18th century. When the Kohillas were subjugated by the nawab of Oudh, with the help of a force lent by Warren Hastings, one of them. Faizullah Khan, was allowed to keep Rampur, and from him the modern ruling family descended. During the Mutiny of 1857 the nawab of Rampur rendered important services to the British.

The country is level and in general fertile, being watered in the north by the Kosi and Nahul rivers and in the south by the Ramganga. The chief crops are wheat, barley, maize, rice and sugar cane.

RAMSAY, ALLAN (c. 1685–1758), Scottish poet. His publications made available to Robert Fergusson and Robert Burns the work of earlier Scottish poets and he also preserved, though in a polished and possibly inferior form, many Scottish folk-songs and with them their tunes. His own poetry varies with some uncertainty of tone and taste between Augustan polish and the rougher freshness of Scottish vernacular poetry. Born at Leadhills, Lanarkshire, Oct. 15, 1684 or 1685. he was probably educated at the parish school of Crawford, and about 1700 left for Edinburgh, where in 1704 he was apprenticed to a wigmaker. He became a burgess in 1710, establishing himself as a wigmaker, and married Christian Ross in 1712. He was one of the founders of the literary Easy club in 1712, adopting the pseudonym first of Isaac Bickerstaff and later of Gawin Douglas. He began by writing occasional verse, the first piece of which was published in 1713: some of his poems were published as broadsheets. In 1718 he published a version of the old Scots poem, Christ's Kirk on the Green, with additional verses of his own, and a collection, Scots Songs; and he turned bookseller. The success of these ventures prompted him to publish his collected poems in 1720, and in 1721 to issue them as a quarto volume by subscription. The subscription brought in 400 guineas, and a similar edition of volume two of his *Poems* in 1728 was an even greater success. He thus achieved financial independence and about 1740 was able to retire to his house on Castle hill.

Meanwhile he had issued The Ever Green (2 vol., 1724) in which he was inspired by nationalist feelings to edit some of the older Scots literature: following the example of James Watson's Choice Collection (1706–11) he transcribed poems of Dunbar, Henryson and others from the 16th-century Bannatyne manuscript. The Tea-Table Miscellany (4 vol., 1724–37), in some editions subtitled "A Collection of Choice Songs Scots and English," contains some by Ramsay and some by his friends, several genuine folk ballads and songs and some 17th-century verse. In 1725 he published his dramatic pastoral The Gentle Shepherd, which had immense popularity. Ramsay wrote little afterward, though new editions of his work continued to appear during his lifetime.

His other activities were to set up what was apparently the first circulating library in Great Britain (before 1728), to encourage the fine arts, and against opposition to help attempts to set up a theatre in Edinburgh. In 1736 he opened a theatre in Carrubber's close, but this was closed by authority a year later.

Ramsay's place in literary history owes less to his merits as a poet than to his immense influence on two much greater men, Fergusson and Burns.

Bibliography.—Ramsay's *Works*, ed. by Burns Martin and J. W. Oliver, 4 vol. (1951–); A. Gibson, New Light on *Allan Ramsay* (1927); B. Martin, *Allan Ramsay*, a Study of His Life and Works (1931). (M. J. C. H.)

RAMSAY, ALLAN (1713–1784), Scottish portrait painter, the son of Allan Ramsay, author of *The Gentle Shepherd*, was born in Edinburgh on Oct. 13, 1713. After rudimentary training in Edinburgh he went to London and worked under the Swedish portrait painter Hans Hysing (1734), but his style was really formed by his studies in Italy (1736–38) under Francesco Imperiali and Francesco Solimena. On settling in London he soon became popular, although George Vertue in 1739 noted with distress that his style differed from the "valuable Manner" of Sir Godfrey Kneller and others and was "rather lick't than pencilled" (*i.e.*, his brushwork was smooth, not free).

His "Dr. Mead" of 1747 (Foundling hospital, London) is in the Italian grand manner, preceding Sir Joshua Reynolds' grand portraits by several years; but perhaps the rise of Reynolds induced Ramsay to return to Italy in 1755–57. During the 1760s Ramsay painted little but royal images on government commission: most of this hack work was done by assistants and Ramsay devoted himself to political pamphleteering, classical studies and conversation — Dr. Johnson said to Boswell: "I love Ramsay. You will not find a man in whose conversation there is more instruction, more information, and more elegance . . ." Ramsay died at Dover on Aug. 10, 1784. while returning from his fourth visit to Italy.

Ramsay's best works are in the National gallery of Scotland, including important drawings, and the National Portrait gallery, Edinburgh; but there are also pictures in London (National Portrait gallery and Tate gallery) and Liverpool. His "Youth With Cap and Gown" was acquired by the Huntington gallery. San Marino, Calif.. and his portrait "Mary Lillian Smith" by the Ringling museum, Sarasota, Fla.

See Alastair Smart, Life and Art of *Allan Ramsay* (1952). (P J. My.)

RAMSAY, SIR BERTRAM HOME (1883–1945), British naval officer,commander in chief of the Allied naval forces during the landings in Normandy in 1944, was born in 1883 and entered the Royal Navy in 1898. As a rear admiral he became chief of staff of the home fleet in 1935, going on the retired list three years later. He was flag officer commanding at Dover, 1939–42, and naval commander of the eastern task force, in the Mediterranean, in 1943. Reinstated on the active list in 1944 and promoted to admiral, Ramsay was placed in command of the Allied naval component, including more than 5,000 ships, that landed Allied soldiers on the Normandy beaches on June 6 and supported them with naval gunfire. He displayed outstanding qualities of leadership in that operation. Admiral Ramsay was created a knight commander of the Bath in 1940 and knight of the British empire in 1943. He died Jan. 2, 1945. (J. B. Hn.)

RAMSAY, SIR WILLIAM (1852–1916), British chemist who discovered the inert gaseous elements in air, was born in Glasgow, Scot., on Oct. 2, 1852. From 1866 to 1870 he studied in his native city. He then went to Heidelberg and studied under Robert Wilhelm von Bunsen and in 1871 went to work under R. Fittig at Tiibingen. In 1872 he became assistant in the Young laboratory of technical chemistry at Anderson's college, Glasgow. He received his Ph.D. from Tiibingen in 1873 and from 1874 was tutorial assistant in the university. In 1880 he was appointed to the chair of chemistry at University college, Bristol, and made principal in the following year. In 1887 he succeeded A. W. Williamson as professor at University college, London, a position from which he resigned in 1913. He was awarded the Davy medal of the Royal society in 1895 and the Nobel prize for chemistry in 1904. He mas made a knight commander of the Bath in 1902. He died at High Wycombe, Buckinghamshire, on July 23, 1916.

Ramsay's earliest investigations covered a wide field—from a new bismuth mineral to the physiological action of certain alkaloids —in the course of which he showed that the alkaloids are related to pyridine. which he synthesized from acetylene and prussic acid in 1876. Later he specialized definitely in inorganic and physical chemistry. With Sidney Young (1857–1937) and others he investigated the critical state, the relationship between vapour pressure and temperature and other properties of liquids (Ramsay-Young rule). In 1887 he found that absolutely dry ammonia and hydrogen chloride do not combine.

With J. Shields (1869–1920) he verified the Eotvos law of the constancy of the rate of change of molecular surface energy with temperature, and obtained evidence concerning the molecular complexity of certain liquids. In 1892 Lord Rayleigh asked for suggestions from chemists to account for the difference between the densities of chemical and atmospheric nitrogen, and Ramsay became interested in the problem. He at once predicted that an unknown heavy gas was present. Rayleigh preferred to believe that a heavy modification of nitrogen, analogous to ozone, was the disturbing factor. Ramsay devised methods for removing oxygen and nitrogen completely from air and found that there was present in addition a small quantity of a hitherto unknown gas. In hug. 1894 Ramsay and Rayleigh announced the discovery of this new gas, afterward called argon, present to the extent of almost 1% in the atmosphere. Its presence had been indicated as early as 1785 by Henry Cavendish (*q.v.*). The high density of this gas accounted for the atmospheric nitrogen having a greater density than the chemical variety. In 1895, while searching for new sources of argon, Ramsay heated the mineral cleveite with acid and obtained a gas which gave a spectrum identical with that of helium, detected in the sun by Sir J. N. Lockyer and Sir E. Frankland in 1368. In this way helium was first obtained, but it was later found to be present in the air to the extent of about 1 part in 250,000.

Both helium and argon were found to be absolutely inactive chemically and so were called the inert gases. They fitted into the periodic system although no provision had been made for chemically inactive elements. Furthermore, a study of their position in the periodic table led to the belief that at least three more such gases should exist. Ramsay, with M. Travers, found them in 1898 in the liquid air residues from which oxygen and nitrogen had been removed; they were called neon. krypton and xenon and mere found to be present in the air only to an extremely minute extent (*e.g.,* xenon, 1 part in 170,000,000). Ramsay next turned to radioactivity, since he noted the association of helium with radioactive minerals. With F. Soddy (*q.v.*) he found in 1903 that helium was continuously produced as a disintegration product of radium emanation. This discovery led to the transmutation theory and its important consequences. In 1910 Ramsay obtained a small quantity of radium. and with Whytlaw Gray he was able, as a result of a wonderful piece of experimental work, to determine the density, and incidentally the atomic weight, of about one three-millionth part of a cubic inch of radium emanation. The atomic weight showed that this gas was the last of the inert-gas series. It was called niton and is now mainly known as radon (*q.v.*) or emanation. Ramsay thus has the unique fame of discovering a whole family of new elements.

Ramsay's works include: *A System of Chemistry* (1891); *The Gases of the Atmosphere* (1896; 4th ed., 1915); *Modern Chemistry,* 2 vol. (1901); *Essays Biographical and Chemical* (1909); *Life and Letters of Joseph Black* (1918); *Elements and Electrons* (1913); *Introduction to the Study of Physical Chemistry* (1904).

Bibliography.—Sir William Tilden, *Sir William Ramsay* (1918), *Famous Chemists* (1921); obituary notice, *Proceedings Royal Soc.* (1916–17); R. B. Moone, *Journal of the Franklin Institute (1918).*

(R. E. O.)

RAMSBOTTOM, an urban district in the Rossendale parliamentary division of Lancashire, Eng., 11 mi. S.S.W. of Burnley by road. Pop. (1951) 14,589. Area 14.9 sq.mi. It includes the villages of Holcombe, Edenfield. Shuttleworth, Summerseat. Stubbins and Holcombe Brook. The main industries are textile spinning and printing, weaving, bleaching and dyeing, papermaking and engineering. Moorland uplands surround developed areas. The name is said to mean "wild garlic valley."

RAMSDEN, JESSE (1735–1800), English astronomical instrument maker, whose celebrated five-foot vertical circle, made for the observatory at Palermo, Italy (1789), quickened the tendency of divided circles to supersede quadrants in observatories toward the end of the 18th century.

He was born at Salterhebble near Halifax, Yorkshire, probably on Oct. 6, 1735. After serving his apprenticeship with a cloth-worker in Halifax, he went in 1755 to London, where in 1758 he was apprenticed to a mathematical instrument maker. About four years afterward he started his own business and secured a great reputation with his products. He died at Brighton on Nov. 5, 1800. Ramsden specialized in divided circles; the Palermo vertical circle was used by the monk-astronomer G. Piazzi in constructing his well-known catalogue of stars.

RAMSEY, a market town and urban district of Huntingdonshire (and in the parliamentary division of that county), Eng., lying on the southwestern border of the Fens, 13 mi. N.N.E. of Huntingdon by road. Pop. (1951) 5,770. Area 25.0 sq.mi. The town came into existence as a result of the founding of the Benedictine abbey in A.D. 969 by Duke Ailwyn, who bore the strange title *Totius Angliae Aldermanus* ("Alderman of all England"). A charter of King Edgar granted lands and privileges for the foundation. Ramsey abbey is one of the most historical features in the Fens. It was a "mitred" abbey; *i.e.,* its abbot was entitled to a seat in parliament. It was granted special privileges and freedom from ecclesiastical and secular control and was a seat of learning long before Oxford and Cambridge. Its library of Hebrew books was famous. After the Dissolution its demesnes were granted to Sir Richard Cromwell and the buildings fell into ruins, loads of stones going to Cambridge for Gonville and Caius. King's and Trinity colleges. Subsequently a new building was erected on the site. Of the ancient Benedictine abbey the only remains are a part of a gateway, now restored (National Trust), a lodge and some buttresses, while broken stone arches and walls remain of the conventual buildings in the basement. A statue supposedly of Ailwyn, once in the abbey, has been placed in the gatehouse.

The church of St. Thomas a Becket is transitional and has a Norman east end. The tower was built in 1672 of stone from the abbey. An oak lectern, dating from the 15th century, carries a chained copy, in a brass binding. of Dean Thomas Comber's (1645–99) book on the Common Prayer and a black-letter copy of Erasmus' paraphrase of the New Testament. There are many interesting tombs in the churchyard, and the church register contains entries relating to the Cromwell family. who moved to Ramsey from Huntingdon and owned the abbey estates until the year 1674.

Ramsey has a market for agricultural produce, potatoes being the chief product of the district, and Ramsey mere, now drained, forms excellent wheat land.

RAMSGATE, a municipal borough, holiday resort, seaport and limb of the Cinque Port of Sandwich, in the Isle of Thanet parliamentary division of Kent, Eng., 18 mi. N.N.E. of Canterbury by road. Pop. (1961) 36,906. Area 5.7 sq.mi. Ramsgate was originally a small fishing hamlet and is mentioned in a charter of Charles II as being under the jurisdiction of Sandwich, of which town Ramsgate became a limb or liberty within the confederation of the Cinque Ports in the reign of Henry VII. From that time Ramsgate developed as a seaport. The present harbour, on which George IV conferred the royal style or title, was built in the mid-18th century, and from that time substantial trade was developed with Baltic and other continental countries. Ramsgate became noted as a health resort in the middle of the Victorian era and is now one of the most popular seaside holiday towns on the coast of Kent. During World Wars I and II the Royal harbour was used as a naval base and some 83,000 troops were landed there at the time of the Dunkirk evacuation (1940). The port has good facilities for commercial traffic and is a centre for motor cruisers and yachts. Promenades and gardens have been constructed along the cliffs rising on either side of the harbour, and attractions for the visitor are numerous, including great sandy beaches. The development of the Kent coalfield during the 20th century brought additional trade to Ramsgate, the nearest pits being Betteshanger and Chislet about 10 mi. away. Small light industrial factories have been established in and near the town. Ramsgate has many historical associations. Cliffsend on the western extremity of the borough is the reputed landing place of Hengest and Horsa in A.D. 449 and of St. Augustine in A.D. 597. At Pegwell bay rests the "Hugin," replica of a Viking ship rowed over from Denmark in 1949 manned by 32 Danish oarsmen. St. Laurence church dates from early Norman times. A. W. Pugin is buried in the Roman Catholic church of St. Augustine, which he built. The town possesses a well-known boys' school (St. Lawrence college) and two grammar schools. Charter flights are available at the municipal airport.

RAMUS, PETRUS, or PIERRE DE LA RAMÉE (1515–1572), French humanist who was noted for his attacks against Aristotle, was born at the village of Cuth in Picardy in 1515, a member of a noble but impoverished family. Having gained admission, in a menial capacity, to the college of Kavarre, he worked with his hands by day and carried on his studies at night. The reaction against scholasticism was still in full tide, and Ramus outdid his predecessors in the impetuosity of his revolt. On the occasion of taking his degree (1536) he took as his thesis "Everything that Aristotle taught is false." In 1543 he published *Aristotelicae Animadversiones* and *Dialecticae Partitiones,* the former a criticism on the old logic and the latter a new textbook of the science. What are substantially fresh editions of the *Partitiones* appeared in 1547 as *Institutiones Dialecticae* and in 1548 as *Scholae Dialecticae;* his *Dialectique* (1555), a French version of his system, is the earliest work on the subject in French. Meanwhile, Ramus had opened courses of lectures, but was interdicted (1544) on the ground of undermining the foundations of philosophy and religion. The decree against him was presently canceled, and in 1551 Henry II made him professor of philosophy and rhetoric at the Collège de France. But in 1561 he embraced Protestantism, and was compelled to flee from Paris, and in 1568 from France. He returned before the massacre of St. Bartholomew (1572), of which he was one of the victims.

The logic of Ramus enjoyed a great celebrity for a time, and there existed a school of Ramists boasting numerous adherents in France, Germany and Holland. There is even a little treatise from the hand of Milton, published two years before his death, called *Artis Logicae Plenior Institutio ad Petri Rami Methodum concinnata.*

RAMUSIO, GIAN BATTISTA (1485–1557), geographer, was born at Treviso in 1485 (June 20), the son of Paolo the Elder (c. 1443–1506). Gian Battista was educated at Venice and at Padua and entered the public service (1505), becoming in 1515 secretary of the senate and in 1533 secretary of the Council of Ten. He served the republic in various missions to foreign states, *e.g.,* Rome, Switzerland and France. He died on July 10, 1557.

Ramusio had witnessed from his boyhood the unrolling of that great series of discoveries by Portugal and Spain in East and West, and geography was his chief study and delight. It appears from a letter addressed to him by his friend Andrea Navagero, that as early as 1523 the preparation of material for his great work, *Navigation; e Viaggi,* had already begun. The task had been suggested by Girolamo Fracastoro, his lifelong friend. Among Ramusio's correspondents were Cardinal Pietro Bembo, Damiano de Goez and Sebastian Cabot; among lesser lights, Vettor Fausto, Daniel Barbaro, Paolo Manuzio, Andrea Navagero, the cardinals Gasparo Contarini and Gregorio Cortese, and the printer Tommaso Giunti, editor after Ramusio's death of the *Navigationi.*

Two volumes only of the *Navigationi e Viaggi* were published during his lifetime, vol. i. in 1550, vol. iii. in 1556; vol. ii. did not appear till 1559, two years after his death. Ramusio had intended to publish a fourth volume, containing, as he mentions himself, documents relating to the Andes, and, as appears from one of the prefaces of Giunti, others relating to explorations towards the Antarctic. Ramusio ransacked Italy and the Spanish peninsula for contributions, and translated them when needful into the racy Italian of his day. The invaluable travels of Barbosa and Pigafetta's account of Magellan's voyage were not publicly known in complete form till the present century. Of two important articles at least the originals have never been otherwise printed or discovered; one of these is the *Summary of all the Kingdoms, Cities, and Nations from the Red Sea to China,* a work translated from the Portuguese, and dating apparently from about 1535; the other, the remarkable Ramusian redaction of Marco Polo (*q.v.*). The *Prefatione, Espositione* and *Dichiarazione,* which precede this version of Marco Polo's book, are the best and amplest examples of Ramusio's own style.

There were several editions of the *Navigationi e Viaggi,* and its bibliography is extremely complicated and the contents of the editions vary. It must suffice here to say that a set of Ramusio, to be as complete as possible, should embrace—for vol. i., 1563 or any subsequent edition; for vol. ii., 1583 or 1606; for vol. iii., 1606.

Besides the circumstances to be gathered from the *Navigationi* regarding the Ramusio family, see the *Iscrizioni Venete* of Emanuele Cigogna. There is also in the British Museum *Monografia letta il 14 Marzo 1883 . . .* by Guglielmo Carradori (Rimini, 1883); but little has been found in this.

RAMUZ, CHARLES FERDINAND (1878–1947), French-Swiss author, born at Cully, in the canton of Vaud. In the opening years of the 20th century he gained a well-merited reputation in a restricted circle; but nearly 25 years were to pass before proper appreciation was accorded by foreign critics to a writer of rare talent with a purely original style owing nothing to the "Latin" and "Classical" tradition. In his numerous works (including *Aline, Samuel Belet, Aimé Pache, Le Règne de l'esprit malin, La Guérison des maladies, Passage du poète, La Beauté sur la Terre* and *The End of All Men,* etc.), Ramuz gave, with broad and simple strokes, a picture of primitive human sentiments in language, the rhythm and phrasing of which intimately recall a definite district — namely, the Leman basin above Lausanne—a narrow strip of vineyard country backed by mountains and looking out over the Rhone and the luminous expanse of Lake Geneva. Though his outlook on the world and mankind was restricted to and conditioned by the influences of this district, Ramuz was the very opposite of a regionalist. In a country where so many others abused the facile picturesque and used "local colour" without distinction, his originality was the more striking. No one approached him in his humble self-subjection to the spirit of the country; he was completely under the spell of nature seen at close quarters. His own thoughts and aspirations were expressed in his characters; nevertheless his work is a most varied and representative picture gallery of a well-defined race, universal in its appeal though in appearance exclusively *Vaudois.* He died on May 23, 1947, in Lausanne. (C. CL.)

RANADE, MAHADEO GOVIND (1842–1901), Indian lawyer, reformer and author, was born on Jan. 18, 1842, at Niphad, in Nasik district, of a Chitpavan Brahman family. When his father was minister at Kolhapur he attended the Anglovernacular school in that town. He joined the Elphinstone institute in Bombay at the age of 14 and was one of the first graduates of the Bombay university, taking the B.A. in 1862 and the LL.B. in 1866. Having entered government service he became presidency magistrate and then fourth judge of the small cause court at Bombay in 1871, first-class subjudge at Poona in 1873 and judge of the Poona small cause court in 1884, after which, as special judge under the Deccan Agriculturists' Relief act from 1887. he came into close contact with the difficulties of the agrarian classes.

In 1886 he was a member of the finance committee appointed to report on the expenditure, both imperial and provincial, with a view to retrenchment. This service won him the decoration of C.I.E. He became a member of the legislative council of Bombay in 1885 and occupied that position until raised to the high court in 1893. Being an energetic social reformer, he directed his efforts against infant marriages, the shaving of widows, the heavy cost of marriages and other social functions and the caste restrictions on travelling abroad.

He strenuously advocated widow remarriage and female education. He was the founder of the social conference movement, which he supported till his death. In the political sphere he iounded the Poona Sarvajanik Sabha. He was also one of the originators of the Indian National Congress.

In Bombay university. where he held the offices of syndic and dean in arts, he displayed much organizing power and great intimacy with the needs of the student class. Himself a thorough Marathi scholar, he encouraged the translation of standard English works and tried, with some success, to introduce vernacular languages into the university curriculum. He joined with his friends Atmaram Pandurang, Bal Mangesh Wagle and Vaman Abaji Modak in founding a new sect in Bombay known as the Parthana Samaj. This community resembles, in all essential points, the Brahma Samaj of Bengal. He died on Jan. 17, 1901.

RANCÉ, ARMAND JEAN LE BOUTHILLIER DE (1626–1700), founder of the Trappist Cistercians. He was ordained in 1651 and embarked on the ambitious and worldly career of a court abbe' in the days of Louis XIV. But after a few years he underwent a complete change, and in 1662 he retired to his abbey of La Trappe, of which he became regular abbot in 1664 and introduced an austere reform. *(See* TRAPPISTS.) The best-known episode of his subsequent life was the "contestation" with Mabillon on the lawfulness of monks' devoting themselves to study, which De Rancé denied. He resigned his abbacy in 1695, because of declining health. and died in 1700.

RANCHI, a city and district of the Chota Nagpur division of Bihar, India. The city, which is situated about 2,100 ft. above sea level, is the headquarters of the division and the district. Pop. (1951) 106,849.

The town contains a cantonment, a radium institute and two mental hospitals, one for patients from the whole of northern India, the other, which can accommodate a total of 1,378 patients, for patients from Bengal as well as Bihar and Orissa.

The DISTRICT OF RANCHI, formerly called Lohardaga after the town which was its headquarters, has an area of 7,015 sq.mi. and a population (1951) of 1,861,207. It consists of two tablelands, of which the higher rises to about 2,000 ft. The whole area is broken by hills and undulations, nhich are terraced for rice. The steep slopes are covered with forest, where wild animals still abound. The principal rivers in the district are the Subarnarekha and the North and South Koel.

Rice is the staple crop; some tea is also cultivated. The only industry on a large scale is the manufacture of shellac. Myrobalans are also exported. Deposits of bauxite have been found and await exploitation. There are two sanatoria for tuberculous patients in the district.

Ranchi is connected with the town of Purulia and the main system of the Eastern railway by a narrow-gauge railway, which was extended through the district to Lohardaga. The most numerous and characteristic races are the aboriginal Mundas and Oraon.

There has been a steady increase in the Christian population, which in 1951 was 422,030.

RAND, a Dutch word, in use in South Africa, meaning rim, edge, ridge of hills; specifically, it is an abbreviated form of Witwatersrand, an elevated ridge in the southern part of the Transvaal, forming the water parting between the Vaal river and the Olifants river.

The Rand is famous for its auriferous reefs ***(see*** GOLD), and the nord is often used as a synonym for the extensive gold mining industry of this area, or for Johannesburg (*q.v.*), the city which the industry created.

RANDALL, JAMES RYDER (1839–1908), U.S. journalist and poet, best known as author of the lyrics of "Maryland! My Maryland!" was born in Baltimore. Md., on Jan. 1, 1839. Educated at Georgetown college, Washington, D.C., he became professor of English literature at Poydras college at Pointe-Coupée, La., in 1860 where he was when the Civil War broke out.

The attack made by citizens of Baltimore upon Massachusetts and Pennsylvania troops as they passed through the city was the occasion of his writing "Maryland! My Maryland!" first published in the *New Orleans Delta,* April 1861. First sung by Hetty Cary to the classic melody of "Lauriger Horatius," it became a rallying song of the Confederacy and later a national favourite. After the war Randall became associate editor of the *Augusta* (Ga.) *Constitutionalist.* He was later Washington correspondent for a number of southern papers. He died in Augusta on Jan. 14, 1908. His *Poems* were published posthumously in 1910.

RANDALL, SAMUEL JACKSON (1828–1890), American politician, was born in Philadelphia, Pa., on Oct. 10, 1828. He was educated in the public schools and in the University academy, Philadelphia. In 1858–59 he was a Democratic member of the state senate. During the Civil War he served in the Union army, rising to the rank of captain and playing an important part in the Gettysburg campaign. From 1863 until his death he was a Democratic representative in congress. During the session of 1874–75 he first gained a national reputation by the masterful manner in which he prevented the Republican majority from passing the force bill or Federal Election law. Under his leadership discipline and party harmony were established among the Democrats for the first time after the Civil War. He was speaker of the house from Dec. 1876 to March 1881, during a period marked by rancorous debates concerning the disputed Hayes-Tilden presidential election. He was noted for his work as chairman of the committee on appropriations and as a member of the committee on banking currency and retrenchment. He was a leader of the Protectionist wing of the party. He died in Washington. D.C.. on April 13, 1890.

RANDAZZO, a town of Sicily, in the province oi Catania, at the north foot of Mt. Etna, 43 mi. N.W. of Catania by rail and 26 mi. direct. Pop. (1951) 12,526. Remains of architecture of the 13th and 14th centuries include three Norman churches and some palaces. The former contain some fine sculptures and goldsmith's work, while the Museo Vagliasindi has interesting objects from a Greek necropolis in the neighbourhood. Randazzo is the nearest town to the summit of Etna (9 mi.).

RANDERS, a town of Denmark, capital of the *amt* (county) of its name in Jutland, on the Gudenaa at the point where it begins to widen into Randers fiord, an inlet of the Kattegat. Pop. (1955) 41,720. Randers is best known in history as the scene of the assassination of Count Gerhard by Niels Ebbesin in 1340. Though a place of considerable antiquity—being mentioned in 1086 as the meeting place of insurgents against Canute IV—Randers has few remains of old buildings and bears the stamp of a compact, modern manufacturing town that owes its importance to its distilleries, manufactories of gloves, railway carriages, etc. St. Marten's church dates from the 14th century. The high school is housed in a medieval monastery. The town is 15 mi. from the open Kattegat and the harbour is 1 j ft. deep.

RANDOLPH, EDMUND (JENNINGS) (1753–1813), U.S. statesman, was born on Xug. 10, 1753, at Tazewell hall, Williamsburg, Va., the family seat of his grandfather, Sir John Randolph (1693–1737), and his father, John Randolph (1727–84), who (like his uncle Peyton Randolph) were king's attorneys for

Virginia. Edmund graduated from the College of William and Mary and studied law with his father, who felt bound by his oath to the king and went to England in 1775. In Aug.–Oct. 1775 Edmund was aide-de-camp to Washington. In 1776 he was a member of the Virginia convention and was on its committee to draft a constitution. In the same year he became the first attorney general of the state (serving until 1786). He served in the Continental Congress in 1779 and again in 1780–82. He had a large private practice, including much legal business for Washington. In 1786 he was a delegate to the Annapolis convention and in 1787–88 was governor of Virginia. He was a delegate to the constitutional convention of 1787, and on May 29 presented the "Virginia plan" (sometimes called the "Randolph plan"). In the convention Randolph advocated a strongly centralized government, the prohibition of the importation of slaves, and a plural executive, suggesting that there should be three executives from different parts of the country, and refused to sign the constitution because too much power over commerce was granted to a mere majority in congress and because no provision was made for a second convention to act after the present instrument had been referred to the states. In Oct. 1787 he published an attack on the constitution; but in the Virginia convention he urged its ratification, arguing that it was too late to attempt to amend it without endangering the union, and thinking that Virginia's assent would be that of the necessary ninth state. In 1788 he refused re-election as governor and entered the house of delegates to work on the revision and codification of the state laws (published in 1794).

Service in Cabinet.—In Sept. 1789 he was appointed by President Washington first attorney general of the United States. He worked for a revision of Ellsworth's judiciary act of 1789, and especially to relieve justices of the supreme court of the duties of circuit judges, and advocated a federal code; in 1791 he considered Hamilton's scheme for a national bank unconstitutional; and in 1792–93, in the case *Chisolm* v. *Georgia* before the supreme court, argued that a state might be sued by a citizen of another state.

On Jan. 2, 1794, he succeeded Thomas Jefferson as secretary of state. In 1795 he wrote 13 letters (signed "Germanicus") defending the president in his attack on the American Jacobin or democratic societies. He was the only cabinet member who opposed the ratification of the Jay treaty. Before it was ratified the delicate task of keeping up friendly diplomatic relations with France fell to him. Home dispatches of the French minister, Joseph Fauchet, intercepted by a British man-of-war and sent to the British minister to the United States, accused Randolph of asking for money from France to influence the administration against Great Britain. Although this charge was demonstrably false, Randolph when confronted with it immediately resigned, and subsequently secured a retraction from Fauchet; he published *A Vindication of Mr. Randolph's Resignation* (1795) and *Political Truth, or Animadversions on the Past and Present State of Public Affairs* (1796). He died at Carter hall, Millwood, Clarke county, Va., on Sept. 12, 1813.

RANDOLPH, JOHN, of Roanoke (1773–1833), U.S. statesman and orator, was born at Cawsons, Va., on June 2, 1773. Through his father, John Randolph, and his mother, Frances Bland, he was related to the Randolphs of Turkey Island and the Blands of Westover, two of the most conspicuous families of colonial Virginia; and, through an ancestress, Jane Bolling, he was a descendant of the Indian princess Pocahontas. He received his collegiate education at Princeton, Columbia and William and Mary colleges. In 1799 he was elected to the house of representatives, after a historic debate with Patrick Henry. In the house, his rise was so rapid that, after the election of Jefferson to the presidency in 1801, he was made chairman of the house committee on ways and means and became the leader of the house Republicans. Soon, however, he drifted away from Jefferson and lost both chairmanship and leadership. Afterward he was, for many years, a mere free-lance, but in 1820 his resolute resistance to the Missouri Compromise made him again a truly powerful figure in the house. After his first election in 1799 he was re-elected to the house every two years until 1829, except in 1813, when his opposition to the War of 1812 resulted in his defeat by John W. Eppes, and in 1817, when he declined to be a candidate. After re-election to the house in 1825, he was elected to the U.S. senate, but he was defeated for re-election by John Tyler. In 1807 he was the foreman of the grand jury which indicted Aaron Burr for treason, and he was a prominent member of the famous Virginia constitutional convention of 1829–30. In 1830 he was sent by Andrew Jackson on a special mission to Russia. In the succeeding year he returned and later denounced, in a series of speeches, the nullification proclamation of Andrew Jackson. He died at Philadelphia on May 24, 1833. Randolph was a passionate partisan of state sovereignty and, therefore, opposed to a national bank, protection and federal internal improvements and interference with slavery; but he disliked slavery and freed his slaves by his will.

At the time of the Missouri Compromise, his influence was so great that Henry Clay afterward declared in a speech: "His acts came near shaking this Union to the centre, and desolating this fair land." After his return to the house in 1827, it was again so great that the failure of John Quincy Adams to be re-elected to the presidency was largely due to it.

One of the most brilliant and disinterested, though by no means one of the most useful, of American public men, he was a captivating talker, a delightful letter writer, a scholar and a devotee of the horse, the dog and the gun. (W. C. Be.; X.)

RANDOLPH, PEYTON (1721–1775), U.S. politician, was born at Tazewell hall, Williamsburg, Va., in 1721, a son of Sir John Randolph (1693–1737), the king's attorney for Virginia. He graduated at the College of William and Mary, studied law at the Inner Temple, London, and in 1748 was appointed the king's attorney for Virginia. Randolph wrote the address of remonstrance to the king on behalf of the burgesses against the suggested stamp duties in 1764. His policy was conservative and moderate, and in May 1765 he opposed Patrick Henry's radical "Stamp Act resolutions." In 1766 he resigned as king's attorney and was succeeded by his brother John (1727–84). In 1769 he acted as moderator of the privately convened assembly which entered into the nonimportation agreement, and in May 1773 he became chairman of the first Virginia intercolonial committee of correspondence. He presided over the provincial convention of Aug. 1774, was a member of the first Continental Congress, of which he was president from Sept. 5 to Oct. 22, 1774, and was re-elected to congress in March 1775. Randolph died of apoplexy in Philadelphia on Oct. 22, 1775.

RANDOLPH, THOMAS (1523–1590), English diplomatist, son of Avery Randolph, a Kentish gentleman, was educated at Christ Church, Oxford, and in 1549 became principal of Pembroke college, Oxford, then known as Broadgates hall. During the reign of Mary, Randolph, who was a zealous Protestant, sought refuge in Paris, where he cultivated the society of scholars. Returning to England after the accession of Elizabeth I, he was employed as a confidential diplomatic agent of the English queen in Scotland. Randolph's dispatches from Scotland between 1560 and 1586 supply important material for the history of the political intrigues of that period.

In 1568 Randolph undertook a mission to Russia which resulted in the concession by Ivan the Terrible of certain privileges to English merchants; in 1570 he returned to Scotland. After missions to France in 1573 and 1576, and Scotland in 1578, Randolph returned in Jan. 1581 to Scotland, where the earl of Morton, the regent, had been arrested a few days previously. Randolph, acting on Elizabeth's instructions, intrigued with Angus and the Douglases in favour of a plot to seize the person of the young King James and to save Morton by laying violent hands on the earl of Lennox. Douglas of Whittingham made revelations which imperilled Randolph, who withdrew to Berwick before the execution of Morton in June 1581.

In 1586, when he next visited Scotland, Randolph helped to arrange a treaty between England and Scotland. He was master of the posts from about 1566 until his death, holding this office jointly with that of a chamberlain of the exchequer. He died in

London in June 1590.

RANDOLPH, THOMAS (1605–1635), English poet and dramatist whose talent lacked time to mature, was born on June 15, 1605, at Newnham-cum-Badby, Northamptonshire, and educated at Westminster school and Trinity college, Cambridge, where he was elected to a fellowship in 1629. Both at Westminster and Cambridge he earned a high reputation for English and Latin verse, and Ben Jonson adopted him as one of his "sons." Of his three poems to Jonson, one renders thanks for his "adoption," while another answers Jonson's despondent ode on the failure of *The New Inn*. He died at Blatherwick in March 1635.

Randolph published *Aristippus* and *The Conceited Pedler* (1631), two dramas for performance at Cambridge, *The Jealous Lovers* (1632), a comedy, and verses in various collections. A posthumous collection of his poems (1638) included two other plays, *The Muses Looking-Glass* (performed 1630) and *Amyntas,* a pastoral drama (probably acted 1631). *Hey for Honesty,* a comedy adapted from *The Plutus* of Aristophanes, was published in 1651 with a number of contemporary allusions inserted by the editor. Randolph had a real lyrical gift and some dramatic ability; his early death robbed 17th-century England of an accomplished and genial poet.

The Poetical and Dramatic Works were edited by W. C. Hazlitt, 2 vol. (1875); *The Poems and Amyntas* by J. J. Parry (1917); and *The Poems* by G. Thorn-Drury (1929).

See G C Moore Smith, *Thomas Randolph* (1927); *S* **A** and *D R.* Tannenbaum, *Thomas Randolph* (1947). (*V.* DE S. P.)

RANELAGH, formerly a resort by the river Thames in Chelsea, London, England. About 1690 land lying east of Chelsea hospital and bordering the river was acquired by Richard, Viscount Ranelagh, later earl of Ranelagh. He built a mansion and laid out gardens. which in 1742 were thronn open as a proprietary place of entertainment. A building called the Rotunda was erected for concerts, and the gardens became a resort of fashionable society. By the close of the 18th century Ranelagh was ceasing to attract, and in 1803 the Rotunda was closed. The buildings were removed, and the grounds passed to Chelsea hospital.

RANGABÉ, ALEXANDROS-RIZOS (1810–1892), Greek poet, archaeologist and statesman. born at Constantinople in 1810, was the son of Jean-Rizos Rangabé, a celebrated poet and scholar. In 1829 Alexandros entered the ranks of the Bavarian army, but after the establishment of the Greek republic he returned to his native country where he became successively minister of education (1833) and director of the royal printing press (1841). In 1844 he became professor of archaeology at the University of Athens, and for the next 12 years. in company with C. Bursian, he investigated the ruins of the temple of Juno, near Argos, bringing to light many statues and bas-reliefs and discovering the entire formation of the building. He died at Athens on Jan. 28, 1892.

Rangabé advocated a revival of the ancient Greek language and wrote poetry and dramas in Greek, including *Phrosyne, The Vigil* and *The Thtrty Tyrants*. He also wrote various archaeological uorks in French, notably *Antiquités helléniques* (1842–55) and *Antiquités troyennes* (1874).

RANGE (IN AGRICULTURE) refers to extensive areas of more or less "natural" grasslands. The vegetation of ranges may include tall grass prairies, steppe, desert shrub, savanna, woodland, chaparral, tundra or forest, the only criterion being that there be enough grass in the vegetation to be profitably grazed. The true tall grass prairies such as those of the North American midwest, the Ukraine, parts of Hungary and Argentina are usually too well suited to cultivated crops to be left in range. Ranges are more generally confined to areas of marginal or submarginal farming or to areas entirely unsuited to cultivation.

Range Formation. — The naturalness of range vegetation is a matter of degree. In much of the coast and foothill ranges of California the original, largely perennial grassland has been almost completely replaced by an introduced annual Mediterranean flora. These areas are called annual range perhaps because the replacement of one vegetation by another was not intentional even though brought about by the activities of man and his livestock. Extensive areas of forest have been converted to grassland by fire or cutting or both. In other areas, selective cutting and good forest management have opened up stands of timber permitting an increase of grass for grazing purposes. Good forest management and good range management are often complementary rather than competitive. Few, if any. ranges are totally uninfluenced by man or his livestock. They are natural only in the sense that they are not artificially established by cultural means.

Fire is a natural feature of grassland vegetation, whether set by man or other agencies. The elimination of fire may be considered a disturbance which in desert shrub, savanna or woodland vegetation frequently invites the dominance of trees and shrubs to the near exclusion of the grass. Effective fires are prevented primarily by heavy grazing which removes most of the combustible material. They are also reduced in frequency by precautions against the setting of fires.

The use of fire as a management practice is common in many parts of the world, but is frequently ineffective in the control of woody vegetation because of heavy grazing. Satisfactory burns usually require deferment for a growing season to accumulate combustible material, and the value of the unused grass must be weighed against the expected value from brush control.

Management Practices. — Some of the most important range management practices are given below. (1) Proper stocking. An adequate surplus of grass must always be left at the end of the grazing season to protect the soil and to supply food reserves for the next season's growth. (2) Uniform grazing. Livestock graze more closely near water, salt, feeding areas, fence corners and other places where animals concentrate. They graze the steep parts of the range much less than the flats. Some corrective measures are: cross fencing into smaller pastures, placing salt in little used parts of the range, developing more watering and salting places, herding with greater care, etc. (3) Deferment. Ranges may be deferred early in the season to protect the grass during a period when it is using up food reserves; they may be deferred late in the season to allow the grass to recover from grazing and store food reserves; they may be deferred for an entire season for burning or to permit seed production in order to improve the vigour and density of the stand. (4) Control of undesirable plants. This may be accomplished by manipulation of livestock to either graze hard or rest at critical times or by selective herbicides, fire or mechanical treatments such as mowing, beating, root plowing, etc. (5) Encouragement of desirable plants. This is usually done by livestock manipulation or burning, but in special cases overseeding and/or fertilizing result in substantial improvements. (6) Proper seasonal use. High mountain ranges can be used only in summer, annual ranges are most productive in spring and many desert ranges are best used in winter. In order to use many ranges at the proper time, livestock must often be trailed or trucked considerable distances. (7) Pest and game control. In order to obtain maximum yields, animals that compete with livestock for forage must be controlled as well as parasites that attack livestock.

Overgrazing. — The most pernicious and chronic problem in the management of ranges is overgrazing. Too heavy use of the vegetation reduces production of forage, exposes the soil to sealing. baking and erosion, reduces the infiltration of water and the effectiveness of precipitation, increases runoff and flood hazards and induces changes in the botanical composition of the vegetation. These changes invariably involve an increase in unpalatable, woody, thorny or poisonous plants and a decrease in the more palatable and desirable species.

Overstocking and the fire control that goes with it have resulted in an alarming increase in woody vegetation in the savanna, woodland, chaparral and desert shrub areas of the world. Overstocking has practically denuded vast areas of rangeland in nearly every continent and the degeneration of range condition is one of the most serious problems in agriculture.

Stockmen and technicians alike have consistently overestimated the capacity of ranges to produce. One must become resigned to low yields per acre, and ranges can be profitably used only because the forage is cheap. As soon as elaborate management practices are required as correctives for bad management, the range forage is no longer cheap and its use often becomes unprofitable.

See also GRASS AND GRASSLAND. (J. R. HN.)

RANGE FINDERS. Range finders are used to establish surveys and maps, to enable the accurate direction of gun, rocket and missile fire, to test and study air vehicle characteristics and to determine the lens focus setting for cameras. Triangulation methods have long been used for the determination of ranges, and precise optical methods have been devised for this purpose.

With the development of pulse-time techniques for use with radio equipment, a new series of instruments evolved for the determination of range. (See RADAR.) The development of radio ranging at the beginning of World War II became an important factor in naval gunnery and anti-aircraft fire; large optical range finders formerly indispensable in the direction of such fire assumed a secondary or stand-by role. Optical range finders have the advantages of high resolution, compact size, relatively simple maintenance and accuracy at short ranges, but they are unreliable during bad visibility conditions and at long ranges, require a relatively long time to make the range determination and, for most purposes, are useless at night. Radio range finders consist of a highly complex electrical network which requires large electrical power supplies and constant attendance by highly trained technicians.

Basically, an optical range finder is a triangulation device with which two angles and the included base are measured to determine the range to the target situated at the apex of the triangle so formed. The most accurate ranging is accomplished by: (1) a two-station system of triangulation in which the base line 'is long and the optical stations are separated by distances of several hundred yards or many miles; (2) the short base monostatic range finder, a one-station system of triangulation which is a self-contained optical system; its accuracy depends on the precise mounting of its optics on an optical bar. The two-station system suffers from the difficulty of establishing time coincidence when measuring ranges to moving or intermittent targets, the complex communication network required to co-ordinate the ranging, and the difficulty of insuring that the two stations are set on a common target and the lengthy process of calculating the range. The one-station system, at the expense of accuracy, avoids these difficulties.

Two-Station System.—The two-station system of triangulation has undergone a high degree of development throughout recorded history beginning, perhaps, with the attempts of the Egyptians who were required to re-establish property lines after the annual inundation of the Nile. In modern times, the development of the optical theodolite resulted in highly precise measurements. The theodolite is used to measure angles—measurements which, in order to minimize operators' errors, are averaged from a number of readings in order to determine the true angle. By United States coast and geodetic procedure an angle is turned 16 times in a first order survey, 4 times in a second order survey, and twice in a third order survey. The accuracy of the distances so measured must not have an error exceeding 1 in 25,000 in a first order survey, 1 in 10,000 in a second order survey, and 1 in 5,000 in a third order survey. This precision is possible only because the targets are fixed and easily identifiable from each other.

In many situations, especially in military usage, the targets are either moving or intermittent, as in the determination of the ranges to vehicles or gun flashes. In such cases, a reading can be taken only once and the two base angle readings must be taken simultaneously. An elaborate communication network between the stations must be set up and timing coincidence must be established. One military system consists of a shutter assembly which is attached to the objective of a sighting telescope. A network of these instruments is established by survey with the shutters connected over communication wires so that the shutters can be simultaneously opened or closed electrically from a central control station. This system is particularly useful in spotting muzzle flashes from artillery fire. When an observer notes a muzzle flash through his telescope he closes the shutters, thus establishing time coincidence. The operalors then take a reading of the bearing of their sighting telescope and relay the bearing position to the central control station where a range plot is made.

For proof-testing and in checking the accuracy of anti-aircraft fire, a more elaborate network is established by using phototheodolites. A phototheodolite, as shown in fig. 1, consists of a camera with a long focal length lens mounted on a theodolite base. The theodolite is turned by a hand wheel or synchronous motor directed by an operator, who sights through a telescope which is fixed to the theodolite base. Time coincidence among the phototheodolite stations is established by a signal which is transmitted over a communication system. Time markers are actuated to give an indication printed on the film; the signal may also operate the shutter. It is possible to operate the phototheodolites over base lines as long as 1j mi. The camera, usually a 3j-mm. movie type, takes a picture of the target being tracked by the operator and prints fiducial marks. or reference points. which establish the zero position on the film, as well as pictures indicating the position of the theodolite base in both azimuth and elevation. The angular errors in tracking are reduced by developing the film and making corrections to the indicated azimuth and elevation readings by applying tracking corrections determined from the measured position of the target with respect to the fiducial marks. By

FIG. 1—PHOTOTHEODOLITE

averaging measurements made by a system of four or five phototheodolites, it is possible to obtain range accuracies of 1 in 10,000 at ranges less than 10 000 yd.

Short Base Range Finders.—Attempts mere made as early as 1770 to couple two theodolites closely on a short base line to circumvent communication difficulties in military range finding. Georg Friedrich Brander in 1781 built a range finder for one operator and Alexander James Adie (1860) constructed a split coincidence range finder Archibald Barr and William Stroud in England culminated a rapid development of range finders in 1888 nhen they brought out their coincidence range finder a prototype of modern instruments. Later, in 1893 the Carl Zeiss firm in Germany huilt a stereoscopic range finder The Germans continued to favour the stereoscopic type made by both Zeiss and Carl Goerz; the British favoured coincidence types U S manufacturers, Bnusch and Lomb Eastman Kodak and Keuffel and Esser. continued to make hoth types Prior to and during World War II. developments in military range finders were concerned largely nith refinements of these two designs.

In the years following World War II, military developments begun during the war culminated in the perfection of both coincidence and stereoscopic range finders in tanks. In most instances, the range finder nas coupled to the tank cannon so that aiming and ranging pointed the cannon automatically in the proper direction and at the proper elevation for the target range and projectile in use. (See Tank Range Finders below.)

Coincidence and Stereoscopic Range Finders.—In the development of the modern range finder there was considerable controversy concerning the comparative effectiveness of the coincidence and stereoscopic range finders. The general advantage of one over the other had not been proved by mid-20th century. The two appear similar except that usually the coincidence type has a single eyepiece as compared with two in the stereoscopic type. Fig. 3 and 5 illustrate the schematic arrangement of the commonly used coincidence and stereoscopic range finders. Monostatic range finders are built. self-contained, with tno optical extended "arms" which define the base length. The outer case usually contains windows, the optical square and the eyepieces. An inner "optical bar." insulated from temperature differentials and vibrations, contains the objectives, deviation prism and the reticles. As the field of view is small, the range finder is mounted on bearings and must be rotated to follow the target. The range operator who observes the images formed by the two objectives adjusts the range drum to establish coincidence or stereoscopic contact; the range can then be read from the drum. Monostatic range finders having a base length of one-half yard to a yard are portable and used by armies in the field; they are accurate to several thousand yards. Larger range finders having base lengths of $4\frac{1}{2}$ ft. to 40 ft. are used to measure ranges up to 20 mi. to adjust naval and anti-aircraft fire.

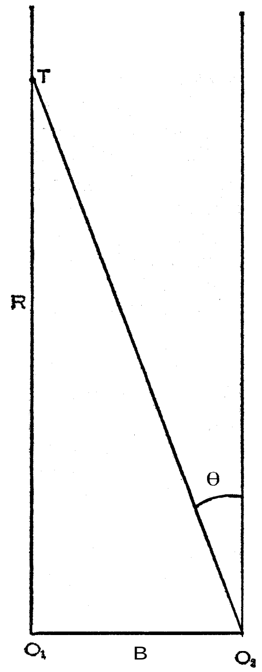

FIG 2

The fundamental equation for the range finder can be stated simply from fig. 2. At O_1 is a right angle and at O_2 is an angle θ which gives the bearing to the target. As this angle is always very small, the range is given as $R = B/\theta$ (approximately), where B is the base separation.

Assuming ideal conditions. the accuracy of optical range finders diminishes as the distance between observer and target increases. Standard formulas show that the theoretical range error varies as the square of the distance. In this respect optical instruments differ from radio range finders, which determine distance by measuring the time required for radio waves to travel from the range finder to the target and back again. Because the speed of radio waves is high and substantially constant, the range error is largely independent of distance.

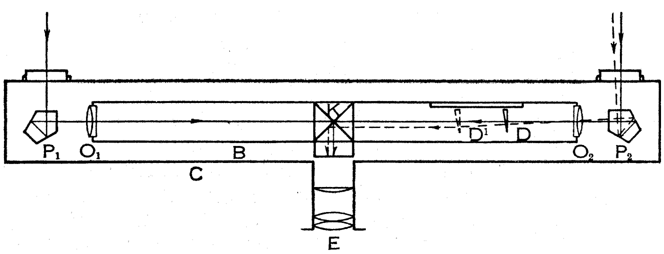

FIG. 3 — COINCIDENCE RANGE FINDER

Construction.—The two ends of the base line are defined by the optical square which changes the incoming light path at the two arms of the range finder by 90°. A penta prism P, as shown in fig. 3, is ideally suited for the purpose since it has the characteristic of changing the light path through a constant fixed angle independently of the incident angle. The prism has its two reflecting surfaces 45° to each other. In larger range finders it is necessary to use mirror surfaces M as reflecting surfaces: as shown in fig. 5, for it is impossible to obtain satisfactory prisms in the larger sizes. The choice of penta prisms or mirrors depends on the size of range finders and not on the type.

In order to effect coincidence or establish .stereoscopic contact it is necessary to displace the image which is formed through one arm of the range finder. This can be accomplished by movement of one of several optical components. To accomplish the displacement in military instruments it proved most suitable to use a sliding lens compensator or deviation prisms; two types of deviation prisms were found most useful. One type consists of a low power prism placed in the converging beam of one arm of the range finder (fig. 3), which, if displaced to the position indicated by the dotted line, results in a corresponding displacement of the image formed from that arm. The prism must be placed in the converging beam. A calibrated scale and indicator coupled to the prism indicate the range. The second type of deviation prism device, known as a diasporameter, consists of two low power prisms placed in the parallel beam ahead of one objective lens. When the

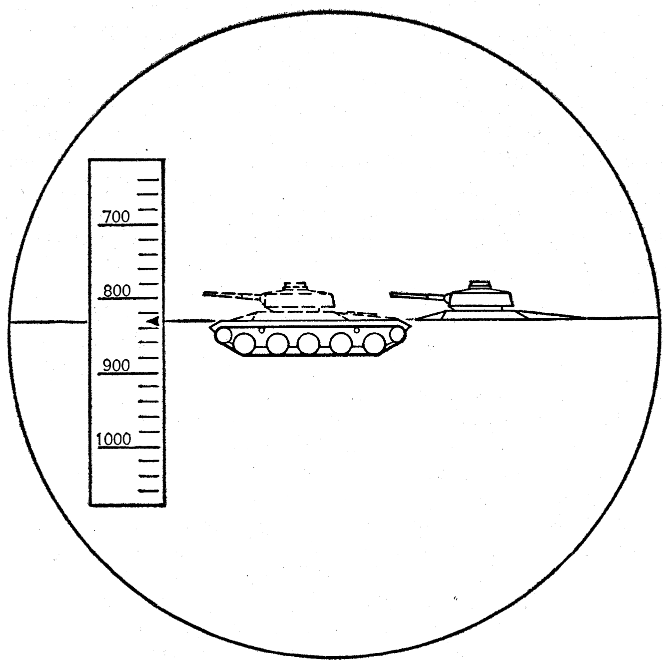

FIG. 4 — FIELD OF COINCIDENCE RANGE FINDER

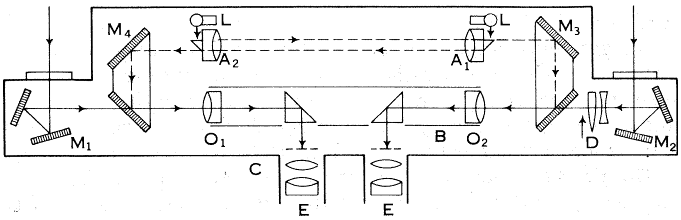
bases of the prisms are vertical and opposed, the deviation caused by one prism is cancelled by the deviation from the other. If the prisms are rotated in opposite directions about the optical axis, the vertical displacements still will cancel. but the horizontal displacements introduced by the rotation will add. The result will be a horizontal displacement of the image.

The sliding lens compensator consists of two low power lenses, one convex and one concave, placed in the parallel beam ahead of one objective lens, as indicated in D, fig. 5. When both lenses are centred on the optical axis of the range finder, no deviation is introduced. If one lens is moved horizontally, a corresponding deviation of the image will result, because the off-axis section of the lens then in use introduces a convergence of light rays toward the displaced axis of this lens.

The range finder includes a telescope not only for the purpose of forming an image from the radiation arriving at the penta prisms but also to aid the operator in seeing objects at a distance. The difierence in the two types of range finders is apparent in the telescopic system. The two objectives of the coincidence range finder form an image in a common focal plane which may be viewed by either a single or a binocular eyepiece. In a stereoscopic range finder two complete telescopes are used with their own objectives and eyepieces. Stereoscopic contact is established physiologically by the operator.

The coincidence in a range finder is achieved by melding the images from the two arms by a combination of prisms. In simpler types of range finders half-silvered mirrors may be used; in more precise instruments the prism combination becomes complex to achieve the proper presentation. In fig. 3 the prism is only indicated; actually it is made up of a combination of roof prisms. The prism combination may be so constructed that not only the fields from the two arms are shown but also, as indicated in fig. 4, a scale indication of the range is made. As shown in fig. 4, the target may be presented as a split image with the field divided in the centre. Adjustment of the range drum shifts one field until coincidence is established as shown by the dotted line in the figure. Other presentations might be used: as a superimposed image as shown in fig. 7; as a double image one above the other; or as a double image with one inverted. The split image adjustment is particularly effective when definite vertical lines are visible on the target; the invert double image is effectivewith targets where



BY COURTESY OF U.S. ARMY ORDNANCE CORPS

FIG. 5— STEREOSCOPIC RANGE FINDER WITH AUTOCOLLIMATOR

the sense of symmetry aids in the adjustment. In using the split image the fineness of the dividing line is important; for precise instruments, a satisfactory line can only be produced by coincidence prisms. In order to insure the optimum performance an adjustment to correct the relative location of the two target images must be provided so that upon adjustment the images match in the field. This is done with a "halving adjustment." The adjustment may be effected by rotating a parallel plate in the converging beam of one of the arms.

The two telescopes of a stereoscopic range finder have reticles marked with a single mark or a "picket" of spaced marks. The marks are so placed that, when they are viewed by the two eyes of the observer, the marks are fused and appear to float in space because of the stereoscopic perception of the observer. If the image of the target is positioned on the reticle with the proper spacing, the target will be seen stereoscopically in three dimensions. The effect may be altered by displacing the image on the reticle and objects will appear to approach or recede. By means of the deviation prisms the target may be displaced and stereoscopic contact is established when the target appears to be at the same position in depth as the reticle spot. The reticle spot, known as the wandermark, may have various shapes such as a circle, a line or a diamond. Under adverse lighting conditions it is advantageous to illuminate the wandermark so that a spot of light appears in the field. If the picket of wandermarks as shown in fig. 6 is used, the spacing of pickets on each reticle is such as to form a series of lines which in the field of view apparently recede into space. It may be that such an arrangement is helpful in correcting the range drum reading on targets when there is not time to establish stereoscopic contact with the central wandermark.

A large variety of novel presentation arrangements have been made by U.S. range finder makers in order to improve the stereoscopic range finder. One arrangement worthy of note, the pseudo-stereoscopic range finder has, in addition to the normal field, a second crossed field produced from opposite objectives so that a double image of the target is produced. As the adjustment for stereoscopic contact is made the two images appear to move, one moving forward toward the wandermark and the other moving away from the observer toward the wandermark.

As the range finder is a precise optical instrument, it is subject not only to the shifting of its parts because of temperature changes, vibration and shock, but is also subject to the idiosyncrasies of the operator. For these reasons it must be calibrated often in use and when operators are changed. The most effective adjustment is to range on an object at infinity such as the moon or stars. Lacking these a "lath" is used for small range finders which consists of a board having two marks spaced in accordance with the dimensions of the optical separation of the instrument. This board when viewed through the range finder has the appearance of being at infinity.

Large stereoscopic range finders often contain a built-in autocollimator to eliminate the need for frequent. calibration. The autocollimator, shown in fig. 5, consists of two identical lenses A, which are engraved with marks and illuminated through small prisms. The mark on lens A_2 is at the focus of lens A, and is projected by the Porro reflector M_3 to the objective O_2 and thus to the operator's right eye. The mark on lens A_1 is similarly projected to the operator's left eye. The marks appear as an object at fixed depth, because each lens is a target for the other; an accidental shift of one lens produces equal shifts in both images and no change in the apparent depth of the mark. Range measurements are made by manipulating the deviation device until the image of a target is brought to the same apparent depth as the mark. Thus, range measurements are unaffected by misalignment of any optical element in the instrument, because the light rays from the target and the reference marks are combined, and any shifting of parts in the two telescopes has equal effects on the images of the target and the mark.

Height Finders.—When ranging on air targets, the range finder determines the slant range. Often the altitude or vertical component to the target is required. This, a function of the elevation angle and the slant range, may be computed mechanically by a system of cams.

Photographic Range Finders.—With the development of press photography and the interest in the candid camera: rapid adjustment of the camera focus became important. A range finder made by the Kalart company, permitting the rapid and accurate focusing of the lens! is shown in figure 7. Photographic range finders are invariably of the coincidence type and may be of either the split image or superposition of image type. They may be coupled directly to the camera through a mechanical linkage or they may be separate and give a range scale reading. An attachment is also available that projects a spot of light which, under unfavourable lighting conditions, forms a target reflected from the subject which can easily be brought into coincidence in the range finder. A number of range finders made b~ various camera manufacturers have appeared on the market. These, although simple in construction, may have various complexities. (See Coincidence and Stereoscopic *Range Finders* above.)

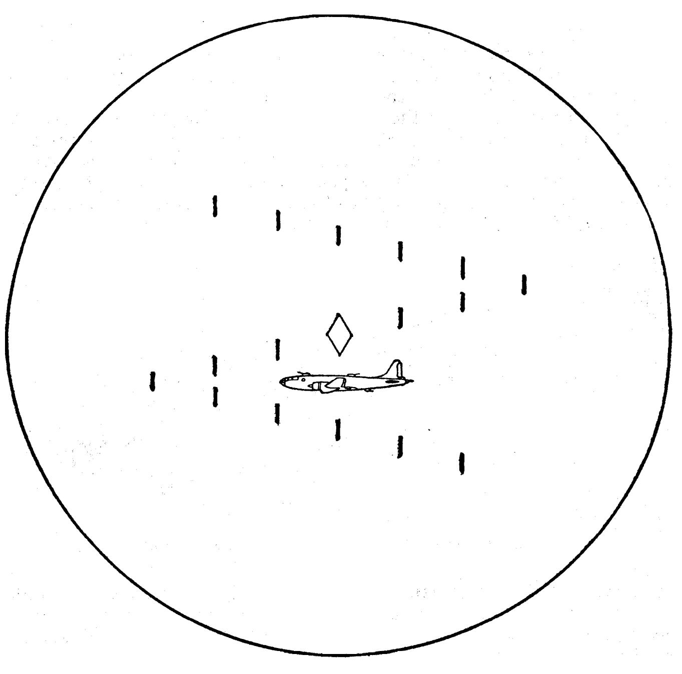


FIG. 6—FIELD OF STEREOSCOPIC RANGE FINDER

Eastman Kodak company marketed split image coincidence finders, one type with a split image coincidence prism and adjusted by moving one objective. Zeiss made a range finder having an adjustment by a diasporameter. The Leica range finder is similar to that shown in fig. 7.

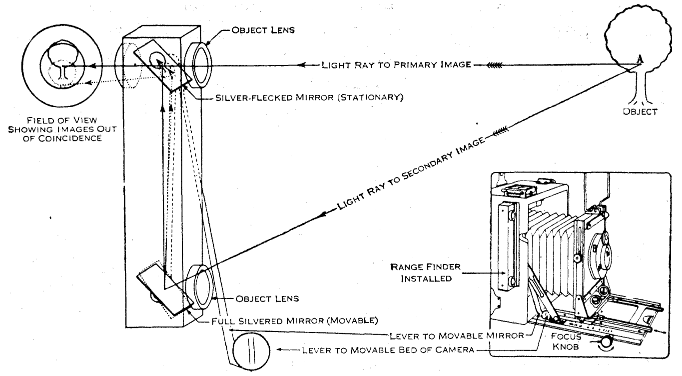
Camera range finders have base lines which may be an inch and a half long to about four inches. That the instrument must be carefully made can be understood. as a movement of 3° in the mirror corresponds to a change in the setting of the range finder from three and one-half feet to infinity.

Tank Range Finders.— Range finders for use in tanks were developed in Germany and the United States during World War II to increase the accuracy of gun fire at long range. The stereoscopic range finder was used to avoid the double or split image required in coincidence instruments, and thus permit clear observation of the target during firing.

One U.S. instrument, which was produced in quantity starting in 1948, had a 60 in. base length and seven-power magnification. A later model with a 79 in. base length and 10-power magnification (shown in fig. 8) also was produced. This range finder was accurate within 40 yd. at 2,000 yd., which is equivalent to a vertical error on the target of only 15 in., for typical tank ammunition.

Special tank turret shapes are required to house and protect the range finder, and the instrument must be carefully designed and mounted to withstand the ballistic impact shocks encountered by tanks in combat. To retain accuracy under these severe conditions and to eliminate the need for frequent calibration, tank range finders contain autocollimators, as shown in fig. 5.

A ballistic computer is used in conjunction with the range finder to reduce the time required to fire the tank gun and to utilize the



BY COURTESY OF U.S. ARMY SIGNAL CORPS

FIG. 7— PHOTOGRAPHIC RANGE FINDER COUPLED TO CAMERA

accuracy of the range finder effectively. The range setting of the deviation device is converted by the computer into the angle at which the gun must be aimed above the target to compensate for the effect of gravity on the shell. If the range finder is used as the gun sight, the computer is built into the range finder, and points the gun at the required angle above the target when the range finder is aimed at the target. If a separate instrument, such as a periscope, is used to aim the gun, the computer is a separate instrument, and is connected either electrically or mechanically to the range finder and the periscope; however, its function and purpose are the same.

FIG. 8—STEREOSCOPIC TANK RANGE FINDER

Stadiometric Ranging.— The determination of distances by stadia rods has long been used in survey work. The method depends upon solving the triangle established by the angle subtended at the observer's position by an object of known size to determine the range to the object. In surveying procedure a stadia rod having markings with known spacings is observed through a theodolite and standard tables give the range to the rod. A range finder using similar principles is used for military purposes. It consists of a telescope or binoculars having either a lattice of horizontal markings, or a single mark or pattern of adjustable size. By observing the image of a man, or a vehicle of known size, superimposed on the reticle the angle subtended by the object is determined. Inasmuch as aircraft have well-known dimensions, the stadiometric device is used for a simple ranging device to determine ranges to aircraft.

RANGER, in U.S. military usage, a soldier specially trained to act in small groups which make rapid surprise raids on enemy territory; the corresponding British term is commando (*q.v.*). In the U.S. ranger has also been the designation for the Texas state constabulary and for national park supervisors and forest wardens.

Ranger units originated during the French and Indian War (1754–63), when the British formed special units of expert woodsmen and marksmen to range the forests on scouting, screening and harassing missions. Notable among these was Rogers' rangers, a battalion commanded by Maj. Robert Rogers (*q.v.*).

During the American Revolution both British and American forces employed rangers. At that time infantry tactics were based on the volley fire of close-ranked infantry of the line. Each regiment also contained a light infantry company, often armed with rifles rather than the muskets of line companies, for employment in advance of the main force or on its flank. These companies were sometimes detached from their parent units and grouped to fight as a body. This led to the formation of entire regiments of light infantry. sometimes referred to as rifle corps or rangers. Among American units of this type were Daniel Morgan's Virginia rangers and Thomas Knowlton's Connecticut rangers. Similar British forces were recruited from loyalists, notably Maj. John Butler's battalion (Butler's rangers), formed to operate in conjunction with Indians, and the Queen's rangers.

The term "ranger" recurred in U.S. military usage when on Jan. 12, 1812, congress authorized enlistment of six companies of these troops for service on the frontier. The *Army Register* of May 1, 1813, lists 12 companies of rangers among the units of the army. In 1832, the force authorized for the Black Hawk War included 600 mounted rangers. This first suggestion of combining the functions of rangers and cavalry was an outgrowth of changed tactical needs; the tide of settle'ment having moved beyond the eastern forests, military operations were now in more open terrain, where mounted forces had superior mobility.

The concept of ranger-cavalry was reinforced by the experience of the Republic of Texas, which recruited mounted ranger companies to protect its outlying areas against Indians and Mexicans. During the Mexican War companies of Texas rangers were formed into regiments and mustered into federal service. They operated both as conventional cavalry and as rangers, on scouting, patrolling and raiding duty. Their detached duty, independent attitude and distinctive appearance probably provided an initial basis for the association of the term "ranger" with irregular, paramilitary forces.

During the Civil War, both Union and Confederate organizations adopted "ranger" as part of their unit designations without reference to their actual military character and employment. However, true ranger units played a significant part in Confederate operations. Partly because of the type of service it performed and partly, no doubt, because of its state origin, the 8th Texas cavalry was known as Terry's Texas rangers. The concept of rangers as irregular forces was given impetus when the Confederate congress passed the Partisan Ranger act in 1862. Partisan rangers were entitled to reimbursement for equipment which they captured—an attempt to apply the law of maritime prize to land warfare. The best-known leader and foremost exponent of ranger operations in the Civil War was a Confederate, Col. John S. Mosby (*q.v.*).

Ranger units reappeared in U.S. military organization in World War II, when six ranger battalions were formed, five serving in the European-African-middle eastern theatre and one in the Pacific theatre. Composed of specially trained and conditioned men, these units made sudden, hard-hitting raids behind enemy lines, carrying out demolition and intelligence missions. The lessons of this experience led to the formation in 1950 of the air-borne ranger infantry company as an integral part of each U.S. infantry division. Six such companies were eventually employed in the Korean war. In 1951, however, it was decided that concentration of these trained men in special units was less desirable than spreading them through conventional units, where a larger number of soldiers would have the benefit of learning the combat techniques in which the rangers were especially skilled. Thereafter the U.S. army continued to conduct special ranger-training for individuals but maintained no ranger units:

The Texas rangers, after their federal service in the Mexican War, served as a state constabulary organized along military lines, maintaining law and order against Indians, bandits and other lawless elements. As local government became more effective the need for such a force declined. In 1901 it was reorganized as a state law-enforcement agency. In 1935 the Texas rangers were merged with the state highway patrol under the department of public safety.

In the national park service, the U.S. department of the interior established in 1916 a force of national park rangers, 1%-hosefunctions include protection and conservation of forests and wildlife in the national parks, enforcement of park regulations (for which they have police power) and assistance to visitors.

Similar functions with respect to the national forests were assigned to the forest rangers of the forest service, established in 1905 as an agency of the U.S. department of agriculture. Forest rangers are particularly noted for their activities in the prevention and fighting of forest fires.

RANGOON, the capital of Burma, situated on the left bank of the Hlaing or Rangoon river, 21 mi. from the sea, in 16° 47′ N. lat. and 96° 13′ E. long. In 1880 the city was detached from the main district, called Hanthawaddy, and formed into a separate district, with an area of 19 sq.mi. This was continually increased; the census area of Rangoon town district in 1931 was 77 sq.mi. The population was 501,219 in 1941 and 737,079 in 1953. On Aug. 1. 1926, the district became part of the Pegu division. From a comparatively insignificant place, Rangoon rose in less than half a century to be the third seaport in India, being surpassed only by Calcutta and Bombay in the volume of its trade. During the busy season of rice export, which lasts from the end of December to the middle of May, the pool forming the port of Rangoon presents almost as crowded a scene as the Hooghly at Calcutta. Rangoon has the double advantage of standing near the sea and being in easy communication with a great river navigable for 900 mi. behind it. It is, in addition: the centre of the Burmese railway system. In the broad and deep river is concentrated the whole of the rich trade of the delta of the Irrawaddy. A great part of the river frontage is occupied with rice mills. teak wharves and similar buildings. Because of the need for wharfage accommodation. the majority of the mills were removed to the opposite or Dalla shore of the Rangoon river, or along the banks of the Pegu river east of Rangoon.

Architecture and History.— The city is dominated by the great golden pile of the Shwe Dagon pagoda, the centre of Burmese religious life. Rising to a height of 368 ft., this magnificent building stands on an eminence itself 168 ft. above the level of the city. It is covered with pure gold from base to summit, and once in every generation this gold is renewed by public subscription. The pagoda is a solid stupa of brick. in the form of a cone. raised over a relic chamber; and the place of worship is the surrounding platform with a perimeter of nearly 1,400 ft.

Though traditionally a site of great sanctity. Rangoon owes its first importance to its rebuilding in 1753 by Alompra, the founder of the Burmese monarchy, who gave it the name of Yan Kon, "the end of strife." The modern Burmese designation of the town is Yangon. The city was taken by the British on the outbreak of the first Burmese War in 1824, but was subsequently restored. It was captured a second time in 1852 and passed with the province of Pegu into the hands of the British. It was destroyed by fire in 1850, and serious conflagrations occurred again in 1853 and 1855.

Administration and Improvements.— Until 1874, when the modern municipality was constituted, the administration was in the hands of the local government, which devoted itself to raising the centre of the town above the river level, providing land fit for building purposes from the original swamp, which was flooded at spring tides, and making roads, bridges, culverts and surface drains. In 1892 the sewage system was introduced, and Rangoon developed an excellent drainage system. The water supply. drawn at first from the Victoria lake, j mi. distant. was later drawn from a large reservoir lake 17 mi. distant. and from the Pegu Yoma water scheme completed in 1941. The city proper of Rangoon with the Kemmendine suburb is laid out on the block system. each block being 800 by 860 ft., intersected with regular streets. Rangoon has many fine public buildings.

There are two large maidans. or commons, which are used as military parade grounds and for sport, the larger being used as golf links. There are also spacious and well-kept zoological gardens. botanical gardens and a well-kept garden in the cantonments under the pagoda. Beyond these lie the Royal lake and Dalhousie park, with 160 ac. of water and well laid out and well timbered park land. There are two cathedrals. Church of England and Roman Catholic, a Presbyterian church and churches of most denominations with services in English. Burmese and the principal Indian languages. Buddhists. Hindus, Moslems, Parsees, Armenians and Jews all own lands and pagodas, temples, mosques, churches and synagogues.

The chief educational institution is the University of Rangoon, constituted in 1920. It formerly included the university college, Judson (American Baptist mission) college, the medical college and the teachers' training college in Rangoon, together with the agricultural college and an intermediate college at Mandalay, but it abandoned the collegiate system in favour of the unitary principle. The greater part of the university occupies magnificent buildings, erected bet een 192; and 1930 on a site overlooking Victoria lake; but some of its buildings suffered severe damage by air bombardment in 1945. By 1950 the total number of students was about 4.000.

Rangoon has several hotels, a number of cinemas, the largest of which are used fór stage plays by traveling companies, fine shops and a number of clubs, notably the Pegu, Orient, Golf and Boat clubs. The European residences are mainly on the outskirts of the city to the northwest in what is called the cantonments. At Mingaladon is one of the finest 18-hole golf courses in the east. The development of Rangoon was placed in the hands of the Rangoon Development trust, which administered the Rangoon government estate on behalf of the government. The trust developed the land, then handing over the completed roads, etc., for maintenance by the Rangoon corporation. A race course at Kyaikkasan was completed in 1926.

The affairs of the port were placed under the administration of the Rangoon port commissioners. Rangoon handles about 85% of the total trade of the province. Rangoon town is the business centre of Burma, but the rice milling (at Dalla), oil refining (at Syriam) and teak working, which form the staple industries, are carried on outside the town proper. The chief exports of Rangoon are rice, bran and pollard, mineral oils. timber, oil cake, pulse, lead, zinc ore. wax candles, cotton. oilseed and tobacco.

Before World War II most of the labour in the port and the town was immigrant Indian labour; much of the skilled labour, especially in building trades. had been supplied by Chinese. The trading and clerical communities were also mainly Indian. Rangoon was thus by no means a typical Burmese city; in 1931 out of a population of 400,415 there were only 121,998 Burmese, compared with 140,458 Hindus. 57.535 Moslems, 30.000 Christians (mainly Europeans, Anglo-Indians and Indians', and 30,626 Chinese. As a result of the Japanese invasion of Burma in 1941–42 the Indian and European populations were much reduced, and the attainment of independence by Burma in 1948 caused a second exodus by many who had returned after the mar.

RANGPUR, a municipal town and district in East Pakistan.

The town is situated on the little river Ghaghat. Pop. (1951) 31,759. It is a long straggling town, with a railway station at one end and the public offices 3 mi. away at the other.

RANGPUR DISTRICT, with an area of 3,699 sq.mi. and a population (1951) of 2,929,466, is one vast plain. The greater part of it, particularly toward the east, is inundated during the rains, and the remainder is traversed by a network of streams. The river system is constituted by the Brahmaputra and its tributaries, chief of which are the Tista, Dharla, Sankosh and Dudhkumar. About three-fourths of the district is under continuous cultivation. The staple crops are rice, oilseeds, jute and tobacco. The district is well served by railways. Saidpur (pop. [1951] 61,369), with the workshops of the metre-gauge system of the East Bengal state railway, is an important railway town.

RANJIT SINGH, MAHARAJA (1780–1839), Indian ruler, who was known as the "Lion of the Punjab," was born on Nov. 2, 1780, the son of Sirdar Mahan Singh, whom he succeeded in 1792 as head of the Sukarchakia branch of the Sikh confederacy. He was by birth only one of many Sikh barons, and rose rapidly entirely by force of character and will.

At the age of 20 he obtained from Zaman Shah, the king of Afghanistan, a grant of Lahore, which he seized by force of arms in 1799. He attacked and annexed Amritsar in 1802, thus becoming master of the two Sikh capitals. When Jaswant Rao Holkar took refuge in the Punjab in 1805, Ranjit Singh made a treaty with the British, excluding Holkar from his territory. Shortly afterward acute difficulties arose between him and the British as to the Cis-Sutlej portion of the Punjab. Ranjit Singh aspired to weld all of the Punjab into a single Sikh empire, while the British claimed the territory south of the Sutlej by right of conquest from the Marathas. The difference proceeded almost to the point of war, but at the last Ranjit Singh yielded. In 1808 Charles Metcalfe was sent to settle this question and a treaty was concluded at Amritsar on April 15, 1809.

The maharaja organized a powerful force, which was trained by French and Italian officers such as Generals Ventura, Jean François Allard and Paolo di Bartolomeo Avitabile, and thus forged the formidable fighting instrument of the Khalsa army, which afterward gave the British their hardest battles in India in the two Sikh wars. In 1810 he captured Multan after many assaults and a long siege; by 1820 he had consolidated the whole of the Punjab between the Sutlej and the Indus under his dominion. It was not until 1834, five years before his death, that Peshawar passed into Sikh hands. Though he disapproved of Lord Auckland's policy of substituting Shah Shuja for Dost Mohammed, he supported the British in their advance on Afghanistan. He died of paralysis on June 27, 1839. *See* also PUNJAB: *History*.

RANJITSINHJI, KUMAR SHRI (1872–1933), maharajah of Nawanagar, was born at Sarodar in Kathiawar, India, on Sept. 10, 1872. By birth a Rajput, he was educated first at Rajkumar college, Rajkot, and afterward at Trinity college. Cambridge. He soon won a high place in English cricket. From 1895 to 1904 he played for Sussex and was captain from 1899 to 1903; his last appearance was in 1920. He went to Australia with A. E. Stoddart's team in 1897–98 and took a team to the United States in 1899. He made in all 14 scores of more than 200 and in 1900 made more than 3,000 runs for an average of 87 and more than 200 five times. His greatest feat was at Hove against Middlesex. On the last day of the match, on a bad wicket, he made 202, when Vine (17) was the only other man on the side to get into double figures. In 1907 he succeeded his cousin as chief of the state of Nawanagar and proved an enlightened ruler. He provided troops for the Allies in World War I and himself served at the front. He died on April 2, 1933.

See Roland Wild, *The Biography of Colonel His Highness Shri Sir Ranjitsinhji* (1934).

RANK, OTTO (1884–1939), Austrian psychologist, was one of the earliest and most influential adherents of the psychoanalytic school. He was born in Vienna on April 22, 1884, and took his doctorate in *Germanistik* at the University of Vienna in 1912. While most of Freud's other disciples devoted themselves primarily to clinical applications, Rank applied his principles to the study of mythology, literature and art. His first important work was *Der Künstler* (1907; later expanded and rewritten under the title of *Art and Artist*, Eng. trans. by C. F. Atkinson, 1932); it invoked the Freudian theory of dream mechanisms to explain the mental processes of the artist. His two best-known publications, *Der Mythus von der Geburt des Helden* (1909; Eng. trans., *The Myth of the Birth of the Hero*, 1914) and *Das Inzest-Motiv in Dichtung und Sage* ("The Incest-Motive in Poetry and Legend," 1912), attempted to show how the so-called Oedipus complex supplied an abundance of themes and motives for poetry and myth.

Rank was editor of *Imago* and *Internationale Zeitschrift fur Psychoanalyse*, the first European journals on psychoanalysis. from 1912 to 1924; in 1919 he founded the Internationale Psychoanalytische Verlag, of which he was director until 1924. Freud endorsed and freely quoted Rank's earlier contributions, but violently opposed the more original theories developed in Rank's last important book, *Das Trauma der Geburt* (1924; Eng. trans., *The Trauma of Birth*, 1929). Consequently they parted company. After leaving Vienna in 1924 Rank divided most of his time between Paris and the United States, being engaged chiefly in teaching and in psychotherapeutic work. In 1936 he finally settled in New York city. There he sought to modify the Freudian theory, which had developed under the social conditions formerly prevailing in Vienna, and to adapt it to the contemporary needs of an industrial society, like that in the United States. He died on Oct. 31, 1939, five weeks after Freud. (CY. B.)

RANKE, LEOPOLD VON (1795–1886), German historian, who is generally regarded as the first of modern historians, was born on Dec. 20 or 21, 1795, at Wiehe, in Thuringia. He studied classics and theology at Halle and Berlin. In 1818 he began to teach history in a school at Frankfurt-on-Oder, thereby entering the service of the Prussian government.

With the scholar's dislike of textbooks, he rapidly acquired a thorough knowledge of the ancient historians, quickly passed on to medieval times and determined to make a study of universal history. At Frankfurt he wrote his first work, *History of the Latin and Teutonic Nations, 1494–1514* (1824; Eng. trans., 1887 and 1909), which included a critical dissertation on the historians of this period *(Zur Kritik neuerer Geschichtschreiber)*. exposing the untrust orthiness of much traditional history. This dissertation was as important for modern history as the criticai work of B. G. Niebuhr had been in ancient history. A copy of the book was sent to the Prussian minister of education K. A. Kamptz, and Ranke was appointed supernumerary professor in the University of Berlin, and began his 50-year connection with that university. His *Fürsten und Volker von Südeuropa im 16 und 17 Jahrhundert* ("Princes and Peoples of Southern Europe in the 16th and 17th Centuries"; 1827) was based on the study of manuscript records in the Berlin library. In later editions the book was called *Die Osmanen und die spanische Monarchie* ("The Ottomans and the Spanish Monarchy").

The Prussian government now provided him with means to prosecute his researches abroad. He visited Vienna. where the friendship of Friedrich von Gentz and the protection of Metternich opened to him the Venetian archives, of which many were preserved in that city—then a virgin field. He wrote a short book on the history of the Serbian revolution (1829; Eng. trans. by A. Kerr, 1847), afterward expanded into *Serbien* und *die Tiirkei im 19 Jahrhundert* (1879) from material supplied to him by Wuk Stephanovich. a Serbian who had himself been witness of the scenes he related. He spent three years (1828–31) in Italy. The recommendations of Metternich opened to him almost every library except the Vatican.

For a time Ranke was editor of a periodical in which Friedrich Perthes sought to defend the Prussian government against the democratic press. He failed; men desired not the scientific treatment of politics, but satire and invective. He earned the hatred and suspicion of the liberals and did not satisfy the Prussian conservatives, and after four years the *Historisch-Polifische Zeitschrift* came to an end. Two-thirds of the matter had been contributed by the editor, and the two stout volumes in which the numbers were collected contained the best political thought which had for long appeared in Germany. For Ranke the failure was not to be regretted; the rest of his life was to be wholly devoted to history proper. *Ecclesiastical and Political History of the Popes During the 16th and 17th Centuries* (3 vol.. 1834–36, and many other editions; Eng. trans. by S. Austin, 1840, and others), in form as in matter one of the greatest of his works, contains the results of his studies in Italy. The English translation by Mrs. Austin was the occasion of one of Macaulay's most brilliant essays. Before it was completed Ranke had already begun the researches for the second of his masterpieces, his *History of the Reformation in Germany* (Eng. trans. by S. Austin, 1845–47), a necessary pendant to his book on the popes. In 1837 he became full professor at Berlin; in 1841 Frederick William IV appointed him Prussian historiographer. In this capacity he wrote the *Neun Bücher preussischer Geschichte* (1847–48), a work on Prussian history which makes severe demands on the attention of the reader—he is the "Dryasdust" of Carlyle's *Frederick;* but in it he laid the foundation for the modern appreciation of the founders of the Prussian state. The 9 books were subsequently. expanded to 12 (1874). His *Civil Wars and Monnrchy in France in the 16th and 17th Centuries* (Eng. trans., 2 vol., 1852) was followed by his *History of England* (Eng. trans.. 6 vol.. 1875). This, the longest of his works, lacked something of the freshness of his earlier books; he was over 70 when it was completed, and he was never quite at home in dealing with the foundations of English public life. In his 81st year he began to write the *Weltgeschichte* ("Universal History"; 9 vol., 1883–88). Drawing on the knowledge accumulated during 60 years, he had brought it down to the end of the 15th century before his death in Berlin on May 23, 1886.

Ranke's other writings include biographies of Frederick the Great and Frederick William IV for the *Allgemeine Deutsche Biographie.* In addition to those previously mentioned, works translated into English include *Ferdinand I and Maximilian II of Austria; State of Germany After the Reformation,* by Lady Duff Gordon (1853); *Memoirs of the House of Brandenburg and History of Prussia During the 17th and 18th Centuries,* by Sir Alexander and Lady Duff Gordon (1849). A collected edition of Ranke's works in 54 volumes was issued at Leipzig (1868–90), but this does not contain the *Weltgeschichte.*

Ranke's wide reputation was due, in part, to his success as a teacher. In his more private classes, where he dealt with the technical work of a historian, he trained generations of scholars. No one since C. G. Heyne has had so great an influence on German academic life, and for a whole generation the Berlin school had no rival. Ranke's example and training has made it impossible for anyone to attempt to write modern history except on the "narratives of eye-witnesses and the most genuine immediate documents" preserved in the archives. He was determined never to allow himself to be misled, in his search for truth, by those theories and prejudices by which nearly every other historian was influenced—Hegelianism, liberalism, romanticism, religious and patriotic prejudice. For details of Ranke's life and work. *see* his own *Zur eigenen Lebensgeschichte,* ed. by A. Dove (1890).

RANKINE, WILLIAM JOHN MACQUORN (1820–1872), Scottish engineer and physicist, was born at Edinburgh on July 5, 1820, and completed his education in its university. He was trained as an engineer under Sir J. B. Macneill, working chiefly on surveys, harbours and railroads, and was appointed in 1855 to the chair of civil engineering in Glasgow. He was the earliest of the three founders of thermodynamics (*q.v.*) on the bases laid by Sadi Carnot and J. P. Joule respectively, and the author of the first formal treatise on the subject; 150 scientific papers are credited to him in the Royal society's *Catalogue.* The more important of these were collected and reprinted in *Rankine's Scientific Papers* (1881), which contains a memoir of the author by P. G. Tait. Rankine died at Glasgow on Dec. 24, 1872.

RANSOM, JOHN CROWE (1888–), U.S. poet and critic, was born on April 30, 1888, in Pulaski, Tenn. Graduated from Vanderbilt university, Nashville, Tenn., in 1909 and from Oxford, where he was a Rhodes scholar, in 1913, he taught English at Vanderbilt from 1914 to 1937, when he went to Kenyon college, Gambier, O., as professor of poetry and editor of the *Kenyon Review.*

From 1922 to 1925, Ransom and his pupils—Donald Davidson, Allen Tate, Merrill Moore and Robert Penn Warren—published a magazine of their own verse called *The Fugitive.* The same group (excepting Moore), joined by others at Vanderbilt, published *I'll Take My Stand* (1930), which criticized current notions of industrial progress. Ransom turned to literary criticism in *The World's Body* (1938) and *The New Criticism* (1941), the latter of which gave the name to the critical school that is concerned with the close reading of poetical texts. Ransom's poems. collected in *Chills and Fever* (1924), *Two Gentlemen in Bonds* (1926) and *Selected Poems* (1945), are remarkable for their wit and irony, their understatement and their southern urbanity. (R. St.)

RANSOM, the price for which a captive in war redeemed his life or his freedom. a town secured immunity from sack and a ship was repurchased from its captors. The customs of feudal warfare recognized that captives of knightly rank had the right of buying their liberty from their captors. It was the duty of a feudal tenant to contribute toward his lord's ransom, and a king would often show his appreciation of a knight's services by redeeming him from captivity. The practice introduced a commercial element into medieval warfare, which became very prominent in the Hundred Years' War between England and France and in the internal wars of Italy in the 15th century. In the former war, the ransom paid by John, king of France. and David II, king of Scotland. sensibly relieved the finances of Edward III's administration and at an earlier date the ransom paid by Richard I to the emperor led to the introduction of new financial devices which are important in the history of English taxation.

RANTERS, an antinomian and spiritualistic English sect in the time of the Commonwealth. which may be described as the dregs of the Seeker movement. Their central idea was pantheistic. *See* Rufus M Jones, *Studies in Mystical Religion,* ch. 19 (1909).

RANTOUL, a village of Illinois, U.S., in Champaign county, was incorporated in 1869 and named for Robert Rantoul, an early member of the board of directors of Illinois Central railroad. Located about 15 mi. N.E. of Champaign in the grand prairie of east central Illinois, the village originally had an agricultural economy. Chanute air force base, adjacent to Rantoul, was built in 1917 and has been permanent since 1921. Building and maintenance of the base provided new and varied opportunities for employment to local people. School-building programs received federal aid; churches and recreational facilities were also provided. Residential development, largely to accommodate air force personnel, contributed to changing this rural community into an urban one.

For comparative population figures *see* table in ILLINOIS: *Population.* (T. J. T.)

RANUNCULACEAE, a plant family of the order Ranales that includes many familiar and ornamental flowers. There are 30 genera with about 700 species in temperate and cold regions, especially in the northern hemisphere. The family contains many well-known forms, such as buttercup, larkspur, anemone, columbine, clematis, marsh marigold, peony, etc. In North America there are about 25 genera, in Great Britain 12. The plants are dicotyledons (*i.e.,* with two seed leaves), and the family retains many of the primitive characters of the extinct ancestors of the higher dicotyledons and monocotyledons. Most of the plants are herbs (rarely woody vines, as in some species of *Clematis)* with alternate leaves (opposite in *Clematis)* usually without stipules. The flowers, which show considerable variation in the number and development of parts, are characterized by free hypogynous sepals and petals, numerous free stamens, usually many free one-chambered carpels and small seeds containing a minute straight embryo embedded in a copious endosperm. The parts of the flower commonly are arranged spirally on a convex receptacle. The fruit is one-seeded (an achene) or many-seeded (a follicle) or rarely, as in *Actaea,* a berry.

The family falls into well-defined tribes distinguished by characters of the flower and fruit.

Tribe I, Paeonieae (peonies). are mostly herbs with deeply cut leaves and large solitary showy flowers in which the parts are arranged spirally, the sepals, generally five in number. passing gradually into the large coloured petals. There are two to five free carpels which bear a double row of ovules along the suture. There are no special stalked nectaries, but nectar is secreted by a ringlike swelling around the bases of the carpels. The pistils become fleshy in the fruit and each dehisces along the suture. There are only three genera; the largest, *Paeonia,* occurs in Europe, temperate Asia and western North America. *P. officinalis* is the common peony; P. *suffruticosa* is the tree peony, native to China. This tribe possibly constitutes a separate family.

Tribe II, Helleboreae, are almost exclusively north temperate or subarctic. The leaves may be entire or nearly so, as in *Caltha,* but more often palmately divided as in hellebore, aconite (monkshood) and larkspur. The flowers are solitary *(Eranthis)* or in cymes or racemes, and are radially symmetrical as in *Caltha* (marsh marigold), *Trollius* (globeflower), *Helleborus* (hellebore), *Aquilegia* (columbine) or sometimes bilaterally symmetrical as in *Aconitum* (aconite) and *Delphinium* (larkspur). The carpels. generally three to five in number, form in the fruit many-seeded follicles. except in *Actaea* (baneberry), where the single carpel develops into a many-seeded berry, and in *Nigella,* where the five carpels coalesce, forming a five-chambered ovary. The sepals are usually five and are white or brightly coloured. Thus in *Caltha* and *Trollius* the sepals form a brilliant golden-yellow globe, and in *Eranthis* a pale-yellow star; in *Nigella* they are blue or yellow. In *Helleborus* the greenish sepals persist until the fruit is ripe. *Aconitum* and *Delphinium* differ in the bilaterally symmetrical development of the sepals. the posterior one being distinguished from the remaining four by its helmet shape (*Aconitum*) or by its spur *(Delphinium).* In *Trollius* the petals are long and narrow with a honey-secreting pit at the base; in *Nigella* and *Helleborus* they form short-stalked pitchers; in *Aquilegia* they are large and coloured with a showy, petallike upper portion and a long basal spur in the tip of which is the nectary. In *Delphinium* they are also spurred. and in *Aconitum* they form a spurlike sac on a long stalk. The parts of the flower usually are arranged in a spiral (acyclic), but are sometimes hemicyclic. the perianth forming a whorl as in winter aconite; rarely is the flower cyclic. as in *Aquilegia,* in which case the parts throughout are arranged in alternating whorls. In *Caltha,* where there are no petals, nectar is secreted in two shallow depressions situated on the side of each carpel. Monkshood is a source of medicinal febrifuges.

Tribe III, Anemoneae, are chiefly temperate, arctic and alpine herbs. They differ from the two preceding tribes in the usually numerous carpels, each with only one ovule, forming achenes. The subgenus *Bntrachium* of the genus *Ranunculus* (*q.v.*) contains aquatic plants with submerged or floating stems and leaves. The flowers are solitary as in *Anemone pulsatilla* (pasqueflower), cymose as in species of *Ranunculus,* or in racemes or panicles as in *Thalictrum.* The parts are arranged spirally throughout as in *Myosurus* (mousetail). where the very numerous carpels are borne on a much-elongated receptacle, or the perianth appears whorled as in *Anemone* and *Ranunculus.* In *Anemone* and *Thalictrum* there is only one series of perianth parts, and these are petaloid and attractive in *Anemone,* in which nectar is secreted by modified stamens. In *Anemone nemorosa* (European wood anemone), there is no nectar and the flower is visited by insects for pollen; in *Tkalictrum* the perianth is greenish or slightly coloured, and the flower is wind-pollinated (*T. minus*) or visited for its pollen. On the petal of *Ranunculus* there is a basal nectary usually covered by a scale. In *Anemone* the achenes bear the persistent naked or bearded style which aids in dissemination; the same purpose is served by the prickles on the achenes of *Ranunculus arvensis. Clematis* (*q.v.*) is characterized by its shrubby. often climbing habit. opposite leaves and the valvate (not imbricate as in the rest of the family) estivation of the sepals. The fruit consists of numerous achenes prolonged into the long feathery style. whence the popular name of the British species, old-man's-beard (*Clematis vitalba).*

See also ACONITE; ADONIS; ANEMONE; BANEBERRY; CIMICIFUGA; CLEMATIS; COLUMBINE; HELLEBORE; LARKSPUR; RANUNCULUS, etc.

BIBLIOGRAPHY.—L. Benson, *Plant Classification* (1957); A. Engler and K. Prantl, *Die natürlichen Pflanzenfamilien* (1887–1908); G. H. M. Lawrence, *Taxonomy of Vascular Plants* (1951). (L. BN.)

RANUNCULUS, familiarly known as buttercup, or crowfoot, a characteristic genus of the botanical family Ranunculaceae (*q.v.*). The Latin name, which means a little frog or tadpole (diminutive of *rana,* frog), was also given to a medicinal plant, which has been identified by some with the crowfoot. The members of the genus *Ranunculus* are more or less acrid herbs, sometimes with fleshy root fibres. or with the base of the stem dilated into a kind of tuber *(R. bulbosus).* They have tufted or alternate leaves. dilated into a sheath at the base, and generally, but not universally, deeply divided above. The flowers are solitary, or in loose cymes, and are remarkable for the number and separation of their parts. Thus there are five sepals, as many petals. and numerous spirally arranged stamens and carpels. The petals have a little nectary or honey gland at the base. The fruit is a head of achenes — dry, one-seeded fruits.

RUTHERFORD PLATT

RANUNCULUS, COMMONLY KNOWN AS BUTTERCUP OR CROWFOOT. PETALS AND SEPALS HAVE BEEN REMOVED FROM FLOWER AT LEFT SHOWING THE PISTIL AND STAMENS

The genus contains a large number of species (about 250) and occurs in most temperate countries in the northern and southern hemispheres, extending into arctic and antarctic regions, and appearing on the higher mountains in the tropics. Inclusive of the water buttercups, 100 native species of *Ranunculus* occur in North America, widely distributed throughout the continent. Representative species are *R. septentrionalis, R. abortivus* and *R. recurvatus,* of the eastern states. and R. *californicus* of the Pacific coast. About 15 species are found in Great Britain. *R. acris, R. repens* and *R. bulbosus* are the common buttercups. *R. arvensis,* which is found in European cornfields, has smaller pale-yellow flowers and the achenes covered with stout spines.

R. lingua and *R. flammula,* the spearwort, grow in marshes, ditches and wet places. *R. ficaria* is the pilewort or lesser celandine, an early spring flower in European pastures and waste places, characterized by having heart-shaped entire leaves and clusters of club-shaped roots.

The section *Batrachium* comprises the water buttercups, denizens of pools and streams, some of which vary greatly in the character of the foliage according to whether it is submerged. floating or aerial, and when submerged varying in accordance with the depth and strength of the current.

The ranunculus of the florist is a cultivated form of *R. asiaticus,* a native of the eastern Mediterranean Levant region, remarkable for the range of colour of the flowers (yellow to purplish black) and for the regularity with which the stamens and pistils are replaced by petals forming double flowers.

RANVIER, LOUIS ANTOINE (1835–1922), French histologist, a master of technical methods and a true scientist, one of the great French biologists; was born on Oct. 2, 1835, at Lyons. He began his medical studies in Lyons and worked in the hospitals there under such well-known clinicians as Charles Jacques Bouchard and Raphael Lépine. He was nominated interne in the Paris hospitals in 1860 and graduated M.D. five years later, presenting a thesis on the development and diseases of bone. By this time he had formed a close friendship with Andre Victor Cornil (1837–1908), with whom he shared an intense interest in the rapidly developing science of histology. The two friends opened a private laboratory where they gave special courses for students. Cornil soon obtained academic promotion, and Ranvier, having attracted the attention of Claude Bernard, was appointed his assistant in 1867. In 1869–76 Cornil and Ranvier brought out their *Manuel d'histologie pathologique*, a revelation to their contemporaries and one of the landmarks in 19th-century medicine. In 1872 a special histological laboratory was opened for Ranvier at the Collkge de France, and in 1875 he became the first occupant of the chair of general anatomy.

Apart from the *Manuel* Ranvier's most important published works were his *Traité technique d'histologie* (1875 ff.), *Leçons sur l'histologie du système nerveux* (1878) and *Leçons d'anatomie générale, faites au Collège de France* (1880–81). He also wrote many papers and edited seven volumes of the *Travaux* of his laboratory (1874–88). His own researches were concerned particularly with the histology of nerve fibres, the regeneration of nerves, the bipolar nature of ganglionic cells and the minute structure of the skin, conjunctival tissue and cornea. In 1878 he first described the constrictions seen in medullated nerve fibres which are known as the nodes of Ranvier. He was elected a member of the Académie de Médecine (1880) and of the Institut (1887). During his pioneer researches Ranvier had many pupils and disciples, but in the period 1880–85 the interest aroused by Louis Pasteur's discoveries in bacteriology led to a decline in histological studies. Ranvier's laboratory was no longer frequented, his courses lapsed and he made few further contributions to science. Thereafter he spent most of his time on an ancestral estate at Vendrages (Loire), to which he finally retired *c.* 1900, occupying himself with country pursuits. He never married, and in his later years was a solitary figure. He died on March 22, 1922, leaving part of his fortune to the town of Roanne for the erection of a sanatorium for tuberculosis. (W. J. Bp.)

RAOUL DE CAMBRAI, the name of a French *chanson de geste.* The existing romance is a 13th-century recension of a poem by a trouvkre of Laon called Bertholais, who professed to have witnessed the events he described. Raoul de Cambrai, the posthumous son of Raoul Taillefer, count of Cambrai. by his wife Alais, sister of King Louis (d'Outre-Mer), demanded the fief of Vermandois, which was the natural inheritance of the four sons of Herbert, lord of Vermandois. On King Louis's refusal, he proceeded to war. Bernier, a grandson of Count Herbert. eventually slew Raoul, but in his turn was slain, after an apparent reconciliation. Flodoard *(Annales, Anno* 943) states that Count Herbert died in that year, and was buried by his sons at St. Quentin; that when they learned that Raoul, son of Raoul de Gouy, was about to invade their father's territory, they attacked him and put him to death.

RAOULT, FRANÇOIS MARIE (1830–1901), French chemist, best known in connection with work on solutions (*q.v.*), was born at Fournes, Nord, on May 10, 1830. In 1862, after holding various teaching posts, he became professor of chemistry in the *lycée* at Sens. In 1867 he was put in charge of the chemistry classes at Grenoble, and three years later he succeeded to the chair of chemistry, which he held until his death on April 1, 1901. In his doctoral research on the heat of reaction and electromotive force of galvanic cells, he made the important observation that the two did not correspond on the theory that heat is a measure of affinity.

One of his most important contributions was the discovery that the freezing point depression of aqueous solutions is proportional to the solute mole fraction. His most valuable finding (Raoult's law) was the discovery that the vapour pressure of the solvent in a solution is proportional to the mole fraction of the solvent. Raoult's law has been of fundamental importance in the development of the theory of solutions. (N. H. N.)

RAPALLO, a seaport and winter resort of Liguria, Italy, in the province of Genova. Pop. (1951) 11,455. It occupies a beautiful and ell-sheltered situation on the east side of the Gulf of Rapallo, 18½ mi. E. by S. from Genoa by rail. The bridge, known as "Hannibal's Bridge," is medieval. To the south lies the small seaport of Portofino (the Roman *Portus Delphini*) under the southeast extremity of the promontory of Portofino (2,001 ft.) crowned by the remains of a castle. On the way from S. Margherita to Portofino is the suppressed monastery of Cervara, in which Francis I of France was confined after the battle of Pavia on his way to Madrid. At all these places are beautiful villas.

On the south side of the promontory is the small village of S. Fruttuoso. with the tombs of some of the Doria family of Genoa (1275–1305).

RAPALLO, TREATY OF (April 16, 1922). During the conferenceof Genoa *(see* GENOA, CONFERENCE OF), at which it was designed to consider the economic relations of the participating powers with Soviet Russia, the Soviet delegates showed no desire to resume relations with the Allied and Associated powers, but to the consternation of the latter signed an agreement with Germany, after secret negotiations. The treaty was initialled on April 16, 1922 by Georghy V. Chicherin and Walther Rathenau. Germany and Russia renounced reciprocally all claims to war indemnities of any sort, including payment for the maintenance of prisoners of war. Germany renounced any compensation for losses incurred by German subjects in consequence of Russian socialization of private property "provided that the Soviet Government does not satisfy similar claims of other states." Diplomatic and consular relations were resumed, the principle of the most-favoured nation was to be mutually applied, with a Russian reservation in favour of states formerly belonging to the Russian empire. Economic relations were to be regulated "with mutual feelings of goodwill." The main result of the Rapallo treaty, secret at that time, was that Germany was able to produce in Russia new prototypes of arms forbidden by the treaty of Versailles.

RAPE, one of the six administrative divisions of the county of Sussex, Eng., with their centres at Chichester, Arundel, Bramber, Lewes, Pevensey and Hastings. Rapes were probably established soon after the settlement and are first mentioned in Domesday Book. Their boundaries ran roughly parallel from north to south and each rape contained a river, a castle and a forest.

RAPE, various plants of the genus *Brassica* (mustard family, Cruciferae), the source of oil-yielding rape seed. Most of the cultivated varieties appear to belong either to *Brassica napus* or *B. campestris.* Both may be grown as annuals or biennials, depending upon the variety and the time of sowing. *B. napus* is a much-branched, glaucous plant growing to 3½ ft. tall, with lobed or toothed, succulent leaves, yellow flowers and elongate narrow pods. *B. campestris* is similar, but it is more weedy, its leaves are less succulent and the plant is less glaucous. Leading producers of rape seed are China, India, Pakistan, Japan, Sweden, France and the U.S.S.R. Some rape is grown for seed in Canada, but in the United States the plant is used mainly as a forage and green manure crop. Oils derived from the various kinds of rape seed are closely similar and are used mainly as edible oil and in lubricants. (J. W. Tt.)

RAPE, in law, is the crime committed by a man in obtaining unlawful carnal knowledge of a woman, without her consent, by fear, force or fraud. **A** husband cannot commit rape upon his wife unless she is legally separated from him.

A felony at common law, rape was reduced in England to a misdemeanour in 1275, but in 1285 was again declared a felony, with benefit of clergy, and so remained until 1575, when the punishment was made more severe. It became a capital offense by the Offences Against the Person act, 1861, and is now punishable with imprisonment for life. The law of England regards as immaterial whether the woman is chaste or unchaste, married or single. The offense is complete if consent is extorted by threats of death or immediate bodily harm, by fraud or by false pretenses or personating the woman's husband.

In the United States the elements of the crime under statute are similar to those at common law. The age when effective consent can be given by the woman has commonly been set by the various states between 14 and 18 years. Want of age on the part of the man is not a defense, as at common law, but simply presumptive evidence of lack of physical capacity. Many states require the testimony of the woman to be corroborated by other evidence as well as requiring the prosecution to be initiated within a year or less after the commission of the offense. The punishment is imprisonment, though a few southern states prescribe death as the penalty. (P. E. L.)

RAPE OIL, an important fatty oil, known also as "sweet oil," either expressed or extracted from the crushed seeds of cultivated varieties of the cruciferous genus *Brassica*. Under the names rape oil. rapeseed oil and colza oil (*q.v.*) are included the produce of several varieties of B *napus* and *B. campestris*. Summer rape. an annual variety of *B. napus*, is an important oilseed crop in Europe while varieties of *B. campestris* are grown in India and China. *(See* RAPE)

The oil yielded by these seeds is, in physical and chemical properties, practically the same, the range of fluctuations not being greater than would be found in the oil of any specific seed under similar varying conditions of production; the winter varieties of all the seeds are more productive than the summer varieties. Newly pressed rape oil has a dark sherry colour with. at first. scarcely any perceptible smell; but after resting a short time the oil deposits an abundant mucilaginous slime, and by taking up oxygen it acquires a peculiar disagreeable odour and an acrid taste. Refined by the ordinary processes *(see* OILS. FATS AND WAXES), the oil assumes a clear golden-yellow colour. In specific gravity it ranges between 0.9112 and 0.9117 (ra) and from 0.9127 to 0.9136 (refined); the solidifying point is from −4° to −6° C.

The principal uses of rape oil are for lubrication and lighting; but after the introduction of mineral oils for both these purposes the importance of rape considerably decreased. It is but little employed in soapmaking, as it saponifies aith difficulty and yields only an indifferent product. In Germany it is very considerably used as a salad oil under the name of *Schmalzöl*, being for that purpose freed from its biting taste by being mixed with starch, heated until the starch is carbonized and filtered after the oil has cooled. The offensive taste of rape oil may also be removed by treatment uith a small proportion of sweet spirits of nitre (nitrous ether). In Indonesia rape oil and its equivalents. known under various names, are the most important of oils for native use. They are largely consumed as food instead of ghee under the name of *metah* or sweet oil. but for all other purposes the same substance is known as *kurwah* or bitter oil It is preferred for the preparation of curries and other hot dishes. Rape oil is the subject of extensive adulteration. principally with the cheaper hemp oil, rosin oil and mineral oils These sophistications can be most conveniently detected first by taste and next by saponification, rosin oil and mineral oil remaining unsaponified. hemp oil giving a greenish soap and rape oil yielding a soap with a yellow tinge.

Rape oil and the other cruciferous oils are characterized by the presence of the unsaturated fatty acid erucic acid, $C_{21}H_{41}COOH$, the identification of which affords a means of detecting rape oil in admixture with other oils. Lead plaster boiled in rape oil dissolves, and, sulfide of lead being formed, the oil becomes brown or black. Other lead compounds give the same black coloration from the formation of sulfide.

See E W Eckey, ***Vegetable*** *Fats and Oils* (1954).

RAPHAEL (meaning "God heals"), in the Old Testament Apocryphal Book of Tobit (*q.v.*), the name of the angel who in human disguise and under the name of Azarias ("Yahweh helps") accompanied Tobias in his adventurous journey and conquered the demon Asmodaeus. He is said to be "one of the seven holy angels [archangels] which present the prayers of the saints and go in before the glory of the Holy One." In the Book of Enoch (ch. 20) Raphael is "the angel of the spirits of men," and it is his business to "heal the earth which the angels have defiled."

RAPHAEL (RAFFAELLO SANTI or SANZIO) (1483–1520), one of the greatest Italian painters of the Renaissance, was born in Urbino, the son of Giovanni Santi. His birth, probably on April 6, 1483. took place in a house which still contains a fresco of the "Madonna and Child" that is either by his father or is a very early work of his own Giovanni Santi was not a very good painter as may be seen from his surviving works such as the "Madonna and Child With Saints" (1489, Urbino gallery). but he presumably gave Raphael his first grounding as a painter. He died in 1494, and, as Raphael's mother had already died.in 1491, parental influence can have counted for little. What was far more important was Urbino itself, for this little hill town was one of the most civilized in Europe in the 15th century, under its Duke Federigo da Montefeltro and his son and successor Guidobaldo. The palace is one of the masterpieces of Italian architecture; Piero della Francesca had worked in Urbino in the 1460s and 1470s; Bramante was a citizen and was later to play a major part in Raphael's career; and Baldassare Castiglione. the arbiter of manners and author of *The Courtier*, was an Urbinate. The latter was to become a friend of Raphael, ahose portrait of him (1516, Louvre, Paris) is one of the first modern portraits—a study of character distinct from that accumulation of details which the 15th century had regarded as essential to portraiture.

Earliest Works.—Raphael's earliest years are still obscure. He is first recorded on Dec. 10, 1500, when he shared in a commission for a "St. Nicholas," completed on Sept. 13, 1501, which is now lost but is known in part through drawings. Extant works which are probably of this very early period include the large "Mond Crucifixion" (National gallery. London) and the two tiny panels of the "Knight's Dream" (also National gallery) and the "Three Graces" (Chantilly. France). Before this time he had almost certainly assisted Perugino in his frescoes in the Sala del Cambio at Perugia. and for the next few years the influence of Perugino was dominant; indeed. Raphael might well have settled down to succeed to Perugino's business had it not been for his visit to Florence which fertilized his imagination. The figure of Fortitude in the Sala del Cambio is usually agreed to be by Raphael's hand. but here, of course, he was merely executing Perugino's cartoon. Between 1501 and 1503 Raphael was commissioned to paint an "Assumption" for the nuns of Monteluce, but the picture (now in the Vatican gallery) was actually finished after his death by his pupils. The earliest surviving work by him that is completely certain is the "Sposalizio." or "Marriage of the Virgin." which is signed and dated 1504 (Brera gallery, Milan). The types are markedly Peruginesque and the composition derives from Perugino's "Christ Giving the Keys to St. Peter" (Sistine chapel. Vatican) and from another "Sposalizio" attributed to Perugino now in the museum at Caen. France. It has. however, been suggested that the Caen picture derives rather from Raphael; what is certain is that the Brera "Sposalizio" is no more than an improved Perugino and falls short of the great masterpieces Raphael was to paint no more than five years later.

Florentine Period.—Probably late in 1504 Raphael went to Florence and this date marks the first decisive phase in his career. By 1505 he was once again in Perugia. where he was commissioned to paint a fresco in S. Severo; this seems to have been still unfinished at his death and was completed by his former master Perugino. who outlived him. Nevertheless, the upper part of the fresco contains the germ of his first great Roman work. the "Disputà" Probably immediately after he received this commission Raphael returned to Florence, where he set himself to relearn his whole art under the influence of the two greatest living artists, Leonardo da Vinci and Michelangelo, both then in Florence. Also, he became friendly uith Fra Bartolommeo (*q.v*), but here the influence was mutual. A series of Madonna compositions (Florence, Paris, Vienna. Washington, D.C.. and elsewhere) shows Raphael learning the Florentine method of building up his composition in depth with pyramidal figure masses, uith figures grouped as a single unit yet each retaining its own individuality of character and shape. This new sense of unity in composition and the suppression of inessentials he owed mainly to Leonardo. in particular to his "Madonna and Child and St Anne" cartoons. To Leonardo he also owed a new sense of softness in modeling and skill in chiaroscuro. shown in his portraits of Angelo and Maddalena Doni (Pitti, Florence), in which he adapted the model provided by Leonardo's "Mona Lisa." To counterbalance any tendency to imitate the slightly overripe quality of Leonardo's modeling. Raphael made a profound study of Michelangelo's cartoon of the "Battle of Cascina," with its stress on dramatic action and expressive anatomy. The "Ansidei Madonna" (c. 1506, National gallery, London) shows something of both these influences, but the full impact of Michelangelo on Raphael at this date is best seen in the "Borghese Entombment" (1507, Borghese gallery, Rome), painted for Atalanta Baglione of Perugia in memory of her murdered and murderous son. It contains several more or less direct quotations from Michelangelo and there can be no doubt that in it and other works of the same period Raphael set himself deliberately to learn from Michelangelo the expressive possibilities of human anatomy.

Roman Period.—On April 21, 1508, Raphael was still in Florence, as we know from a letter of that date, and the "Cowper Madonna" (National Gallery of Art, Washington, D.C.) is signed and dated 1508 and must therefore be one of his last Florentine works. Traditionally it was Bramante who summoned him to Rome, since he was distantly related to Raphael and knew that there were good commissions to be had from his own splendid patron, Pope Julius II. The tradition is the more likely to be correct in that Raphael was still virtually an unknown provincial painter. by no means yet the third member of the Leonardo-Michelangelo-Raphael triumvirate that springs automatically to the mind. He was still only in his middle zos, but he was soon to receive a commission from the irascible but extremely discerning pope that placed him practically on a level with Michelangelo. Raphael was certainly at work in the Vatican by Jan. 13, 1509, and on Oct. 4 of that year he was granted a papal sinecure, presumably in payment for work done in the Stanze (Italian, "rooms").

The *Stanze*.—Julius II, who detested the memory of his predecessor Alexander VI, refused to use the Borgia apartments and, as a consequence of his remodeling of the Vatican palace, Bramante built the Cortile di S. Damaso, later to be completed by Raphael and decorated by his pupils under the name of "Raphael's Loggie." As his first great work for the pope. Raphael was commissioned to paint a cycle of frescoes in a series of medium-sized rooms known simply as the Stanze. The Stanza della Segnatura and Stanza d'Eliodoro are practically entirely decorated by Raphael himself; the Stanza dell' Incendio, though designed by Raphael, was largely executed by his numerous assistants and pupils; the last and largest of the apartments, the Sala di Costantino, was hardly even designed by Raphael, and was not finished until about four years after his death.

The main themes of the Stanze are fairly simple and easily grasped, but the details of the iconography have never been completely worked out since no two scholars are satisfied with the same interpretations. It is highly probable that there was a written "program" for the series as a whole and perhaps also for each fresco, but it has not survived and the two most important questions are left unanswered: to what extent was it imposed on Raphael by the pope or his advisers, and to what extent was each and every detail of each fresco charged nith a meaning that had been worked out in advance? When Raphael arrived in Rome he was young, almost unknown. and certainly not particularly well educated in the humanist sense; yet long before he died he was famous not only as a painter but also as a scholar and was clearly on easy and familiar terms with the papal court in general. The most likely reason for this is that he had shown himself the ideal humanist artist; that is, he was able to devise great works of art which at the same time were heavily charged with allegorical or symbolic meaning. One example will perhaps make this clear. The figures of Plato and Aristotle in the fresco known as the "School of Athens"—the identity of these two figures is shown by the books they hold—are not only exactly right from the formal point of view, as two contrasted figures set in the optical centre of the composition, but also the simplest and most telling visual symbols of the two contrasted philosophies. Plato is a grave old man, pointing upward as though to emphasize the heavenly origin of those Ideas which are the basis of his philosophy; Aristotle, a much younger and more vigorous man, gestures in a decisive and forthright way toward the earth as an expression of his unidealistic philosophy.

The four Stanze consist of a single enfilade of rooms, the first three (in the order in which the visitor sees them) being those of the Fire in the Borgo (dell' Incendio), of the Tribunal (della Segnatura) and of Heliodorus (d'Eliodoro). Each of these is about 30 ft. by 25 ft. in size, but the last and largest room, the Sala di Costantino, is about 30 ft. by 45 ft. It communicates directly with the Loggie di Raffaello.

The first to be painted was the Stanza della Segnatura, frescoed bet een 1509 and 1511. It seems to have been used for the sittings of a legal tribunal, and its title implies that important state documents were signed or sealed in it. The ceiling is decorated with four roundels and four rectangular panels in imitation of mosaics, representing Theology, Justice, Philosophy and Poetry (in the roundels), and Adam and Eve, the Judgment of Solomon, Astronomy and Apollo and Marsyas (in the rectangles). The four main fresco fields are occupied by the "Disputi" and the "School of Athens" on the larger walls and "Parnassus" and the "Cardinal Virtues" on the smaller. The two latter have subsidiary scenes representing "Augustus Preventing the Burning of the Aeneid," "Alexander the Great Depositing the Homeric Books in the Tomb of Achilles," and "Justinian Receiving the Pandects" and "Gregory IX Approving the Decretals." As the principal theme of the room is the scope of human knowledge, the main walls are given up to the contrasted representations of secular knowledge and theology—the so-called "School of Athens" and the so-called "Disputi." Presumably neither name was used by kaphael, but the "Disputi" is referred to by G. Vasari as showing "an infinite number of saints, who write down the Mass and hold dispute about the Host which is on the altar . . ." This should not be understood as meaning a dispute in the ordinary English sense of the term, but rather a medieval disputation or philosophical discussion.

It is clear that both the "Disputi" and the "School of Athens" are intended as allegories in a very general sense, and many of the highly involved "explanations" which have been propounded are no more than misplaced ingenuity. The "Disputi" is, in fact, no more than a general symbolic representation of the church on earth and in heaven, for the centre of the composition is the monstrance on the altar, with the heavenly host and the representatives of the church on earth both converging on it. At the same time the Host in the monstrance is the lowest part of the vertical axis which consists of the figures of God the Father, Christ and the Holy Spirit, again a simple piece of symbolism. The upper part of the composition is very reminiscent of the fresco in S. Severo in Perugia, with its row of saints seated on rather solid clouds. but the lower part is more freely handled. The device of the steps, which serve to lead the eye into the picture space, and the railing at the left, balancing the awkward shape made by the door cutting into the fresco field at the right, both prove Raphael's extraordinary powers as a composer. It is very likely that this was the first time he had worked on so large a scale (something like 24 ft. across), and it is nothing short of astounding that he was able to compose the "School of Athens," one of the most subtle arrangements of a large number of figures ever painted, as his second attempt on this scale.

The "School of Athens" is perhaps the most famous of all his frescoes. as the "Sistine Madonna" is the most famous of all his Madonnas. It differs from the "Disputà" in that the symbolism is less obvious and the intention vaguer, for it represents a number of the more famous classical philosophers in a splendid basilica—based on Bramante's design for the new St. Peter's—which, in a general way, symbolizes both the dignity of philosophical enquiry and the secular nature of the subject.

At about the same time, probably in 1511, Raphael also painted a more secular subject still, the "Triumph of Galatea" in the Villa Farnesina, Rome, for the Sienese banker Agostino Chigi, for whom he was later to decorate the Chigi chapel in Sta. Maria del Popolo. The Stanza della Segnatura was completed in 1511 and Raphael began to work on the next Stanza, that of Heliodorus, in 1512, completing it in 1514. The whole character of the Stanza d'Eliodoro is entirely different from that of the Stanza della Segnatura. The generalized allegories of the "School of Athens" or the "Disputi" give way to representations of specific events, all miraculous, which, since they represent the direct interventions of God on behalf of His chosen people, had a political intention in the 16th century. The four principal subjects are: "The Expulsion of Heliodorus From the Temple," "The Miracle at Bolsena." "The Liberation of St. Peter" and "Attila the Hun Turned Back From Rome." Raphael's original patron, Julius II, died in 1513 and was succeeded by Leo X (elected March 11, 1513); as both the "Expulsion" and the "Miracle at Bolsena" (which is dated 1512) contain superb portraits of Julius II while the Leo I who is shown meeting Attila has the features of Leo X, these frescoes can be closely dated. The Stanza takes its name from the fresco of "Heliodorus Expelled From the Temple of Jerusalem" and "compassed in darkness" (II Macc. 3), which had a contemporary allusion to the efforts of Julius against the French and in support of the temporal power. The fresco of the "Mass at Bolsena" records a miracle that took place in 1263, when a priest who doubted the reality of transubstantiation found the Host bleeding in his hands; the Feast of Corpus Domini was instituted as a result (1264), and Julius' own devotion to the Sacrament is probably the principal reason for the choice of this subject. The composition is one of Raphael's most accomplished, since the shape to be filled is exceedingly awkward and asymmetrical, and the celebrated group of the Swiss guards at the lower right is introduced to fill the space where it was necessary to paint a continuation of the real architecture.

In all these miraculous themes the colours are much deeper and more Venetian in feeling than the colour schemes in the earlier room, the "Liberation of St. Peter" providing a particularly notable example of the new interest in colour and light since it is a night scene and contains three separate lighting effects—moonlight, the torch carried by the soldier and the supernatural light emanating from the angel. It is usually thought that the presence in Rome

ALINARI

"SISTINE MADONNA" BY RAPHAEL. IN THE DRESDEN GALLERY, DRESDEN, GERMANY

at this time of Sebastiano del Piombo may have been responsible for this marked Venetian influence on Raphael, but it is also certain that Michelangelo's Sistine ceiling was unveiled while the room was in progress; yet a renewed influence of Michelangelo is not noticeable until somewhat later, most clearly in the frescoes of "Isaiah" (c. 1512, S. Agostino, Rome) and the "Sibyls" in Sta. Maria della Pace, of about 1514.

The most important other work undertaken by Raphael at this period was probably the "Sistine Madonna" (Dresden gallery), which has always been one of his most famous paintings, although its early history is unknown. The most likely explanation for its existence is that it was painted to be carried in the funeral procession of Julius II in 1513 and that it subsequently came into the possession of the monks at Piacenza who owned it before its transfer to Dresden. By 1513 Raphael was one of the most celebrated of living artists and already employed a large studio of assistants and pupils, so that it is extremely unlikely that an obscure community of monks could have commissioned a large altarpiece from him (or have got delivery if they had commissioned it).

Immediately after completing the Stanza d'Eliodoro, Raphael began work on the third Stanza, which is first in order of visiting. The Stanza dell' Incendio was begun in 1514 and completed by 1517, but the proportion of it executed by assistants is much higher than was the case in the first two rooms. Nevertheless, it must be stressed that Raphael was responsible for the decoration as a whole. The reason for this delegation of the execution is twofold: St. Peter's and the Tapestry cartoons. In August, 1514, Raphael succeeded Bramante as chief architect of the new St. Peter's, and, although he built very little of it, the administrative responsibility for the greatest work in Christendom must have been considerable. The first payment for the cartoons was made on June 15, 1515, so it is probable that this new commission had been occupying much of Raphael's attention, rather than the frescoes in the Stanza dell' Incendio. The last and largest of the Stanze, the Sala di Costantino, was commissioned in 1517 but was finished only in 1524, four years after Raphael's death.

The Tapestry Cartoons.—Leo X commissioned a set of tapestries to hang below the 15th-century fresco cycle on the walls of the Sistine chapel. Almost certainly there were 10 (10 tapestries are preserved in the Vatican museum), but a contemporary, probably by a slip of the pen, mentions 16. Seven of the original cartoons still exist in the British royal collection (on permanent loan to the Victoria and Albert museum, London) and other sets of the tapestries, woven at various times from the cartoons, exist elsewhere. The seven cartoons represent "Christ's Charge to Peter," "The Miraculous Draught of Fishes," "The Death of Ananias," "The Healing of the Lame Man," "The Blinding of Elymas," "The Sacrifice at Lystra" and "St. Paul Preaching at Athens"; the other three tapestries, for which no cartoons exist, are "The Conversion of St. Paul," "St. Paul in Prison" and "The Stoning of St. Stephen." The last payment was made in Dec. 1516, when the cartoons must have been sent to Brussels, where the tapestries were woven. Seven were finished by Christmas 1519 and were exhibited in the Sistine chapel, when an eyewitness wrote that "by universal consent there is nothing more beautiful in the world." They were woven by the low-warp (*basse-lisse*) method which involves reversal of the designs, so that the designer has to remember to depict right-handed actions as taking place with the left—a point which was not invariably borne in mind in the cartoons (see A. P. Oppé, "Right and Left in Raphael's Cartoons." in Journal of the *Warburg* and Courtauld Institutes, vol. vii, pp. 82 ff., 1944). It is now generally agreed that Raphael actually drew much more in the cartoons himself than was previously allowed to be the case. but the use which has been made of them and the fragile nature of the medium (size colour on paper) have combined to damage them severely in many parts. Nevertheless, the amount of damage and repainting is relatively unimportant for it cannot be too strongly emphasized that they could have been executed entirely by assistants and then completely repainted without losing their importance and value, for they are supreme examples of the art of composition. It is hardly an exaggeration to say that the normal western conception of the apostles as grave. bearded men in togas derives very largely from the visual images created by Raphael in these works. There has been a great deal of discussion about the way the tapestries were originally arranged. (For a later hypothesis *see* J. White and J. Shearman in *The Art Bulletin*, xl, pp. 194–222, 299–323, 1958).

By April 19, 1516, Raphael had completed the portrait of Count Castiglione, his fellow townsman and the leading authority of the day on polite behaviour. It is indicative that Raphael should have been on terms of intimate friendship with him and also with A. Navagero and other poets and at least two princes of the church, Cardinals Bembo and Bibbiena. For the latter he decorated a bathroom in his suite in the Vatican. It is in a private part of the palace and is now much damaged, but it is of interest since the decorative motifs are based on those in the newly discovered Golden House of Nero, from which the type of decoration known as "grotesque" is derived. Similar motifs were used by members of Raphael's studio, notably by Giovanni da Udine, in the stucco decorations at the Villa Madama and elsewhere. Raphael now occupied a position held by no other artist of modern times (not even Michelangelo is quite comparable), on terms of friendship with the pope and the whole Curia and with almost every prince in Christendom intriguing to obtain a work by his hand; almost over night. the whole social position of the artist was thus revolutionized by the three great artists of the Renaissance, Leonardo, Michelangelo and Raphael. During all this time he was busy on innumerable enterprises, most of which were actually executed by his army of pupils and assistants: the remainder of the Stanza dell' Incendio, the numerous small biblical scenes in the Loggie of the Vatican (works which deserve more study than they tend to get), the sculpture and mosaics of the Chigi chapel and the work on the new St. Peter's as well as other architectural works—he designed S. Eligio degli Orefici and the Vidoni-Caffarelli and Branconio dell' Aquila palaces in Rome as well as the Palazzo Pandolfini in Florence—and the duties involved in his conservatorship of the antiquities of Rome. By employing Marcantonio Raimondi, Raphael ensured the spread of his designs all over the civilized world! for this excellent engraver produced numerous plates from designs made specially by Raphael for the purpose of spreading his ideas.

The Last Works.— A letter from Leonardo Sellaio to Michelangelo at Carrara on Jan. 19, 1517, gives the first indication of what was to become Raphael's last masterpiece, the "Transfiguration," now in the Vatican. Cardinal de' Medici (later Pope Clement VII) commissioned two enormous altarpieces for his cathedral at Narbonne in France; one was Sebastiano del Piombo's "Raising of Lazarus" (now in the National gallery, London) and the other was Raphael's "Transfiguration," unfinished at his death and never sent to Narbonne. In fact, the "Transfiguration" was not begun until 1518 and must therefore be considered along with the "Holy Family of Francis I" and "St. Michael Vanquishing Satan" (both dated 1518 and in the Louvre, Paris), both of which were destined for presentation'to Francis I of France by Leo X. All three pictures were major commissions and any new or unusual features in them are therefore extremely unlikely to be due to pupils or assistants working unsupervised; at the very least, Raphael must have approved any innovations. It is necessary, indeed, to stress this point and also to refer to the series of superb drawings for individual figures in the "Transfiguration," for there is a tendency to write off the last works, and especially the "Transfiguration," as by Giulio Romano, Gianfrancesco Penni and other pupils. Vasari noted, of the "Holy Family of Francis I," that the execution was almost entirely by Giulio Romano, and the "Transfiguration" was certainly completed after Raphael's death; yet Vasari stresses that much of it was in fact painted "with his own hand." There is every reason to suppose that the design is his, and it is in the design that the innovations are chiefly visible. The tendency in all these late works is toward a crowding together of the figures which had hitherto been lucidly arranged in accordance with the classical canons Raphael himself had done so much to impose. At the same time there is a feeling of violence and tension which is not entirely due to the demands of the subject. Indeed, one might argue that the subject was adapted to satisfy a desire to depict a scene of violence, since the boy possessed of a devil is the next stage in the Biblical narrative (Matt. 17). In short, it may be held that Raphael was the first Mannerist.

On Good Friday, April 6, 1520, after an illness lasting a week, Raphael died. He was buried in the Pantheon and his grave is marked by a slab with a commemorative epitaph by Cardinal Bembo. At the head of the bier the unfinished "Transfiguration" stood as his memorial, perhaps the first of what would have been a series of new works in the middle period which Raphael never lived to achieve. He died at 37, when most great artists are approaching their first maturity. *See* also PAINTING: *Raphael.*

RAPID CITY, a city of South Dakota, U.S., and the county seat of Pennington county, is the western gateway to the Black hills (*q.v.*). Located 3,200 ft. above sea level on Rapid creek, from which it derived its name, it was settled in 1876 during the days of the Black hills gold rush, and was incorporated in 1878.

Millions of tourists have been attracted by the beauty of the Black hills, with nearby Mt. Rushmore, Crazy Horse mountain and Custer National park being of particular interest. Although it is located in what is basically an agricultural and grazing area, Rapid City's industries range from lumber. millwork and building materials to Black hills gold jewelry. In addition, gold, silver, beryllium, feldspar, gypsum, mica. uranium and other minerals are mined and processed in the area. Rapid City is the site of the state-owned cement plant. the Sioux Indian sanatorium, the South Dakota School of Mines (established 1885) and Ellsworth air force base. For comparative population figures *see* table in SOUTH DAKOTA: *Population.* (C. J. P.)

RAPIER: *see* FENCING; SWORD.

RARE EARTHS, in chemistry the name originally given to a group of metallic oxides since they resemble the substances then known as earths (lime, magnesia, etc.). The corresponding elements comprising this group are unique in that they are so similar in chemical properties that they can be separated from one another only by taking advantage of the slight differences in their properties. Since there was no place for these elements in the older periodic tables they were grouped in the space allotted to lanthanum.

With a modern understanding of atomic structure it is now recognized that the rare earths include the elements with atomic numbers 58 to 71 and are now placed in a special group in the periodic table. The work of H. G.-J. Moseley (1913) definitely established the maximum number of rare earths and set up procedures by which their purity and existence could be determined. The theories of Niels Bohr and subsequent workers have shown that the electron structure of the trivalent rare-earth ions is: $1s^2$, $2s^2$, $2p^6$, $3s^2$, $3p^6$, $3d^{10}$, $4s^2$, $4p^6$, $4d^{10}$, $4f^x$, $5s^2$, $5p^6$. The neutral atoms contain three extra electrons which distribute themselves between the $6s$, $5d$ and $4f$ subshells. These three electrons, however, are removed to the negative ions in the rare-earth trivalent compounds and do not take a direct part in the electronic configuration of the rare-earth ions. The completed subshells produce diamagnetism in the rare earths. The true rare-earth group arises from the filling in of the $4f$ subshell and since this subshell can contain from 1 to 14 electrons there are only 14 true rare earths. These electrons give rise to the paramagnetic properties of the ions.

Since the rare-earth elements have the same configuration of outer electrons and since it is these electrons which mainly determine chemical properties, the elements are very similar chemically and physically. The relatively small progressive changes in the properties of these elements with the addition of $4f$ electrons make them particularly useful for testing various theories of matter such as the relation of the solid state to atomic structure. In fact, their properties are so similar that suggested procedures for the separation of isotopes are often first tested with the rare earths. Lanthanum (57), yttrium (39) and scandium (21) have similar external atomic structures and always occur in mixtures of the rare earths. Hence, lanthanum and yttrium, and sometimes scandium, are also included in discussions-of the rare earths and with the possible exception of scandium are never found free from the rare earths.

The principal source of the rare earths is the mineral monazite found as an alluvial sand in India, Brazil and Idaho. This material is es-

TABLE I.—*Properties* of the Rare-Earth Ions and Salts

Atomic number	Name	Symbol	Atomic weight	4f electrons	Effective Bohr magneton numbers	Colours of trivalent ions

sentially a complex phosphate. Other important mineral sources are gadolinite (a silicate found in Norway, Sweden, Colorado and Texas), fergusonite (a columbate and tantalate found in Norway, Texas and Australia), samarskite (a tantalate and uranate found in the Urals and North Carolina), xenotime (a phosphate found in Brazil and Norway), yttrocerite (a fluoride found in Scandinavia), cerite (a basic silicate found in Sweden) and allanite (a silicate found in Greenland and Scandinavia). The relative abundance of these elements in the earth's crust is summarized in Table III. It will be noted that the elements with even atomic numbers are much more abundant than those with odd atomic numbers. Contrary to the earlier ideas, these elements are not so rare as the name implies; for example, cerium is more common than cadmium, tin, mercury, antimony, molybdenum, silver, tungsten, bismuth, gold or platinum. The rare earths, however, are widely distributed in low concentration and are so difficult to separate from one another that, with the exception of cerium, lanthanum and neodymium, they were not available for commercial distribution until after 1946.

Methods for separating the mixed rare earths from their ores vary with the type of ore. Prior to 1945, with the exceptions of certain rare earths such as cerium, europium, samarium and ytterbium which can have valencies different from three, the individual rare earths were separated from one another by laborious processes such as fractional crystallization, fractional decomposition, etc. Since these procedures had to be repeated thousands of times, only a few chemists had the patience to devote the required time to this routine work. Hence, only limited amounts of the scarcer rare earths were prepared in the pure state. In order to carry out these processes it was convenient to place the elements in subgroups such as the ceria group (j7 to 64) and the yttria group (64 to 71); another classification introduces the terbia group (63 to 65). Such groups are arbitrary since there are no clear-cut separations between successive members of the series; they are based on the solubility relationships of various compounds of the elements. The solubilities of some of the rare-earth trivalent compounds are summarized in Table II.

Some of the rare earths are always found among the fission products of plutonium, thorium and uranium, and a number of new radioactive isotopes of the rare earths have been obtained from this source. In addition, it is now possible to make artificial radioactive isotopes of any of the rare earths and a large number have been identified. For details concerning these isotopes see the article on RADIOACTIVITY, ARTIFICIAL. In 1945 a rapid method for separating the rare earths was developed in connection with the atomic bomb research program. The procedure involves the use of adsorption columns of organic resins and subsequent elution with complexing agents such as citric acid. The separations are based on the slight differences in the equilibrium constants. It is expected that, by use of such procedures, the pure rare-earth metals eventually will become more available and less expensive for detailed scientific studies and possible industrial uses.

TABLE 11.—Solubilities of Several Rare-Earth *Trivalent Compounds*

Compound	Cerium group (57–62)	Yttrium group (63–71)
Carbonates	Insoluble in water and in $(NH_4)_2CO_3$ solution	Insoluble in water; soluble in $(NH_4)_2CO_3$ solution
Hydroxides . . .	Somewhat soluble in water	Slightly soluble in water
Fluorides. . . .	Insoluble in water	Insoluble in water
Formates. . . .	Slightly soluble in water	Moderately soluble in water
Nitrates	Soluble in water; less soluble in HNO_3	Soluble in water; less soluble in HNO_3
Basic nitrates. . .	Moderately soluble in water	Slightly soluble in water
Double nitrates (*e.g.*, $Mg_3R_2(NO_3)_{12}.24H_2O$)	Easily crystallized	Not easily crystallized
Oxalates. . . .	Very insoluble in water and in $(NH_4)_2C_2O_4$ solution	Very insoluble in water, soluble in $(NH_4)_2C_2O_4$ solution
Phosphates	Insoluble in water	Insoluble in water
Potassium sulphates ($K_3R(SO_4)_3$) . .	insoluble in K_2SO_4 solution	Soluble in K_2SO_4 solution

From D. M. Yost, H. Russell and C. S. Garner, 1944.

The common valence of the rare-earth elements is three and many of them possess no other valence in their compounds. Since their chemical properties differ so slightly from member to member, the customary methods of qualitative analysis for these elements are of no real value. All accurate analyses for their purity are therefore based on their physical properties. The five general criteria available are: average atomic weight, magnetic susceptibilities, absorption spectra, X-ray spectra and arc spectra. Several of these properties are listed in Table I.

In Table III are listed some of the physical properties of the rare-earth elements as known at mid-20th century. Since the pure rare earths have been so difficult to obtain, many of the properties and

physical constants of the elements are probably inaccurate and may be altered considerably as better data become available through the use of new methods for their separation and purification. The metallic elements can be produced by electrolysis of the molten salts (such as the chloride or fluoride) or by chemical reduction of the oxides or halides by means of the alkali or alkaline-earth metals. All of them except promethium, formerly called illinium, have been produced in small amounts by the above methods, but in many cases the salt was not pure and most of them undoubtedly contained various amounts of the neighbouring rare-earth metals in solid solution.

As was so well stated by J. W. Mellor: "A large proportion of unconfirmed discoveries belongs to the rare earth series, and this may be taken as a tribute to the difficulties attending their isolation." A brief chronological summary of the isolation of the various rare earths follows. In 1794 J. Gadolin separated a new rare earth, yttria, from a black mineral found in Ytterby, Swed. In 1803 J. J. Berzelius, M. H. Klaproth and W. Hisinger independently found ceria in a mineral from the Bastnäs mine in Sweden. C. G. Mosander, in 1839, showed that ceria also contained a new oxide, lanthana; in 1842 he found didymia in the lanthana fraction. In 1843 he found that yttria contained terbia (called erbia since 1860) and erbia (called terbia since 1877). Erbia was subsequently found to contain ytterbia (J. C. G. de Marignac, 1878), holmia (J. L. Soret, 1878) and thulia (P. T. Cleve, 1879). In 1879 L. de Boisbaudran claimed the discovery of a new element in didymia which he called samarium, and in 1880 De Marignac found another element in samarium which he later called gadolinium. In 1885 C. A. von Welsbach split didymia into praseodymium and neodymium and in 1886 J. de Boisbaudran obtained dysprosia from holmia. In 1901 E. Demarçay separated europia from samaria and in 1907 G. Urbain found lutetia in ytterbia. In 1926 B. S. Hopkins announced the discovery of element 61 which he named illinium In the same year J. C. Corke, C. James and H. C. Fogg obtained 61 independently and measured the lines of its X-ray spectrum. This discovery was challenged. (See PROMETHIUM.)

RASH, a breaking out of the skin. The term rash was originally descriptive of certain skin diseases in which dandrufflike scales and some degree of redness were prominent features. The term is now commonly used with much less specificity, referring to various skin abnormalities in which the affected skin may be red, swollen, have scales or small blisters. Hence, breaking out of the skin such as that occurring in measles, dandruff conditions of the scalp, hives and diseases characterized by small blisters (*e.g.,* "prickly heat rash" or "poison ivy rash") are examples of diverse skin eruptions that are known as rashes. Generally excluded from the category of rashes are fleshy growths (*e.g.,* warts, moles or tumours) and acute mechanical, thermal or corrosive chemical injuries.

The generally broad meaning of "rash" that has developed through its popular use excludes it from use in strict medical terminology. See also Skin Diseases. (E. J. V. S.)

RASHI (1040–1105), Jewish scholar, called "the Commentator," was born at Troyes. Fr., in 1040 and died there in 1105. His real name was Rabbi Solomon (Shelomoh) ben Isaac, his nickname being derived from the initial letters of those words. Little is known about his life, though many legends have gathered around it. He is known to have worked at Worms, as a young man, under Jacob ben Yaqar, and at Mainz under Isaac ben Judah, perhaps combining at the same time the functions of teacher and student. He returned at the age of 25 to Troyes, which under his guidance became a recognized centre of Jewish learning. There he acted as rabbi and judge, and he and his family worked in the vineyards. His learning and character raised him to a position of high respect among the Jewries of Europe, though Spain and the east were long outside the range of his influence. As was said of him soon after his death: "His lips were the seat of wisdom, and thanks to him the Law, which he examined and interpreted, has come to life again." The latter part of his life was saddened by the massacres in the Rhineland at the time of the first crusade.

Besides minor works, including a recension of the prayer book, Rashi wrote two great commentaries on the whole of the Hebrew Bible and on about 30 treatises of the Talmud. His commentary on the Pentateuch, in particular, has been printed in hundreds of editions and is still to Jews the most beloved of all commentaries on the Mosaic books. More than a hundred supercommentaries have been written on it. Rashi's influence in Christian circles was great, especially because of the use made of the commentary by Nicholas of Lyra (*q.v.*), who in his turn was one of the main sources of Luther's version. More important was his commentary on the Talmud, which is nearly the definitive interpretation.

RASHID AL-DIN FADLULLAH (1247–1318), Persian statesman and historian, author of a universal history, *Jami al-tawarikh,* belonged to a Jewish family of Hamadan but was converted to Islam, and as a physician joined the court of the Mongol ruler of Persia, Abaqa-khan (1265–1282). He became vizier to Ghazan-khan in 1298 and served under his successor Uljaytu. Accused by his rivals of having poisoned his sovereign, he was put to death by Uljaytu's son Abu Sa'id.

Rashid al-Din's history covers a vast field even outside the Moslem world. His sources of information for Mongolia and China were high officials of the Mongol empire and the Mongol records, for India a Buddhist from Kashmir, for the popes and emperors a Catholic monk, etc. There are important chapters describing the social and economic conditions of the Islamic countries under Ghazan-khan (1295–1304) and the reforms introduced by this ruler on the advice of the author himself. Rashid al-Din uses a great number of Mongol and Turkish terms but his style is lucid and matter-of-fact.

The important parts of Rashid al-Din's history were published by E. Quatremère (1936), I. M. Berezin (1858–1888), E. Blochet (1911), K. Jahn (1940), Ali-zade (1958), A. Atesh (1957). The parts on the Mongolian tribes, on Jenghiz-khan and on Ghazan-khan appeared in a new Russian translation (1946–52). Rashid's interesting correspondence with his sons and dependents was published by M. Shafi (1947). (V. F. M.)

RASHTRAKUTA, an Indian dynasty which ruled in the Deccan (*q.v.*) from about A.D. 754 to 973. The Rashtrakuta or Ratta clan are supposed to have held power during the historical blank before the 6th century, but they came to the front in A.D. 754 when Dantidurga overthrew the Chalukya dynasty and made himself ruler of the Deccan. He was succeeded by his uncle Krishna I (c. 768), who completed his conquests and whose reign is memorable for the Kailasa, the rock-cut temple at Ellora. His grandson Govinda III (793–814) extended the power of the family from the Vindhya mountains and Malwa on the north to Kanchi on the south. The reign of Krishna III (939–968) was remarkable for a war with the Cholas, in which the Chola king was killed on the field of battle in 949. The last of the Rashtrakuta kings was Karka II, overthronn by the Chalukyas in 973.

RASIN, ALOIS (1867–1923), Czechoslovak statesman, was born at Nechanice. While a university student he took an active part in politics, and his abilities as an orator, journalist and organizer brought him into the forefront of the Czech progressive movement. After serving a prison sentence for anti-Austrian activities, he gained a prominent position in the Czech Liberal ("Young Czech") party. During the anti-Czech persecution in the World War I period, Rasin was arrested, charged with treason and condemned to death. The sentence, however, was not carried out, and after the accession of the emperor Charles I, Rasin, with other political prisoners, was amnestied. He then took part. as a member of the National committee, in the preparations for the revolutionary coup of 1918. In the first Czechoslovak government he became finance minister. In Jan. 1923 he was attacked by a demented youth and died of his injuries on Feb. 16. 1923.

RASK, RASMUS CHRISTIAN (1787–1832), Danish philologist. a founder of the science of comparative linguistics, mas born at Brandekilde, Fiinen, on Nov. 22, 1787. He studied at Copenhagen, and was appointed assistant keeper of the university library in 1808 and later professor of literary history. Rask was one of the first to recognize that the Celtic languages are Indo-European; he anticipated Grimm in the formulation of the first Germanic consonant shift; and De Saussure in his realization of the function and character of minimal speech-sounds (the phoneme). He wrote grammars of Icelandic, Old Norse, Old English, Spanish, Frisian and Itaiian; treatises on Jewish, and on Egyptian chronology; edited parts of the *Edda;* and published innumerable papers on linguistic and literary topics. He also brought out the Icelandic Lexicon (1814) of Bjorn Haldorson.

Rask was the first president of the Icelandic Literary society; but in 1816 he left Denmark to prosecute inquiries into the languages of the east and collect manuscripts for the university library at Copenhagen. From Stockholm he went to St. Petersburg, thence through Tatary into Persia, and resided for some time at Tabriz, Tehran, Persepolis and Shiraz. From Persia he went to India and Ceylon. Rask returned to Copenhagen in May 1823, bringing a considerable number of oriental manuscripts, Persian, Zend, Pali, Sinhalese and others, with which he enriched the collections of the Danish capital. He died at Copenhagen on Nov. 14, 1832.

Bibliography.—See his collected essays, *Samlade Afhandlinger, 3* vol. (1834–38); selected essays, *Udvalgte Ajhandlinger,* ed. *by L.* Hjelmslev (1932); Otto Jespersen, *Rasmus Rask* i *hundreddret efter hans Hovedværk* (1918). (J. Wh.)

RASMUSSEN, KNUD JOHAN VICTOR (1879–1933), Danish polar explorer and ethnologist who possessed an unsurpassed ability to win the confidence and understand the character of the Eskimo, was born at Jakobshavn, Greenland, on June 7, 1879. His maternal grandmother was a Greenlander (*i.e.,* of mixed race), and he acquired a thorough mastery of the Eskimo language. After studies at Copenhagen university and a visit to Lapland (1901), he accompanied L. Mylius-Erichsen to northwest Greenland in 1902–04, where he wintered with the most northerly

Eskimo tribe in the world (the Polar Eskimo). He was in west Greenland in 1905 to study the possibilities of introducing reindeer husbandry, but spent the next two years with the Polar Eskimo, and in 1910 established, with the aid of privately contributed means, the permanent station at Thule. The object was to provide a trading centre for the population, a base for expeditions and a foundation for the raising of the Polar Eskimo's spiritual, cultural and material level. In 1912 Rasmussen led the first Thule expedition. With three companions he traveled with dog sledges across the Greenland ice sheet from Thule to the northeast coast and back, making valuable geographical discoveries. The second Thule expedition (1916-18) surveyed the north coast of Greenland under very hard conditions. Rasmussen did not personally accompany the third Thule expedition; the fourth (1919) was his journey to Angmagssalik in east Greenland to collect Eskimo tales. The fifth Thule expedition (1921-24) was Rasmussen's greatest. After investigations in northeast Canada, Rasmussen, with two Eskimos, accomplished the longest dog-sledge journey ever made, across the American arctic. He left Danish Island on March 11, 1923, and reached Point Barrow on May 23, 1924. He made a scientific study of every Eskimo tribe, tracing their migration routes and showing the basic unity of their cultures. The sixth and seventh Thule expeditions made cartographic, archaeological and ethnographical studies in southeast Greenland. He died on Dec. 21, 1933, in Gentofte, Denmark.

A brilliant expedition leader, Rasmussen inspired an extraordinary devotion in his companions. Probably no polar explorer has so much used the services of the Eskimo, while he was himself a superb dog-sledge driver. His rich literary production embraces travel descriptions and translations of Eskimo mythology and songs, as well as strictly scientific works, including *Grønland Langs Polhavet* (1919; Eng. trans. *Greenland by the Polar Sea*, 1921) and *Across Arctic America* (1927). (P. A. B. G.)

RASPBERRY (genus *Rubus*), an old and well-known fruit-bearing bush, mentioned by Pliny as a wild fruit. John Parkinson (*Paradisus*, 1629) speaks of red, white and thornless varieties of raspberries, and their culture began about this time. Raspberry bushes bear juicy red or black (rarely orange, amber or pale yellow) berries which separate from the core that remains on the plant; in blackberries, the core is a part of the fruit.

ROCHE

BLACK RASPBERRIES (RUBUS OCCIDENTALIS)

Distribution. — The raspberry section of *Rubus* probably evolved in eastern Asia, where there are more than 200 species known.

In Great Britain and throughout Europe only one species, *R. idaeus*, is known, from which the European cultivated varieties are derived. In the United States and Canada, three species (*R. strigosus*, the red raspberry; *R. occidentalis*, the eastern black raspberry; and *R. leucodermis*, the western black raspberry) are found. American red varieties are derived from *R. strigosus* and hybrids of it with *R. idaeus*. They are much hardier and less prickly than European varieties. Black varieties came from *R. occidentalis;* purple varieties are hybrids of the black and red. Related edible berries, often called raspberries, are the two flowering raspberries of northern American woodlands, *Rubus odoratus* and *R. parviflorus;* the Rocky mountain flowering raspberry, R. *deliciosus;* and the salmonberry, *R. spectabilis*, of the Pacific northwest. Three other raspberries are grown for their fruit in other parts of the world—the Andes black raspberry, *R. glaucus*, in northern South America and Central America; the southern Asian black raspberry, *R. niveus;* and the wineberry, R. *phoenicolasius*, introduced from northeastern Asia. R. *kuntzeanus* from China has been hybridized with the Cuthbert to give the Van Fleet, and *R. biflorus*, also from China, has been hybridized with Latham to give the Dixie, both adapted to southern U.S.

Acreage and Varieties. — In Great Britain about 10,000 ac. of red raspberries are cultivated. The Blairgowrie district is the centre of production in Scotland; Kent. the eastern counties and Worcestershire are important centres in England. Raspberries are sometimes grown in mixed plantings with other fruit, the plants being set at 18-in. intervals in rows 6 or 7 ft. apart. Lloyd George is a leading variety, having very large berries that are excellent for canning and jam. Red Cross, Pynes Royal and Malling Promise are other good varieties.

The acreage of raspberries in the United States is about 20,000. Black raspberries are nearly as important as red; the acreage of purple varieties is small. Important raspberry sections are western Maryland, southern New Jersey, the Hudson river valley, western New York, western Michigan, near Minneapolis, Minn., the Puyallup valley of Washington, and the Willamette valley of Oregon. Few plantings in the United States, except in the Hudson river valley, are mixed with other fruits. Good red varieties are Willamette, Canby and Washington, in the Pacific northwest; Sunrise, for early, and Latham, for late, for eastern states; and Taylor and Milton, in New York and New England. Cumberland is the chief black variety. In eastern Canada, Viking and Newman red varieties are widely grown. Sodus and Marion are desirable purple varieties. September and Durham are red sorts that also bear fruit on the young canes in late summer and fall.

Propagation. — Red raspberries are propagated by suckers from the roots of the parent plant. Root cuttings about three inches long are also used for rapid increase of new varieties. Black and purple varieties have arched canes and are propagated by tip layers, the tips of the shoots being buried about two inches deep in August and the rooted tips being dug in early spring. Leaf-bud cuttings may be used for the rapid propagation of new black varieties. Red raspberries are usually planted 2½ ft. apart, the black and purple about 4 ft. apart in rows 6 to 9 ft. distant. Shoots are produced in spring and summer that bear fruit the following year and then die. These old canes are cut away each year just after the harvest to make room for the new shoots. The new shoots of the black varieties are tipped or cut off at 12 in. to induce branching; those of the purple at 18 to 24 in. The branches are shortened the following winter to about 8 in. for the black and 12 in. for the purple. The canes of the red raspberries are either not pruned or are shortened to 3 to 5½ ft., depending on the variety and vigour. However, surplus suckers should be cut away early in the summer, leaving seven or eight of the strongest canes per plant or per 30 in. of row. The stouter the canes of both black and red varieties, the more productive they are. Stakes or trellises are commonly used to support the canes of the red raspberry. Two-wire trellises with a wire on each side of the row about 3 ft. high or with one wire above the other at 30 in. and 54 in. are common.

Virus diseases, leaf spot, anthracnose, crown gall, wilt and orange rust are serious diseases, while the red spider mite, crown borer and fruit worms are serious insect pests.

RASPE, RUDOLF ERICH (1737–1794), the original author of the *Adventures of Baron Munchausen* (see MUNCHAUSEN), was born in Hanover in 1737, and studied at Göttingen and Leipzig. In 1767 he was appointed professor in Cassel, and subsequently librarian. In 1775 he went to Italy to buy curios for the landgrave of Hesse, to whom he was keeper of the gems, and sold the landgrave's valuables for his own profit. On orders being issued for his arrest, he decamped to England. Later, he found a patron in Sir John Sinclair of Ulbster, whom he deceived by pretending to discover valuable and workable veins on his estates; but Raspe had "salted" the ground himself, and on the verge of exposure he absconded. He betook himself to Ireland, and died at Muckross in 1794. His authorship of *Munchausen* was only revealed in 1824, by the biographer of its translator Bürger.

RASPUTIN, GREGORY EFIMOVITCH (1871–1916), Russian monk, was born in 1871 in the village of Pokrovskoe, near Tyumen, in the province of Tobolsk, Siberia. In 1904 Rasputin left his family and devoted himself to religious exercises, declaring to his people that he was inspired by God. His passionate nature, his great physical strength and the superstitious atmosphere in which he had been brought up, gave an unexpected direction to his religious exaltation. He adopted the views of the sect known under the name of "Khlysty," the leading idea of whose teaching was that salvation could be achieved only by repentance.

"Sin in order that you may obtain forgiveness"—was the practical rule which he drew from this doctrine. "A particle of the Supreme Being is incarnated in me"—he told his hearers. "Only through me you can hope to be saved; and the manner of your salvation is this: you must be united with me in soul and body. The virtue that goes out from me is the source of light, the destruction of sin" (E. J. Dillon, *The Eclipse of Russia).* This extravagant and dangerous teaching, which resulted in practice in the wildest orgies, not only created for Rasputin immense popularity and the reputation of a holy man among his fellow-peasants. but opened before him the doors of some of the most fashionable Russian houses and even those of the Imperial palace. Looking for new experiences Rasputin left his native village, and made long pilgrimages to various holy places, and even went to Mount Athos and Jerusalem. He spent some time in different monasteries and applied himself to the study of holy books.

In 1907, during a stay in St. Petersburg (Leningrad), Rasputin was introduced to the archimandrite Feofan, rector of the theological academy and confessor to the empress, who took an interest in the story of his conversion. The archimandrite, with the assistance of the grand duchesses Militza and Anastasia, presented Rasputin at court, and he produced a deep impression on the empress and emperor. The mystic atmosphere which always prevailed at the Russian court and the constant fear for the health of the tsarevich created a favourable background for the appearance of such a man. The eventual improvement in the health of the grand duke Alexis procured for Rasputin a commanding influence over the empress.

For some time Rasputin was satisfied by his social success, and at first he did not interfere in politics. But his activity was felt in church questions. His friendship with the famous monk, Heliodor, and the bishop of Saratov, Hermogen, which resulted in a complete rupture between them and in a series of scandals, had a painful echo in the country. The appointment of Varnava, an illiterate peasant and a friend of Rasputin, to be bishop of Tobolsk in 1911, and the servility with which the Holy Synod followed the wishes of the favourite, provoked a strong opposition among all classes of society. An unsuccessful attempt to kill him, made by a certain Guseva in 1914, incited by the monk Heliodor, only strengthened his influence. No important nomination was made without his approval, and the most unexpected people rose to the highest offices as the result of his influence. Rasputin was too ignorant to have any opinion on political questions: he was in most cases a mere instrument of the reactionaries. At length a small group of men of the highest social position, which included the grand duke Dimitri Pavlovich, Prince Yussupoff and Purichkevich determined to end the empire of Rasputin. He was invited to a supper at the Yussupoff palace on Dec. 16 (O S.; 29 N.S.), 1916, and shot dead, after an attempt at poisoning him with a strong dose of potassium cyanide mixed with wine had not produced the desired effect.

RASTELL (or RASTALL), **JOHN** *(c.* 1475–1536), an English printer and author, belonged to a Coventry family, and was educated for the law. He began his printing business some time before 1516, for in his preface to the undated *Liber Assisarum* he announced the forthcoming publication of Sir A. Fitzherbert's *Abbreviamentum librorum legum Anglorum,* dated 1516. In that year he undertook an expedition to America, but got no further than Ireland when his sailors left him. Among the works issued from the "sygne of the meremayd at Powlysgate," where he lived and worked from 1520 onwards, are *The* XII. *Mery Gestys of the Wydow Edyth* (152j), and *A Dyaloge of Syr Thomas More* (1529). The last of his dated publications was *Fabyl's Ghoste* (1533), a poem. In 1530 he wrote, in defence of the Roman doctrine of Purgatory, *A New Boke of Purgatory* (1530), dialogues on the subject between "Comyngs and Almayn a Christen man, and one Gyngemyn a Turke." This was answered by John Frith in *A Disputacion of Purgatorie.* Rastell replied with an *Apology against John Fryth,* also answered by the latter. Rastell had married, at some time before 1504, Elizabeth, sister of Sir Thomas More, with whose Catholic theology and political views he was in sympathy. More had begun the controversy with John Frith, and Rastell joined him in attacking the Protestant writer, who, says Foxe *(Actes and Monuments,* ed. G. Townsend, vol. v. p. 9), did so "overthrow and confound" his adversaries that he converted Rastell to his side. Separated from his Catholic friends, Rastell does not seem to have been fully trusted by the opposite party, for in a letter to Cromwell, written probably in 1536, he says that he had spent his time in upholding the king's cause and opposing the pope, with the result that he had iost both his printing business and his legal practice, and was reduced to poverty. He was imprisoned in 1536, perhaps because he had written against the payment of tithes. He probably died in prison, and his will was proved on July 18, 1536.

Rastell's best-known work is *The Pastyme of People, the Chronycles of dyvers Realmys and most specially of the Realme of England* (1529), a chronicle dealing with English history from the earliest times to the reign of Richard III., ed. T. F. Dibdin (1811). His *Expositiones terminorum legum Angliae* (in French, trans. into English, 1527; reprinted 1629, 1636, 1641, etc., as *Les Termes de la Ley*), and *The Abbreviacion of Statutis* (1519), of which 1j editions appeared before 1625, are the best known of his legal works.

To Rastell is generally attributed the morality play, *A new Interlude and a Mery of the 1111 Elements (c.* 1519). The fullest details available on John Rastell's life are in A. W. Reed, *Early Tudor Drama* (1926). For the books issued from his press *see* a catalogue by R. Proctor, in *Hand-Lists of English Printers* (Bibliographical Soc., 1896).

RASTELL, WILLIAM *(c.* 1508–156j), English printer and judge, son of the preceding, was born in London about 1508. At the age of 17 he went to the university of Oxford, but did not take a degree, being probably called home to superintend his father's business. The first work which bears his own imprint was *A Dyaloge of Sir Thomas More* (1531), a reprint of the edition published by his father in 1529. He also brought out a few law-books, some interludes ascribed to John Heywood *(q.v.),* an edition of *Fabyan's Cronycle* (1533), and *The Apologye* (1533) and *The Supplycacyon of Soulys* of his uncle Sir Thomas More. He became a student at Lincoln's Inn on Sept. 12, 1532, and gave up the printing business two years later. In 1547 he was appointed reader. On account of his Catholic convictions he left England for Louvain; but upon the accession of Mary he returned, and was made serjeant-at-law and treasurer of Lincoln's Inn in 1jj5. His patent as judge of the Queen's Bench was granted on Oct. 27, 1558. Rastell continued on the bench until 1562, when he retired to Louvain where he died on Aug. 27, 1565.

It is difficult to distinguish between the books written by William and those by his father. The following are believed to be his: *A Colleccion of all the Statutes* (1559), *A Table collected of the Yeares of the Kynges of Englande* (1561), both frequently reprinted with continuations, and *A Colleccion of Entrees,* **of** *Declarations, etc.* (1566), also frequently reprinted.

RAT, probably in its original sense the designation of the rodent known as the black rat *(Rattus rattus),* but also applied to the brown or Norway rat *(R. norvegicus),* and in a wider sense to all the larger representatives of the family Muridae.

ABOVE: BLACK RAT (RATTUS RATTUS); BELOW: BROWN RAT (R. NORVEGICUS)

Rats have more rows of scales on the tail (reaching to 210 or more) than mice, in which the number does not exceed 180. For the distinctive characteristics of the family Muridae *see* RODENTIA. Of the two species the brown or Norway rat *(R. norvegicus)* is distinguished by its large size, brownish gray colour, short tail and ears, stout skull, and the possession of from 10 to 12 teats. It is fierce and cunning, and overcomes all allied species with which it is brought in contact. Its original home would seem to have been some part of Central

Asia. Thence it has spread over much of the world, driving out the house-haunting species everywhere, as it has in England all but exterminated the black rat. The brown rat migrated westward from Central Asia early in the 18th century, and is believed to have first reached Great Britain about 1730. The black rat (R. *rattus*) is smaller in size than the brown rat, with longer ears and tail. It is typically glossy black in colour, but brownish varieties, which may be distinguished readily from the brown rat, are common, especially in southern lands. It frequents ships and on them has reached most parts of the world. It is more common and more \vide-spread in the tropics than the brown rat, which in these climes is often restricted to the coast or to ports. This long-tailed rat, originally a native of southern Asia, first penetrated to all parts of the world, in many places nearly exterminating the indigenous rats. After this followed the advance of the more powerful brown rat. The black rat first reached Europe in the 13th century. The Isle of Dogs and Yarmouth in Norfolk are chief English strongholds of the black rat. It is this species that is the chief disseminator of bubonic plague. Both species agree in their predaceous habits, omnivorous diet and great fecundity. They bear, four or five times in the year, from four to ten blind and naked young, which are in their turn able to breed at an age of about six months; the time of gestation being about 20 days.

See J. Millais, "True Position of *Mus* rattus and its Allies," Zoologist (June 1905); M. Hinton, "Rats and Mice . . . ," Brit. Mus. Pamphlets; U S Fish and Wildlife Service, *Wild* Life Circular 6 (1941).

RATCHET AND PAWL is an important mechanical device in many machines and appliances, enabling a movement to be effected in one direction but not in the opposite direction. The mechanism is used to lock a part so that it cannot slip or reverse, to hold a load as in a winch or to give a positive feed. Ratchets may be straight or curved, the majority being circular. In fig. 1, motion of the arm (B) in the direction of the arrow rotates the wheel **(A).** When the arm (B) reverses, supplementary pawl (D) prevents backward motion of the wheel, providing the typical intermittent motion in one direction for the wheel.

FIG. 1.—SIMPLE RATCHET AND PAWL

(A) ratchet wheel, (B) oscillating lever carrying (C) driving pawl; (D) supplementary pawl prevents backward motion of the wheel

Slack in the engagement of the teeth may be reduced by using smaller teeth, additional stationary pawls or by using the silent (free-wheeling) ratchet (fig. 2). A variety of constructions employ balls, rollers or eccentrically pivoted pa ls to wedge in tapered slots and provide silent smooth, slack-free motion in one direction.

Various drives and brake mechanisms are made safe by ratchet devices, the ship's capstan being one of the oldest examples. Screwdrivers and wrenches are operated by ratchet for access in difficult situations, or to help the worker in manipulative power. Braces and metal drills are actuated by ratchets when it is not possible to make the complete revolution of a handle. So also are jack screws for lifting loads rapidly. Many counting devices are based on the use of ratchets. Ratchet feed, by which an arm holding the pawl is moved, thus moving a ratchet wheel and a feed screw, is utilized in many types of machines and is usually automatic in action. For example, the workpiece table on a shaper may be moved sideways a small space for each stroke of the cutting tool, a movement which will provide a complete traverse of the surface of the piece being machined. RATE. In England the term is specially applied to the levying of public money contributions for local purposes, as distinguished from the taxes raised for what are treated as general state purposes. By the Rating and Valuation acts of 1925 and 1928 the English system of rating has been amended and the law partially consolidated as also for Scotland by the Rating act, 1926, and the Rating (Scotland) Amendment act, 1928. In the United States the term rate does not signify a form of taxation, but is used to indicate the assessment percentage. *See* further POOR LAW; TAXATION; TAXATION, LOCAL.

RATEL or HONEY BADGER, the name of certain Indian and African small clumsy-looking creatures of the size and appearance of badgers, representing the genus Mellivora in the family Mustelidae (see CARNIVORE). Only one living species of ratel is known (Mellivora *capensis*), represented by several races in various parts of Africa, south of the Sahara and in India. Ratels are normally black with whitish crown and grizzled back, a style of coloration that is found also in the grison (*q.v.*). Pure-black individuals are known. The body is stout and thickly built; the legs are short and strong and armed (especially the anterior pair) with long curved claws; the tail is short; and the ears are reduced to rudiments. The Indian ratel is found throughout India, chiefly in hilly districts, but also in the north of India in alluvial plains. It lives usually in pairs; eats rats, birds, frogs, white ants and various insects. Like its Cape congener it occasionally partakes of honey and is often destructive to poultry. In confinement the Indian ratel becomes tame and even playful. (J. E. HL.)

RATEL, OR HONEY BADGER (MELLIVORA CAPENSIS)

RATHENAU, WALTHER (1867–1922), German statesman, industrialist and philosophical writer, was born in Berlin on Sept. 29, 1867. His father was Emil Rathenau, who became a pioneer of the modern power industry by acquiring Thomas A. Edison's European patent rights and founding the 'Allgemeine Elektrizitats-Gesellschaft. Having completed an academic curriculum in philosophy, physics, chemistry and engineering, Walther Rathenau successively filled responsible positions in various industrial enterprises, and in 1899 entered the service of the Allgemeine Elektrizitats-Gesellschaft. Although he had always been interested in public affairs, it was not until the beginning of World War I that he became a public figure.

The cause of Rathenau's prominence was the fact that, almost alone among German industrialists, he realized in the early days of the war the dependence of the German war effort on the supply and prudent management of raw materials. His proposal to organize a special board of the war ministry for this purpose was accepted, and he was put in charge, directing this vital work until the spring of 1915. Then he returned to business activity and writing; his best-known book, Von kommenden *Dingen* (1917; Eng. trans. by Eden and Cedar Paul, In Days to Come), was produced during this period.

Rathenau's knowledge of the world outside Germany, and his genuine love for peace, co-existed in his mind with strong national feelings. In Oct. 1918, in despair over the Gernian armistice request, which he correctly interpreted as in effect an act of unconditional surrender, he proposed in vain a *levée* en masse of the German people. In his economic views, Rathenau held an intermediate position between capitalism and democratic socialism; after the revolution of 1918, he founded with others the middle-class Democratic party, but he tried to keep that party in a relationship of co-operation with the Social Democrats, despite his critical view of many of their policies. In his book Die neue Wirtschaft, he supported the idea of industrial self-government with the participation of employees and effective state control rather than universal nationalization.

Rathenau was one of relatively few Germans who combined democratic convictions and a strong belief in international conciliation with economic experience and knowledge of foreign countries. In 1921 Joseph Wirth, who had just formed a cabinet, appointed Rathenau minister of reconstruction, a position involving responsibility for important aspects of reparation policy; later he exchanged this portfolio for that of foreign affairs. As one of his first achievements, Rathenau negotiated an agreement with France on German deliveries in kind for the reconstruction of French war-devastated areas. Rathenau believed that a practicable settlement of the reparations issue could best be obtained as part of a European reconstruction scheme, in which the economic rehabilitation of Russia would have to play a vital role. He induced Lloyd George to make this idea the core of the British proposal at the international conference at Cannes (Jan. 1922). No progress was made, however, either at Cannes or at the subsequent conference of Genoa. To forestall an Allied understanding with Russia at Germany's expense, Wirth decided to conclude a German agreement with the Russians for the mutual cancellation of all claims (the Rapallo treaty) and Rathenau reluctantly agreed. Through the Rapallo treaty, Germany for the first time after its defeat asserted its position as an independent agent in international affairs. The treaty antagonized the Allies; its wisdom has remained a matter of controversy.

Even among the conservatives, some leaders had a great deal of personal admiration for Rathenau, though others attacked him nith bitterness. For the extreme nationalists Rathenau was the symbol of everything they hated, especially because he was a Jew. On June 24, 1922, some young nationalist fanatics shot Rathenau to death on his way to his office. His assassination initiated the disintegration of the Wirth cabinet and the sequence of events that led to the French occupation of the Ruhr.

Rathenau's collected works (5 vol.) were published in 1918. Of his later writings, the most important are: Die neue Wirtschaft (1918); Kritik der dreifachen *Revolution* (1919); Die neue Gesellschaft (1919. Eng. trans., The New Soczety, 1921).

See Harry Kessler, *Walther Rathenau, sein Leben und sein Werk* (1928), Eng. trans., *Walther Rathenau* (1929). (*C.* L.)

RATHENOW, a town in the district of Potsdam, Germany, on the Havel, 45 mi. W.N.W. of Berlin. Pop. (1950) 29.353. Rathenow was incorporated as a town in 1295. In 1394 it was taken and partly destroyed by the archbishop of Magdeburg. It suffered much from the ravages of the Thirty Years' War. The Protestant church of St. Mary and St. Andrew, originally a basilica, was transformed to the Gothic style in 1517–89.

RATIBOR (Polish Raciborz), formerly a town of Germany, in the Prussian province of Silesia, situated on the left bank of the Oder at the point where the river becomes navigable, 97 mi. S.E. of Breslau by rail. on the main line to Oderberg. Pop. (1950) 26,400. Ratibor, which received municipal privileges in 1217, was formerly the capital of an independent duchy, 380 sq.mi. in extent, which existed from 1288 to 1532, and afterward passed successively into the hands of Austria and Prussia. In 1821 a small mediate principality was formed and was conferred upon the landgrave of Hesse-Rotenburg, as compensation for some Hessian territory absorbed by Prussia. In the partition of Upper Silesia between Germany and Poland in 1921 (see SILESIA) Ratibor was retained by Germany; after 1945 it became part of Opole province, Poland.

RATICHIUS (RATKE. RATICH), **WOLFGANG** (1571–1635), German educator, an early experimenter in education, was born at Wilster, Schleswig-Holstein, on Oct. 18, 1571. He devised a method for the rapid teaching of Latin by basing the work upon the learner's native language. He taught in a dozen different places, trying various methods, but his most consistent work was done in Kothen, where he established a school in which there were also classes for girls. Ratichius' "experiments" were not important in themselves, as he had little idea of proper method. His chief influence upon education was through the borrowing from him by many other men (notably Comenius) who were university students during the feu years that Ratichius' activities and ideas were being discussed. Ratichius died at Erfurt on April 27, 1635.

See J. Lattmann, *Ratichius und die Ratichaner* (1898); *K.* Setler, *Das pädagogische System des Wolfgang Ratkes* (1931). (L. CE.)

RATIOCINATION, a term used in logic and psychology for those processes by which the mind proceeds from general to particular truths. The steps involved in ratiocination may perhaps be most clearly seen in the form of reasoning followed in the syllogism (*q.v*).

RATIONALISM is that system of philosophical belief which asserts that human reason unaided is competent to attain objective truth. In its basic form it is an epistemological doctrine in which reason is contrasted with sense-experience, ahich is held to be unnecessary. or even a hindrance, to the attainment of truth. The inspiration of rationalism has always been mathematics, and rationalists have stressed the superiority of the deductive over all other methods in point of certainty. They attach a peculiar value to the capacity to recognize necessary connections between abstract ideas or concepts (*e.g.,* the connection between being a Euclidean triangle and having angles equal to 180°). Euclid's Elements presents the ideal to which rationalists hold that all human thinking should conform.

According to the extreme rationalist doctrine all the truths of physical science and even history could in principle be discovered by pure thinking and set forth as the consequences of self-evident premises.

Few rationalists, however, have been so extreme, and we may distinguish in different philosophers different degrees of rationalism. Locke, for example, is a rationalist in the weakest sense, holding that the materials of human knowledge (ideas) are supplied by sense-experience or introspection, but that knowledge consists in seeing necessary connections between them, which is the function of reason (Essay Concerning Human *Understanding*). Most philosophers who are called rationalists have also maintained that the materials of knowledge are derived. not from experience, but from the reason itself; *i.e.,* they are innate ideas.

Ethical rationalism is the application of epistemological rationalism to the field of morals. The primary moral ideas (good, duty) are held to be innate and the first principles of morals (*e.g.,* the Golden Rule) self-evident. It is further claimed that the possession of reason provides an adequate motive for moral conduct In ethical rationalism, reason is generally contrasted with feeling or moral sense.

Theological rationalism asserts the claims of reason against those of revelation or authority. The fundamental principles of religion are held to be innate or self-evident and revelation unnecessary. Theological rationalism thus stresses the importance of natural as opposed to revealed religion. By an easy extension of meaning, the word "rationalism" then came to signify a skeptical or antireligious attitude. This is the most common use of the word in the 19th and in the 20th centuries. Rationalism is conceived as the ally of liberalism in the struggle against religious intolerance (see W. E H. Lecky, History of the Rise and *Influence* of the Spirit of Rationalism in Europe, 2 vol., 1910 or alternatively as the enemy of religion (see J. F. Hurst, History of Rationalism, 1865). It thus came to be connected, somewhat paradoxically, with empiricism (*q.v.*), the antithesis of epistemological rationalism.

EPISTEMOLOGICAL RATIONALISM

Epistemological rationalism was first explicitly formulated by Plato. According to him there is a system of eternal necessary truths accessible to the human reason apart from sense-experience (Republic, vi and vii) and his theory of learning as recollection, developed in the *Meno* and in the Phaedo, is the first form of the doctrine of innate ideas. The typical innate ideas are mathematical concepts such as equality, which, he holds, are not perfectly exemplified in the material world (Phaedo).

In later antiquity and in the middle ages, wherever Platonism is influential, we have implicit epistemological rationalism (*e.g.*, in the Neoplatonists, in St. Augustine, in Boethius and in St. Anselm). but it is subordinated to the dominant ethical and theological interests. Medieval theological rationalism, however, makes one important contribution to epistemological rationalism. This is the ontological argument of St. Anselm, in which he seeks to prove that the existence of God follows from His essence, and thus to provide a connection between the abstract system of innate ideas and the actual world. (See ANSELM, SAINT; THEISM.) When rationalism became self-conscious at the Renaissance, both Kepler and Descartes felt the need for this connection, and both use the idea of God, Descartes deliberately reviving Anselm's ontological argument.

Epistemological rationalism reached its highest development in the 17th century under the double impetus of the revival of Platonism and the development of mathematical physics by Kepler, Copernicus, Galileo and Descartes. The new science rests on the basis of mathematics, and it recognizes as clear and distinct only what can be expressed in mathematical form. All scientific truth is derived from certain axioms and principles which can be comprehended by reason as universal and necessary. Thus, according to Galileo, "Truth is written in the great book of Nature, but only he can read it who can decipher the letters in which it is written." These letters, however, are the terms of mathematics, especially of geometry: the concepts of the straight line, the circle, the sphere, etc. None of these concepts is derived from experience; the mind rather takes them "from itself" in order to apply them to sense-perceptions. In the same way, Kepler considers number and magnitude as innate ideas not drawn from experience but required for the scientific investigation of nature (see E. Cassirer, Das *Erkenntnisproblem*, 3rd ed., i, pp. 328 ff., 1922; and E. A. Burtt, *Metaphysical* Foundations of Modern Physical Science, ch. ii and iii, 1925).

Descartes enlarges this view by setting forth a system of universal concepts of reason which are obtained by analysis of certain fundamental — logical and mathematical — relationships and which can be applied to all empirical data. These concepts are valid, not only for the actual world, but for all possible worlds, so that, in understanding by means of them every effect from its cause, we can obtain a priori knowledge of the universe as a whole. As instances of such fundamental concepts, Descartes cites primarily the concept of being, then the ideas of number and time and of space, figure and motion.

As physics thus becomes a purely deductive science, epistemological rationalism has to draw, as was said above, on theological rationalism for support. The innate ideas are within the mind, and sense-experience constitutes no proof of the reality of the external world (Descartes, Meditation *I*). We can, therefore, get outside the system of our own ideas only by proving the existence of reality external to us. This demands the idea of a Necessary Being, that is, God. But in order to show the applicability of the system, something must also be known of the nature of God. Descartes states that He is veracious; *i.e.*, that He will not allow us to be deceived in our clear and distinct thinking. The world is, therefore, constructed on the plan according to which we think. It is the construction of an infinite intellect. The applicability of pure mathematics is assured because nature itself is the product of a divine mathematics: Cum Deus calculat, *fit* mundus.

Leibniz' system may be regarded as the crowning achievement of epistemological rationalism. He attempts to deduce from fundamental laws of logic the basic propositions of his system, which are so repugnant to common sense that only a boundless confidence in the powers of pure reason could recommend them. The universe is said to consist of an infinite number of spiritual substances (monads), each regarding the whole from a distinct point of view and with a specific degree of confusion. The human mind occupies an intermediate position in the hierarchy of monads, its perceptions being clear in comparison with those of animals but still involving a great degree of confusion, of which the spatio-temporal and qualitative appearance of things is the product. This confusion also accounts for the fact that the truths of science and history, although logically necessary, cannot be known a priori by human beings.

The gap between truths of reason and truths of fact remains unbridgeable by the human mind. The aim of human science must, however, be to order knowledge so that it approximates as far as possible to the ideal deductive system (see L. Couturat. La *Logique* de Leibniz, especially ch. vi, 1901; and B. Russell, *A* Critical Exposition of the Philosophy of Leibniz, 2nd ed., 1937).

Leibniz attempted to lay the foundation for this in the grandiose scheme of his *characteristica* universalis, which was to give a catalogue of primary simple ideas together with a method by which all truths, however complex, could be exhibited as combinations of them. This project of Leibniz inspired later development in symbolic logic and investigation of the foundations of mathematics, particularly the work of Gottlob Frege, Giuseppe Peano, Bertrand Russell and A. N. Whitehead, in which it is sought to reduce all mathematics to logic. In the 18th century, however, the immediate outcome of the Leibnizian subordination of empirical to rational knowledge was the philosophy of Christian Wolff (1679–1754), who produced the voluminous system now chiefly remarkable as being the form of rationalism in which Kant was reared. Epistemological rationalism was meanwhile subject to attack from the British empiricists, especially Locke and Hume, who stressed the necessity for empirical data in the acquisition of scientific knowledge.

Immanuel Kant (*q.v.*), aroused by Hume from the "dogmatic slumber" induced by Wolff, attempted to combine rationalism and empiricism into a single system, the "critical philosophy." He adheres, however, to the rationalist position in stressing the importance of the a priori element in knowledge; and the "pure forms of intuition" and the "categories," in so far as they belong to the mind, have something of the nature of innate ideas But he differs from preceding rationalists in holding that, because of their nature, we cannot know that the pure forms of intuition (space and time) or the categories (cause, substance, etc.) apply to reality as such (the thing-in-itself). In short, according to Kant, rationalism provides a satisfactory basis for science only if we adopt skepticism as regards metaphysics. The a priori truths of reason apply only to things as they appear to us (phenomena), and reason is inadequate to solve the metaphysical problems of God, freedom and immortality (*Kritik* der *reinen* Vernunft, preface to 2nd ed., 1787). It is Kant who provides the classical refutation of the ontological argument (*op. cit.*, "Dialektik").

Hegelianism, in spite of the slogan "The Real is the Rational and the Rational is the Real," is only apparently a return to rationalism, being opposed to the mathematical method and inspiration which provide the keynote of classical rationalism. In fact it may be said that epistemological rationalism has not survived Hume's devastating criticism (Treatise of Human Nature, book i). Even the milder Kantian form was subject to severe criticism in the 20th century by the logical positivists, whose conventionalist theory of a priori truth challenges the basic rationalist claim to insight into objective necessary connection.

But however unacceptable as a complete theory of knowledge, rationalism as an attitude has been and still is an inspiration in science. It is the rationalist spirit which urges us to approach nature as masters rather than as pupils and to construct bold hypotheses and verify them later.

Some eminent 20th-century physicists have even put forward deductive systems entirely in the spirit of Leibniz: for example, A. Eddington in his Philosophy of Physical Science (1939) and E. A. Milne in his Modern Cosmology and the Christian Idea of God (1952).

ETHICAL RATIONALISM

Ethical rationalism was also first developed by Plato, partly under the inspiration of the Socratic dictum "Virtue is knowledge." In the Republic the reasoning element of the human soul both recognizes what is right and good and is itself the spring of action which prompts moral conduct. The Stoics, however, among the philosophers of the ancient world, developed the form of ethical rationalism which was most influential in later times. Although they rejected the theory of innate ideas, they held that there is in every man a spark of the divine reason which is sufficient, properly used, to discover the universally binding rules of conduct. On these rules positive law is properly based. Thus the Stoic doctrine gives rise to the theory of natural lam and natural right. It was popularized by Cicero, whose writings were later extremely influential (De *Republica,* iii; De Legibus, i).

As did epistemological rationalism, ethical rationalism underwent a considerable revival at the Renaissance, when it also had great influence on political theory. The first clear statement that the rules of conduct discovered by reason are independent of the commands of God was made by Hugo Grotius (De Jure belli et *pacis,* Prolegomena § 11). Ethical rationalism had a considerable vogue in the 17th and 18th centuries, especially in England, where it was developed by Lord Herbert of Cherbury, by Samuel Clarke, by John Balguy, by William Wollaston and by Richard Price.

The ethical systems of Spinoza and Kant have moreover considerable affinities with rationalism: Spinoza's is even developed in the mathematico-deductive form (*Ethica, ordine geometrico* demonstrata) in close connection with his metaphysics and theory of knowledge, though it depends in fact on certain empirical propositions concerning the nature of man; and Kant holds that the form of the moral law, the categorical imperative, is purely a priori, though it provides not a premiss from which we may deduce our duties but a test that enables us to discern the moral character of any proposed course of action.

The classical criticism of ethical rationalism is to be found in Hume's Treatise, books ii and iii. A modified form of rationalism was developed in the 20th century under the name "intuitionism" (W. D. Ross, Foundations of Ethics, 1939).

THEOLOGICAL RATIONALISM

The question "Is theological truth discoverable by reason or solely by revelation?" could arise only in the context of religions such as Judaism, Christianity and Islam. The relations between revelation and reason were much debated in the middle ages. E. Gilson (Reason and Revelation in the Middle Ages, 1939) distinguishes two positions which may be called rationalist as distinct from the antirationalist view that reason is totally unable to grasp religious truth. The less extreme position is the Augustinian, namely that, once revelation is accepted, its content may be grasped by the intellect; this is adopted by St. Anselm, who sums it up in the phrase credo *ut intelligam,* "I believe in order that I may understand." The complete rationalist position, which makes revelation unnecessary at least for the philosopher, was worked out by Averroes in Moslem Spain and adopted by his Christian followers.

Rationalism in theology developed rapidly after the Reformation. A clear statement of the position is given by Lord Herbert of Cherbury in De *Veritate* and De Religione *gentilium.* Leibniz' introduction to the *Théodicée* shows that the word "rational" had already come into use in this context. The position was further developed in the 18th century by the English deists, by the French *philosophes* (*e.g.* Voltaire and Condorcet) and by the German theologians called rationalists (particularly S. J. Baumgarten and J. S. Semler, who were influenced both by Wolffian rationalism and by biblical criticism). (See ENLIGHTENMENT.)

By the end of the 19th century rationalism had become a frankly antireligious movement, often combined with empiricism and materialism and identified with practically atheistic forms of agnosticism (*q.v.*): see for example J. McCabe, Biographical Dictionary of Modern Rationalists (1920) and *A* Rationalist Encyclopaedia (1948). (M. KE.)

RATIONING, a term of military origin, meaning apportionment to each member of a group of his due share of supplies, was first applied to the nation-wide distribution of food in World War I. During World War II it was practised not only by belligerent governments but also in neutral countries faced with shortages and high prices.

Rationing of consumers is carried out by supplying them with a card or booklet containing numbered and dated sections which have to be presented for cancellation or surrender when a purchase is made. Separate cards with detachable coupons may be issued, like the bread cards first used in Berlin, Germany, in the winter of 1914; or a number of cards with different colouring or pattern may be bound together in a single ration book, like that first introduced in Great Britain in July 1918. The issue of ration books and identity cards from the same office is helpful for checking fraud and recording movements of the population.

Out of straight rationing of a single commodity there was developed in World War II a new "points" system of rationing for a group of articles such as clothing and footwear or miscellaneous groceries. Distinction may be drawn between rationing based on tying consumers to a particular shop, in which case retailers receive buying permits corresponding with the number of their registered customers and have no need to detach coupons; and the alternative system whereby customers are free to buy at any shop, and retailers replenish their stocks against the surrender of coupons collected. The former system was applied in Great Britain to meat, bacon, sugar, fats, milk and eggs; the latter to clothing. motor vehicle fuels and soap, and among foods to tea, chocolate and sugar confectionery and miscellaneous groceries.

German and Continental **Rationing.**—When bread rationing was first introduced in Berlin a few months after the outbreak of World War I, it was wrongly interpreted abroad as a sign of serious shortage rather than as a precautionary measure designed to prevent maldistribution. From the outset the German system embodied the principle of differential rations. Manual workers, later divided into light, heavy and very heavy workers, received more than the normal consumer; children under ten years, less. Rationing was administered by local authorities, who enjoyed more independence than in World War II and sometimes competed with one another for supplies. Co-ordination of supply and distribution by state-controlled war companies was never complete, and this opened the door to illicit trade. Evasion of the regulations from 1917 onward grew to such an extent that maldistribution of food was one of the chief factors in the collapse of the home front in 1918.

Before the outbreak of World War II thorough preparations had been made for rationing as an integral part of war economy. The reich food estate (Reiclzsnaehrstand) had already established centralized control over food supplies and distribution, and disciplinary action reduced illicit trade to the minimum. Rationing of bread, flour, sugar, meat and fats was introduced in Sept. 1939 and continued at a fairly adequate level until 1944. Further refinements were made in the system of differential rations to cover special categories of consumer and different age groups.

Rationing in occupied countries followed the German pattern but varied widely in efficiency and adequacy. Administration was left largely to local officials,and passive resistance by producers, traders and consumers led to an extensive black market.

Great Britain.—Rationing was unknown in Great Britain until toward the end of World War I. In Aug. 1914 a royal commission on sugar supplies had been set up to undertake bulk buying. Toward the end of 1916 sugar supplies fell short of demand, and distributors were allotted only half of their 1915 supplies. Retailers were left to share this out among their customers as best they could, but queues formed and discontent grew. After some months of hesitation the cabinet decided in June 1917 to introduce the first rationing scheme under which householders were invited to register with a particular shop, and retailers received supplies of sugar equal to the rations of their registered customers. One thousand eight hundred food control committees were appointed by local authorities to exercise powers delegated by the food controller. A local rationing scheme for meat and fats in London and the home counties, covering about 10,000,000 people, came into force on Feb. 25, 1918, as a result of which queues largely disappeared. On April 7 a national rationing scheme for meat was started, and on July 14 the whole population received ration books with separate cards for meat, fats, sugar and lard. By May 1919 rationing by coupons was abolished, and sugar registration ended in Nov. 1920. Rationing had lasted for little more than two years.

By contrast in World War II rationing started early in 1940 and was not ended until July 1954. Ration books, which had been printed in 1938, were issued by post from local food offices to every individual on the basis of a special census conducted for national registration on Sept. 29, 1939. Five types of ration books were issued: for children under 5, children 5 to 18, normal adults, travellers and seamen. Emergency cards valid for one week were issued to new arrivals or persons who had lost their books. Straight rationing, which entitled consumers to a fixed weekly amount of each food, was applied in 1940 to meat, bacon, sugar, fats and tea. In 1941 cheese and preserves were added, and milk and eggs came under a scheme of priority rationing. On Dec. 1, 1941, a new system of points rationing was put into force for miscellaneous groceries, under which each consumer received a number of points to spend in each four-week period on any food in the group, each food being given a points price varying according to the expected demand in relation to the supply; thus canned salmon and dried fruits had a high points price, and cereal foods, a low price. This system was adopted after the successful introduction of points rationing for clothing and footwear. In June 1941 everyone had been given a coupon currency of 66 points, roughly corresponding to 66% of prewar average consumption. Later the figure was reduced to 48 a year. Point prices for clothing were based on the amount of cloth used, but other garments mere pointed to equate demand roughly to estimated supply. Rationing of expenditure by value coupons was rejected on the ground that it would have concentrated demand too much on the cheaper goods.

Soap rationing was introduced early in 1942 on the basis of 16 oz. per four weeks for hard soap. Chocolate and sugar confectionery were first rationed in July 1942 under what was called the personal points scheme; distribution to retailers was based on coupons collected without consumer registration. Other foods subject to controlled distribution rather than strict rationing included milk, eggs, oranges and fish. Milk went first to priority consumers — mothers and children up to 5 years old were guaranteed a ration of seven pints a week; children of 5 to 18 years, three and one-half pints; and schools, hospitals and invalids also had priority supplies. The rest of the public got what was left with no definite guarantee of supply, the usual amount being two pints a week in the minter and three to four in the spring. Consumers were tied to one dairyman who received his share of the available supplies according to the number of priority and nonpriority customers registered with him. Controlled distribution of shell eggs started in June 1941. Mothers and infants received priority supplies, and ordinary consumers got allocations as and when supplies permitted, varying from one a month in the winter to two or more a week in the spring. Up to the end of 1944 nonpriority consumers received an average'of 30 eggs a year, which was about one-fifth of prewar consumption. In June 1942 dried eggs, supplied by the United States under lend-lease, were distributed in packets containing an amount equivalent to 12 eggs at the rate of one packet or more per eight weeks; but later priority supplies were allotted to infants and nursing mothers, and the balance went on points. Oranges when available were sold to holders of children's ration books before other customers could be served. It was found impracticable to ration fish, but supplies to retailers were distributed as fairly as possible. Bread, flour and potatoes never had to be rationed during World War II. Bread and flour rationing was introduced in July 1946 and lasted for two years; potatoes were rationed in 1947–48 when a poor potato harvest synchronized with world shortage of wheat.

In contrast with rationing schemes on the continent, differential rations for special categories of workers were kept to the minimum, and coupons did not have to be surrendered for meals in restaurants. The general principle was that everyone should be free to take meals out as a supplement to domestic rations, and caterers received an allocation of rationed foods on the basis of the number of meals served.

Food rationing in Great Britain, which ended with the decontrol of meat and bacon on July 3. 1954, was made easier by the fact that half the total food supply was imported and also by the willing co-operation of food traders and the public. There was general assent to the principle of fair shares which, though it involved some levelling down in the consumption of the majority, also allowed some levelling up of the diet of the poorest by means of food subsidies and welfare food schemes.

United States. — Rationing in the U.S. was an emergency measure accompanying major warfare. Recognized as necessary, rationing nevertheless was adopted with reluctance and abandoned with alacrity. Idealistic self-restraint was the principal recourse of the U.S. during World War I although wheat flour and sugar supplies were eventually controlled by the Food administration headed by Herbert Hoover, to ensure maximum use of food supplies for wartime needs. Disappearing quickly after the Armistice, controls did not appear again until after the attack on Pearl Harbor, Dec. 7, 1941, when it became clear that extraordinary efforts would be needed to fight and win a two-continent war. An Office of Price Administration (OPA) was created April 11, 1941, by executive order to prevent "price spiraling, rising costs of living, profiteering, and inflation." Signing of the Emergency Price Control act on Jan. 30, 1942, gave OPA specific authority to enforce its orders. Leon Henderson, Prentiss Brown and Chester Bowles served successively as OPA administrators.

Although OPA had an army of paid officials, much of the burden of making thankless but necessary daily decisions fell on unpaid local citizens, serving on community ration boards. Their task was not eased by the presence of three antagonistic forces: shortages of goods; government-regulated price ceilings; and war-swollen incomes. The prices of some luxury goods were raised artificially by high federal excise taxes; typewriters, jewelry and luggage continued to bear such federal levies long after the war. OPA rationed some commodities according to individual need, while other items were to be equally available to all. Basic raw materials were controlled at first through priorities and, after mid-1943, by allocations. The change became necessary when the word priority lost its meaning in the light of exhausted supplies Government allocations under a Production Requirements plan and later a Controlled Materials plan were ways of dividing total supplies among essential users

Consumer rationing was handled by several methods. In point rationing, a consumer could select from items in specific groups. Thus small red stamps could be surrendered for meat, butter, fats, cheese, canned milk and canned fish. Blue stamps were used for canned fruits, vegetables and related items. Stamps were good for stated periods. Certificate rationing involved the use of certificates obtainable by those who could prove special need for tires, motor vehicles and similar products.

Ration coupons came to comprise a sort of currency. They passed successively from consumer to retailer to wholesaler to producer to ration authorities. After 1943 a ration banking plan facilitated co-operation by commercial users by permitting depositing of ration currency in banks and drawing on one's existing balance by check. Simplification and refinement in administration came in 1944.

Tires were rationed almost immediately, and sugar was rationed after the first general consumer registration, May 4–7, 1942. Gasoline was rationed first in the east, then throughout the country. Automobile owners with special needs established them with ration boards and were provided with additional rations; many others switched to buses, joined car pools or relearned the joys of walking. Meats, canned goods, butter and other foods eventually joined sugar on rationed lists. Clothing, other than shoes, was unrationed through the war, but scarcities developed, especially after demobilization of uniformed personnel. Fuel oil was rationed in some sections

Rationing was broadened in 1943, and eased briefly in 1944 when key victories seemed to warrant it. Immediately after the Japanese surrender in Aug 1945, most items were released from controls. Sugar and tires, the first to be listed, were the last to be decontrolled OPA ceased May 31, 1947, having lingered on chiefly to handle rent control and to perform final administrative acts.

The very nature of rationing could not but make it unpopular. Yet it performed the task assigned to it. Persons in the U S remained well nourished The black market was kept to a reasonable minimum, in part because OPA in its lifetime instituted over 280,000 enforcement orders against violators of price, rent and rationing regulations, winning 95% of its court cases

There was never any general desire to make rationing a permanent part of the American scene Rapid removal of controls was acclaimed, although in 1945–46 temporary scarcities and a 23% rise in prices indicated that supply had not satisfied pent-up demands.

The Korean War did not bring with it the comprehensive rationing procedures of World War II. An Office of Price Stabilization enforced a limited program of production, wage and price controls. Chrome and other strategic materials were regulated, and the quality of appliances and motor car bumpers suffered for a time.

There was evidence during and after the Korean War that leaders hoped, by planning and stockpiling of critical raw materials, to increase national self-sufficiency in the future. The report of the Materials Policy commission, Resources for Freedom, 5 vol., (Washington, D.C., 1952), was an important step. An indication that future rationing, if any, might vary from the patterns of earlier years could be found in the continuing farm surpluses and in constantly expanding industrial facilities. (See also WAR CONTROL OF FOOD.) (V. D. B.)

RAT KANGAROO or POTOROO, any member of the diprotodont marsupial subfamily Potoroinae (see MARSUPIALIA). None of them exceeds a rabbit in size. They inhabit Australia and Tasmania, are nocturnal and feed on leaves, roots and bulbs, which latter they dig up with their forepaws. About ten species are known. The members of the type genus (Potorous) run, rather than leap, and do not use the hind feet for kicking. In the genus Betfongia the tail is prehensile. (See KANGAROO.)

RATLAM, formerly a princely state within the Central India agency, from 1948 a district of Madhya Bharat, India—the maharaja (a Rathor Rajput of the Jodhpur family) ceasing to rule actively. Madhya Bharat became part of Madhya Pradesh Nov. 1, 1956. Area 1,727 sq.mi.; pop. (1961) 484,006. Chief town, Ratlam (pop.. 1951, 63,403).

RATNAGIRI, a town and district of the Bombay Koukan division of Bombay state, India. The town is on the coast 136 mi. S. of Bombay. Pop. (1951) 27,082. There is no railway, but there is steamer connection with Bombay.

The DISTRICT OF RATNAGIRI has an area of 5.013 sq.mi. It forms a strip between the Western Ghats and the sea. Nearly all the fertile land lies on the banks of the streams which intersect the country. Ratnagiri (pop. [1961] 1,824,343) formed part of the dominions of the Peshwa and was annexed by the British in 1818 on the overthrow of Baji Rao. The district is known for supplying men of outstanding quality to the Bombay police, to the army and to the intelligentsia.

RATNAPURA (*i.e.*, "the City of Gems"), the chief town in the province of Sabaragamuwa, Ceylon. It is the centre of a long-established industry in digging for precious stones—rubies, sapphires, cat's-eyes, etc. There are important tea and rubber plantations in the district, and rice and fruit are cultivated. The town has good rail and road connections with Colombo. Pop. of town (1953) 16.598; of district 421,555.

RATTAZZI, URBANO (1808–1873), Italian statesman, was born on June 29, 1808. at Alessandria. and from 1838 practised at the bar. In 1848 he was sent to the chamber of deputies in Turin as deputy of his native town. For a short time he held the portfolio of public instruction; afterward, in the Gioberti cabinet, he became minister of the interior. and on the retirement of Gioberti in 1849 he became practically the head of the government. The defeat at h'ovara compelled the resignation of Rattazzi in March 1849. His election as president of the chamber in 1852 was one of the earliest results of the so-called *connubio* with Cavour; *i.e.,* the union of the moderate men of the right and of the left. Rattazzi resigned in 1858, but again entered the cabinet under La Marmora in 1859 as minister of the interior. He again retired in Jan. 1860. He was entrusted with the formation of a new ministry in March 1862, but his policy of repression toward Garibaldi at Aspromonte led to his fall in December. He was again prime minister in 1867, from April to October. He died at Frosinone on June 5, 1873.

RATTLESNAKE, any snake of the genera Sistrurus and Crotalus, American pit vipers with the tail terminating in a rattle. The "pit" characteristic of these snakes is a deep depression on each side of the snout between eye and nostril. (See PIT VIPER.) The rattle is developed as a modification of the single scale that covers the tip of the tail; instead of being a simple. conical sheath, as in ordinary snakes, it has two ringlike constrictions so that it resembles three hollow bulbs, gradually diminishing in size and each one opening into its neighbour; the largest is also open at its free end, where the tail enters. All snakes shed the horny, epidermal covering of their scales periodically, a new one forming beneath the old one before the latter is sloughed; when, however, the new covering of the end of the tail is developed in the rattlesnakes, the middle ring of the new segment develops within the basal segment of the old rattle and. though the rest of the old skin is sloughed, the old tail sheath remains loosely fitting over the new one but prevented from slipping off by its shape. Thus, newly born rattlesnakes have no rattle but with each succeeding moult a joint is added; the older joints, however, gradually wear away and are lost so that the number of joints on the rattle is not a criterion of a snake's age unless the rattle is complete with the original terminal button.

The characteristic noise is produced by rapid vibration of the whole tail, when the loosely fitting horny shells produce a shrill sound, which may be audible 20 yd. away. The majority of the species are dwellers of the plains and open spaces and it has been suggested that the development of the rattle was to give a warning audible at a distance, to keep the snake from being trodden upon by hoofed animals, or from molestation by carnivores.

The venom of the rattlesnakes is of the same general type as that of other pit vipers and all of the larger species inject sufficient venom to kill a man. They are, however, not easily provoked and mill usually endeavour to escape or, if cornered, to frighten the aggressor by rattling and puffing themselves out as much as possible. In all species the eggs are retained within the body of the mother until the young are ready to emerge.

Sistrurus, with three species, is confined to the United States, southern Ontario and Mexico. *Sistrurus* may be distinguished from *Crotalus* by the presence of large, regularly arranged shields on the top of the head; all of the forms are small. Crotalus, with small irregular scales on the top of the head, contains about 20 species, most of which occur in North and Central America. The largest and most dangerous species is the eastern diamondback (C. adamanteus) which reaches a length of about eight feet; it is confined to the southeastern U.S. Other well-known species are the prairie rattler (C. *confluentus*), which occurs all over the great plains from Canada to Texas. the timber rattlesnake (C. *horridus*) of the eastern United States and C. *terrificus,* which ranges from Mexico to the Argentine and is the only representative of the genus in South America. The sidewinder (C. cerastes) is a small, desert-dwelling form from southwestern h'orth America and is characterized by the development of a blunt, hornlike process above each eye. (K. P. S.)

RATZENHOFER, GUSTAV (1842–1904), Austrian sociologist and army offickr, who conceived of society as a universe of conflicting ethnic groups, was born in Vienna on July 4, 1842. Ratzenhofer became a cadet at the age of 17 and rose rapidly in the military. Already a voracious reader, he had more opportunity for study when he became director of the army archives in 1878. After subsequent service as chief of the general staff of an army, in 1898 he became field marshal and president of the supreme military court of Vienna.

Intellectually and professionally a tough self-made man, Ratzenhofer was naturally inclined to apply Darwin's biological theory of the struggle for existence and survival of the fittest to human society. Thus he joined the ranks of the social Darwinists who carried Darwin's theory of biological evolution of organisms into sociology by explaining the origin of ever larger social groups as a gradual development from less complex groups in conflict. Ratzenhofer, following his fellow Austrian, L. Gumplowicz, chose racial groups as the units for analysis. As might be expected from a sociologist at the top of the military hierarchy, Ratzenhofer believed that political science must rule society. He thought sociology could engineer the human species to even higher forms of social association. See his three volumes *Wesen* und *Zweck* der Politik, *als* Theil der Sociologie und Grundlage der *Staatswissenschaften* (1893).

See Robert Schmid, "Gustav Ratzenhofer: Sociological Positivism and the Theory of Social Interests" in An Introduction to the History of Sociology, ed. by H. E. Barnes, with bibliography (1948). The life of Ratzenhofer is given in his posthumous work, Sociologie (1908), ed. by his son. (H. S.; X.)

RAU, KARL HEINRICH (1792–1870), German political economist, was born on Nov. 29, 1792, at Erlangen, where he studied at the university, of which he subsequently became a professor (1818). In 1822 he was called to the chair of political economy at Heidelberg where the rest of his life was spent in teaching and research. He took some part, however, in public affairs. In 1837 he was nominated a member of the first chamber of the duchy of Baden; in 1845 he became a privy councilor; and in 1851 he was one of the commissioners sent to England on the part of the *Zollverein* to study the Industrial exhibition. A result of this mission was his account of the agricultural implements exhibited at London (*Die landwirthschaftlichen Geräthe der Londoner Ausstellung,* 1853). He was elected a corresponding member of the French institute in 1856. He died at Heidelberg on March 18, 1870.

His principal work is the *Lehrbuch der politischen Ökonomie* (1826–37), an encyclopaedia of the economic knowledge of his time, written with a special view to the guidance of practical men. The three volumes are respectively occupied with (1) political economy, properly so called, or the theory of wealth; (2) public administration science (*Volkswirtschaftpolitik*); and (3) finance. The two last he recognizes as admitting of variations in accordance with the special circumstances of different countries, while the first is more akin to the exact sciences, and is in many respects capable of being treated, or at least illustrated, mathematically. This threefold division marks his close relation to the older German cameralistic writers. The book passed through many editions; in that of 1870 by Adolf Wagner it was transformed into a new book.

RAU, SIR (BENEGAL) NARSING (Narsinga) (1887–1953), Indian lawyer, diplomat and administrator, who helped draft the Indian constitution of 1950, was born in Mangalore on Feb. 26, 1887. Graduate of the universities of Madras and Cambridge, he entered the Indian civil service in 1910 where he achieved distinction as a jurist by his revision of the entire Indian statute book (1935–37). He served as a judge of the high court of Calcutta (1939–44). As the pre-eminent jurist of India he became constitutional adviser to the constituent assembly (1946–49); also for Burma in 1947 in drafting its constitution. His writings on Indian law include a noted study on constitutional precedents as well as articles on human rights in India.

Rau headed the Indian delegation at several sessions of the United Nations general assembly and was permanent representative of India to the United Nations from 1949 to 1951. He served as vice-chairman of the International Law commission, and in 1951 was elected a judge of the International Court of Justice at The Hague. He died on Nov. 29, 1953, in Zürich, Switz.

(Or. S.)

RAUSCHENBUSCH, WALTER (1861–1918), U.S. clergyman, professor of theology and social reformer, a leader of the Social Gospel movement, was born in Rochester, N.Y., Oct. 4, 1861, the son of a Lutheran missionary among German immigrants in the United States who had become a Baptist and had been engaged to train a German-speaking ministry at the Rochester Theological seminary. After graduating from the Rochester Free academy, Rauschenbusch studied for four years in Germany and then returned to Rochester in 1883, taking simultaneously his final year at the University of Rochester (B.A., 1884) and his first year at the theological seminary. On June 1, 1886, following the completion of his theological studies, he became minister of the Second German Baptist church in New York city. There he was awakened to the social problem by the personal distress he encountered in a depressed neighbourhood and by the influence of Henry George's campaign for mayor. An even more important influence was exerted by two other young Baptist preachers, Leighton Williams and Nathaniel Schmidt. The three young men formed themselves into a Society of Jesus, which was later to be expanded into the influential Brotherhood of the Kingdom. *For the Right,* a monthly periodical published "in the interests of the working people," was launched in Nov. 1889 in an effort to reach the labouring classes and to aid in the formulation of a Christian Socialist program. Publication ceased in March 1891 when Rauschenbusch left for a year's study in Germany. In 1897 he was called to the faculty of the Rochester Theological seminary and in 1902 was installed as professor of church history. The publication of *Christianity and the Social Crisis* (1907) won him national acclaim as the major spokesman of the social gospel. He died, saddened by World War I, on July 25, 1918.

Rauschenbusch always regarded himself as an evangelist, seeking to win men to a "new birth" in Christ and to put them to work in the interests of his kingdom. He seized upon the "kingdom of God" as the only concept adequate to induce repentance and to harness the impulses of new spiritual life. He had little patience with contemporary optimistic views of human nature. "Ethically," he said, "man sags downward by nature. It is ever easy to follow temptation and hard to resist it. The way that leads to destruction is always broad and its asphalt pavement is kept in perfect order, with toboggan slides at either side for those who prefer a steeper grade." Among his other important writings are *Prayers for the Social Awakening* (1910), *Christianizing the Social Order* (1912) and *A Theology for the Social Gospel* (1917). *See* also Christian Socialism.

See D. R. Sharpe, *Walter Rauschenbusch* (1942). (W. S. H.)

RAVAILLAC, FRANÇOIS (1578–1610), the assassin of Henry IV of France, was born near Angoulême. He began life as a *valet de chambre*, but afterward became a lawyer and schoolteacher. He failed to obtain admission either to the recently founded order of Feuillants or to the Society of Jesus. Rumours that the king was intending to make war upon the pope suggested to him the idea of assassination, which he carried out on May 14, 1610. He was executed on May 27, 1610.

RAVAISSON-MOLLIEN, JEAN GASPARD FÉLIX, commonly known as Félix Ravaisson (1813–1900), French philosopher and connoisseur, was born at Namur on Oct. 23, 1813. A protégé of the comte de Salvandy, minister of education, he was taken from a teaching post in Rennes to be inspector general of public libraries (1839–45, 1846–53). Under Napoleon III he was made inspector general of higher education, a title which he retained till 1888, though from 1870 he was curator of antiquities in the Louvre. He died in Paris on May 18, 1900.

His major philosophical works are: *Essai sur la métaphysique d'Aristote,* 2 vol. (1837–46); *De l'habitude* (1838; new ed., 1927); and *La Philosophie en France au XIX^{e} siècle* (1868; 3rd ed., 1889). As a philosopher Ravaisson belonged to the school of Victor Cousin, with whom, however, he was at issue on many important points. The act of consciousness, according to him, is the basis of all knowledge. His influence was extensive in the Latin Catholic world, where it did much to prepare for Bergsonism.

See his *Testament philosophique et fragments,* ed. by Charles Devivaise (1933); also J. Dopp, *Félix Ravaisson: la formation de sa pensée d'après des documents inédits* (1933).

RAVEL, MAURICE (1875–1937), French musical composer, was born at Ciboure, near St. Jean de Luz, Basses-Pyrénées, March 7, 1875. He was the most outstanding figure in modern French music. More than that, he held an assured place in that line of composers, beginning with the *clavecinistes* of the 17th century, who had so powerful an influence on French instrumental music. Educated at the Conservatoire de Paris, where his master in composition was Gabriel Fauré, Ravel won the second prix de Rome for composition in 1901. But he was not awarded the grand prix de Rome, and the judges were severely criticized for thus refusing to recognize his talent; the resignation of F. C. T. Dubois from the directorship of the Conservatoire was in fact attributed to this cause. When Ravel's piano pieces began to be known, notably *Pavane pour une infante défunte* and *Jeux d'eau,* played in Paris by Ricardo Viñes in 1902, a comparison was made between him and C. A. Debussy, whose *Pelléas et Mélisande* (Opéra-Comique, 1902) was then arousing heated controversy.

It is true that such diverse minds as Fauré, A. E. Chabrier and Erik Satie exercised an influence on Ravel during his formative years, but his personality showed itself from the first. This personality became more clearly defined in his subsequent works, which included the *String Quartet in F,* the three *Schéhérazade* melodies for voice and orchestra or piano (both 1903); the

Histoires *naturelles* (1906); Introduction et allegro (septet for harp, strings, flute and clarinet) and the *Rapsodie espagnole* for orchestra (1907). For the piano he wrote Miroirs and *Sonatine* (1905); *Gaspard* de la *nuit* (3 pieces) (1909); Ma mkre *l'Oye* (suite of five pieces) (1908); and Valses nobles et sentimentales (1911). The last two of these are best known in England as orchestrated by the composer.

However daring Ravel's harmony may appear, he was never experimental. He had an unerring sense of direction and knew where he was going, even if he sometimes seemed to watch himself going there with a smile of amusement. The cynical wit of his one-act opera, *L'heure* espagnole (Opéra-Comique, 1911), and the conscious pose of the ballet *Daphnis* et Chlot (choreography by Michel Fokine and produced by Sergei Diaghilev, 1912), emphasize in different ways the detached attitude of Ravel toward his art. His later works include a sonata for violin and violoncello, and a trio for piano and strings (1915); La Valse for orchestra (1920) and Tzigane, for violin and piano (1924).

RAVELLO, a village of Campania, Italy, in Salerno province, 3 mi. N N.E. of Amalfi, 1,227 ft. above sea level. It commands a magnificent view, especially from the Belvedere of Cimbrone. Pop. (1957 est.) 2,566 (commune). The history of Ravello begins in the 9th century. In the 11th it was called Rebellum, because it rebelled against Amalfi; in the 13th, at the height of its prosperity, it had 36,000 inhabitants. The Palazzo Rufolo, begun in the 11th century, has two lofty towers and beautiful Saracenic decoration in the courtyard. The former cathedral of S. Pantaleo has a good campanile, fine bronze doors by Barisanus of Trani (1179) and two pulpits in Cosmatesque work. The larger, supported by six columns resting on the backs of lions, was made in 1272 by Nicolaus of Foggia; the bust over the entrance may be a portrait of Sigilgaita Rufolo, or may symbolize the church. The smaller (*c.* 1130) has curious representations of Jonah and the whale. The parish church of S. Giovanni in Toro contains a splendid pulpit in Cosmatesque work, supported on four pillars, and the crypt some 14th-century frescoes. S. Maria Immacolata is another Romanesque church.

RAVEN, the largest bird of the order Passeres, and a member of the Corvidae. Quick-sighted, sagacious and bold, the raven preys on the spoils of fishers and hunters, also on weakly animals among flocks and herds. A sentiment of veneration or superstition has often been attached to it. Superstition has been generally succeeded by persecution, which in many districts has led to extirpation.

The raven breeds early in the year, in England resorting to its nest, which is usually an ancient structure, toward the end of January. Therein are laid from five to seven eggs of the common corvine coloration (*see* CROW), and the young are hatched before the end of February. The young have bright crimson throats. In more northern countries the breeding season is naturally delayed, but everywhere this species is almost, if not quite, the earliest breeder. The raven measures about 26 in. in length and has an expanse of wing exceeding a yard. It is entirely black, the feathers having a purple iridescence. The common raven (*Corvus* corax) inhabits the whole of Europe, northern Asia and northern America. In Africa its place is taken by allied species, one of which (*Corvus umbrinus*) has a brown neck; farther south are species whose plumage is varied with white.

RAVEN-HILL, LEONARD (1867–1942), English artist and illustrator, was born on March 10, 1867. He studied art at the Lambeth school and afterward in Paris under A. W. Bouguereau and Aim6 Morot. He began to exhibit at the Salon in 1887 and at the Royal Academy in 1889. In 1893 he founded, with Arnold Golsworthy, the humorous and artistic monthly the *Butterfly* (1893–94, revived in 1899–1900). He contributed to many illustrated magazines and was with Punch from 1896 until his retirement in 1935. He illustrated Sir Walter Besant's East London (1901) and J. H. Harris's Cornish Saints and Sinners. His impressions of his visit to India on the occasion of the tour of the prince and princess of Wales appeared as An Indian Sketch-Book (1903); other published sketchbooks include Our Battalion (1902) and The *Promenaders* (1894). He died March 31, 1942.

RAVENNA, a city and archiepiscopal see of Emilia-Romagna, Italy, capital of the province of Ravenna, in a marshy plain 13 ft. above sea level, 6 mi. from the sea and 45 mi. by rail east of Bologna. Pop. (1957 est.) 102,897 (commune)—a considerable increase, as the population of 1881 was only 34,270 (commune). The town is a centre for agriculture, which has been much favoured by extensive drainage and reclamation works. There is also a sugar factory at Classe. The town is connected with the sea by the Corsini canal. Ravenna has railway communication with Bologna (via Castel Bolognese), Ferrara and Rimini, and by steam tram with Forlì. Though the external aspect of the town is not striking, no other in the world offers so many and such splendid examples of the ecclesiastical architecture of the centuries from the 5th to the 8th. The style is commonly called Byzantine, but the colonnades and the mosaics are not so much Byzantine as representative of early Christian art generally.

The cathedral of Ravenna, built by S. Ursus in 370–390, which had a nave and four aisles, was destroyed in 1734–44, only the (inaccessible) crypt and the round campanile remaining from the earlier structure; there are fragments of reliefs from a pulpit erected by Archbishop Agnellus (556–569) in the interior. The present cathedral contains several early Christian marble sarcophagi, a silver cross of the 11th century and the throne of the Archbishop Maximian (546–552), adorned with reliefs in ivory.

The period from the transference of the imperial residence to Ravenna to the death of Valentinian III (404–455) was the first period of great building activity in Ravenna, when the archiepiscopal see of Ravenna attained great importance. It was to it that is owed the erection of the Basilica Petriana at Classe (396–425), which has entirely disappeared, of the churches of S. Giovanni Evangelista (425), of S. Agata (425–432), of the chapel of S. Pier Crisologo (433–449), of the mausoleum of Galla Placidia (440), the church of S. Pier Maggiore (now S. Francesco) (433–58), baptistery of Neon (449–458), S. Giovanni Battista and S. Croce.

S. Giovanni Evangelista, erected by Galla Placidia in fulfilment of a vow made on her voyage from Constantinople, has been entirely rebuilt, though the columns are ancient. The Gothic portal is fine, and the church contains a mosaic pavement of 1213 with representations of the 4th crusade and some frescoes by Giotto, painted during a visit to Dante between 1317 and 1320. S. Agata was almost entirely rebuilt in 1476–94. The chapel of S. Pier Crisologo in the archiepiscopal palace preserves its original mosaics; so also does the mausoleum of Galla Placidia (SS. Nazario e Celso), a small structure in the form of a Latin cross with a dome (in which, as in the baptistery of Neon, the old cathedral, etc., the constructional use of amphorae is noteworthy), with a plain brick exterior, and rich mosaics on a dark blue ground.

S. Francesco has been modernized, except for the crypt and campanile (10th century). The baptistery adjacent to the cathedral was either originally part of the Roman baths, converted to a Christian baptistery by the Archbishop Neon (449–452), or a Christian building dating from before A.D. 396. It is an octagon, with a dome; in the interior are two arcades one above the other. The mosaics of the 5th century, in the dome, are the earliest and perhaps the finest at Ravenna.

Of S. Giovanni Battista, also erected in this period, hardly anything remains after the restoration of 1683, and S. Croce has been overtaken by a similar fate. Honorius and Galla Placidia built a palace about A.D. 402, remains of which have been found under S. Croce.

The reign of Theodoric (493–526) marks another era of magnificence. In the eastern part of the city he built for himself a large palace. There still remains fronting the Corso Garibaldi a high wall built of square Roman bricks, with pillars and arched recesses in the upper portion, which goes by the name of Palazzo di Teodorico, but is a guardhouse erected by the exarchs, recent explorations having made it clear that it was an addition to the palace, while mosaic pavements and a court once surrounded by colonnades and really belonging to the latter were found behind S. Apollinare Nuovo and the so-called Palazzo at a lower level and a different orientation. (See Ghirardini in Monumenti *dei Lincei,* xxiv, 737–838.) A mosaic in the church of S. Apollinare Nuovo gives some faint idea of the palace. The massive mausoleum of Theodoric stands still perfect outside the walls near the northeast corner of the city. It is circular internally and decagonal externally, in two stories, built of marble blocks, and surmounted by an enormous monolith, brought from the quarries of Istria and weighing more than 300 tons. It has been converted into a church dedicated to the Virgin.

S. Apollinare Nuovo, the most important basilica in the town, was built by Theodoric to be the largest of Arian churches. The exterior is uninteresting, and the church lost both atrium and apse in the 16th century. The interior has 24 columns of marble, with almost uniform capitals. The walls of the nave are adorned with mosaics of the 6th century; the scenes from the New Testament above the windows date from the time of Theodoric.

The campanile (850–878) is circular and has perhaps the earliest example of the use of disks of coloured majolica as a decoration. This, like the other campanili of Ravenna, is later than the church to which it belongs Those of the cathedral of S. Apollinare in Classe, S. Maria Maggiore and S. Agata, also circular, probably belong also to the 9th century, while the two square campanili of S. Giovanni Evangelista and S. Francesco probably belong to the 10th century The other churches erected by Theodoric are: S. Teodoro (or S Spirito), erected by Theodoric for the Arian bishops. but entirely modified; the baptistery of this church (afterward the oratory of S. Maria in Cosmedin), formed out of the octagonal hall of a Roman bath, with mosaics of the 6th century; S. Maria Maggiore. founded by the Archbishop Ecclesius (521–534), but almost entirely rebuilt; and S Vittore. which has suffered a similar fate. To the same period probably belong a few columns of the so-called Basilica of Heracles in the Piazza Vittorio Emanuele, with capitals like those of S. Apollinare in Classe.

The impulse given by Theodoric was continued by his successors, and during the regency of Amalasuntha and the reigns of Theodatus and Vitiges (526–539), S. Vitale and S. Apollinare in Classe were constructed by Julius Argentarius contemporaneously with S Lorenzo in Milan and the cathedral of Parenzo—also S. Michele in Africisco, little of the original structure of which now exists; the apse mosaic is in the Berlin museum. The former, well restored by Ricci (except for the dome with its baroque frescoes which has not been altered), is a regular octagon. with a vestibule, originally flanked by two towers on the west, a choir added on the east. triangular outside and circular within; it is surrounded within by two galleries interrupted at the presbytery, and supported by eight large pillars. the intervals between which are occupied by open exedrae The mosaics of the choir (547) are due to Justinian, and, though inferior in style, are remarkable for their splendour of colouring and the gorgeous dresses of the persons represented. and also for their historical interest, especially the scenes representing the emperor and the empress Theodora presenting offerings The marble screens of the altar are wonderfully finely carved The marble mosaic pavement (11th century) is very effective. Remains of the original marble mall lining and stucco decoration also exist.

The architecture of S Vitale according to Rivoira, was inspired not hy Byzantium. where similar churches — S. Sofia and SS. Sergio and Bacco — are slightly later in date. but by the churches of Salonica (AD. 495), while the plan is derived from a Christian baptistery, or from such a building as the so-called temple of Minerva Medica at Rome

It has been ascertained that a 5th century building already occupied the site.

S Apollinare in Classe, erected at the same time outside the walls of Classis, and now standing by itself in the lonely marshes, is the. largest basilica existing at Ravenna. It has a nave and aisles with a closed vestibule on the west, and a fine round campanile of the 9th (?) century. The exterior brick walls are divided by shallow arches and pilasters, as in other churches of Ravenna. It has 24 columns of Carystian (cipollino) marble, with capitals probably of Byzantine work with swelling acanthus leaves; but the rest of the church is the work of native architects. The lofty presbytery and the crypt under it belong to the 12th century. The walls of the interior were stripped of their marble panelling by Sigismondo Malatesta in 1449, for the adornment of his church at Rimini. The apse has mosaics of the 6th and 7th centuries. The 18th-century series of portraits of the archbishops of Ravenna is no doubt copied from an earlier original. There are a number of fine carved sarcophagi in the church (5th to 8th century). The building activity of the Gothic kings was continued by Justinian, to whose time we owe the completion of S. Vitale and S. Apollinare in Classe, and some of the mosaics in S. Apollinare Nuovo.

The buildings of a subsequent period are of minor importance, but the Basilica of S. Maria in Portofuori near the ancient harbour (1096 seqq.), a basilica with open roof, with frescoes by masters of the Rimini school, may be noticed. The campanile dates from 1173–87. The tomb of Dante, who died at Ravenna in 1321, is close to S. Francesco; it is a square domed structure, with a relief by Pietro Lombardo (1483) representing the poet, and a sarcophagus below, in an urn within which lie the poet's remains. Close by is a small court with early Christian sarcophagi, containing the remains of the Braccioforte family. The important museum near S. Vitale has Roman and Byzantine antiquities. inscriptions. sculptures, jewelry, etc. The library has rare manuscripts (including the best extant manuscript of Aristophanes) and incunabula. The Accademia has pictures by local masters.

In the Piazza Vittorio Emanuele are two granite columns erected by the Venetians in 1483. The cloisters of S. Maria di Porto, erected in the town in the 16th century (because of malaria, as in the case of those of Classe), and of S. Vitale are pleasing 16th-century structures. The 15th-century castle in the northeast corner of the town erected by the Venetians is a picturesque brick building. The walls, 3 mi. long, which still surround the town. were also built by them.

History.—Strabo mentions a tradition that Ravenna was founded by Thessalians, who afterward called in the Umbrians and left the city to them. About 191 B.C., by the conquest of the Boii, the whole of this region passed definitely under the dominion of Rome. Under Augustus it rose into importance, when it was made the station for the fleet on "the upper sea." Two hundred and fifty ships could ride at anchor in its harbour. At the same time Augustus conducted a branch of the Po (the fossa Augusta) through the city into the sea. It also became important for the export of timber from the Alps. Strabo gives a description which corresponds closely with modern Venice.

On the other hand, good water was proverbially difficult to obtain at Ravenna—dearer than wine. says Martial. Trajan, however, built an aqueduct nearly 20 mi. long, which was restored by Theodoric in 503. Of this some traces still exist in the bed of the Ronco above Ravenna. Flies and frogs were also complained of. and Sidonius, writing in the 5th century, complains bitterly of the "feculent gruel" (cloacalis *puls*) which filled the canals of the city and gave forth fetid odours when stirred by the poles of the bargemen. The port of Ravenna. situated about three miles from the city, was named Classis. A long line of houses called Caesarea connected it with Ravenna, and in process of time there was such a continuous series of buildings that the three towns seemed like one. It had large gilds of fabri (smiths and carpenters) and *centonarii* (firemen).

A prehistoric station was found in 1894 at S. Zaccaria near Ravenna, belonging to a Terramare. Of Roman Ravenna nothing remains above ground. It was connected with Ariminum, 33 mi. to the south, by the coast road, the Via Popilia, which ran on north to Hatria. and joined the road between Patavium and Altinum at Ad Portum.

Early in the 5th century, Honorius, alarmed by the progress of Alaric in the north of Italy, transferred his court there. From this date (404) to the fall of the Western Empire in 476 Ravenna was the chief residence of the Roman emperors. There Stilicho was slain; there Honorius and his sister Placidia caressed and quarrelled; there Valentinian III spent the greater part of his life; there Majorian was proclaimed; there the little Romulus donned his purple robe; there in the pinewoods outside the city his uncle Paulus received his decisive defeat from Odoacer. The great pinewoods to the east of the city, which is still one of the great glories of Ravenna, must therefore have been in existence in the 5th century. Odoacer made Ravenna his chief residence. Theodoric's siege of Ravenna lasted for three years (489–492); ten days after his entry into the city he slew his rival at a banquet in the palace of the Laurel Grove (March 15, 493). Ravenna was also Theodoric's chief residence (493–526).

In 535 Justinian sent an army to destroy the Gothic monarchy and restore Italy to the empire. The Goths at length, weary of the feebleness of Vitiges, offered to transfer their allegiance to Belisarius on condition of his assuming the diadem of the Western Empire. Belisarius dallied with the proposal until he had obtained an entrance within the walls of the capital, and proclaimed his inviolable fidelity to Justinian (539). Under the rule of Narses and his successors, the exarchs, Ravenna was the seat of Byzantine dominion in Italy. In 728 the Lombard king Luitprand took and destroyed the suburb Classis; about 752 the city itself fell into the hands of his successor. Aistulf, from whom a few years later it was wrested by Pippin, king of the Franks.

It formed part of the Frankish king's donation to the pope in the middle of the 8th century, though the archbishops, as a fact, retained almost independent power. It was an independent republic, generally taking the Guelph side in the 13th century, subject to rulers of the house of Polentani in the 14th, Venetian in the 15th (1441) and papal again in the 16th. St. Romuald and St. Peter Damian were both natives of Ravenna. From this time (1509) down to 1860, except for the interruptions caused by the wars of the French Revolution, Ravenna continued subject to the papal see and was governed by a cardinal legate. In 1849 Garibaldi's wife, Anita, who had accompanied him on his retreat from Rome, succumbed to fatigue in the marshes near Ravenna.

Charles the Great carried off the brazen statue of Theodoric and the marble columns of his palace to his own palace at Aix-la-Chapelle. Lord Byron resided at Ravenna for 18 months in 1820–21, attracted by the charms of the Countess Guiccioli.

BIBLIOGRAPHY.—The most important authority for the history of Ravenna is Bishop Agnellus, who wrote, about 840, the *Liber Pontificalis Ecclesiae Ravennatis* The best edition is that by Holder-Egger in the *Monumenta Germaniae Historica* (1878) *See* G T Rivoira. *Lombardic Architecture* (London, 1910); C Ricci, *Ravenna* (Bergamo, 1902), *Ravenna* (London, 1913); E Hutton, *The Story of Ravenna* (London, 1926). To the careful restorations of Ricci the buildings of Ravenna owe much. (T. H.; T. A.)

BATTLE OF 1512

This battle, one of the principal events of the long Italian wars of Charles VIII. Louis XII and Francis I of France, is, like Marignan (*q.v.*), interesting in a tactical sense, from the fact that the feudalism of the past and the expert soldiership of the future were strangely mingled. It arose out of the attempt of the Spanish and Italian forces to relieve Ravenna, besieged by Gaston de Foix, duke of Nemours. The most celebrated captains of these wars were present on either side—under Gaston de Foix were Bayard. Yves d'Allègre, La Palisse; and under Cardona, the Spanish viceroy of Naples, Pedro Navarro. the great engineer, and Pescara. the originator of the Spanish tactical system. After some preliminary manoeuvres the two armies drew up face to face on the left bank of the Roneo. the Spanish left and the French right resting on this river. The Spaniards Mere entrenched with their heavy artillery distributed along the front, but, thanks to Navarro, they had a more mobile artillery in the shape of 200 *arquebuses à croc* mounted in groups upon carts, after the German fashion. The battle opened with a prolonged cannonade from the Spanish lines. For three hours the professional regiments of all sorts in the French lines rivalled one another in enduring the fire unmoved, the forerunners of the military systems of to-day, landsknechts, Picardie and Piedmont, showing the feudal gendarmerie that they too were men of honour. There was no lying down. The captains placed themselves in the front, and in the centre 38 out of 40 of them were struck down. Molart and Empser, drinking each other's health in the midst of the cannonade, were killed by the same shot. Sheltered behind the entrenchments, the Spaniards scarcely suffered, for they were lithe active troops accustomed to lie down and spring up from the ground. But after three hours, Pescara's light horse having meantime been driven in by the superior light horse of the enemy, the artillery-loving duke of Ferrara conceived the brilliant plan of taking his mobile field guns to the extreme right of the enemy. This he did, and so came in sight of the prone masses of the Spaniards. Disciplined troops as they were. they resisted the temptation to escape Ferrara's fire by breaking out to the front; but the whole Spanish line was *enfiladed,* and on the left of it the papal troops, who were by no means of the same quality. filled up the ditch in front of their breastworks and charged forward, followed by all the gendarmerie. Once in the plain they were charged by the French gendarmes under Gaston himself. as well as by the landsknechts, and driven back. The advantage of position being thus lost, the Spanish infantry rose and flung itself on the attackers; the landsknechts and the French bands were disordered by the fury of the counterstroke, being unaccustomed to deal with the swift, leaping and crouching attack of swordsmen with bucklers. But La Palisse's reserve wheeled in upon the rear of the Spaniards, and they retreated to the entrenchments as fast as they had advanced. The papal infantry, the gendarmes and the light horse had already vanished from the field in disorder; but the Spanish regulars were of different mettle, and it was only after a long struggle that the landsknechts and the French bands broke into the trenches. The conflict continued, but at last La Palisse. with all the gendarmerie still in hand, rode completely around the entrenchments and charged the Spaniards' rear again. This was the end, but the remnant of the Spanish infantry retreated in order along the river causeway, keeping the pursuers at bay with their arquebuses. Gaston de Foix, recklessly charging into the midst of them, was killed.

RAVENNA, EXARCHATE OF, or exarchate of Italy, created by the emperor Maurice (582–602) as a new administrative province to comprise the Byzantine dominions in Italy after the Lombard invasion; it is first mentioned in 584. Soon after, it came to form part of the new system of "themes" established along the frontiers of the empire by Heraclius and his successors. At the beginning of the 7th century, the exarchate included Istria, maritime Venetia, Emilia with Ravenna, the Pentapolis, *i.e.,* the coast from Rimini to south of Ancona with the hinterland, Calabria (then the name of the "heel" of Italy). Bruttium (the "toe" of Italv. called Calabria from the late 7th century), Naples with southern Campania, Rome with northern Campania and-southern Tuscany, Perugia and Liguria

The territory of Ravenna was also called, in a limited sense, the exarchate of Ravenna. It was under the direct administration of the exarch. while the other Byzantine possessions in Italy were governed. under his authority, by dukes or *magistri militum;* below them there were tribunes in charge of towns and castles. The internal organization of the exarchate, like that of the themes, was marked by the combination of military and civil powers in the same hands. The exarch, first created as the military governor of Byzantine Italy. thus soon displaced the existing head of the civil administration, the prefect of Italy, whose office seems to have disappeared about the middle of the 7th century. Sicily formed a separate province directly dependent on Constantinople, although the exarch exercised some control over it during that century; Corsica and Sardinia were placed under the exarchate of Carthage.

During the 7th century, the Byzantines suffered further losses; by the middle of the century. Liguria had fallen to the Lombard kings; by the end of it, nearly the whole of Calabria (*i.e.,* the southeast of Italy) had been conquered by the Lombard dukes of Benevento. In 726 a revolt broke out in the exarchate which seriously threatened the Byzantine government; although primarily caused by the iconoclastic policy of Leo III, it was also due to dissatisfaction with the Byzantine administration. After the suppression of the revolt, or after 750, the south Italian dominions were separated from the exarchate and incorporated in the theme of Sicily. The pope. who had played a leading part in the revolt, was gradually becoming the virtual ruler of Rome and its duchy. King Liutprand took advantage of the difficult situation of the Byzantines and extended his power at their expense. After a brief respite, Aistulf continued this policy of conquest; in *c.* 751 he finally took Ravenna, after its territory (the exarchate in the limited sense) had already been conquered In northern Italy, Istria and maritime Venetia alone remained Byzantine. Subsequent Frankish intervention (*see* ITALY: *History*) made a recovery of the lost dominions impossible; the exarchate in the limited sense and the Pentapolis passed, together with the duchy of Rome, under papal rule.

The Byzantine possessions in southern Italy saw a temporary revival toward the end of the 9th century; in view of the Arab conquest of Sicily, they were then reorganized in the new themes of Longobardia and Calabria. Venice, nominally under Constantinople, became practically independent under its dukes (doges); and this also happened in some of the southern territories, as at Naples. The development toward local and regional autonomy had already started before the downfall of the exarchate, and had undoubtedly contributed to it. Imperial officials became landowners, and local landowners entered the imperial administration. The tribunate tended to become hereditary in the landowning class; the dukes of Venice were elected by the population from the time of the revolt of 726.

RAVENSBURG, a town in the state of Württemberg-Hohenzollern, Ger., on the Schussen, 12 mi. N. of Friedrichshafen on Lake Constance. Pop. (1959 est.) 30,822. Ravensburg was founded in the 11th century by the Guelphs, and in their castle on the Veitsburg, Henry the Lion was born. In 1180 the town passed to the Hohenstaufens, and a century later it became a free town of the empire. It was ceded to Württemberg in 1810. It retains its walls and nine towers and its 15th-century town hall.

RAVENSCROFT, THOMAS (c. 1590–*c.* 1633), English composer and musical editor, received his B.Mus. at Cambridge in 1607 and in 1618–22 was music master at Christ's hospital. He is best known by his *The Whole Booke of Psalmes* (1621), *48* of the 100 harmonizations being his own. His other works, the first three of which show his appreciation of popular and humorous poems, are *Pammelia,* including 100 rounds and catches (1609); *Deuteromelia,* a collection of 31 items, including "Three Blind Mice" (1609); *Melismata,* a collection of 21 items, chiefly short madrigals (1611); and *A Briefe Discourse of the True (but Neglected) use of Charact'ring the Degrees, by their Perfection, Imperfection and Diminution in Measurable Musicke,* etc. (1614).

RAVI, one of the "Five Rivers" of the Punjab. It rises in the Kulu subdivision of Kangra district, Punjab (India), and flows through Chamba, the isolated northern division of Himachal Pradesh. Turning southwest it briefly enters Jammu (Kashmir), traverses the Gurdaspur district (Punjab, India), then forms the India-Pakistan frontier before finally crossing into the Pakistan province of Punjab about 1j mi. N.E. of Lahore, within a mile of which it later passes. Flowing across the Punjab plains, it finally falls into the Chenab about 10 mi. S. of Ahmadpur after a course of about 450 mi. Its water is used for the irrigation of the Bari *doab.* The Cpper Bari *doab* canal (1859), with headworks at Madhupur on the Indian side of the frontier, serves about 1,177,000 ac. and the Loner Bari *doab* canal (completed 1917), with headworks on the left bank of the Ravi at Balloki, about 345,000 ac. The waters of the Ravi are supplemented for the irrigation of the lower *doab* by canals leading from the Jhelum and the upper Chenab. The Sidhnai canal, beginning about 10 mi. above the Chenab junction, was frequently dry in winter until the construction of the Haveli canal (1939), delivering water to the Ravi from the Trimmu barrage at the Chenab-Jhelum confluence. (T. HER.)

RAWALPINDI, interim capital of Pakistan, cantonment and a district and division of West Pakistan. The town, which is 20 mi. E.S.E. of Peshawar and 160 mi. N.W. of Lahore, had a population in 1961 of 340,175 (including cantonment, 142,805). It was formerly the largest military station in India and the key to the British system of defense on the northwest frontier. It is the starting point of the road to the hill station of Murree and of the route into Kashmir. The seat of government was moved there from Karachi in Oct. 1959, and it was proclaimed the capital on Aug. 2, 1960, pending completion of construction of a new capital, Islamabad, near Rawalpindi. Besides the locomotive works of the North-Western railway there are gasworks, a tent factory, an iron foundry, an oil refinery and a brewery. To the northwest lie the ruins of the ancient city of Taxila, an important seat of learning in the 4th century B.C.

RAWALPINDI DISTRICT (area 2,022 sq.mi.; pop. [1961] 1,137,085) contains the Murree hills. In ancient times it formed part of Gandhara and was included in the Persian empire of the Achaemenidae.

RAWALPINDI DIVISION (area 11,206 sq.mi.; pop. [1961] 3,979,139) contains Rawalpindi, Jhelum, Gujrat and Shahpur districts.

RAWANDIS, a Persian sect (from Rawand, a town near Isfahan). Its origin is unknown, but its members held ultra-Shi'ah doctrines (*see* ISLAM). They maintained that the spirit that was in Jesus was in Ali, then in the imams one after the other to Ibrahim ibn Mohammed, and that thus these were divine. They believed in metempsychosis, or the transmigration of souls, and asserted that the lord who fed them and gave them drink was Mansur. In 759 they came to the palace of Mansur in Hashimiya and began to hail him as lord. The caliph, however, secured their chiefs and threw them into prison.

RAWLINS, a city of south central Wyoming, U.S., 163 mi. N.W. of Cheyenne; the seat of Carbon county. It was founded in 1868 when the Union Pacific railway arrived. The town was first named Rawlins Springs for U.S. Army Gen. John A. Rawlins, who had discovered a pleasant spring of fresh water at that point in 1867, but the word "Springs" was soon dropped. Rawlins was incorporated as a city in 1886.

The Cnion Pacific railway company has always been a principal employer. Quite early Rawlins also became known as a cattle and sheep centre. It is also a centre for antelope hunting and in the 1950s became an important shipping point for uranium ore from the Gas Hills area to the north. The state penitentiary is located at the north edge of Rawlins and an oil refinery is 6 mi. away at Sinclair. For comparative population figures *see* table in WYOMING: *Population.* (T. A. LN.)

RAWLINSON, SIR HENRY CRESWICKE (1810–1895), English soldier and orientalist, was born at Chadlington, Oxfordshire, on April 11, 1810. In 1827 he went to India as cadet under the East India company; and after six years as a subaltern he was sent to Persia in company with other English officers to reorganize the shah's troops. He became interested in the hitherto undeciphered cuneiform character. In two years he transcribed as much as he was able of the great cuneiform inscription at Bisitun (*q.v.*), but the friction between the Persian court and the British government ended in the departure of the British officers. He became political agent at Kandahar in 1840. Then, at his own desire, he was sent as political agent to Turkish Arabia; thus he was enabled to settle in Baghdad, where he devoted much time to his cuneiform studies. He was then able to make a complete transcript of the Bisitun inscription, which he deciphered and interpreted. During two years' leave in England (1849–51) he prepared a memoir on the Bisitun inscription. He disposed of his valuable collection of Babylonian, Sabaean and Sassanian antiquities to the trustees of the British Museum, who made him a grant to enable him to carry on the Assyrian and Babylonian excavations initiated by Sir Austen Layard. In 1851 he returned to Baghdad. In 1855 he resigned his post in the East India company and he received the K.C.B. and crown directorship of the East India company. The remaining 40 years of his life were mainly spent in London. In 1858 he was appointed a member of the first India council, but resigned in 1859 on being sent to Persia as envoy extraordinary and minister plenipotentiary. The latter post he held only for a year. Rawlinson rejoined the council of India in 1868, and continued to serve upon it until his death. He was a strong advocate of the forward policy in Afghanistan. He died in London on March 5, 1895.

His published works include four volumes of cuneiform inscriptions, published under his direction between 1870 and 1884 by the trustees oi the British museum; *The Persian Cuneiform Inscription at Behistun* (1846–51) and *Outline of the History of Assyria* (1852), both reprinted irom the Asiatic Society's journals; *A Commentary on the Cuneiform Inscriptions of Babylon and Assyria* (1850); *Notes on the Early History of Babylonia* (1854); *England and Russia in the East* (1875). He contributed to the *Encyclopædia Britannica* (9th ed.) the articles BAGHDAD; EUPHRATES; KURDISTAN; and several other articles dealing with the east; and assisted in editing a translation of Herodotus by his brother, Canon George Rawlinson (1812–1902).

See G. Rawlinson, *Memoir of Henry Creswicke Rawlinson* (1898).

RAWLINSON, HENRY SEYMOUR RAWLINSON, 1ST BARON (1864–1925), British soldier, was born on Feb. 20, 1864. son of Maj. Gen. Sir Henry Rawlinson. Bart. He joined the army in 1884 and a year later became aide-de-camp to Sir Frederick Roberts in India on whose staff he served intermittently for some years. He took part in the Burma operations in 1886–87 and on the Nile in 1898; he had succeeded to the baronetcy in 1891. He served throughout the South African War (1899–1902). Some months after his return to England he became commandant of the staff college and from 1910 to May 1914 commanded the 3rd division. Gen. Rawlinson was in charge of the forces sent to assist Antwerp in 1914, and took part in the first battles of Ypres and in the Neuve Chapelle and the Loos offensives. He commanded the 4th army during the battle of the Somme (1916), achieving important successes. At the end of 1917 he was transferred temporarily to the command of the 2nd army during Gen. Plumer's absence in Italy, and in February and March 1918 he acted for some weeks as British representative on the Supreme War council. Resuming his command of the 4th army in April, his troops on Aug. 8. in conjunction with the French. attacked the enemy near Xmiens and gained a signal victory. which heralded the general advance of the Allies. After World War I he was raised to the peerage as Baron Rawlinson of Trent and received a grant of £30,000. In the latter part of 1919 he was sent to north Russia to conduct the withdrawal of the Allies from Archangel and Murmansk, and on his return he commanded at Aldershot for a year. At the end of 1920 he went to India as commander in chief. He died at Delhi on March 28. 192j.

See Sir F. Maurice, *Life of General Lord Rawlinson of Trent, from his Journals and Letters (1928).*

RAWMARSH, an urban district in the Rother valley parliamentary division of the West Riding of Yorkshire. Eng., about 2 mi. N. of Rotherham. Pop. (1961) 19,603. Area 4.1 sq.mi. Rawmarsh has three collieries, a large ironworks, steel rolling mills, and an 11-in continuous bar mill of advanced design.

RAW MATERIALS: *see* NATURAL RESOURCES.

RAWTENSTALL, a municipal borough (1891) in the Kossendale parliamentary division of Lancashire, Eng., 17 mi. N. of Manchester by road Pop (1951) 25,437. Area 14.9 sq mi. Rantenstall manufactures cotton, felt, shoes. etc. There is an art gallery and museum. which has a collection of footwear.

RAY (WRAY), **JOHN** (1627–1705), English naturalist, famous for his systems of natural classification, was born at Black Notley, Essex. on Nov. 29. 1627. He graduated B.A. from Cambridge in 1647/48 and in 1649 secured a fellowship at Trinity college, obtaining his M.A. degree in 1651. He resigned his fellowship in 1662 because he could not subscribe to the Act of Uniformity. He devoted himself to science, aided through the generosity of Francis Willughby (*q.v.*), with whom Ray agreed to work on a survey and classification of plants and animals. They made several botanical tours in Britain and, from 1663 to 1666, traveled in Europe. In 1667 Ray mas elected a fellow of the Royal society. Willughby died in 1672, leaving Ray an annuity for life. Subsequently Ray published (1673) an account of their European travels. Ray died at Black Notley on Jan. 17. 1705.

Ray's system of plant classification, which greatly influenced the development of systematic botany, appeared in the *Methodus plantarum nova* (1682) and, in final form, in *Methodus plantarum emendata* (1703). Ray was the first to distinguish (1682) the divisions that he later (1703) called "Monocotyledones" and "Dicotyledones" (from cotyledon, a seed leaf; *see* PLANTS AND PLANT SCIENCE; ANGIOSPERMS), both fundamental in modern classifications though altered in content from Ray's concept. His *Catalogus plantarum circa Cantabrigium* (1660) was the first flora of Cambridgeshire, and his *Catalogus plantarum Angliae* (1670; 2nd ed.. 1677) and *Synopsis methodica stirpium Britannicarum* (1690; 2nd ed.. 1696). the former arranged alphabetically and the latter according to his classification system, were the first floras of Britain. The *Historia plantarum* (1686–1704) described all known plants and arranged them in his system. The book's introductory essays, surveying botanical knowledge, formed the most complete treatise that had appeared on plants in general. Ray was the first to attempt to define what constitutes species.

Ray's zoological works were characterized by Georges Cuvier as "the basis of all modern zoology." The "foundation of scientific ornithology" (A. Newton) was laid in the *Francisci Willughbeii . . . ornithologiae libri tres* (1676), amplified and edited by Ray from the incomplete manuscript left by Willughby. The classification, which was for the most part followed later by Linnaeus, appears to have been of Ray's devising. The bases for the natural classification of fishes were laid in *Francisci Willughbeii . . . historia piscium* (1686). wherein the major share of the work was apparently that of Ray. This work greatly influenced Peter Artedi, whose arrangement of fishes was adopted by Linnaeus. The earliest classification of animals based upon anatomical characters was that in Ray's *Synopsis methodica animalium* (1693). He maintained Aristotle's great divisions, animals with blood (*i e.*, vertebrates) and those "without" blood (*i.e.*, invertebrates). In the former he laid the basis for Linnaeus' first four classes. Ray also issued a preliminary *Methodus insectorurn* in 1705 and his *Historia insectorum*, incomplete when he died, was published in 1713 as it stood and without figures. Ray's system of insects, following Jan Swammerdam, was based upon metamorphosis (*q.v.*).

Ray also wrote *A Collection of English Proverbs* (1670; reissued 1855 and 1875) and *A Collection of English Words* (1674; reissued 1874).

The Ray society, for the publication of works on natural history, was founded in his honour in 1844.

BIBLIOGRAPHY.—C. E. Raven, John *Ray*, 2nd ed. (1950); G. Keynes, *John Ray, a Bibliography* (1951); *E.* Lankester (ed), *Memorials of John Ray* (1846), with *a* listing of Ray's works. (J. W. TT.)

RAY, a common name loosely applied to any of the numerous cartilaginous fishes (class Chondrichthyes) of the order Batoidei, distinguished from the related modern sharks by a flattened body, which has the five gill openings and the mouth generally located entirely on the undersurface, and by the greatly enlarged pectoral fins, which extend forward along the sides of the head above the gill openings. Rays are well fitted by their structure for life at the bottom of the sea. On the upper surface of the head, behind the eyes, are large holes leading to the pharynx; these are termed spiracles and serve for the intake of water for respiration. Most bear young live, but the skates (family Rajidae) have eggs enclosed in oblong horny cases similar to those of dogfishes. As in the sharks, the males have the posterior edges of the pelvic fins modified to form copulatory organs. For a detailed discussion of the anatomy and relationships in cartilaginous fishes *see* CHONDRICHTHYES.

The rays (Batoidei) may be broken down into the following special groups: electric rays (family Torpedinidae), guitarfishes (Rhinobatidae). sawfishes (Pristidae). skates (Rajidae), stingrays (Dasyatidae), eagle rays (Myliobatidae), mantas, including the devil rays (Mobulidae).

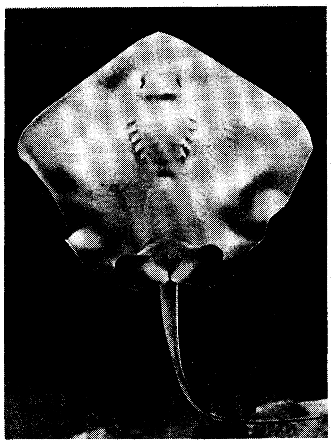
Electric Rays.—The electric rays form an isolated family distinguished by large paired electric organs formed of vertical hexagonal columns. between the pectoral fins and the head. and capable of giving powerful shocks either for defensive purposes or to kill prey. The electric rays have a smooth and naked skin; the head and trunk with the pectoral fins form a circular disc: the tail is short and stout. About 20 species are known from warm seas. some reaching a weight of 200 lb. One representative species is the torpedo *(Torpedo nobiliana),* which occurs from North Carolina to Nova Scotia and from tropical west Africa to Scotland. Another is *Torpedo californica,* which occurs along the

Pacific coast of the United States from central California northward.

Nonelectric Rays.——The other rays, without electric organs, generally have a rough skin, often bearing strong spines. The most sharklike are the guitarfishes (Rhinobatidae) of which about 20 species are known from tropical and subtropical seas; in most of them the pectoral fins are relatively small and the trunk passes gradually into the tail. The sawfishes, or sawrays (Pristis), differ from them in that the snout is produced into a long blade armed with a series of strong teeth on each side; five species are known from warm seas, frequenting sandy shores and estuaries.

The American sawfish (Pristis *pectinatus*) is common in the Gulf of Mexico, about the West Indies and occasionally is found on the Atlantic coast as far north as New Jersey. Small ones are excellent food. Some attain a length of 20 ft.; such large specimens are dangerous, the saw being a formidable weapon.

In the skates the large pectoral fins extend to the snout and backward stopping abruptly at the base of the slender tail. Numerous species of the cosmopolitan genus Raja are known, some living at considerable depths; some species reach a weight of 500 lb. These rays swim by undulating or flapping movements of the pectoral fins: their teeth are small and blunt in some species, pointed in others. Skates have two small dorsal fins on the rear part of the tail; they lack a distinct tail fin and also the long, slender recumbent barbed spine that characterizes the tail of stingrays. Their food consists of mollusks, crustaceans and fishes. Skates produce large, oblong eggs with dark, leathery shells having a tendril at each corner by which they become fastened to seaweed or other objects. The largest western Atlantic species is the Barndoor skate (*Raja* laevis), which is said to reach a length of six feet. Its European counterpart is R. *batis*. A Pacific American species, the California skate (*Raja inornata*), which occurs from San Diego to the Strait of Juan de Fuca, is probably the principal species of commerce in the northeastern Pacific. Around 80,000 tons of skates are caught annually in trawls, traps and beach seines and on hook and line. The largest quantities are landed in Japan, France, Great Britain and Spain. The pectoral fins are cut off and used as food.



BY COURTESY OF MIAMI SEAQUARIUM

UNDERSIDE OF SOUTHERN STINGRAY (DASYATIS AMERICANA), FAMILY DASYATIDAE

The remaining rays are collectively termed "whip-tailed," the tail being long and slender and usually having a barbed spine connected with a poison gland; this spine is capable of inflicting serious wounds and is a dangerous weapon when the tail is lashed. All the whip-tailed rays are inhabitants of warm seas, except a few kinds of stingray in the rivers of South America. In the stingrays (Trygon, etc.), as in most of the rays previously described, the teeth are numerous, small and blunt; in the eagle rays (*Myliobatis*) the teeth are relatively few in number, hexagonal, forming a flat pavement, and in the spotted eagle rays (Aetobatus) are reduced to a single series of broad flat teeth used to crush the shells of mollusks.

The largest rays are the devil rays, Manta and *Mobula*, which may measure 20 ft. across the disc. Unlike other whip-tailed rays. they lack the tail spine. Also the anterior ends of the pectoral fins are free and project forward; when rolled up, the edges look like a pair of horns, but when unrolled. they meet below the mouth to form a scoop. Devil rays have been observed pursuing small fishes and scooping them into their mouths.

(C. T. R.; L. A. WD.)

RAYAH, the name given to the subjects of a Mohammedan ruler; in later usage, to all who pay the poll tax levied on unbelievers (Arabic ra'iyah, "flock").

Five classes of rayahs existed under Turkish rule until the system was destroyed by the revolution follo ing World War I. These were: (1) the Greek, or *Roum* milleti; (2) the Armenian, or *Ermeni milleti;* (3) the Catholic Armenians, or *Ermeni* gatoliki *milleti;* (4) the Latin Christians. or Roum gatoliki nzilleti; and (5) the Jews, or Yahoudi milleti.

The name rayah was most commonly used of the peasants, but did not apply to the agricultural populations.

The same term ("ryot") was applied in India to peasants or landholding tenants.

RAYBURN, SAM (SAMUEL TALIAFERRO) (1882–1961), U.S. political leader who served as speaker of the U.S. house of representatives for 17 years, was born in Roane county, Tenn., Jan. 6, 1882. His family, of predominantly Scottish origin, moved to Texas in 1887, and there Rayburn grew up on a 40-ac. farm. He worked his way through East Texas State college at Commerce, taught school, and became a lawyer. He served in the Texas house of representatives for six years (1907–1913) and in 1911 was elected speaker. In 1912 he was elected to the U.S. house of representatives and served there continuously for 48 years and 8 months, a record tenure. He was elected to congress 25 consecutive times.

Energetic, studious, ambitious and affable, Rayburn quickly became influential behind the scenes in government and party politics. As chairman of the powerful congressional committee on interstate and foreign commerce (1931–37), he was a major architect of the New Deal. As a member of the house of representatives he was coauthor of six important laws — Railroad Holding Company act, "Truth-in-Securities" act, Securities Exchange act, Federal Communications act, Rural Electrification act, and the most bitterly contested of all New Deal laws, the Public Utility Holding Company act.

Rayburn was elected Democratic leader of the house of representatives in 1937 and became speaker of the house on Sept. 16, 1940. He held the latter office for 17 years, exceeding by a wide margin the record set by Henry Clay in the first quarter of the 19th century. Noted for his tart common sense, honesty and unflagging patriotism, he was a trusted adviser to Presidents Roosevelt, Truman, Eisenhower and Kennedy. A dedicated party man who described himself as a Democrat "without prefix, without suffix, and without apology," Rayburn was often called "Mr. Democrat." He was permanent chairman of the Democratic national conventions in 1948, 1952 and 1956. After winning the battle in 1961 to enlarge the house committee on rules — the hardest internal house struggle in 50 years — Rayburn's health failed quickly. Before congress adjourned, he went home to Bonham, Tex., where he died on Nov. 16, 1961. (L. B. J.)

RAYLEIGH, JOHN WILLIAM STRUTT, 3RD BARON (1842–1919), British physicist, was awarded the Nobel prize for physics in 1904 for his discovery (1894) of the inert elementary gas, argon, in collaboration with Sir William Ramsay. He was born near Maldon, Essex, on Nov. 12, 1842, and educated at Trinity college, Cambridge, where he graduated senior wrangler (1865). As successor to James Clerk Maxwell he was head of the Cavendish laboratory at Cambridge from 1879 to 1884, and in 1887 he became professor of natural philosophy in the Royal Institution of Great Britain. Elected (1873) a fellow of the Royal society, he was president from 1905 to 1908. He was an original recipient of the order of merit (1902) and a privy councilor (1905). His researches ranged over almost the whole field of physics, including sound, wave theory, optics, colour vision, electrodynamics, electromagnetism, the scattering of light, hydrodynamics, the flow of liquids, capillarity, viscosity, the density of gases, photography and elasticity as well as electrical measurements and standards. His researches on sound were embodied in his Theory of Sound, 2 vol. (1877–78), and his other extensive studies in physics appeared in his Scientific Papers, 6 vol. (1899–1920). Re died on June 30, 1919, at Witham, Essex. (D. McK.)

RAYMOND, HENRY JARVIS (1820–1869), the first editor of the New *York Times,* who did much to elevate the style and tone of newspapers in his day. Born near the village of Lima, Livingston county, N.Y., Jan. 24, 1820, and graduated from the University of Vermont (Burlington) in 1840, he taught, acted as correspondent for various papers, assisted Horace Greeley (*q.v.*) on the *New Yorker* and the *Tribune* and served on the *Courier and Enquirer* before he obtained backing for a venture of his own. The first issue of the *New York Times* appeared Sept. 18, 1851. Of this journal Raymond was editor and chief proprietor until his death. Raymond was a member of the New York assembly in 1850 and speaker in 1851 and again in 1862. He supported the views of the radical antislavery wing of the Whig party in the north. His nomination over Greeley on the Whig ticket for lieutenant governor and his election in 1854 led to the final dissolution of the famous political alliance of Seward, Weed and Greeley. He took a prominent part in the formation of the Republican party. and drafted the famous "Address to the People" adopted by the Republican convention that met in Pittsburgh, Pa., in Feb. 1856. He was a member of the national house of representatives in 1865–67. He retired from public life in 1867 and devoted his time to newspaper work until his death in New York city, June 18, 1869. He published several books, including a biography of Abraham Lincoln, which in substance originally appeared as *A History of the Administration of President Lincoln* (1864) and which with additions was republished under varying titles.

See A. Maverick, *Henry J. Raymond and the New York Press for Thirty Years* (1870); F. Brown, *Raymond* of *The Times* (1951).

RAYMOND, ROBERT RAYMOND, 1ST BARON (1673–1733), a great English judge, who became lord chief justice, was born on Dec. 20, 1673, the son of Sir Thomas Raymond. a judge under Charles II. He entered Gray's Inn in 1682 and was called to the bar in 1697. He soon acquired an extensive common-law practice, and in 1710 became solicitor general and member of parliament for Lymington, Hampshire, and was knighted. He lost office with the accession of George I in 1714, but by 1720 his Jacobite sympathies had been sufficiently forgiven for Lord Stanhope to make him attorney general. His position was uneasy. however, and in 1724 he surprisingly became a mere puisne judge of the king's bench. He at once displayed judicial powers of the highest order, and this, coupled with Walpole's admiration, led to his appointment as one of the lords commissioners of the great seal on Lord Macclesfield's disgrace in 1725. In the same year he succeeded Sir John Pratt as lord chief justice of the king's bench, an office which he held until his death on March 18, 1733; he had become a peer in 1731. Lord Raymond was a great judge, especially in criminal matters, and his reports, covering nearly 40 years, have a high reputation.

See Lord Campbell, *Lives of the Chief Justices* (1858).

(R. E. MY.)

RAYMUND (1099–1149), prince of Antioch, called RAYMUND OF POITOU, was the son of William VII, count of Poitiers (William IX of Aquitaine), and Philippa of Toulouse. On the death of Bohemund II of Antioch, the principality devolved upon his daughter. Constance, a child of less than ten years of age (1130). Fulk, king of Jerusalem and, as such, guardian of Antioch, sent envoys to England to offer her hand to Raymund, who was then at the court of Henry I. Raymund reached Antioch in 1135, where he was married to Constance. As prince of Antioch he faced no easy task Alice, the mother of Constance, uho had expected Raymund to marry her. was hostile to him. The atabeg Zengi, now firmly established in both Mosul and Aleppo, was beginning to extend his possessions at the expense of Antioch. while the eastern emperor. John II Comnenus. was preparing to enforce his claims to suzerainty over the city. In 1137 Raymund was forced to do homage to the emperor, and even to promise to cede his principality as soon as he was recompensed by a new fief. which John promised to carve for him in the Mohammedan territory to the east of Antioch. The expedition of 1138, in which Raymund joined with John and which was to conquer this territory, failed. The emperor made a solemn entry into Antioch, but the city was never handed over to him, and at his death in 1143 he still did not control the principality. Zengi's conquest of Edessa in 1144 and the subsequent collapse of that Frankish county further weakened Raymund's position. He was forced to visit Constantinople and to renew his oath of homage to Manuel I Comnenus. In 1149 he fell in battle against Nureddin, Zengi's successor.

(R C SMA.)

RAYMUND IV (c. 1042–1105), count of Toulouse, called also RAYMUND OF SAINT-GILLES (from his original countship), leader of the Provencal contingent on the first crusade, was the younger son of Pons, count of Toulouse (died 1061). Raymund became marquis of Provence by his marriage to his first cousin the heiress (1066); but this marriage was condemned by the church, and their son Bertrand held to be a bastard Raymund's second marriage (1080) was with Matilda of Sicily, niece of Robert Guiscard, his third (1094) with Elvira, daughter of Alphonso VI of Castile. In 1093, on the death of his brother Count William IV (with whom he had divided the paternal heritage), Raymund succeeded to the whole countship of Toulouse.

Having previously fought against the Moors in Spain, Raymund was the first of the princes of the west to take the cross after Pope Urban's sermon at Clermont. The oldest and the richest of the crusading princes, the count of Toulouse started, in Oct. 1096, with a large company, which included his wife. his son and Adhemar of Monteil, the papal legate. His march lay by Ragusa and Scutari to Durazzo, whence he struck eastward. along the route also used by Bohemund, to Constantinople. At the end of April 1097 he was with difficulty induced to take a somewhat negative oath of fealty to Alexius. He was present at Nicaea and Dorylaeum; but he first showed his hand in Oct. 1097, when. as the army neared Antioch and a rumour was spread that Antioch had been deserted by the Turks, he sent a detachment in advance to occupy the city—an action which presaged his future difficulties with Bohemund (*q.v.*), the would-be prince of Antioch.

In the siege of Antioch (which was far from having been deserted) Raymund played his part. When the city was taken by Bohemund (June 1098), the count garrisoned the palace of the amir Yagi Sian and the tower over the Bridge gate. He lay ill during the second siege of Antioch by Kerbogha; but in his camp a great spiritualistic activity culminated in the discovery of the Holy Lance by the Provençals. The miracle stimulated the crusaders to defeat Kerbogha; the Lance itself, discovered by the Provencals and carried thenceforward by their count, became a valuable asset in Raymund's favour. A struggle arose between the Provencals and the Normans, partly with regard to the genuineness of the Lance and partly with regard to the possession of Antioch. Raymund moved southward in the autumn of 1098 to the siege of Marra, leaving a detachment of his troops in Antioch. With Bohemund left in Antioch. with the Holy Lance to give him prestige and with the wealth which he had at his disposal, the count of Toulouse began to figure as the leader of the crusade. But he delayed the advance to Jerusalem to besiege Arca with the intention of founding a principality to check the extension of Bohemund's kingdom. A wave of indignation in the ranks and the inducements which the amir of Tripoli offered to the other princes forced Raymund to desist from the siege (May 1098) and to march southward to Jerusalem. Bohemund meanwhile had expelled Raymund's men from Antioch. Raymund took part in the storming of Jerusalem, but he hampered Godfrey in the campaigns which followed.

Raymund had come to the east with the intention of founding a principality. During the crusade his ambition had been thwarted at Antioch, Marra. Arca, Jerusalem and Ascalon. He then decided to advance his interests by upholding Byzantine claims in Syria. In Sept. 1099 he joined forces with the Greek garrison of Laodicea. then besieged by Bohemund. From Laodicea he went to Constantinople, where he fraternized with Alexius, the great enemy of Bohemund Joining in the ill-fated crusade which followed the first, he escaped from the debacle and returned to Constantinople. In 1102 he went by sea from Constantinople to Antioch, where he was imprisoned by Tancred, regent of Antioch during the captivity of Bohemund. and dismissed only upon promising not to attempt any conquests in the country between Antioch and Acre. He broke his promise, attacking and capturing Tortosa and beginning to build a castle on the Mons Peregrinus for the reduction of Tripoli, of which he is recognized as the first count (Raymund I). In this policy he was aided by Alexius. In 1105 Raymund died. He was succeeded by his nephew William who, in 1109, with the aid of Baldwin I, captured the town and definitely established the county of Tripoli. William was ousted in the same year by Raymund's eldest son Bertrand, and the county continued in the possession of his house during the 12th century. After partition between Bertrand and Alphonse (*q.v.*; Raymund's son by his third marriage), the county of Toulouse was united under Alphonse alone on Bertrand's death in 1112.

RAYMUND **III** (d. 1187), count of Tripoli, was the most famous of the descendants of Raymund IV of Toulouse (reckoned as Raymund I of Tripoli), a great-grandson of his eldest son Bertrand and son of Raymund II and Hodierna, a daughter of Baldwin II of Jerusalem. He became count of Tripoli in 1152, on the assassination of his father. He was captured by Nureddin in 1164 and was released in 1172 after a captivity of eight years. In 1174 he claimed the regency on behalf of Baldwin IV (*q.v.*) (at once a minor and a leper) in virtue of his close relationship, and the claim was acknowledged. After two years the regency passed successively to the two husbands of Sibyl, the king's sister and heiress; but Raymund, who had married the heiress of the county of Tiberias, continued to figure in the affairs of the kingdom. His great ability procured him enemies; for two years, 1180–82, they induced Baldwin IV to exclude Raymund from his territories. But as Saladin grew more threatening, Raymund grew more indispensable; and in 1184, when Guy of Lusignan, Sibyl's second husband, had proved his incapacity, Raymund became regent for Baldwin V, on condition that, if the king died before his majority, his successor should be determined by the great powers of the west. Raymund conducted the regency with skill, securing a truce from Saladin in 1185; but when Baldwin V died, in 1186, the supporters of Guy of Lusignan had him crowned, in defiance of the stipulation under which Raymund had become regent. Raymund, left in isolation. retired to Tiberias and negotiated a truce for himself with Saladin. His ambiguous position led contemporaries to accuse him of treasonable correspondence with Saladin; but his loyalty to the Christian cause was nobly shown in 1187, when he reconciled himself to Guy and aided him in the battle of Hattin, which was engaged, however, against his earnest advice. He escaped from the battle wounded and ultimately retired to Tripoli, where he died. With the growth of faction which marked the reign of Baldwin IV. Raymund emerged as leader of the native baronage against the "court" party that included the Lusignans, the Courtenays and Raynald of Châtillon. He was the most able statesman among'the Syrian Franks and might well have saved the Latin kingdom from its destruction by Saladin. (R. C. SMA.)
