The church was organized for its work, but the conditions which it faced were full of difficulties. As a result of the Revolutionary War there was much popular prejudice against any institution claiming connection with England, in the communities influenced by Puritanism there was strong opposition to the principles and teachings of the Episcopal Church and there were divisions within its own household. At the convention of 1811 only one of the six bishops attended: and there were few more clergy and laymen present. than in 1789.

Period of New **Vigour.**—With the coming of a new generation, the church found more vigorous leaders, whose zeal and devotion were exemplified in the careers of three men. John Henry Hobart, Alexander Viets Griswold and Richard Channing Moore, consecrated bishops respectively of New York, the eastern diocese and Virginia. In Virginia, Bishop Moore's powerful preaching and strong personality roused the church to new life. Bishop Griswold's diocese included an immense region comprising the collapsed diocese-of Massachusetts (which had already had two bishops, Edward Bass in 1797 and Samuel Parker in 1804), Maine, Rhode Island, New Hampshire and Vermont. His achievements were truly amazing; with only 16 clergy in all at the outset of his episcopate, he had the satisfaction of ending it with a five-fold increase in the number both of parishes and communicants, and with .the redivision of his cumbersome territory into five separate dioceses.

Bishops Griswold and Moore were Evangelicals. Bishop Hobart, who had brill ant success in building up the church in New York state and founded a number of important church institutions, was a high churchman who anticipated some of the positions of the Oxford movement. An awakening interest in theological education led to the foundation of General Theological seminary in New York in 1819, and of the Theological seminary in Virginia in 1824.

The church was now aroused to meet the new conditions and opportunities of its reconstituted life. The Domestic and Foreign Missionary society, founded in 1820, gave fresh impetus to the work of church extension. In 183j its membership was made co-extensive with the church. Philander Chase, the pioneer bishop of the west, did his great work in Ohio and founded Kenyon college, obtaining from churchmen in England funds for this undertaking; Jackson Kemper. the first officially designated missionary bishop, went further into the northwest where his arduous labours prepared the way for future dioceses; James Harvey Otey did noble missionary work in Tennessee and the southwest. James Lloyd Breck. priest and missionary, founded Nashotah hall, originally an associate mission. but later a theological seminary, in Wisconsin; he also started schools in Minnesota, at Faribault, and pushed on across the country. establishing new foundations as he went, until he reached the Pacific coast. During this period the Episcopal Church grew steadily from a proportion of 1 communicant to 400 of the population in 1830 to 1 communicant to 107 at the end of the century. With the growth and development of the country new dioceses and missionary districts were established. In 18j3 Bishop William I. Kip began his labours as first bishop of California; in 1854 bishops were consecrated for Oregon and Iowa; in 1859 Bishop Henry B. Whipple was sent to Minnesota to take up his work among white people and Indians. Foreign missionary work was begun with the opening of an educational mission in Greece in 1829, and expanded with the founding of missions in Liberia in 1835, China in 1840 and Japan in 1859.

The Oxford movement. whose influence began to be felt in the United States during the 1840s, though destined to enrich and broaden the life of the church, excited a bitter controversy which was interrupted but not ended by the Civil War. The hluhlenberg memorial, presented to the house of bishops in 1853, made an impassioned plea to the church to rise above partisanship and realize the full possibilities of its position. Its proposals were too daring for the time, but many of them were later adopted in modified forms. The spirit of controversy reached its peak at the General convention of 1874, but gradually subsided thereafter, through a growing realization that the church's nature was essentially comprehensive and that its Catholic and Protestant traditions could both make important contributions to its mission. The rise of the liberal movement aided in the growth of this realization.

Civil War and After.—The Civil War necessarily led to a separate administration of the church in the confederate states, but the whole body was quickly reunited at the close of the conflict. The war period saw the formation of two new seminaries, the Philadelphia Divinity school and the Episcopal Theological school at Cambridge, Mass. During the years following, the church-controlled University of the South was organized at Sewanee, Tenn.

After the period of the Civil War, the church made progress, its growth more than keeping pace with the increase in population. Its organization came to cover every part of the United States and its dependencies, and it continued to expand its missionary work in other lands, with bishops and organized missionary work in Alaska, Puerto Rico, the Panama Canal Zone, the Hawaiian Islands, the Republic of the Philippines, Cuba, Mexico, Brazil, China, Japan, Liberia, Haiti and the Dominican Republic. In 1867 and thereafter, bishops of the Episcopal Church participated periodically in conferences of the entire Anglican episcopate held at Lambeth, Eng.

Among the educational institutions of the church in the latter 1950s were Trinity college, Hartford, Conn.; the University of the South, Sewanee. Tenn.; Hobart college. Geneva. N.Y.; Kenyon college, Gambier, O.; St. Augustine's college, Raleigh, N.C.; and St. Paul's Polytechnic institute, Lawrenceville, Va. The theological schools, in addition to the General Theological seminary in New York (official institution of the whole church) and the Virginia seminary previously mentioned, were the Berkeley Divinity school, New Haven. Conn.; the Divinity school, Philadelphia; the Episcopal Theological school. Cambridge, Mass.; Nashotah house. Nashotah. Wis.; the Theological school. Sewanee. Tenn.: the Seabury-Western Theological seminary. Evanston, Ill.; the Church Divinity School of the Pacific. San Francisco, Calif.; The Episcopal Theological Seminary of the Southwest. Austin. Tex.; Bexley hall, Gambier. O. The church also had established! especially in the east; many important schools for boys and girls.

Church Development. — The life of the church continued to find expression in a great number of societies and organizations, such as the Women's auxiliary to the National council; the Brotherhood of St. Andrew; the Girls' Friendly society; the Church Association for Seamen's Work; the Social Service commissions; the church clubs of the various dioceses; the Episcopal Service for Youth; the American Church union; and the Church congress in the United States. Among the religious orders in the latter 1950s were the Society of Mission Priests of St. John the Evangelist; the Order of the Holy Cross; St. Barnabas brotherhood; the Community of St. Mary; the Community of St. John the Baptist: the Society of St. Margaret; the All Saints Sisters of the Poor; the Sisterhood of the Holy Nativity; and others. The institutions for the training of deaconesses included the New York Training School for Deaconesses; and the Central House of Deaconesses, Sycamore, Ill. St. Margaret's house, Berkeley, Calif., and Windham house, New York city, provided training for women church workers.

The governing body of the Protestant Episcopal Church is the General convention which meets every three years, and which consists of the house of bishops and the house of deputies, the two houses sitting and deliberating separately. The house of bishops has as its members all the bishops of the church. The house of deputies is composed of not more than four presbyters and four laymen elected by each diocese and not more than one presbyter and one layman elected by each missionary district. Either house may originate and propose legislation, and all acts of the convention must be adopted and authenticated by both houses. In the house of deputies the vote on any question may be taken by orders, the clerical and lay deputies voting separately and a concurrent vote of the two orders being required for the adoption of the resolution. The laity thus have their full share and responsibility in the legislative action of the church. No alteration in the Book of Common Prayer may be made unless this is proposed at one meeting of the General convention and adopted at the next succeeding triennial meeting. Each diocese holds its own annual convention, presided over by the bishop, in which both clergy and laity have their part. The diocese adopts its own constitution and canons for the regulation of its internal affairs, with the provision that these must not conflict with the constitution and canons of the General convention. A bishop is elected by the diocese, but the election must be confirmed by a majority of the bishops exercising jurisdiction within the United States, and by a majority of the standing committees of all the dioceses. Missionary bishops are elected by the house of bishops, the choice being subject to confirmation by the house of deputies if the General convention is in session. and at other times by a majority of the standing committees of the several dioceses. As regards the ministry, the Episcopal Church, in common with the Anglican Communion, holds to the historic threefold order of bishops, priests and deacons. The official pronouncements on this subject are contained in the Preface to the Ordinal. The constitution of the church (article viii) provides that no person shall be consecrated bishop, or ordained priest or deacon, until he shall have made in writing, in presence of the ordaining bishop or bishops, the following declaration: "I do believe the Holy Scriptures of the Old and New Testaments to be the Word of God and to contain all things necessary to salvation; and I do solemnly engage to conform to the Doctrine, Discipline, and Worship of the Protestant Episcopal Church in the United States of America." And every person before being baptized and received into membership in the church is required to answer affirmatively the question "Dost thou believe all the articles of the Christian Faith as contained in the Apostles' Creed?" Neither the clergy nor the laity are required to subscribe to the Thirty-Nine Articles.

Church Activities. — An important change in the organization of the church was made in 1919 by the establishment of a national council. with the presiding bishop at its head, to act as the executive body of the General convention between its sessions, and to have charge of the general missionary, social and educational work of the church; with the provision that, for the future, the presiding bishop should be elected instead of succeeding to this office by seniority of consecration. The national council gave new impetus to the work of the church and strengthened its corporate life. The revision of the Book of Common Prayer, undertaken in 1913, was completed in 1928.

At the General convention in 1910 a movement was initiated to bring about a world conference on faith and order. After 17 years of preparation and effort, the conference was held in 1927 at Lausanne, Switz., and was attended by representatives of all the major churches of Christendom with the exception of the Roman Catholic Church. Similar conferences were held in Oxford in 1937 and in Amsterdam, Neth., in 1947. The Episcopal Church joined the Federal Council of the Churches of Christ in America (later the rational Council of Christian Churches) in 1940. Missionary work in Asia was disrupted by World War II. It was renewed with fresh vigour afterward though it was soon confronted with new problems resulting from the rise of Communism in China and the general resistance of the eastern world to western institutions. In the latter 1950s there were 102 dioceses and missionary districts, about 1,923,000 communicants and 7,900 members of the clergy.

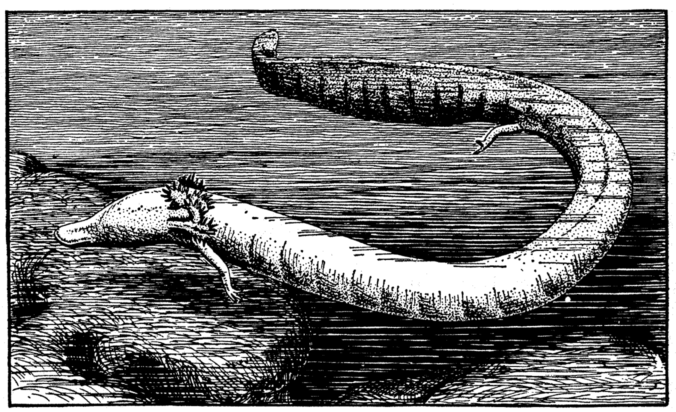
PROTEUS or OLM, a blind, water-breathing, tailed amphibian (*Proteus anguinus*) inhabiting the limestone caves to the east of the Adriatic. It is a small eel-like salamander, with minute limbs, the anterior pair having three toes on each, the posterior



CAVE SALAMANDER OF EUROPE CALLED THE "OLM" (AFTER BREHM) two; a narrow head, with flat truncate snout; minute vestigial eyes hidden under the skin which is pale flesh-coloured. with the short, plumelike external gills blood-red. Proteus forms with the American *Necturus* the family Proteidae. The second genus is more generalized in structure, with better developed limbs, with four digits, and is adapted to live in the light. Its thyroid gland is very much reduced, but, unlike the axolotl it cannot be transformed into a terrestrial form by feeding with thyroid. Exposure to white light causes the skin to become black, even over the eyes; however. in red light, no blackening occurs, and the eyes grow large and functional. See also SALAMANDER.

See H Gadow, Amphibia and *Reptiles* (Cambridge Natural *Hist.*)

PROTEUS, the prophetic old man of the sea in Greek mythology and shepherd of the sea's flocks (seals, etc.). According to Homer, his dwelling place was the island of Pharos, near the mouth of the Nile; in Virgil his home is the island of Carpathus, between Crete and Rhodes. He knew all things, past, present and future, but disliked telling uhat he knew Those who wished to consult him had first to surprise and bind him during his noonday slumber in a cave by the sea, where he spent his time during the heat of the day surrounded by his seals. Even when caught he would try to escape by assuming all sorts of shapes, that of a lion, a serpent, a leopard, a boar, a tree, fire. water. But if his captor held him fast the god at last returned to his proper shape, gave the wished-for answer and plunged into the sea. He was subject to Poseidon. In post-Homeric times the story (invented by the Greek lyric poet Stesichorus?) ran that Proteus was the son of Poseidon and a king of Egypt, to whose court Helen was taken by Hermes after she had been carried off, Paris being accompanied to Troy by a phantom substituted for her. This is the story followed by Herodotus, who got it from Egyptian priests, and by Euripides in the Helena. From his power of assuming whatever shape he pleased, Proteus came to be regarded, especially by the Orphic mystics, as a symbol of the original matter from which the world was created.

PROTHESIS, in the liturgy of the Orthodox Eastern Church, the name given to the act of "setting forth" the oblation; *i.e.,* the arranging of the bread on the paten, the signing of the cross on the bread with the sacred spear, the mixing of the chalice and the veiling of the paten and chalice (Gr. prothesis, "a setting forth"). In Eastern Orthodoxy the more common term for the preparation of these elements is "proskomide." The term is used, architecturally, for the place in which this ceremony is enacted, a chamber on the north side of the central apse in a Greek church; the term is also applied to the small table on which it is done.

During the reign of Justin II (565–574) this chamber was located in an apse and another apse was added on the south side for the diaconicon, so that from his time the Greek church was triapsal. In the churches in central Syria both prothesis and diaconia are generally rectangular, and the former constitutes a chamber for the deposit of offerings by the faithful. Consequently it was sometimes placed on the south side, if when so placed it was more accessible to the pilgrims. There is always a much wider doorway to the prothesis than to the diaconicon. There are cases where a side doorway from the central apse leads direct to the diaconicon, but never to the prothesis.

PROTIĆ, STOJAN (1857–1923), Yugoslav statesman, was born at Krusšvak Jan. 29, 1857. He entered the government service and soon came into conflict with the repressive régime of King Milan. In 1882 Protić became editor of Samouprava and a leader of the new Radical party. He was imprisoned for a press offense in 1883 and again in 1885. He held subordinate posts in the Radical cabinet of 1887. In 1899 an attempt on King Milan's life mas used by the government to rid itself of its Radical rivals. Protić was sentenced to 20 years' hard labour, although, in fact, he had no connection with the crime. Pardoned nine months later. he became director of the National library. After the revolution of 1903 he represented the Radicals in the first provisional cabinet under King Peter and remained minister of the interior in most of the succeeding cabinets down to 1907.

Protić was finance minister during the Bosnian crisis and again became minister of the interior during the period of the Balkan Wars and the European crisis of 1914. In 1914, when leaders of the secret "Black Hand" organization were implicated in the murder of Serajevo, this organization was actually at daggers drawn with the Serbian government owing to a quarrel with Protić.

Protić remained out of office during the period of coalition government from Dec. 1914 to June 1917, but continued to exercise great influence in the background. He was returned to officein 1917 and played an active part in the negotiations leading to the Corfu agreement between the Serbian government and the Yugoslav committee.

He showed more comprehension for the Croat and Slovene standpoint than his colleague Pašić, and when the conflict between Pašić and Trumbić in 1918 delayed the recognition of Yugoslavia by the Allies and created an awkward situation with Italy, Protić was appointed the first premier of the new Yugoslav state. He was keenly interested in the constitutional problem, and after his resignation in Aug. 1919 published his own draft project.

Disagreeing with the exaggerated centralism of Pašić, he declined office in 1921 and drifted steadily away from his old colleague.

Protić died in Belgrade in Nov. 1923.

His publications include The Aspirations of Bulgaria (1916) and Le *problème Albanais,* etc. (1913), issued under the pseudonym of "Balkanicus."

PROTISTA: see PROTOZOA.

PROTOCOL, in diplomacy, the name given to a variety of written instruments.

In diplomacy the name of "protocol" is given to the minutes (*procès-verbaux*) of the several sittings of a conference or congress; these, though signed by the plenipotentiaries present, have only the force of verbal engagements (see CONFERENCE, INTERNATIONAL). It is also given to certain diplomatic instruments in which, without the form of a treaty or convention being adopted, are recorded the principles or the matters of detail on which an agreement has been reached, *e.g.,* making special arrangements for carrying out the objects of previous treaties, defining these objects more clearly, interpreting the exact sense of a doubtful clause in a treaty (protocoles *interpretatifs*) and the like.

Occasionally also an agreement between two or more powers takes the form of a protocol, rather than a treaty, when the intention is to proclaim a community of views or aims without binding them to eventual common action in support of those views or aims.

Finally, "the protocol" (protocole diplomatique, protocole de chancellerie) is the body of ceremonial rules to be observed in all written or personal official intercourse between the heads of different states or their ministers. It lays down the styles and titles of states, their heads and public ministers. and indicates the forms and customary courtesies to be observed in all international acts. "It is," says M. Pradier-Fodéré, "the code of international politeness."

PROTOGENES, a Greek painter, born in Caunus, on the coast of Caria, but resident in Rhodes during the latter half of the 4th century B.C. He was celebrated for the minute and laborious finish which he bestowed on his pictures, both in drawing and in colour. Apelles, his great rival, standing amazed in the presence of one of these works, could only console himself by saying that it was wanting in charm. On one picture, the "Ialysus," Protogenes spent seven years; on another, the "Satyr," he worked continuously during the siege of Rhodes by Demetrius Poliorcetes (305–304 B.C.). notwithstanding that the garden in which he painted was in the middle of the enemy's camp. Demetrius, unsolicited, took measures for his safety; more than that, when told that the "Ialysus" just mentioned was in a part of the town exposed to assault. Demetrius changed his plan of operations. Ialysus was a local hero, the founder of the town of the same name in the island of Rhodes, and he was probably represented as a huntsman. This picture was still in Rhodes in the time of Cicero, but was afterwards removed to Rome', where it perished in the burning of the Temple of Peace.

The picture painted during the siege of Rhodes consisted of a satyr leaning idly against a pillar on which was a figure of a partridge, so lifelike that ordinary spectators saw nothing but it. Enraged on this account, the painter wiped out the partridge. The "Satyr" must have been one of his last works. He would then be about 70 years of age, and had enjoyed for about 20 years a reputation next only to that of Apelles, his friend and benefactor. Both were finished colourists so far as the fresco painting of their day permitted, and both were laborious in the practice of drawing, doubtless with the view to obtaining bold effects of perspective as well as fineness of outline. It was an illustration of this practice when Apelles, finding in the house of Protogenes a large panel ready prepared for a picture, drew upon it with a brush a very fine line which he said would tell sufficiently who had called. Protogenes on his return home took a brush with a different colour and drew a still finer line along that of Apelles, dividing it in two. Apelles called again, and thus challenged. drew with a third colour another line within that of Protogenes, who then admitted himself surpassed. This panel was seen by Pliny in Rome, where it was much admired, and where it was destroyed by fire.

In the Propylaea at Athens was a painting by Protogenes representing personifications of the coast of Attica, Paralus and Hammonias. For the council chamber at Athens he painted figures of the Thesmothetae, but in what form or character is not known. Probably these works were executed in Athens, and it may have been then that he met Aristotle, who recommended him to take for subjects the deeds of Alexander the Great. In his "Alexander and Pan" he may have followed that advice in the idealizing spirit to which he was accustomed. To this spirit must be traced also his "Cydippe" and "Tlepolemus," legendary personages of Rhodes. Among his portraits are mentioned those of the mother of Aristotle, Philiscus, the tragic poet, and King Antigonus. Protogenes was also a sculptor to some extent, and made several bronze statues of athletes, armed figures, huntsmen and persons in the act of offering sacrifices.

PROTON, a particle which is the nucleus of the hydrogen atom and a constituent of the nuclei of other atoms. It carries a positive electric charge.

Historical Background. — Lord Rutherford, in the course of experiments performed in 1919 during which he bombarded atoms of the lighter gases with alpha particles, found that the atoms disintegrated under the impact, liberating particles that he believed to be hydrogen nuclei. At the Cardiff meeting of the British Association for the Advancement of Science (1920), Rutherford suggested the name proton — Greek for "the first" — for the nucleus of the hydrogen atom, to denote that it is a primary substance. In the same year, in the Bakerian lecture at the Royal society. he offered the speculation that there might exist yet another particle, this one electrically neutral. This hypothetical particle — the neutron — was brought from the realm of speculation to reality in 1932 by a succession of discoveries by W. Bothe, Frédéric Joliot-Curie and Sir James Chadwick, who made the decisive experiments. The nuclei of all atoms except hydrogen contain neutrons as well as protons. In the case of hydrogen, the atom consists of a single proton as the nucleus, plus a single electron.

Characteristics. — The main properties of the proton are its electric charge. mass, spin, magnetic moment and statistics. The charge, e, is identical in magnitude to the charge of the electron, 4.8029×10^{-10} esu (electrostatic units), but of opposite sign; and the mass of the proton is 1.007596 esu, or 1.6729×10^{-24}g. This is 1,836.2 times as large as the mass of the electron. It is thus apparent that almost the entire mass of an atom is concentrated in the nucleus. The equality in magnitude of the charge of the proton and of the electron is shown by the fact that hydrogen atoms are neutral; hence, in order to know the charge e it makes no difference whether one measures the charge of the proton or of the electron. The latter is perhaps technically easier to measure. The mass of the proton may be determined by mass spectrograph experiments involving the deflection of a beam of protons of known velocity in a known magnetic field. In this way one obtains a measurement of the momentum mv of the proton which, once the velocity v is separately measured, gives the mass *m*.

In addition to charge and mass, the proton has an intrinsic angular momentum or spin of magnitude $\frac{1}{2}h/2\pi$ where h = 6.6252×10^{-27} erg-sec. (Planck constant). If we visualize a proton as a little sphere of matter, the spin tells us that the proton is rotating around an axis in a way similar to the rotation of the earth around the polar axis. The proton spin is revealed by a detailed study of the hydrogen atom spectrum and by many other phenomena. Connected with the spin there is a magnetic moment $\mu_p = 1.4104 \times 10^{-27}$ erg per gauss. In terms of the natural unit $he/4\pi m_p c$ (where m, is the mass of the proton and c the velocity of light), this moment has the value 2.7928. This means on our model that the small rotating sphere also has north and south magnetic poles similar to those of the earth. The magnetic moment of the proton, and its spin, can be measured spectroscopically or, with extreme precision, by magnetic methods involving the currents induced by the nuclear magnetic moments of the protons moving in a constant magnetic field. The size of the proton (or its radius, if we consider it as a sphere) is not precisely defined because its value depends on what phenomenon or method we use to measure it. For instance, we can use the exploration of the electric charge density by observing the deviation of high energy (600 Mev) electrons projected on a proton; we thus obtain a radius of 1.2×10^{-13} cm. Similar values are obtained by considering the neutron-proton collision at high energy in which only specific nuclear forces are operative.

In addition to the properties mentioned above, the proton has a very important characteristic which is expressible only in terms of quantum mechanics: it obeys Pauli's exclusion principle. This can be expressed by saying that in a system there cannot be two or more protons with the same quantum numbers, or that the wave function of a system containing several protons must be symmetrical with respect to the exchange of any two protons. This property has far reaching consequences in nuclear structures and is one of the most fundamental ones shared by proton, neutron, electron and other particles having spin $\frac{1}{2}\, h/2\pi$. A nucleus of mass number A having a positive electric charge Ze contains Z protons and has a number of neutrons N given by the number $A -$ Z. A is the integer closest to the number expressing the nuclear mass M in units equal to the 16th part of the mass of the oxygen nucleus, O^{16}.

The Proton in Theoretical and Applied Science. — The proton appears in many different aspects in a variety of chemical and physical phenomena. For example. as the hydrogen ion, it plays a very important role in chemistry, especially in all aqueous solutions (see HYDROGEN IONS). In spectroscopy it is the centre around which the electron revolves in the hydrogen atom, giving rise to the hydrogen spectrum, one of the most important subjects in atomic physics. In nuclear physics the proton is commonly used as a projectile to bombard other nuclei in modern particle accelerators such as the cyclotron or the bevatron.

In nuclear bombardments at relatively low energies, up to a few million electron volts, the general behaviour of the proton is to enter the nucleus, if it has enough energy to overcome the electrostatic repulsion of the target nucleus. Having entered the target nucleus it produces enough excitation to evaporate other particles from it. For instance if it evaporates one neutron, the target nucleus does not change its mass number, but is transformed into an element with the atomic number (Z) one unit larger.

At very high energies the proton gives rise to a host of more complicated effects connected with the structure of the nucleons (neutrons and protons are called nucleons). It is by proton bombardments that mesons, hyperons and antinucleons are most frequently produced in the large accelerators.

It is a matter of great importance that the number of protons plus the number of neutrons is conserved in all nuclear reactions. This principle of the conservation of the nucleons is at present to be considered as an empirical fact still disconnected from the other fundamental principles of physics.

P. A. M. Dirac of England pointed out in 1928 that the phenomena of nature exhibit a special kind of symmetry between the positive and negative electric charge. On this basis he predicted the possible existence of the positive electron (positron), later discovered in 1932 by C. D. Anderson. Dirac's theory predicted also the possible existence of a negatively charged proton (antiproton) mhich was discovered in 19jj by Owen Chamberlain, Emilio Segrè, Clyde Wiegand and Thomas Ypsilantis. The theory predicted the following properties for this particle: (1) it has the same mass as the proton; (2) it has equal but opposite electric charge; (3) it has the same spin as the proton; (4) it has a magnetic moment opposite to that of proton; (5) it is stable in the sense that when isolated in a vacuum it does not transform spontaneously into other particles; (6) antiprotons and nucleons annihilate each other in pairs; (7) antiprotons and protons are generated in pairs.

Property (4) means that a proton and an antiproton having their spin equally oriented have opposite magnetic moments, or that if the two small rotating spheres representing them rotate in the same way, their magnetic north and south poles are interchanged.

Properties (6) and (7) are not in contradiction with the principle of conservation of nucleons. On the contrary, if we consider an antiproton as "minus one proton," the condition that generation and annihilation occur only in pairs becomes a direct consequence of the conservation of nucleons. The fact that one antiproton and one proton must be generated together determines a high energy threshold for this process. Thus, for instance, the production by proton-proton collision can occur only at a projectile energy higher than 5.6×10^9 ev (electron volts) in the laboratory system; hence, huge accelerating machines are necessary. Antineutrons are characterized by a set of properties which bear a relation to those of the neutron similar to those listed above for the antiproton in relation to the proton. In particular properties 1, 2, 4, 6, 7 are the same provided the word neutron is substituted for proton and antineutron for antiproton. Neutron and antineutron are both electrically neutral and both spontaneously undergo a beta decay the neutron emitting electrons, the antineutron positrons.

Antineutrons have been generated from antiprotons by causing the antiproton to collide with a proton. In this process most frequently the proton and antiproton annihilate each other, generating pi mesons, but in about 1% of the cases they disappear, generating a neutron-antineutron pair. The antineutron is best detected in the subsequent annihilation process with a nucleon.

The symmetry between positive and negative electricity manifested by the electron and positron, and nucleon and antinucleon, opens the possibility of the existence of "antimatter." This would be formed by atoms in which every nucleon is replaced by the corresponding antinucleon and every electron by a positron. In many ways this antimatter would be indistinguishable from ordinary matter. For example, no ordinary astronomical observation including the study of the spectra and of the Zeeman effect, could distinguish between matter and antimatter in a star. However, a collision of matter and antimatter would result in annihilation with the immediate production of pi mesons which would in turn decay, leaving as their ultimate residue gamma rays, neutrinos and, if the system is not initially electrically neutral, electrons.

As of the late 1950s there was no experimental evidence in favour of or against the existence of antimatter in the cosmos. From a cosmic point of view the existence of antimatter would allow the creation of the universe from energy without the violation of the principle of the conservation of nucleons.

PROTOPHYTA. The designation Protophyta ("primitive plants") is applied to all simple one- or many-celled organisms that obtain their carbohydrates by means of photosynthesis. The Protophyta are not a natural division of the plant kingdom since they include organisms from various divisions of an algal nature.

There is diversity of opinion concerning what should be considered a "primitive plant." Many restrict them to those algae in which the vegetative cells are flagellated and motile. According to such an interpretation the Protophyta would include the motile members of the Chlorophyta, Chrysophyta and Pyrrophyta (see ALGAE). (G. M. S.)

PROTOPLASM is the actual living substance of the cells of animals and plants. It is a highly organized system endowed with properties, the sum total of which is life. The term was introduced long after the discovery of the microscope and not until investigators began to be aware of a visible substance enclosed within what had been known as cells of plants and animals. It was probably first coined in 1839 by Johannes Evangelista Purkinje (1787–1869) of Prague, who adopted it from Protoplastus, a liturgical term having reference to Adam. Shortly thereafter Hugo von Mohl (1805–72), a German botanist, applied the same term, as meaning "first plasma," to the slimelike, granule-filled material which he observed undergoing circulatory movements within plant cells. In 1835 Felix Dujardin (1801–60), a French protozoologist, had introduced the term sarcode for the material he saw in protozoa which had been called a living jelly. He described it as "a substance, viscid, translucent, homogeneous, elastic and contractile." In 1861 Max Schulze (1825–74) called attention to the similarity of the protoplasm of plants and animals and of the sarcode of protozoa and proposed the term protoplasm for the physical basis of all life. Thus, the unification of biological science was begun by the recognition of the cell and of its protoplasm as the physical basis of all living beings.

The multifarious activities of protoplasm within the dimensions of a living cell require a complexity of constitution and structure. The earlier investigators sought for this in the fibrils (Walter Flemming, 1843–1905), granules (Richard Altmann, 1852–1901) and alveoles (Otto Biitschli. 1843–1920) familiar to the cytologist (see CYTOLOGY). William B. Hardy (1864–1933) emphasized the colloidal state as being essential for the manifestations of life (see COLLOID).

According to the present concept, protoplasm possesses an ultramicroscopic, labile system of structural proteins offering large internal surfaces for the promotion of heterogeneous catalyses, the interstices of the system being filled with a liquid. This interstitial liquid is generally regarded as aqueous, and the protein fabric as capable of imbibing water.

The characteristic properties of protoplasm are irritability, motility, metabolism, growth and reproduction. Adaptability must also be included to account for the evolutionary changes. The ovum, from which an organism springs, possesses potentialities for changes. but these changes ordinarily lie within the limits of the organization of a particular species. Occasionally mutations occur spontaneously and have even been induced experimentally. The surprising feature is that, with the complexity of the protoplasmic constitution and the variety of environmental conditions, there should be such an extraordinary stability of protoplasm as we find it in nature.

The properties of protoplasm which are most readily observable through a microscope are motility, irritability, reproduction and growth. Motility is expressed in two types of motion, the amoeboid locomotion of entire cells and the currents of flow within the protoplasm of a cell. Both vary greatly in rate. It is of interest to note that the apparent inertia of most plants and the constant activity of animals are in striking contrast to what is observed within their cells. The protoplasm of most plant cells generally exhibits a marked streaming which is barely perceptible in most animal cells. The property of irritability may be easily observed by the cessation or, conversely, the acceleration of protoplasmic flow when mechanical or electrical stimuli are applied. The phenomena of reproduction and growth can be observed readily in young root hairs, in yeast and in cells of tissue culture by the cleavage of parent into daughter cells and the increase in size of the latter. (See ANIMAL CELL [TISSUE] CULTURE; PLANT CELL [TISSUE] CULTURE.)

The three most prominent constituents of the protoplasmic unit of a cell are the nucleus. the cytoplasm and the protoplasmic surface film. This surface film, called plasma membrane by Wilhelm Pfeffer (1845–1920) who first recognized its existence, maintains the integrity of the protoplasmic unit. If. in the normal, aqueous medium of cells, it is torn and does not repair itself quickly. the protoplasm undergoes progressive disintegration or cytolysis. The nucleus is usually a spheroidal body first described in plant cells by Robert Brown (1773–1858). It contains specific nuclear structures, chromosomes and the so-called nucleoplasm. The cytoplasm constitutes the remainder of the protoplasmic unit and usually contains granules and vacuoles of various sizes, mitochondria, etc.

The discovery of the virus, which is beyond the visibility of the light microscope, has posed a question as to the size limits of a viable unit of structure. Some viruses, *e.g.*, the tobacco mosaic virus, are regarded as consisting of no more than one or a few thousand molecules of nucleoprotein. This is much smaller than the structural elements or particles generally seen in protoplasm. Structural elements of protoplasm may have a higher degree of autonomy than is generally assumed, and their survival, when removed from protoplasm. may become possible when a medium is found mhich is compatible with their environment. There is no evidence of spontaneous generation, but a beginning must be inferred. There must have been a time when existing conditions brought about syntheses of compounds containing asymmetric carbons which led to the formation of proteins as prerequisites for the creation of living matter. The present era seems to be one in which protoplasm persists and perpetuates its properties of individuality, adaptability, growth and reproduction.

METHODS OF STUDY

Cytochemical Methods.—The technique involves primarily the analysis of extracts of disintegrated cells and tissues. Our knowledge of the chemistry of protoplasm has been greatly enhanced by developments of physicochemical techniques and improved methods of extraction and isolation of various constituents of these extracts; *e.g.*, by electrophoresis and by ultracentrifugation. Specific proteins have thus been isolated and studied. In particular, various important enzymes have been isolated, and a study in *vitro* of their activities, separately and combined. is helping to explain many of the mechanisms by means of which living cells maintain and perform their functions (see BIOCHEMISTRY).

An important corollary to the above is the mechanical isolation of morphologically visible cell components from freshly disintegrated cells. Cell nuclei, cytoplasmic granules. mitochondria and even nuclear chromosomes can be separated by virtue of their different size and density and isolated by micro-needles or by differential high-speed centrifugation or by exposure to certain salt solutions which dissolve some and not others. Chemical analyses and enzyme-activity tests are then performed on the separated fractions. A limitation to this type of study, mhich involves crushing of protoplasm, is the injury inflicted on many of the components.

In some cytochemical techniques the cells are not destroyed but are subjected to various physical and chemical treatments while intact. In the incineration method. thin layers of cells and of cellular tissues are placed on transparent sheets of mica and exposed rapidly to high temperatures. The morphological contours of the ashed cells persist and, through the microscope, the distribution of mineral constituents may be mapped by chemical and electron-optical means.

Other cytochemical methods employ specific colour reactions to demonstrate the distribution; *e.g.*, of enzymes, of nucleic acids and of arginine-rich proteins. Use has also been made of purified enzymes to determine the structural importance of substances such as lipids, proteins and nucleic acids in the framework of certain cell constituents (chromosomes, etc.).

Information on important biocatalysts has been gathered by studying the effect on living cells of specific enzyme inhibitors (carbon monoxide, cyanide, azide, etc). Thus, the hemin nature of the respiratory ferment and of the Pasteur enzyme has been elucidated by determining the effect of monochromatic light of different wave lengths on the carbon monoxide inhibition of cell respiration or the Pasteur reaction (Warburg's photochemical method).

Still another method is to explore living tissues with the aid of heavy and radioactive isotopes; e g., deuterium, heavy nitrogen, radioactive carbon. etc. These become incorporated and serve as "tracer" atoms to determine the origin and fate of protoplasmic constituents, *e.g.*, proteins, also the movements of certain chemical elements into and out of living cells.

Physical Methods.—The light microscope (see MICROSCOPE) is of prime necessity for observing protoplasmic structures. The unaided eye, at a distance of 10 in.. can discern objects 0 1 mm. (1/250 in.) apart. This is the resolving power of the unaided eye. The light microscope increases the resolving power 400 times; in other words, it can discriminate objects 0.00025 mm. or 0.25μ apart. The resolution is limited by the wave length of the light illuminating the object. An increase of resolving po er can be obtained by utilizing radiations of wave lengths shorter than those of visible light. This has been achieved by means of the ultraviolet microscope. with which objects 0.1μ apart may be photographically recorded. Visibility to the eye is made possible by the use of fluorescent screens and fluorescent dyes The usefulness of this instrument is not so much in its resolving power, which is only about twice that of visible light. but more as a means for detecting cell components which specifically absorb ultraviolet radiations; *e.g.*, nucleoproteins. The phase-contrast microscope accentuates minute, refractive index differences with the aid of artificially created interference phenomena. Photoelasticity, form and flow birefringence may be studied with the polarizing microscope. When the exact shape of particles is less important than their detection or behaviour (*e.g.*, Brownian motion), the dark field and the so-called ultramicroscope are used. Particles, down to 5 millimicra (0.000005 mm.) appear as luminous diffraction disks (see LIGHT: The Scattering of Light).

A further extension of the range of observability is accomplished by the electron microscope. This is essentially a vacuum tube with accessories for utilizing electrons in the same manner that light waves are utilized in a light microscope. A stream of electrons, after passing through an object, is focused in magnetic or electrostatic fields which act as condenser lenses analogous to the glass lenses of a light microscope. The resulting magnified image of the object is projected on a photographic plate, or on a fluorescent screen for direct observation. Electron-optical magnifications as high as 50,000 diameters have become possible; the resolving power of the present electron microscopes under optimum conditions is estimated at 15Å or 1.5 millimicrons. By means of this microscope, viruses and even single protein molecules have been photographed. A limitation to its use is the necessity of working with dried films of extreme thinness and in a high vacuum. The visibility of the dried objects, *e.g.*, tendon fibrils, has been enhanced by impregnating them with multivalent, heavy metal acids (electron stains), also by coating objects, such as viruses and protein molecules, with noble metal films placed under oblique angles of incidence (shadow casting). The centrifuge microscope permits observation of the effect of intense gravitational fields on living cells. This and the centrifuge method, in general, has been used to determine the relative mass and density of particles, also to study differences in rigidity of certain regions in protoplasm.

Electromagnets, mounted on the microscope stage, have been used to measure protoplasmic viscosity by observing the rate of travel of minute particles of iron or nickel introduced into cells. Hydraulic pressure chambers mounted on the microscope stage have been devised for directly observing the reversible liquefaction of gelated protoplasm under high pressure. The microspectroscope is an attachment to an ordinary microscope which facilitates the identification, through their absorption spectra, of pigments contained in living cells.

The thickness of films, such as cell envelopes and nuclear membranes, may be determined with the aid of the leptoscope, which enables comparison of the intensity of the light reflected from the object with that reflected from a barium stearate film of known dimensions. The fine structure of living systems, *i.e.*, their molecular organization, can be studied by the X-ray and the electron diffraction method. The application of X-ray analysis to fibrils, virus-protein crystals, and similar objects has thrown light on their molecular pattern and has yielded quantitative information on backbone and side-chain spacings of regularly built units and molecules. The irradiation of living cells with intense monochromatic ultraviolet radiation or with X-rays, as well as their bombardment with gamma rays (from radium) and with neutrons (by the use of the cyclotron), produces lesions and mutations which have been of value in the study of chromosome structure, mitosis and gene action. Electrophoresis (migration of particles in electrical fields), produced by the application of electric currents, has been used for determining the electrical charge on cell granules and on intact cells. Microrespirometers of the constant volume (manometric) and constant pressure (volumetric) type, *e.g.*, the Warburg manometric apparatus and the Cartesian diver, are used for making quantitative measurements of the rate of energy-yielding reactions of intact cells, of cell extracts and of formed elements isolated from cells. Micrurgy. or the micromanipulation technique, employs mechanical devices for operating on living cells in the field of the compound microscope (see MICROMANIPULATION). The varied techniques used in micrurgy make possible microscopic observations on differences in the relative stiffness or viscosity of visible constituents of protoplasm. effects of mechanical injury in various regions of single cells and the reparability of these regions under experimental conditions, etc. The tensile strength and torsional resistance of protoplasmic strands have also been studied.

The microinjection of various chemical solutions and the application to the surface and to the interior of protoplasm, of oil drops differing in interfacial tensions have afforded new insight into the physical and chemical state of living protoplasm. The importance of this technique is appreciated since protoplasm exists only within microscopic dimensions. There is no way of securing a sizable mass of protoplasm for gross handling. In most instances it exists as microscopic units. In macroscopic cells, *e.g.*, some plant cells, plasmodia of myxomycetes and the avian yolk cell the contained protoplasm is microscopic in at least one of its dimensions.

Maintenance of Environmental Conditions for Living Cells.—A usual way of observing or operating on protoplasm is to secure cells which either occur singly or can be isolated from tissues. Examples of such cells are the relatively yolk-free, microscopic egg cells of many marine organisms, protozoa, plant hairs, teased out or finely sectioned layers of plant and animal tissues, and cells present in blood and body fluids.

Marine eggs and protozoa are best studied in their natural aqueous environment, while tissues and single cells from higher organisms are usually suspended in body fluids (serum) or in synthetic media—such as Ringer's solution—which contain salts in the concentration of their normal medium. An important adjunct is the use of the tissue-culture technique by means of which fragments of tissue from plants or animals are grown in suitable media outside the organism (see ANIMAL CELL [TISSUE] CULTURE; PLANT CELL [TISSUE] CULTCRE).

Constitution of a Physiological Medium.—The natural environment of all living cells, plant and animal, is aqueous and contains electrolytes, the indispensable ions of which are sodium, potassium and calcium. Of evolutionary significance is the fact that these electrolytes are present in body fluids in the same relative proportions as in the ocean. The total concentration of these salts, within well-defined groups of living organisms, is constant but varies greatly among different groups.

Water freely penetrates most cells. and special provisions exist to prevent what otherwise would result in an excessive osmotic swelling of the protoplasmic unit and an eventual bursting of the cell. Among plant cells the provision is partly mechanical through the presence of rigid cell walls. Many unicellular fresh-water organisms are similarly protected. while others have devices for the periodic elimination of excess water. Unicellular organisms which live in the sea are in osmotic equilibrium with their environment. The cells of the more highly organized animals are in osmotic equilibrium with their body fluids; this equilibrium is maintained independently of external variations.

Temperature.—Raising the temperature only a few degrees above the optimum destroys protoplasm. This may be explained by the effect of the temperature on the rate of enzymatic reactions and on the native configuration of proteins which undergo irreversible denaturation. On the other hand, lowering the temperature slows down chemical reactions and thus tends to prolong vital activities without irreversibly affecting them. Many cells survive subcooling to several degrees below 0° C. Even when the extracellular fluids are frozen solid, the fine capillarity of the fluid spaces within living cells prevents internal freezing. Death may eventually occur through irreversible dehydration. Furthermore, death occurs if, at any time, ice crystals form intracellularly. This can be induced either by sudden agitation of the cooled tissue or by introducing an ice crystal into the cell by means of a micropipette.

Hydrogen-ion Concentvation.—The maintenance of an acid base equilibrium of the medium is essential for most cells. Physiologically, the hydrogen-ion concentration is chiefly regulated by bicarbonate in equilibrium with gaseous carbon dioxide. This may occur with the participation of proteins in the body fluids of higher animals.

THE NATURE OF PROTOPLASM

Physical State and Morphology of Protoplasm.—To appreciate the implications involved in a study of protoplasm it is advisable to begin with results obtained on its physical state and that of its structural components. Protoplasm is to be regarded as a microheterogeneous system in which particles and molecules of varying solubility are dispersed in an aqueous phase. The state of the protoplasm of many cells is such that the cells round up into spheres when freed of their extraneous envelopes. This is also true for the protoplasts of plant cells removed from their rigid cell walls.

The protoplasmic surface film is a tenuous structure usually interposed between an external envelope of varying rigidity and an internal layer of gellike, cortical material of the protoplasm. The external material which serves as a supporting envelope is an excretion product of the protoplasmic body. It is extraneous to the protoplasm, since it can be removed without interfering with the viable properties of the latter. This envelope depends for its rigidity upon the presence of calcium in the surrounding medium. In multicellular tissues the envelope of contiguous cells serves as intercellular cement for binding the cells together. When calcium is deficient or absent from the medium the cement loses its cohesiveness and the cells become separated. The protoplasmic surface film beneath the extraneous envelope also depends for its maintenance on the electrolytes of the medium but. in this case, the chief ions responsible are sodium and potassium. Thus, of the three electrolytes, sodium, potassium and calcium present in the aqueous environment of living cells, calcium is essential for the external cell envelopes and hence for the intercellular cement of multicellular forms, while sodium and potassium are required for the protoplasmic surface film. The older literature which stressed the importance of calcium, to the extent of introducing the phrase "calcium is essential for life:" arises chiefly from observations on multicellular organisms. Plant and animal tissues: immersed in nutrient media lacking calcium. break down into isolated cells but, as long as sodium and potassium are present, maintain their individual vitality.

Theoretical considerations. supported by certain experimental observations. lead to the concept that the surface layer of protoplasm consists of a palisadelike arrangement of lipoproteins, the more water-soluble groups of which are directed outward. It is ,suggested that the extraneous envelopes of animal cells are produced by the continual casting off of denatured. proteinaceous material. Experimental tearing of the protoplasmic surface results in the outflow of the fluid parts of the interior, provided that calcium has been removed from the environment. Otherwise, irreversible clotting of the exuding material occurs and spreads into the interior. The protoplasmic surface layer disappears in a wave spreading from the torn region, as if the palisade arrangement

PHOTOMICROGRAPHS OF VARIOUS BIOLOGICAL SPECIMENS EXAMINED WITH DIFFERENT TYPES OF RADIATION

1. *Light microscope.* Living, immature egg (70 microns in diameter) of sea urchin, magnified 300 x. Cytoplasm, with dispersed, brown pigment-granules which appear dark, and nucleus which is translucent and contains a hyaline nucleolus

2. *Ultra-violet* light microscope. Similar specimen, same magnification, exhibiting opaque regions because of the presence of nucleic acids which strongly absorb ultra-violet light of 2,600 Ångstrom units

3. Polarizing *microscope.* Side view of a myelinated nerve fibre freshly removed from the sciatic nerve (frog), magnified 460 x and viewed between crossed nicol-prisms showing the bi-refringent bright myelin-sheath against a dark background

4. X-ray *diffraction pattern* of a tendon (kangaroo) taken with a pin-hole camera. Fibre axis is vertical to the X-ray beam. Inset, to right, shows the central portion of a pattern more highly magnified and taken with a slit camera. It indicates a repeating period of 145 Ångstrom units along the fibre axis

5. Electron microscope. Side view of a fibril from a guinea pig tendon (aried in vacuo). Width of fibril is slightly greater than 0.1 of a micron, therefore, barely within limit of resolution by the light microscope. Here it appears as a relativviv broad structure with cross-bands of alternating light and dark material

6. *Electron microscope.* Fibril of fig. 5, impregnated with phosphotungstic acid. This eiectron stain enhances the resolution of the finer, cross-band elements within spacings of 0.01-0.02 of a micron

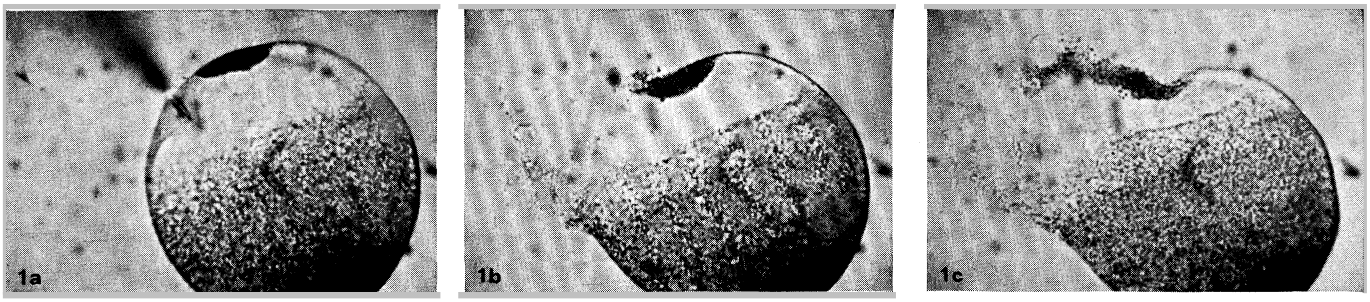
7. *Electron* microscope. Paramyosin fibril (from a clam), impregnated with phosphotungstic acid. The resolving power is so great that cross-bands of 145 Ångstrom units (0.0145 microns) apart can be distinguished

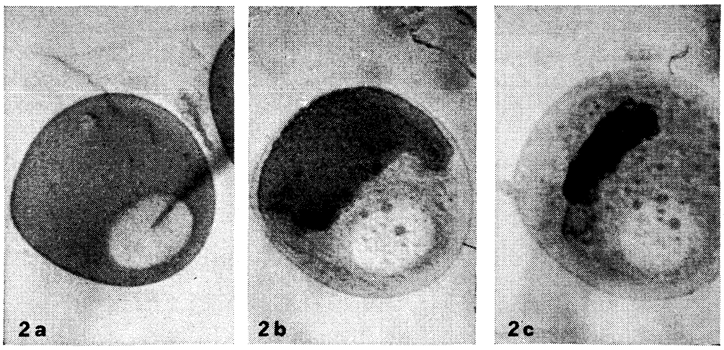
8. *Electron microscope.* Detail of much flattened part of a cell (macrophage) in tissue culture, showing filamentous mitochondria (fixed with osmic acid, magnification 4,000 x)

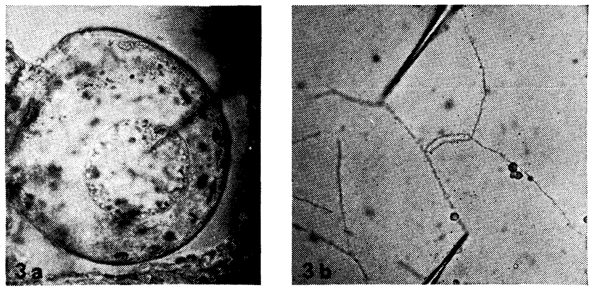
9, 10, 11. Photomicrographs to compare magnifications obtained with the visible light and those with the eiectron microscope. 9. *Light microscope.* Section of liver (Amphiuma) fixed and stained. Three liver cells are shown in which the nucleus of one is evident. The cytoplasm contains many granules, among which the melanin granules (0.5 microns in diameter) are clearly seen as small, black dots (magnification 1,000 x). 10. *Light* microscope. A cluster of melanin granules from the *Amphiuma* liver, obtained by crushing the cells and collecting the melanin granules by centrifugation (magnification 2,000 x). 11. Electron microscope. The same melanin aranules maanified 20.000 times

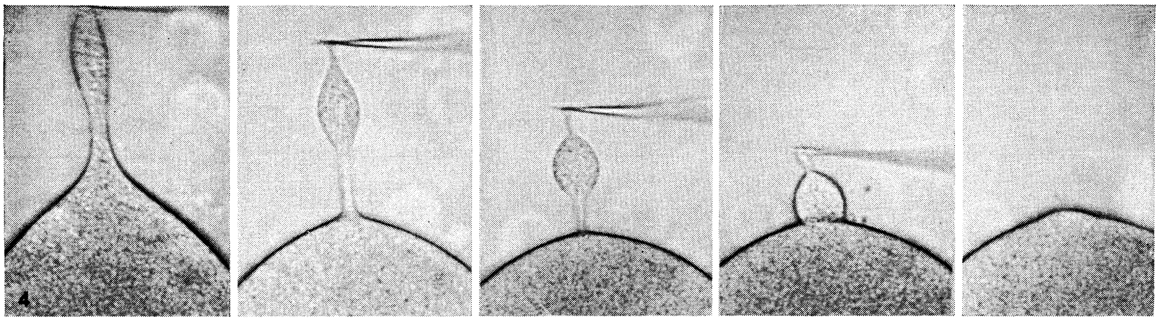
PLATE II

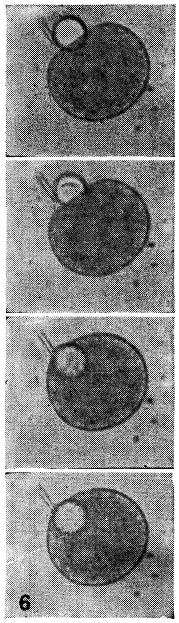
PROTOPLASM

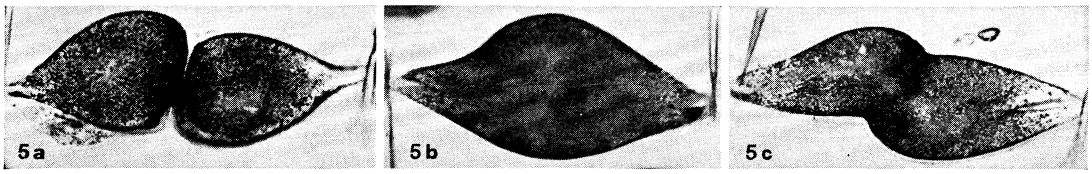












BY COURTESY OF (3) DR. WM. R. DURYEE, CARNEGIE INSTITUTION, WASHINGTON, D.C.

ALL THE FIGURES ARE FROM PHOTOMICROGRAPHS OF MICRURGICAL OPERATIONS ON LIVING OVA UNDER THE LIGHT MICROSCOPE TO DEMONSTRATE FEATURES OF THE PHYSICAL STATE AND STRUCTURE OF PROTOPLASM

1a. Living sea-urchin egg (70 microns in diameter) after having been centrifuged so as to sediment its visible components into several zones according to their relative weights. The tip of a microneedle has been inserted into the fluid, hyaline zone, above which is a dark mass of fat droplets. Just below can be seen a clear spherical body, the nucleus. Below the hyaline is a granular zone, the lowest layer of which consists of dark-brown pigment-granules

1b, c. Two successive micrographs, one and two seconds after tearing the surface layer of the egg. They show the escape of fluid and the outward dispersal of the various granules. In 1c the extruded nucleus can be barely seen in advance of the out-streaming fat globules

2a, b, c. Three successive micrographs of a starfish egg after tearing the nuclear membrane. They show the destructive effect of suddenly mixing nuclear and cytoplasmic material

3a. Ovarian egg of an amphibian with centrally located nucleus

3b. Highly magnified view of a filamentous chromosome being stretched after it had been removed from the nucleus. The chromosome appears to consist of an elastic thread of cohering granules

4. A strand of protoplasm drawn out with a microneedle from the surface of a starfish egg. The strand behaves as a viscous fluid since. on causing the needle-tip to approach the egg's surface, the release of tension results in a shortening and beading of the strand until finally the strand flows back and disappears in the protoplasm of the egg

5a. A sea-urchin egg which underwent successful cleavage after it had been stretched along the polar axis into the shape of a ribbon. b. A sea-urchin egg which did not cleave after being stretched at right angles to its polar axis. c. A sea-urchin egg which cleaved after having been stretched diagonally to its polar axis. The cleavage persisted in the plane at right angles to the original, polar axis. On each side of the cleavage furrow can be seen bulges which are not to be expected if the consistency of the stretched mass of the egg were uniform. The bulges are caused by the gelated regions which resist the pull exerted by the microneedles

6. Four photomicrographs of a sea-urchin egg, taken at Intervals of one-twentieth of a second, showing the rapid penetration of an oil drop applied to the surface of the egg with no evidence of rupturing the surface

forming the boundary were disrupting or breaking down. Repairs from such injuries. if not too extensive, have been observed. Minute vacuoles appear in the cytoplasm of the torn region. These break open and the linings of the vacuoles spread out and join until a sufficient area of film separates the disintegrating from the intact cytoplasm underneath.

The formed elements of protoplasm are of two general types: well-defined inclusion bodies and regions of gelation. the latter being transitory and serving special purposes. Of the inclusion bodies: some in highly differentiated cells, are specific organellae such as the elastic. contractile trichocysts of paramecia (see PROTOZOA; PARAMECIUM). Other inclusion bodies are fat and yolk globules, pigment-containing and colourless vacuoles some of which may he very large (especially in plant cells), rod-shaped or spherical mitochondria and microsomes. the last being barely within the limits of vision. These bodies mostly float freely in the cytoplasm, and their constant movements reveal the existence of currents flowing in various directions in the cell. The function of many of these bodies is unknown. Some are doubtless reservoirs of foodstuffs. while for others there is suggestive evidence that they carry enzymes and are concerned with oxidation-reduction activities and various anabolic and catabolic processes.

The so-called ground substance of protoplasm exhibits at one time the properties of a fluid (solj and at another, those of a deformable solid (gel).

It is known that many colloidal substances, *e.g.,* certain proteins. bentonite or vanadium pentoxide, in solution readily pass from the sol to the gel state and vice versa. This phenomenon, called thixotropy, is exhibited by these systems upon shaking: application of pressure, temperature changes or the action of chemical agents. Protoplasm thus may be regarded as a thixotropic colloid.

The nucleoplasm of the cell nucleus varies widely in viscosity. In some cells it behaves like a stiff gel. In others it is so fluid that the nucleolus suspended in it is readily affected by gravity. Within the nucleoplasm are siender chromatin strands of an elastic consistency. During cell division these filaments shorten into the chromosomes. which are considered to be the carriers of hereditary characters (genes).

It is well recognized that the life of the cell depends upon its nucleus. A case in point is given in fig. 1, which illustrates a binucleated cell in tissue culture. It shows the damage caused by puncturing one of the nuclei and the subsequent repair because of the presence of the second, unharmed nucleus. If the cell had been mononucleated. the initial damage would have destroyed the cell.

A micro-needle (*see* MICROMANIPULATION), when inserted into a gland cell or a starfish egg and rapidly agitated. generally produces cytolytic reactions involving rhe liberation of acid and the progressive breakdown of the vacuoles, mitochondria, etc. A cloud of microsomes is generated which tends to convert the translucent protoplasm into an opaque mass. On the other hand, the gradual insertion and cautious manipulation of the needle in the cytoplasm produces no appreciable effect.

Theories on Ultrastructure of Protoplasm.—According to A. Frey-Wyssling. the cytoplasm forms a network of fibrils having the dimensions of a single polypeptide chain of a protein molecule. These chains are considered to be angular in shape and periodically branched. The side chains interact through points of attachment which may be of various types. This creates a finely meshed. three-dimensional net or molecular sponge the interstices of which are occupied by aqueous solutions of salts and also by lipids. The entire assembly is n-ell ordered through the hydrophilic and lipophilic groups present in the protein network. Such a spongy fine structure would explain many properties of protoplasm. such as reversible swelling by imbibition of fluid or dehydration by constriction of the interstitial spaces. The salient feature of this concept is the presence of an organization of the materials constituting a scaffold, so as to ensure an orderly progression of the reactions over the surfaces of the structure, presumably through the alternate adsorption and desorption of substrate molecules on the stationary centres of enzymatic, active proteins. Obviously, any detailed picture of protoplasmic fine structure must be based largely on our knowledge of the structure of proteins.

Work on proteins has indicated the inadequacy of the original concept by Emil Fischer of their molecular structure. namely of long, straight polypeptide chains of different amino acids A more complex structure is required to explain such important features as specificity, biological activity, and the phenomena encountered in the denaturation of proteins. Some (*e.g.,* W. T. Astbury) assume that the polypeptide chains in the globular and fibrous protein molecules are folded or contracted in varying degrees and are kept so by hydrogen bonds and similar forces According to this view, protein denaturation would consist in the unfolding of compact units similar to the opening up of the bellows of an accordion or to the unraveling of a spool of thread. Others (*e.g.,* D. M. Wrinch) postulate more elaborate structures such as the so-called cyclol fabric involving the formation of six-membered carbon rings through secondary valencies. Whatever the true picture of a protein molecule may be, it can no longer be doubted that these large molecules possess a high degree of geometrical symmetry. This is already indicated by the nell-defined X-ray diffraction patterns exhibited by a variety of proteins (Astbury, J. D. Bernal, I. Fankuchen and D. Crawfoot).

A striking phenomenon is the streaming of the cytoplasm. This is accompanied by a greater or smaller degree of flow birefringence to be explained by the alignment, through shearing stresses, of asymmetric. rod- or platelike particles. When observed in the Tyndall beam of the slit ultramicroscope or with dark-field illumination. the cytoplasm reveals the presence of immense numbers of particles, as small as jo Å. which are in active Brownian motion. These may represent the basic building blocks of protoplasm of which the larger particles. ranging up to 5,000 Å, are aggregates.

There appears to be a close correlation between the submicroscopic and the visible structure of cellular components. A fibril, for instance, has its special form and properties, *e.g.,* elasticity, because the protein molecules which it contains are themselves fibrous and contractile. Experimental observations have also indicated that cilia. flagellums, sperm tails and linear chromosomes consist of interlinked bundles of submicroscopic fibrous protein particles which are oriented with their long axes parallel to the fibre axis. Likewise, membranes and films seem to be built up of submicroscopic iayers or lamellae of single molecules. It is of interest to note that the plasma or protoplasmic surface film appears to contain also lipid molecules. with their long axes perpendicular to the surface. On the other hand, the nuclear membrane

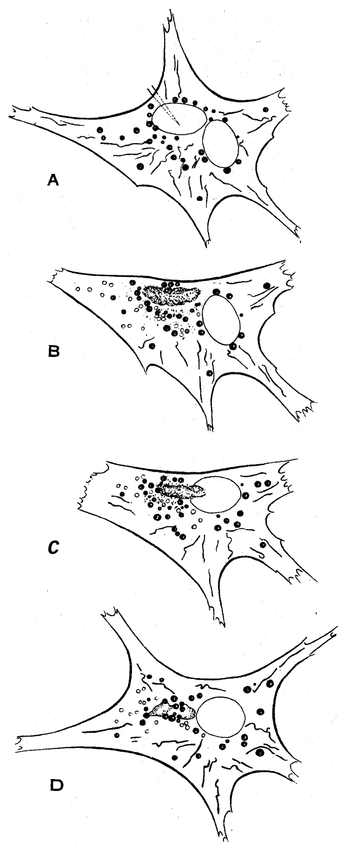


FIG. 1.—SUCCESSIVE STAGES OF A CELL WITH TWO NUCLEI (FIBROCYTE) IN TISSUE CULTURE. SHOWING THE EFFECT OF PUNCTURING ONE OF THE NUCLEI

(A) The cell showing extended pseudopodia before the microoperation. The tip of a micro-needle is about to puncture one of the nuclei. In the cytoplasm can be seen the mitochondria as slender filaments and the fat droplets as highly refractive spheres. (B) The same cell, four seconds after the nuclear puncture. The punctured nucleus has been changed into an opaque mass of material. The cytoplasm near the damaged nucleus is abnormally granular and the mitochondria in the vicinity have changed into pale, spherical bodies. The fat droplets are unaffected. (C) Six seconds later. The damaged nucleus is fading and the cytoplasm surrounding it is becoming less granular. (D) Twenty seconds later.. The cell has recovered because of the presence of the second, undamaged nucleus seems to contain little or no oriented lipid material. The most highly organized protein-lipid system thus far encountered is the myelin sheath of nerve fibres. The sheath appears to consist of concentric lipid-protein layers, each layer about 180 Å thick, containing one or two thin protein leaflets of about 2 j A lying between two double molecular sheets of mixed lipids. Water molecules seem to be distributed over the polar interfaces of this highly organized structure which is irreversibly destroyed by dehydration.

These complex, fine structures of protoplasmic organization constitute a reversible, dynamic system, continually being built up and broken down during the course of normal cell metabolism. This has been demonstrated through the use of isotopic tracer elements, carbon, nitrogen, etc.. which, when fed to animals or cells, rapidly replace the corresponding elements forming essential parts of the molecular structure (R. Schönheimer).

Chemistry of Protoplasm. — From a quantitative point of view, water represents the major component: animal tissues contain up to about 80% water while the plasmodia of myxomycetes (slime molds) may contain as much as 94%. The water may be a basic constituent additional to serving as the solvent or suspension medium of many components of protoplasm.

The chemical composition of the protoplasmic solids may be deduced from the analysis of such animal tissues as lung, muscle, brain or liver. They contain about 20% solids. The protein content is, on the average, about 10%, that of muscle about 16.5%. The total lipid content of brain and liver is about 456, that of lung 2.7%. The mineral content of tissues in general is approximately 1 5%. In addition to these there is a series of minor substances, such as reserve carbohydrates (glycogen), organic acids, creatine and creatinine, free amino acids, pigments, urea, etc. Some of these minor constituents vary in amount, depending on the functional state of the tissue; they may be classified as metabolites and excretion products rather than as essential constituents of protoplasm.

The compounds classed under the general terms of "protein" or "lipid" may be subdivided into conjugated and straight proteins, or neutral fats, cholesterol, cephalin, etc. The conjugated proteins comprise such different complexes as nucleoproteins, lipoproteins, mucoproteins, iron proteins, etc.

The nucleoproteins are of signal importance: those containing desoxyribose (thymonucleoproteins) appear to occur exclusively in the nucleus, while those containing pentose (yeast or ribose nucleoproteins) are found predominantly in the cytoplasm and in the nucleolus The desoxyribose nucleoproteins are integral components of the chromosomes and are considered by many to be the carriers of the inherited characters of the organism (genes). The ribose nucleoproteins of the cytoplasm appear to be related functionally to the mitotic cycle. which involves the chromosomal nucleoproteins. and to the synthesis of proteins and protoplasmic substance of the cell in general. The functional aspects of the nucleoprotein problem, of great importance for the genesis and maintenance of protoplasmic structures. was still largely inferential and speculative. Nucleoproteins within the cell may be detected and quantitatively estimated with the aid of ultraviolet microscopy and microphotometry. This method utilizes the strong absorption of nucleic acids in the ultraviolet region (near 2.600 Å) nhere ordinary proteins and other cellular constituents are fairly transparent. It should be pointed out, however, that this technique does not differentiate between the two basic types of nucleic acids which can be detected by certain staining and colour reactions (Feulgen and Dische reactions).

The lipoproteins constitute an Important group of conjugated proteins. They appear to be secondary valence complexes in which various proteins and lipids, e.g , lecithin. cephalin or sphingomyelin. are held together by forces of the van der Waals type. The lipoproteins appear to be contained chiefly in the cell or plasma membrane. in the mitochondria, microsomes and other cytoplasmic inclusions. The lipoprotein "mosaic," present in the plasma membrane, plays an Important role in determining its permeability

The components just enumerated represent either building blocks or metabolites of protoplasm. There are also many catalysts; *i.e.,* substances capable of accelerating and promoting reactions which, in their absence, would take place only at negligible rates (see CATALYSIS and ENZYMES). The catalysts are either enzymatic or nonenzymatic. The enzymes (or thermolabile, colloidal catalysts) are classified as hydrolytic or as oxidative, according to their action on suitable substrates. The hydrolytic enzymes split lipids and proteins by introducing the elements of water. The oxidative enzymes are the oxidases which cause substrates to combine with molecular oxygen and the dehydrogenases which serve as hydrogen acceptors, thereby removing hydrogen atoms from the substrate. The action of many of these enzymes has been shown to be reversible, thus indicating that they not only promote the breakdown but also the synthesis of protoplasmic constituents. Another important group of intracellular enzymes are the phosphorylases which store energy by forming energy-rich phosphate bonds and also, by splitting the same phosphate esters, *e.g.,* adenosine triphosphate, yield readily available energy for vital processes. Examples of intracellular enzymes are catalase, which splits hydrogen peroxide into oxygen and water; cathepsin, a proteinase which attacks the peptide bonds in native proteins at the hydrogen-ion concentrations prevailing in the cell; and cytochrome oxidase (or respiratory ferment), which through the intermediary catalyst, cytochrome, induces molecular oxygen to oxidize suitable substrates, such as paraphenylene diamine. Cytochrome is an example of a nonenzymatic or intermediary catalyst. The oxidative enzymes, together with nonenzymatic catalysts, play an important role in the energy metabolism (respiration and fermentation) of the cell, while the hydrolytic enzymes are mainly concerned with the breakdown of foodstuffs and the rebuilding of protoplasm from the split products. The distribution of the various enzymes and other catalysts between the different formed elements of the cell and the cytoplasm has as yet not been completely elucidated. However, it would seem as if all important enzymes occur both in the nucleus and in the cytoplasm. It would appear that the mitochondria are particularly rich in enzyme content. The control of the orderly flow of the reactions in protoplasm is accomplished by various devices, such as the mechanical separation of catalysts and substrates and the regulation of the hydrogen-ion concentration which, in turn, affects the rate of enzymatic processes. The orderly progress of reactions of these various catalysts and their substrates, all within the confines of a single protoplasmic unit, postulates the existence of regulatory mechanisms. For example, the rate of enzymatic processes is markedly affected by changes in the hydrogen-ion concentration of the medium. Spatial separation may also be assumed to play a role since there is evidence that some of the enzymes concerned with the terminal oxidation of metabolites are anchored, in a definite pattern, to the surface of macromolecular particles within the living cell.

Protoplasmic Reactions. — Cell Respiration *and* Energy *Production.*—Perhaps the most valid criterion of life is metabolism, a term which covers the intricate processes concerned in the breakdown of foodstuffs (substrates or metabolites) and the utilization of the reactions to release energy required for the proper functioning as well as for the repair and growth of protoplasm. Energy-yielding reactions are of two types: respiration and fermentation. Respiration utilizes the molecular oxygen of the air. Fermentation. on the other hand, proceeds in the absence of air and, in many instances, is adversely affected by the presence of oxygen (Pasteur effect). In the metabolism of the most primitive types of cells, represented by certain strictly anaerobic microorganisms, the primary requisite of life appears to be the ability to ferment carbohydrate, yielding end products such as lactic acid, butyric acid, carbon dioxide or hydrogen. From an energetic point of view. fermentation is not very economical since it releases only a small fraction of the energy available in foodstuffs. In contrast to this the respiratory or oxidative process releases all the available energy from a given substrate by burning it to carbon dioxide and water. Aerobic cells possess both types of mechanism. Fermentation is an indispensable prerequisite for respiration, since the latter utilizes chiefly products made available by anaerobic splitting of foodstuffs. The Pasteur effect allows only that portion of fermentation to persist in the presence of air which is required for the production of the substrates needed by the respiratory system.

It had been assumed that the ability to respire was restricted to intact and complete cells. It is now known that neither the cell membrane nor the nucleus is indispensable for this process and that the ability to utilize oxygen for the combustion of suitable substrates resides in the smallest particles which can be obtained from the protoplasm by mechanical means. Cell-free extracts retain the ability to ferment sugar but lose the ability to respire normally. It appears that the mechanical methods which break up the architecture of the protoplasm destroy the intricate correlations which are necessary for normal cell respiration. The same is true for the Pasteur reaction. However, it has been possible to demonstrate in cell-free solutions the presence of many of the enzymatic components of the respiratory system. This shows that the steps catalyzed by single enzymes do not depend upon the coordinated, vital activities of protoplasm (see ENZYMES).

Chemical energy is required for all of the so-called "vital" functions of the cell, such as the maintenance of membrane potentials, selective permeability, the maintenance of optimal hydrogen-ion concentration, of oxidation-reduction potentials, as well as cell division and protoplasmic movements. While primarily this energy can be made available only by fermentation or respiration processes, it is becoming increasingly clear that the immediate source of readily available energy for these diverse functions is to be found in energy-rich phosphate bonds. The energy released from the foodstuffs by the metabolic activity may be stored up by the synthesis of compounds of the type of adenosine triphosphate and creatine phosphate. The energy can then be released for such processes as the cpntraction of a muscle fibre or the excitation of a nerve fibre with the aid of specific enzymes which split the energy-rich phosphate bonds.

Oxidation-Reduction Potentials in Living Cells.—Oxidation-reduction systems are classified as reversible or irreversible. However, there exist many intermediate types such as the fully electroactive, the sluggish and the semireversible systems, depending on the ease with which the state of oxidation of the system may be reversed or with which electrons may be exchanged with other systems. A cell cannot be regarded as a system endowed with a uniform degree of oxidation-reduction intensity. It is possible that certain materials of a suitable reduction intensity are being continuously depleted by irreversible oxidation and are as continuously being replenished by the formation of fresh amounts. The physiological function of the reversible systems would then lie in their continual oscillation between the oxidized and reduced state, thus enabling the systems to play the role of nonenzymatic, intermediary catalysts. Systems composed of certain oxidative enzymes and their substrates, in the presence of suitable, electroactive dyestuffs (mediators) have been shown to constitute truly reversible oxidation-reduction systems, the potential of which is determined by the ratio of the oxidized and the reduced form of the substrate. In the living cell, we do not encounter such a state of thermodynamic equilibrium but rather a steady state resulting from the incessant and simultaneous flow of oxidative and reductive reactions in both directions; this balance has been designated as "aerobic" and "anaerobic" potential. It is evident that any disturbance of this steady state by changing the oxygen tension of the medium or by the addition of strongly reducing or oxidizing agents will profoundly affect the physiological activity of the cell, provided they break through the defensive mechanism which may be described as the oxidation-reduction buffering capacity of protoplasm.

Hydrogen-ion Concentration.—Attempts at determining the intracellular hydrogen-ion concentration or pH (see HYDROGEN IONS) have been made in various ways. The earliest was to crush a mass of cellular tissue and determine the pH of the extract electrometrically and also by means of colorimetric pH indicator-solutions. Considerable variations were found to occur, not only with different tissues but with the same tissue at different times. It was later observed that the damage produced in crushing the protoplasm of cells causes the appearance of what has been termed an "acid of injury" which upsets the evaluations. The only method to prevent this kind of injury is to obtain values in single cells while the cells are known to be still alive. Such a method has been made possible by means of microinjection (see MICROMANIPULATION). Colorimetric indicators in aqueous solution can be injected into living cells and have produced results on which this section is based. In the determinations it is necessary to realize that the values obtained refer to the aqueous portion of the protoplasm.

The two chief constituents of protoplasm are protein and water. The water is continuous throughout the protoplasmic matrix and serves as a dispersing medium for granules of various sorts, fatty droplets and vacuoles, also as a solvent for electrolytes and the ionizable portions of the other main constituent, namely protein. The nature and degree of the ionization depend upon the hydrogen-ion concentration, which is a conditioning factor for the metabolic activities of protoplasm. For the cytoplasm the pH value has been found to be 6.9 ± 0.2 where pH 7.0 represents neutrality. For the nucleus the value is 7.7 ± 0.2 indicating that the aqueous phase or portion of the nucleus is definitely more alkaline than that of the cytoplasm. It is significant that these values have been found to be constant in a large variety of animal and plant cells, both of unicellular and multicellular organisms. This constancy is maintained by the so-called buffers; *e.g.*, the bicarbonate-carbonic acid system and the amphoteric proteins. Otherwise, the normal functional state of the protoplasm would be seriously disturbed by the acids which are produced during the various metabolic reactions occurring in the cell. For example, such metabolic end products as lactic and carbonic acid are immediately neutralized. The resulting neutral compounds are carried to the surface of the cell where their acid components are released to the outside.

The cytoplasmic vacuoles are liquid-filled sacs. Their enveloping membranes consist of a nonaqueous material and serve as mechanical and selectively permeable barriers to keep the vacuolar contents separated from the surrounding cytoplasm. The membranes of the vacuoles map allow certain solutes to enter but not to leave. In other words, these membranes exhibit the remarkable property of a one-way permeability, a property which has caused considerable speculation as to their physicochemical structure. The vacuolar contents are usually more acid and, in some instances, more alkaline than the cytoplasm. They are only slightly if at all buffered. Because of this the pH of the vacuoles may vary considerably with the nature of the environment. On the other hand, the pH of the cytoplasm and of the nucleus is independent of the environment as long as the cell is alive. This constancy of the protoplasmic pH is of great significance for the maintenance of the normal physiological state of the protoplasm and of its metabolic activities. Therefore, when one speaks of intracellular pH, it is necessary to discriminate between the pH of the protoplasm and of the contained vacuoles.

Gel-Sol Reversal.—The peculiar property of protoplasm to maintain or to change its physical state occurs generally in such a way that one part of the protoplasm is gelated while another remains in the sol state. These changes, together with protoplasmic streaming, are related to various protoplasmic activities such as amoeboid movement, cell division and possibly the periodic torsion observed in extended strands of myxomycete plasmodia. The gelated regions are more or less transient in character and revert to the sol state either spontaneously or when subjected to certain experimental conditions.

Amoeboid Movements.—An amoeba or a leucocyte is unable to advance were it not for the ability of its protoplasm to undergo gel-sol reversals. While at rest, most of the body of the amoeba is extended into several. long-tapering pseudopodia. Its protoplasm is in the state of a gel except for the innermost region which is in the sol state and exhibits a slow, shifting flow of the granules suspended in it. When an amoeba begins to advance. the action is initiated by a return. at some spot on its periphery, of the gel into the sol state. There follows a streaming from within the amoeba into this region, which bulges outward. The streaming progressively develops into a "fountain flow"; *i.e.,* an axial forward and a peripheral return flow (fig. 2). When the peripherally returning fluid reaches the base of the bulge, it gelates. A pseudopodium thus develops by the formation of a progressive lengthening of a cylinder, the walls of which are in the gel and the interior in the sol state. The interior is flowing forward to the tip where the "fountain flow" continues. Retrogression of the pseudopodium occurs by a change in direction of the flow, accompanied by a liquefaction of the walls of the cylinder progressing backward from the tip. Mechanical agitation accelerates the reversal to the state of a sol.

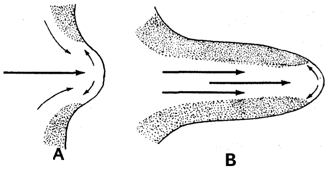

FIG. 2.— FORMATION OF AN AMOEBOID PSEUDOPODIUM

(A) Initial solation of the peripheral gelated protoplasm accompanied by a "fountain flow" in that region. (B) Extension of the pseudopodium by means of forward, axial streaming of the protoplasm in the sol state and a progressively lengthening, hollow column of gelated protoplasm being added to by peripheral back flow at the tip

Cell Division.—This process als~ exhibits sol-gel reversal. The first sten in cell division is the disappearance of the nuclear membrane. followed by a mixing of the nucleoplasm with the cytoplasm. At this time the mitotic spindle appears and the chroinosomes collect at its equator (see CYTOLOGY). During this period two regions of the protoplasm, one at each pole of the cell. progressively undergo gelation. This phenomenon is accompanied at the equator by a streaming which is directed toward the centre of the cell. The stream, as it approaches the centre, separates into two currents to the two opposite poles of the cell. The inward streaming produces a depression at the surface around the equator of the cell. This depression forms an ever-deepening furrow which ultimately divides the cell in two. As it advances, the walls of the furrow become gelated. In brief, there are two principal phenomena which accompany the process of cell division. One is a specifically directed protoplasmic flow and the other is a localized sol-gel reversal.

Selective Permeability of Protoplasm.— Ever since the cell was discovered as the structural unit of protoplasm, it has been abundantly proven that protoplasm exhibits a unique selectivity in the incorporation of certain materials and not of others from the surrounding medium. Water and dissolved gases readily pass in and out; so do certain ions, but not others. Nonionized molecules, *e.g.,* of weak acids and bases, appear to penetrate readily. while water-insoluble fatty acids do not. The penetration of particles in suspension and of nonelectrolytes appear to be a matter of size.

Electric charges play an important role with ion-valency as a determining factor. Most cells appear to be readily permeable to monovalent and distinctly less so to polyvalent cations. Some types, *e.g.,* blood cells, have been found to be permeable to anions and not to cations; but this is not true for all species of red cells. The fact that, in general, weak acids and weak bases penetrate more readily the less they are dissociated, has been used as an argument for a predominantly lipoid nature of the protoplasmic surface.

Paul Ehrlich (*q.v.*) and Charles E. Overton (1865–1933) made extensive use of a great variety of dyestuffs, especially coal-tar products, dissolved in the normal. aqueous environment of living cells. They found that the predominating condition for penetration is that the dye be the salt of a basic dye, the colour base of which is fat-soluble. Overton used this fact as the chief argument for his theory that the superficial layer of protoplasm is a lipoid membrane. Later. H. A. Bethe pointed out that the normal environment of cells is relatively alkaline and that protein, which is the chief constituent of protoplasm, should exist on the alkaline side of its isoelectric point and, therefore, react as an acid. Bethe opposed the Overton theory by concluding that the observed staining with basic dyes is explained more simply on the basis of chemical -affinity, namely the basic dye-radical combining with the acid-radical of the intracellular protein. Uniortunately for Bethe's assumption. chemical combinations of foreign compounds with the proteins in living cells are often toxic.

The following three types of processes may be mentioned, using dyestuffs as examples.

Penetration *of* Particles by *Virtue* of Size.——Most of the vital acid dyes are salts of weak acids which. at the pH of the normal cell environment, tend to be dispersed either molecularly or in aggregates of molecules. The diffusibility of many of these dyes into living cells has been shown to be a property of particle size, the size varying between j or 6 Å to 10 or 11 Å for different types of cells.

Penetration *of* Solubility.— Vital basic dyes. such as neutral red (an amino-azin), are salts of a weak. coloured base. It tends to be both fat-and-water soluble and is also more soluble in acid, aqueous media while it becomes increasingly nonionized and tends to precipitate in more alkaline media. The environment of cells is usually more basic than the aqueous phase of the protoplasmic interior. The dye diffuses readily into the cell where its accumulation predominates in the still more acidic, cytoplasmic vacuoles giving them a bright red colour. Moreover. by virtue of its lipid solubility. neutral-red also colours lipid granules.

Penetration Depending *Upon Metabolic* Activities.— This phenomenon. recognized as a so-called secretory process, may be illustrated by referring to the cells of the wall of the kidney tubule. It can be demonstrated on living fragments of kidney tubules immersed in solutions of highly dissociated salts of coloured acids, such as phenolsulphonphthalein, which do not penetrate cells generally.

There is evidence that this type of penetration is caused by some type of a metabolic process. Optimum temperature and oxidation-reduction conditions are obligatory, conditions which are not needed with the usual vital dyes, such as neutral red.

A significant feature to be pointed out is that the cells do not exhibit this phenomenon during the period when they are undergoing reproduction by division. Evidently, the metabolic functions for the performance of "secretion" and of division do not occur simultaneously.

There is no generally accepted opinion regarding the nature of the protoplasmic surface to explain its selective permeability. Some have claimed the surface layer to be a mosaic of water and lipoid soluble regions, both of which may be present simultaneously or may alternate in appearance with time. Others adhere to Overton's theory, according to which the passage of ions is explained by their conversion into lipoid soluble compounds at the time of their passage. Still others lay stress on the role played by electric charges on the surface. The selective permeability of the protoplasmic surface layer also may be conditioned by the interstices of the molecules constituting it, and by the chemical affinity for cations or for anions, according to whether carboxyl or amino groups predominate in the surface layer.

CONCLUSION

Protoplasm is an organized entity in which structure and chemical reactions are closely integrated. It possesses the physical properties of a plastic. deformable material. Although a major part of its substance is water. dispersed through it as a continuous phase, protoplasm contrives to maintain its structural integrity in an aqueous environment. It follows that water-insoluble materials, such as lipids and fibrous proteins, must predominate at its surface.

The physicochemical nature of this surface film largely conditions the interchange of materials with the environment. The mechanical rigidity of a living cell is a function of the nature of its envelope. of the water-imbibing property of its protoplasm. and of the ability of protoplasm to undergo reversible sol-gel transformations.

The kinetics of the catalytic and other chemical reactions of protoplasm are aided by the ultrastructure of its ground substance with its large multiplicity of surfaces. blechanisms which regulate these reactions involve the control of hydrogen-ion concentration and of levels of oxidation-reduction intensities. Of particular importance are the enzymes which, by means of reversible. coupled reactions, make energy available for the functioning of the cell. It is an interesting iact that cells are built up of the same kind of materials that are used as substrates for their energy-yielding reactions.

In summary, protoplasm, as the physical basis of life, is a dynamic system of organized matter constantly absorbing and expending energy. Its uniqueness is due to the fact that part of the absorbed energy it utilizes for its own regeneration and growth, the remainder being largely expended as work and heat.

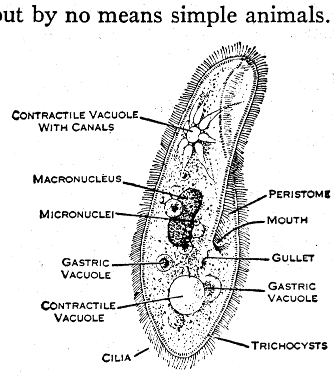
(R. CH.; K. G. ST.)

PROTOPOPOV, ALEXANDER DMITRIEVICH (1864–1918), Russian statesman, was born in 1864 and educated in a military school. He served for some time in the army before going into business. As a big landowner of the Simbirsk province, he took an active part in the Zemstvo life, and was elected member of the executive board of the Simbirsk Zemstvo and marshal of the nobility of the Simbirsk province. He was elected member of the third (1907) and of the fourth State Duma, where he joined the left wing of the Octobrist (Moderate Liberal) party. Later he became vice-president of the State Duma. In March 1916 he visited the capitals of western Europe as one of the leaders of the Russian parliamentary delegation. At the beginning of Oct. 1916 he was appointed minister of the interior in the Stürmer cabinet, proving to be now the strongest upholder of reaction. He enforced the censorship, and interfered dangerously with the food-supply work of the Zemstvos and Towns union. At a stormy meeting held at the Duma he was asked to resign his post, and when he refused his name was struck off the list of members of the party. Hated by the Liberal circles and by the Duma, Protopopov not only supported the reactionary policy of Stürmer and Prince Galitzin, but he is said also to have been one of the secret organizers of the disturbances of Feb. 1917, which he proposed to suppress by military force, and which, unexpectedly for him, resulted in the overthrow of the empire and of himself. He was arrested by the provisional government and committed for trial. He remained for many months in the Peter and Paul fortress and was executed by order of the extraordinary commission in Sept. 1918.

PROTOZOA. The Protozoa are usually defined as unicellular animals in contrast with the higher animals, or Metazoa, in which the body is composed of many structural and physiological units, or cells, differentiated to perform the various functions of life. Under the influence of the "cell theory," this interpretation was definitely suggested in 1843 by M. Barry and formally made in 1845 by T. H. von Siebold, the latter establishing the term Protozoa, previously used in a general sense for primitive animals, for the basic phylum of the animal kingdom. However, in view of the fact that each protozoon is a complete independently-living organism, a few zoologists, under the impetus of C. Dobell (1911), prefer to regard the Protozoa as "noncellular" and to restrict the term cell to the units of the tissues of the Metazoa. But this unduly minimizes, for instance, the significance of the fundamentally similar structure and method of division of the Protozoa and the cells of Metazoa and also the highly probable, and generally accepted, view that the Metazoa have evolved from the Protozoa by the aggregation and specialization of these units to allow tissue differentiation. The Protozoa apparently have accomplished all that is possible within the confines of a cell, and have endowed the Metazoa with potentialities that are essentially unlimited. (Fig. 1.)

The Protozoa are the simplest but by no means simple animals. Most species are too small to be seen with the naked eye, so their discovery awaited the advent of microscopes in biological studies during the 17th century. In 1674 the Dutch microscopist, Antony van Leeuwenhoek, focused his lenses on pond water, vegetable infusions, etc., to reveal a new and prolific microcosm of "animalcules," and became the founder of protozoology and bacteriology.



FROM WOODRUFF, "FOUNDATIONS OF BIOLOGY" (MACMILLAN)
FIG. 1.—PARAMECIUM AURELIA. MAGNIFIED ABOUT 350 TIMES

Significance of Protozoology.—When the Protozoa were discovered they naturally provoked amazement by their small size, stupendous numbers and enormous powers of multiplication, and were seized upon as support for the current views on spontaneous generation which were being undermined, in particular by the work of Francesco Redi on the propagation of flies in 1668. The spontaneous origin of "animalcules" appeared highly plausible, but it was believed by Leeuwenhoek to be fallacious. This was definitely indicated as early as 1718 by the experiments of Louis Joblot, who found that boiled infusions, thoroughly sealed, remained devoid of life.

Although the problem of the origin of the tiny animals long persisted, interest gradually centred on their description and classification. Thus, John Hill in 1752 formally assigned to them the basic position in the animal kingdom, under the title Animalcules, but the first great contributions to their taxonomy were made by O. F. Mueller, chiefly in his monograph published in 1786. This broad survey naturally led to intensive studies on protozoan structure. Is it essentially a tiny replica of the body of higher animals with somewhat similar organs and organ systems, or is it unique? C. G. Ehrenberg presented the culmination of the former view in 1838 and F. Dujardin of the latter in 1841. Dujardin's ideas prevailed during the ensuing decade with the recognition that the protozoan body is relatively simple, being composed of a unit mass of sarcode, now called protoplasm, which is the physical basis of life common to all animals and plants. Then came the realization, as already indicated, that the individual protozoon is comparable to the cellular unit of structure and function in higher organisms. So it appeared that the Protozoa present animal life in primitive form—isolated cells in which the answers to some of the fundamental life problems can be sought more readily than in multicellular animals with tissue differentiation. This viewpoint led to a wealth of important investigations begun shortly after the middle of the 19th century and still continuing unabated, but now with the full realization that the intricacies of protozoan morphology and physiology within the cell—the *multum in parvo* plan of structure—does not necessarily spell simplicity. Indeed, one wonders whether the performance of all the functions of an individual's life within the confines of one cell, instead of in myriads of differentiated cells, is the more simple. Be that as it may, the fact remains that these primitive animals have served as an important approach to many basic questions such as the structure of protoplasm, the intricacies of growth and regeneration, the significance of fertilization, and the factors underlying senility—to cite only a few of many. All told, these studies have contributed greatly to the grasp of general biological problems, even though it may be admitted that the little animals have divulged their secrets somewhat more grudgingly than the earlier workers anticipated in their enthusiasm.

It should be emphasized that much of our information in regard to the Protozoa has been derived from investigations conducted with no immediate object in view other than to broaden the horizon of knowledge. But the facts secured have proved a necessary foundation for other studies of medical and economic importance. It has become increasingly apparent that many Protozoa are disease-producing parasites of man and beast. Although Leeuwenhoek observed some protozoon parasites, it was not until about the start of the 20th century that the causal relation of Protozoa to certain diseases, notably malaria, amoebic dysentery and African sleeping sickness, attracted wide attention. This aspect of protozoology came to form a large and important part of parasitology, and so from the practical as well as the theoretical standpoint studies on the Protozoa afford invaluable information.

Types of Protozoa.—Broadly speaking, all Protozoa are aquatic organisms since they demand a fluid environment for active life. They abound in pools and puddles, lakes and seas, and the soil, as well as in the bodies of higher animals and plants—essentially everywhere that moisture is available and elsewhere when they are in a dormant state. Nearly every animal that has been carefully studied has revealed one or more species especially adapted to live in its body, and therefore it seems probable that there are actually more kinds of Protozoa than there are of all the rest of the animal world, although by 1945 only about 20,000 species had been described.

Active phases of the Protozoa are provided with suitable locomotor organs, and it is on the type of these organs that three of the four great classes of the phylum are chiefly based. The Mastigophora or Flagellata (*e.g., Euglena*) move by flagella, the Sarcodina or Rhizopoda (*e.g., Amoeba*) by pseudopodia and the Ciliophora or Ciliata (*e.g., Paramecium*) by cilia. The remaining class, the Sporozoa (*e.g., Plasmodium*), comprises solely parasites which possess no diagnostic locomotor organs though all species are motile at some stage in their life history. It might appear, then, that the separation of the Protozoa into clearly defined classes should be relatively easy, but since some species exhibit, for example, both flagella and pseudopodia at different phases in their life history as well as other intermediate characters, their relationships must be appraised on the ensemble of characters presented. Comparable difficulties arise in the taxonomy of the various subdivisions of the classes. (Figs. 1–4.)

Although the class Mastigophora comprises the most primitive animals, no hard and fast line can be drawn between the plant and animal kingdoms—one merges into the other when their simplest forms are approached. In fact botanists claim, with considerable justice, some of the flagellates, chiefly because they possess chlorophyll and are able to synthesize food by the energy of sunlight as do typical green plants. But in the absence of light, many of these forms with chloroplasts or chromatophores, such as *Euglena,* are able to use relatively complex food material in solution, and are similar in structure to other species without chlorophyll that are typically holozoic, *i.e.,* engulf solid food. Accordingly, it is to a considerable extent a matter of emphasis on one or another of the various aspects of flagellate physiology and structure which determines whether certain species are regarded as unicellular Algae or Protozoa—a condition recognized by zoologists who stress the animal nature of the flagellates but divide the class into two major divisions, the Phytomastigophora and Zoomastigophora.

Form.—Protozoa in general exhibit a definite "adult" form characteristic of the species, although many of the rhizopods, in particular, readily change their shape by protoplasmic flowing, known as amoeboid movement from the name of the common genus, *Amoeba.* Furthermore, many species have complicated life cycles in which the individual cells at various stages are quite different in appearance so that more than one and often many stages are necessary for identification. Indeed, polymorphic life cycles in which a series of forms follow one another in a definite sequence complicate the concept of "individuality" in the Protozoa just as they do in many higher animals and plants. (Fig. 4.)

The protozoan body form is so exceedingly diverse that nearly every possibility seems to be realized. For instance, the range is from homaxonic or spherical types, typically seen in various floating rhizopods such as most of the fresh-water Heliozoa and marine Radiolaria, to monoaxonic types in which a mouth, or cytostome, is at or near the anterior end of the long axis, resulting usually in imperfect bilateral symmetry as in many flagellates and ciliates. Some of the latter in particular show a marked dorsoventral differentiation with the cytostome on the ventral aspect.

Although the vast majority of the Protozoa are microscopic in size, the lower limit being about 2/1000 of a millimetre, there are giants among the rhizopods; a few of the Foraminifera approximate 15 cm. in diameter and are exceeded by the plasmodia of some Mycetozoa. Well-known species such as *Amoeba proteus* and *Paramecium aurelia* are barely visible to the naked eye under the most favourable conditions. While a fairly definite size characterizes each species, as well as the various stages of polymorphic species, many are composed of races showing size differences, and all are especially susceptible to nutritional and other changes in their environment. Accordingly, size alone is a precarious specific character. (Figs. 1, 2.)

Shells and Skeletons.—External and internal protective and supporting structures, usually permanent but sometimes temporary and restricted to certain stages, are widespread. In some instances the secreted substance is solely organic in nature, such as gelatinous material, tectin or cellulose. In other types there are added to this basis various inorganic elements, in particular calcium and silicon, and also foreign bodies, such as diatom tests and sand grains. The protective covering may be closely applied to the cell surface or separated by a space. In many of the Foraminifera elaborate shells of calcium carbonate are largely internal structures, becoming permeated and surrounded by the protoplasm of the animal. In other species the cell may be supported by a skeleton, often both external and internal, reaching the climax of complexity in many of the Radiolaria. So again, as in the case of form to which they contribute, nearly every shape of protective and supporting structure that can be imagined in a unicellular animal has been attained, and even the most elaborate of these are necessarily formed anew during reproduction and often repaired after mutilation. An example of the complexity of the process of shell-building is afforded by certain common freshwater rhizopods. Thus in *Difflugia*, with a simple shell composed of siliceous particles embedded in an organic matrix, the foreign material is gathered before fission and passed to the offspring during the process; while in the closely related *Euglypha,* plates and spines are secreted by the parent cell and later become arranged on the surface of the young animal. (Fig. 5.)

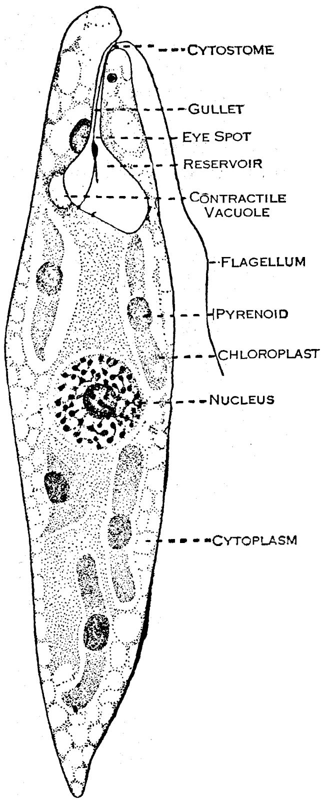
Cell Body.—The cytoplasm of the protozoan body usually exhibits two general regions: an outer, clear, relatively homogeneous layer, or ectoplasm, and an inner, granular mass, or endoplasm, forming the bulk of the cell. The ectoplasm proper is physiologically delimited from its surrounding by an altered surface, or plasma membrane, which by virtue of selective permeability controls the diffusion of materials into and from the cell. Usually there is also a definite skin, or pellicle, that may either appear structureless or show striations, grooves, ridges or sculpturing in various ways,



FROM MACDOUGALL & HEGNER, "BIOLOGY: THE SCIENCE OF LIFE" (MCGRAW-HILL BOOK CO.), AFTER BAKER

FIG. 3.— EUGLENA AGILIS, A GREEN FLAGELLATE. MAGNIFIED ABOUT 1,500 TIMES

sometimes in relation to the protrusion of cilia or flagella. Also in the ectoplasm there may be skeletogenous material in the form of rods, plates and fibrils, and contractile fibres or myonemes, as well as specialized organelles serving other functions, particularly those which are in direct relation to the environment of the cell.

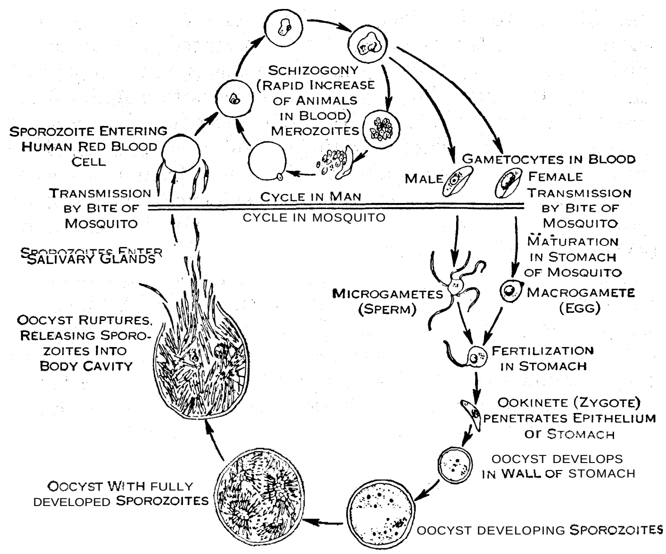
The endoplasm, in contrast with the ectoplasm, is relatively fluid, markedly granular and vacuolated; the last character giving the impetus to O. Buetschli's well-known "alveolar theory" (1878, 1892) of the finer structure of protoplasm. Within the endoplasm is the nuclear apparatus, comprising one or more nuclei, and most of the organelles, such as gastric vacuoles, contractile vacuoles and chromatophores, as well as stored proteins, carbohydrates and fats, and crystals and other metaplasmic bodies. Chondriosomes and Golgi bodies have been described in many species and probably are always present.

Motor Organelles. — Motor organelles—pseudopodia, flagella and cilia—have served from the time of Felix Dujardin (1841) to demark three of the great groups of Protozoa. Pseudopodia are temporary extensions of the body which range in complexity from mere outflowings of the protoplasm of the cell, as seen in Amoeba *proteus* and its allies, to more definitely formed structures as found in the Heliozoa and many Radiolaria. All pseudopodia function to some extent in locomotion and prehension of food, but the latter use predominates in many species. Four general types of pseudopodia may be distinguished, each of which is characteristic of certain species, though subject to considerable modification under varying surroundings. Lobopodia are relatively broad and usually blunt outflowings of both ectoplasm and endoplasm (*e.g.,* in common Amoebae); filopodia are long, slender, pointed threads of ectoplasm (*e.g.,* in *Euglypha*); myxopodia are threadlike and tend to branch and fuse to form large meshworks (*e.g.,* in the Foraminifera); and axopodia are relatively stiff raylike processes, each consisting of an axial filament arising from a basal body in the cell and enclosed by a layer of flowing protoplasm (*e.g.,* in the Heliozoa). Axopodia in certain species approach the structure of flagella and have been regarded as evidence of a close relationship between the Heliozoa and Mastigophora. (Figs. 2, 6.)

Flagella are long, vibratile threads of protoplasm which extend from the surface of the cell and function chiefly as locomotor organs, but also may serve to waft food-bearing currents toward the animal or to explore the immediate surroundings in a sensory capacity. The number of flagella varies in different species from one to hundreds, but usually does not exceed four. Typically they arise at the anterior end of the cell and project forward, but in many common species with two flagella (*e.g.,* Bodo sp.) one flagellum trails posteriorly, acting as a gliding organ or rudder. There may be considerable variations in length and also in form of the flagella in the same and different species. Most flagella are circular in cross section, but some are flattened or form the edge of an undulating membrane as in certain parasitic flagellates (*e.g.,* Trypanosomes). The finer structure of flagella is extremely difficult to determine, but from the study of favourable examples it evidently consists of two parts—an elastic sheath which envelopes an axial vibratile filament, the latter being an outgrowth of a basal body, or blepharoplast. The mechanism of flagellar movement is apparently inherent in the flagellum itself because it retains activity when isolated with its basal body. The basal body is a centriole, or a derivative of a centriole, which is usually situated just under the cell surface near the point of exit of the axial filament but may lie deeper and be closely associated with the nucleus. In many species the kinetic system is complicated by multiple basal bodies, parabasal bodies, axostyles, rhizoplasts and other elements of unknown function too diverse to be briefly summarized. (Figs. 3, 16, 19.)

Cilia are relatively short protoplasmic threads which arise from basal bodies in the ectoplasm of all species of the Ciliophora. They are usually exceedingly numerous and form longitudinal rows that may be evenly distributed over the surface of the cell or restricted to certain regions and differentiated for special functions. Thus the union of the cilia in a row or the union of rows of cilia, or both, form such complexes as undulating membranes and membranelles in the oral region for wafting food into the peristome, while the fusion of tufts of cilia constitutes bristlelike cirri for crawling and tactile purposes. The basic structure and mechanism of movement of cilia appear to be similar to that of flagella, but the effectiveness of ciliary action is caused by waves of contraction passing along the rows, each composed of a multitude of cilia coordinated by underlying fibres that connect the basal bodies. (Figs. 1, 14.)

Nucleus. — The nuclei of the Protozoa have the same basic structure and function as in metazoan cells: a nuclear membrane encloses the karyolymph in which are embedded achromatic and chromatic elements; the latter constitutes the definitive chromosomes. However, the nuclei show much more variation in general structure than do those of the 'Metazoa, and in many cases kinetic bodies are intranuclear. All attempts to arrange a satisfactory evolutionary series of nuclear types have failed, largely because diverse types may occur in obviously closely related species. It is customary to classify protozoan nuclei in a broad way as either vesicular or massive. In the former type



FROM WOODRUFF, "FOUNDATIONS OF BIOLOGY" (MACMILLAN)

FIG. 4.—GENERAL SCHEME OF THE LIFE HISTORY OF A HUMAN MALARIAL PARASITE. PLASMODIUM

the chromatin is concentrated in a centrally located body, the endosome, surrounded by a zone of clear karyolymph; but there are many gradations between this condition and the massive type in which the chromatin is distributed evenly throughout so that the nucleus presents a comparatively homogeneous appearance. Both nuclear types may be found in the same genus: the micronuclei are typically vesicular in some species of Paramecium and approach the massive in others.

The majority of Protozoa contain a single nucleus, but there are many species with two or more nuclei, and some with hundreds. Common forms with many nuclei are represented by the large freshwater rhizopod, *Pelomyxa,* certain stages of the Mycetozoa and some of the parasitic ciliates of the frog, such as *Opalina.* Multiple nuclei may be present during nearly the whole life of a species, or only in stages preparatory to reproduction by multiple division.

A unique and characteristic condition prevails in nearly all of the ciliates, where the typical nuclear apparatus comprises two structurally differentiated parts: usually one relatively large macronucleus and one or more micronuclei. Both types divide during cell division, but the macronucleus is apparently a composite nucleus which as a whole divides amitotically in distributing its component elements which may individually divide mitotically. The micronuclei divide by typical mitosis and on them depends the origin of gametic nuclei, and the formation of a new macronucleus after fertilization as well as in a nuclear reorganization process known as endomixis (&. ').

FIG. 5.— (A) ARCELLA SHOWING THE PROTOPLASM THROUGH THE TRANSPARENT SHELL AND ALSO PROTRUDING AS PSEUDOPODIA, (B.) DIFFLUGIA SHOWING THE SAME; (C-F) SHELLS OF FOUR SPECIES OF FORAMINIFERA. VARIOUSLY MAGNIFIED

In addition to the formed nuclei, sometimes there are granules distributed in the cytoplasm that have been released from the nucleus. Many of these take nuclear stains and are undoubtedly chromatin, but the chromatin nature of others is highly questionable. The chromatin granules, or chromidia, gave rise to elaborate theories, by R. Hertwig and his school, in regard to their cell function, particularly in reference to the nucleo-cytoplasmic relationship and to the origin of the nuclei of gametes. It is generally accepted that a delicately balanced proportionality normally exists between the volume of nucleus and cytoplasm of a cell, a relationship which, however, varies within limits during different phases of cellular activity. Granting this, it is assumed that the nucleo-cytoplasmic ratio is under certain conditions maintained by the elimination of chromatin from the nucleus. This may well be true, though crucial evidence that chromidia function in this way is lacking. But the aspect of the "chromidial hypothesis" which is of most interest assumes that formed nuclei, especially of the gametes, arise from chromidia in certain species. A number of categorical descriptions of such an origin have been given, but more recent observations demonstrate beyond peradventure in all cases that have been critically re-examined (*e.g.,* in the Foraminifera) that the nuclei of the gametes are formed by a continuous series of mitotic divisions involving definite chromosome distribution.

It is clear then that nuclear division, long believed to be amitotic in many Protozoa, is really mitotic since it involves the exact distribution of chromosomes or elements comparable with chromosomes in metazoan cells. This has been demonstrated by observations on dividing nuclei in certain species, and also by the results derived from genetic studies that can be interpreted only from the standpoint of a segregating mechanism as in Metazoa. It is true that the macronucleus of ciliates divides as a whole amitotically but, significantly, is replaced periodically from mitotically dividing micronuclei. Although in many species of Protozoa definitive chromosomes have not, actually been seen, in others specific chromosomes have been unequivocally identified in both the haploid and diploid state; *e.g.,* the diploid number in the sporozoan, *Aggregata eberthi,* is 12, and in the foraminifer, *Patellina corrugata,* is 24. In most cases the chromosome nurnber is within the usual range of that found in metazoan cells, say less than 50, although polyploidy may greatly increase the number, as in certain races of *Paramecium bursaria.* Again the number may mount to more than a thousand, as in the so-called polyenergid nuclei of some of the Radiolaria that may be essentially aggregates of nuclei.

In contrast with metazoan nuclei, the protozoan nuclear membrane usually persists during mitosis, and the centrioles or comparable kinetic agents, as well as the spindle, are intranuclear. However, variations are very numerous and range from cases where part of the mitotic apparatus is outside the membrane to those in which the whole mitotic figure arises in the adjacent cytoplasm (figs. 8, 9).

Nutrition. — Various methods of nutrition occur in the Protozoa and, in general, these are characteristic of particular groups. Autotrophic, or holophytic, nutrition is found in the chlorophyll-bearing species, particularly in the phytoflagellates, and involves photosynthesis as in green plants, but some of these species, even in the light, require nitrogen in organic combinations, such as amino acids. In the absence of light most. autotrophic forms (*e.g., Euglena*) can absorb organic substances dissolved in the medium and so live by the saprozoic method, whereas many of the free-living flagellates without chlorophyll and nearly all parasitic Protozoa are solely saprozoic. But variations in details of nutrition are legion. For example, it appears that some of the free-living, colourless flagellates can be cultivated on a remarkably simple inorganic medium to which acetate has been added as a carbon source. Indeed, it is becoming increasingly clear from extensive studies on pure cultures of various species and races of flagellates, rhizopods and ciliates in controlled media, where the significance of vitamins, trace elements, and so on may be determined, that there are many intermediate gradations between typical autotrophic and saprozoic nutrition and between the latter and holozoic nutrition in which particulate food is required. To define this nutritional versatility a highly elaborate but unsettled terminology has been developed.

The majority of the free-living species are holozoic, ingesting solid food. usually micro-organisms, such as bacteria and yeasts, and other Protozoa. This involves the development of a wide variety of methods for securing and ingesting the food. In most rhizopods the mere contact of the nutrient material with nearly any point on the exposed surface of the protoplasm is followed by its gradual engulfment by pseudopodial action; in other species a special receptive point for ingestion is provided. This may consist, as in some flagellates, merely of an exposed region at the anterior end near the base of the flagellum, or, as in many ciliates, of a definite cytostome leading into the endoplasm. The cytostome may be terminal but more often in the ciliates it is situated laterally and ventrally in a funnel-like depression of the surface, the peristome, and opens into a tubular gullet extending into the endoplasm. Ciliary action in the peristome wafts the food particles in a vortex toward the mouth and accordingly it is in this region that special groups of cilia, such as undulating membranes and membranelles, are present. Species so provided feed continually if food is available because the mouth is permanently open. It has been conservatively estimated that a *Paramecium* may ingest as many as 5,000,000 bacteria in 24 hours. In various other species the mouth is open only when occasion demands. This is particularly true in the case of carnivorous forms which capture prey when chance brings it within reach, as is well illustrated by ciliates such as *Didinium,* whose sole diet consists of *Paramecium,* and *Spathidium,* which feeds on *Colpidium* and closely similar small ciliates. In such cases the food is "selected" by limitations imposed by the character of the oral apparatus. Thus the seizing organ of *Didinium* is in some way adapted so that it adheres to the pellicle of Paramecium and not to that of other organisms with which it happens to come in contact. Quite a different method of food capture is employed by the free-living Suctoria, which in the adult state are devoid of cilia but are provided with tentacles. Prey, such as a small ciliate, coming in contact with the tentacles is paralyzed, presumably by some poisonous secretion, and thereupon its endoplasm is sucked out until there is merely a collapsed remnant. (Figs. 10, 11).

In some species the ingested food appears to lie directly in contact with the endoplasm, but more often it is in a droplet of water, taken in at the same time, that constitutes a gastric vacuole. In most ciliates, such as Paramecium, the vacuole passes from the gullet into the endoplasm, where it is carried along a more or less definite course through the cell by cyclosis. During this passage digestive enzymes, etc., are secreted into the vacuole. The reaction of the vacuolar content varies from acid to alkaline, and the presence of proteinases and amylases has been demonstrated, but in very few Protozoa is there definite evidence of the digestion of fats. although this undoubtedly occurs. However, the details of digestion are largely undetermined, not only because of the delicacy of the technique involved in the study but also because the process varies in different species and in the same species with the nature of the available food. In any event the digestible contents of the vacuole gradually disappear as it circulates through the endoplasm and then the useless residue passes out of the cell, usually at a definite point, the cytoproct. It appears that gastric vacuoles containing material of no food value are rejected after a relatively short course in the cell. (Fig. 1.)

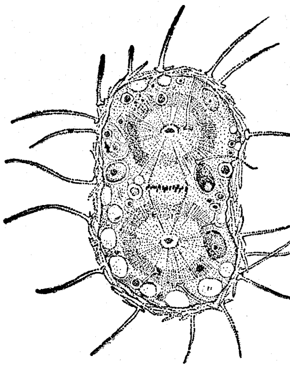
FIG. 7.—A RADIOLARIAN, THALASSICOLLA NUCLEATA. MAGNIFIED ABOUT 15 TIMES

Respiration. — With the wide distribution of Protozoa in nearly every ecological niche of nature, it is not strange that their respiratory processes show considerable variation. The majority of species are strictly aerobic, demanding free oxygen for their normal metabolic processes. This is secured with the intake of water with food and also by diffusion through the whole surface of the body, since structurally differentiated respiratory organs are not present. Similarly the outgo of CO_2 is apparently accomplished by the cellular membrane, probably incidentally aided to some extent by the contractile vacuolar system when it is present. The oxygen uptake and the CO_2 output varies greatly in different species and in the same species under altered internal and external conditions. Experiments indicate that the hourly rate of oxygen consumption of Paramecium *calkinsi* at 20° C. is of the order of magnitude of 28 cu.mm. per 100,000 animals.

Some typically aerobic forms are able to exist for a considerable time as facultative anaerobes and obtain energy from processes that do not require free oxygen, such as the breakdown of glycogen into lactic acid. Paramecium can survive for about 12 hours in the absence of free oxygen. But there are many species that are largely or entirely anaerobic, in particular various endoparasitic forms and those inhabiting mud and highly polluted sewage water. Indeed, free oxygen is lethal for certain species.

Contractile Vacuole.—One of the most interesting among the organelles of the Protozoa is the contractile vacuole that occurs in the majority of fresh-water species, but is usually absent in marine and parasitic forms other than the ciliates. The vacuole appears and disappears rhythmically from view as it gradually accumulates and then expels fluid from the cell. In most forms the vacuole occupies a definite position in the cell, but in Amoebae the general location changes as the animal flows along. Commonly there is only one vacuole, but some species possess two or several. Furthermore, the definitive vacuole, especially in the ciliates, may be the focus of a vacuolar system comprising accessory canals that radiate from the vacuole (*e.g.*, in Paramecium) or ramify widely through the endoplasm (*e.g.*, in Frontonia). In most cases the vacuole is supplied by the migration of tiny droplets of fluid and accessory vacuoles which coalesce at the contractile vacuolar locus or with some part of the canal system when such is present. Many observations indicate that at least some of the droplets of fluid originate in association with osmophilic material, probably representing the so-called Golgi apparatus.



FROM STERN, "ARCHIV F. PROTISTENKUNDE" (FISCHER)

FIG. 8.—MITOSIS (METAPHASE) DURING DIVISION OF A HELIOZOAN, ACANTHOCYSTIS ACULEATA. MAGNIFIED VERY HIGHLY

Although it is difficult to determine the nature of the deliminating surface of the vacuole, it seems clear that some types are surrounded by a structural membrane in addition to the theoretically necessary physiological membrane. Again in some cases the vacuole discharges through a definitive excretory pore, while in others the pore is temporary. The rate of vacuolar contraction varies in different species and also in the same species with changes in the osmotic pressure of the surrounding medium, temperature, and other factors, but in general the vacuolar cycle ranges in duration from a few seconds to a minute.

The first significant suggestion relative to the function of the contractile vacuolar system was made in 1776 by Lazzaro Spallanzani, who regarded it as respiratory, but it is now believed, as first emphasized by M. Hartog in 1888, to be chiefly associated with the maintenance of the proper osmotic relations between the cell and its surroundings by regulating the water content of the protoplasm. A *Paramecium* with two contractile vacuoles may eliminate its own body volume of water in less than 20 minutes. That this system also acts in an excretory capacity to eliminate CO_2 and nitrogenous wastes has not been satisfactorily determined, though undoubtedly such material must incidentally, at least, pass out in the vacuolar fluid. However, the fact that many Protozoa are without contractile vacuoles makes it clear that these organelles are not invariably necessary for such indispensable functions.

Reproduction. — Although reproduction in all animals and plants is basically dependent upon cell division, this is most evident in unicellular forms where the parent individual divides into daughter cells and so loses its individuality. The important types of cell multiplication in the Protozoa are commonly referred to as binary fission, budding and sporulation — all intrinsically asexual processes though in certain instances leading to the formation of gametes. Binary fission involves the division of the cell, both nucleus and cytoplasm, into two essentially equal daughter cells that grow into replicas of the parent. So stated the process seems simple, but obviously it involves making each half into a whole. Dedifferentiation of various structures in the parent cell must be followed by differentiation in the daughter cells. Although some organelles are taken over intact, in general the daughter cells are essentially "new" organisms. For instance, in many of the specialized ciliates it has been possible to show that the highly modified groups of cilia, or cirri, are resorbed and new ones arise in, or migrate to, the proper relative positions on the daughter cells.

Many gradations occur between binary fission and budding, or gemmation, in which the parent cell retains its identity while producing by division one or many daughter cells. Sometimes a bud is essentially as large as the parent, so the result is nearly the same as binary fission except that parent and offspring can be distinguished; but usually the bud is much smaller, less differentiated, and gradually assumes the parent form after it has become free. This condition is well seen in the sessile Suctoria, where the buds become detached as free-swimming, ciliated embryos which finally settle down and develop tentacles and other adult characters. In some species the buds arise on the surface of the parent and in others within deeply invaginated "brood chambers" from which they escape at "birth." The former is referred to as exogenous and the latter as endogenous budding.

Multiple budding leads by various transitions to sporulation, in which the nucleus of the parent cell divides a number of times, followed by the division of the cell body into as many cells as there are nuclei, so that the parent cell becomes resolved into many progeny. Sporulation is obviously a method of very rapid multiplication and is especially characteristic of parasitic forms, such as the Sporozoa with complicated life cycles including asexual and sexual phases. Thus in many species an asexual phase. known as schizogony, is followed by the development of sex cells and zygote formation. This in turn leads to spore formation, or sporogony, and so completes the life cycle. But other variations in reproduction are legion. For instance, so-called plasmotomy sometimes occurs in multinucleate species such as some of the Opalinid ciliates; the cytoplasm divides into two parts, each retaining the nuclei that are in it at the time. A continuation of this process may produce uninucleate cells. (Fig. 4).

Colonies.---Reproduction in the vast majority of the Frotozoa results in individuals that move apart and live a completely separate existence, but in certain species the cells formed by division remain associated so that colonies result. Protozoan colonies vary widely in form ranging from essentially amorphous groups of individuals, or zooids, embedded in a gelatinous substance, to those in which the zooids assume definite spatial relations with each other so as to constitute linear, platelike, spherical or arboroid colonics. All of the individuals composing a colony are, with few exceptions, structurally the same and physiologically independent, though the colony may swim by the combined action of the flagella of its component zooids (*e* g., *Gonium*) or contract as a whole by virtue of a common stalk (*e.g.*, certain arboroid colonies among the ciliates).

Colony formation in some of the phptoflagellates of the family Volvocidae is of special interest because there are various gradations from small groups of individuals, in structure quite similar to those of closely related noncolonial species. to complex colonies of thousands of cells. Representatives of the simpler types are the several species of *Gonium* that ere square, platelike colonies of from 4 to 16 zooids, usually in a gelatinous matrix; and of *Pandorina* and *Eudorina* that consist of spherical groups of 16 or 32 zooids similarly embedded. All of the zooids have the same structure and are capable of asexual and sexual reproduction. But a differentiation of somatic and reproductive zooids appears in various species of *Pleodorina,* comprising up to 128 zooids, and *Volvox,* often consisting of many thousands of zooids connected by protoplasmic strands and forming the surface of a gelatinous sphere. So there is a demarcation of somatic and germinal regions of the colony that is prophetic of the further individualization and attendant physiological division of labour characteristic of the true multicellular organisms. In the case of *Volvox,* particularly, the fact that it is difficult to draw a hard and fast line between a colony and a metazoan individual is evident, and probably such a colony would be regarded as an individual mere there not gradations between it and closely related noncolonial species. Students of phylogeny consider most acceptable the view that the Metazoa were derived from a spherical colony of flagel-

FIG. 10.— SECTION OF THE SURFACE OF A SUCTORIAN, TOKOPHRYA LEMNARUM, SHOWING TENTACLES CONTRACTED, FULLY EXTENDED AND IN THE ACT OF FEEDING. MAGNIFIED ABOUT 2.000 TIMES

lates, not greatly dissimilar to *Volvox.* This view receives support from similarities in the method of development of *Volvox* and some calcareous sponges. (Fig. 12.)

Sex.—Sexual phenomena are wide-spread in the Protozoa but evidently are not universal, as was formerly assumed, because intensive studies of many species have given no supporting evidence. Sex in the Protozoa is expressed in the same basic way as in the rest of the animal kingdom. involving intrinsically the formation of male and female sex cells, or gametes, whose nuclei unite in the zygote to form a composite nucleus! or synkaryon. In some species mature sexual individuals, which are not recognizably differentiated except by their behaviour, unite in pairs and melt together, cytoplasm with cytoplasm and nucleus with nucleus, to form a zygote. In various other species the gametes show nearly all possible gradations in differentiation, both of size and behaviour, finally resulting in minute active sperm and large passive eggs as in most Metazoa. Furthermore, in the ciliates (*e.g.*, in *Paramecium*) a unique process known as conjugation prevails, in which two similar individuals come in contact and temporarily unite about the oral region. Then in each of the conjugants two gametic nuclei of micronuclear origin are formed. one of which migrates into the other conjugant and fuses with its "stationary" nucleus to form a synkaryon. Accordingly this exchange results in mutual fertilization of the conjugating animals which thereupon separate, re-establish the typical nuclear apparatus from the synkaryon, and proceed to reproduce by binary fission. However, in some ciliates, represented by the sessile Vorticellids, mutual fertilization does not occur; the conjugants are differentiated in size and behaviour so that free-swimming microconjugants unite with and fertilize sessile macroconjugants. (Fig. 13.)

In most instances the uniting, gametes are produced by distantly related cells, but sometimes the reverse is true. They may be separated merely by a cell division or two from a common parent, as in some heliozoans, *e.g.*, *Actinophrys* and *Actinosphaerium,* so that very close inbreeding, known as paedogamy, occurs; while in extreme cases the gametic nuclei arise and fuse in the

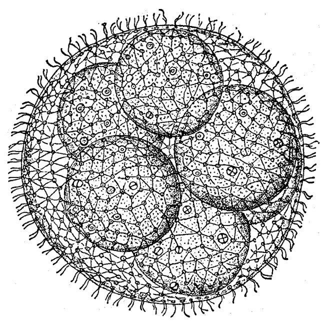
FIG. 11.—A CILIATE, SPATHIDIUM SPATHULA, CAPTURING AND SWALLOWING A COLPIDIUM. HIGHLY MAGNIFIED

same cell. that produced them and so-called autogamy results. The latter takes place under certain conditions in Paramecium and some other ciliates, as also does endomixis in which a synkaryon is not formed although a new nuclear apparatus arises from a micronucleus. Endomixis simulates many of the nuclear phenomena of autogamy but without the attendant genetic possibilities involved in fertilization.

Furthermore, so-called mating types exist in various ciliates. Thus in Paramecium aurelia six such types have been described, each type conjugating with its companion mating type but not with any of the others. When many animals of two companion mating types are mixed together, usually they soon become clumped in large groups which gradually are dispersed as the conjugating pairs swim away. The types are typically established at the reorganization of the exconjugants and are recognizable solely by their mating behaviour, which obviously differentiates the members of the species into physiologically incompatible genetical varieties from the standpoint of fertilization. Variations in mating types occur in other ciliates, involving both the number of types and of companion types for each. The significance of these types in regard to sex phenomena in general is not as yet clear, some authorities interpreting them as evidence of multiple sex systems.

The nuclei throughout the trophic life of most Protozoa contain the diploid number of chromosomes characteristic of the species. Reduction to the haploid condition occurs, as typically in the Metazoa, during the formation of the gametic nuclei, and their union restores the diploid number in the zygote. However, some instances are know, especially among the phytoflagellates and sporozoans, where reduction takes place immediately after fertilization so that only the zygote is diploid. (Fig. 9.)

Genetics.— Reproduction by division unaccompanied by fertilization, *i.e.*, uniparental reproduction, results as a rule in offspring with all their characteristics the same; collectively they constitute a clone. But there are some exceptions of great interest because the clone becomes differentiated into lines of descent with divergent characters. Some of these changes are physiological, such as acclimatization to various temperatures and chemicals, whereas others are morphological, such as size and shape. Some are adaptive and some are not. In certain cases the changes directly attributable to the influence of environmental conditions are inherited for hundreds of generations after the conditions leading to their establishment no longer are present, but in most instances, perhaps all, they gradually disappear. This supports the view that such so-called enduring modifications are chiefly cytoplasmic and are not established in the basic genetic system, as also does the fact that most of them are altered or disappear after sexual reproduction. But some of the heri'table variations within a clone occur without obvious environmental influence, and long-continued selective breeding may isolate and establish different strains. Presumably these are the result of mutations, but how any of the changes during asexual reproduction actually arise is not as yet clear, although the fact remains that they form divergent lines of descent, some of which may be important in the differentiation of species.



FROM DOFLEIN, "PROTOZOENKUNDE" (FISCHER), AFTER KLEIN

FIG. 12.—VOLVOX SP. WITH FIVE DAUGHTER COLONIES PRODUCED ASEXUALLY. MAGNIFIED ABOUT 150 TIMES

However, the chief immediate source of variation arises, as would be expected, from sexual reproduction. In all of the diploid species, as well as in the relatively few haploid forms, inheritance, so far as known, follows the typical Mendelian principles and their extensions, involving segregation, independent assortment, dominance, linkage, crossing-over, etc. But, of course, there are no recessives in haploid species; the offspring manifest combinations of all the characters evident in the parents.

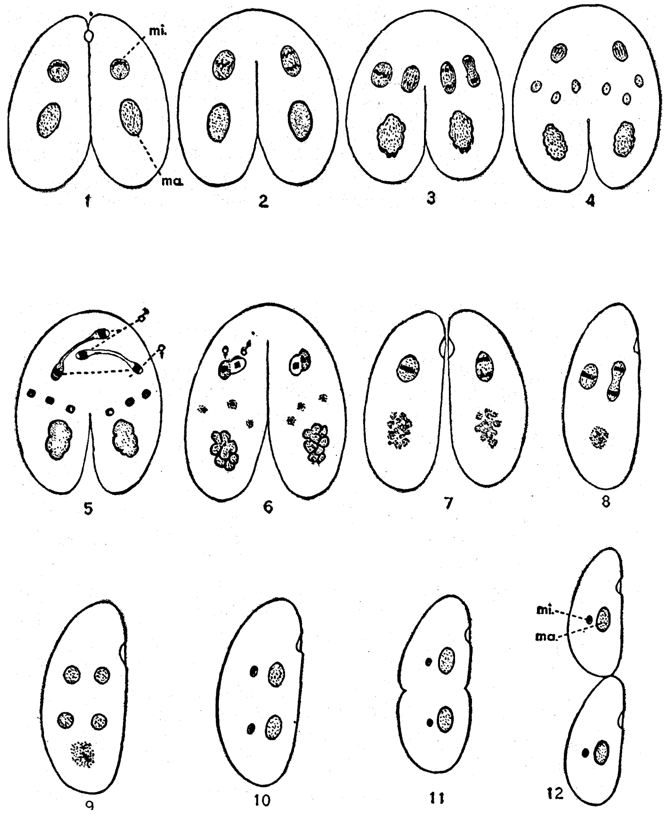
Furthermore, recent work with pedigreed cultures of Paramecium aurelia reveals definite proof of the interaction of specific dominant genes and cytoplasmic factors, both of which must be present if the character involved is to be expressed in the individual, or phenotype. The cytoplasmic element cannot be perpetuated in the absence of the dominant gene in the macronucleus, and the gene cannot initiate the synthesis of the cytoplasmic element. The latter has been referred to as a "primer" of the gene. Obviously this result offers highly significant data for the interpretation of so-called cytoplasmic inheritance in general.

In brief, fertilization in the Protozoa, as elsewhere in animals and plants, produces hereditarily diverse strains from the two uniting gametes and thus is a source of variation that is of crucial importance in adaptation and evolution. And from the standpoint of evolution it is of great significance that the intrinsic genetic mechanism involved is the same from the Protozoa to the highest organisms, including man.

"Cycles."—In addition to its genetic results, fertilization contributes a dynamic effect that arises from the profound reorganization process involved. This aspect of fertilization has been widely studied in pedigreed races of many species of Protozoa ever since it was emphasized by the work of E. Maupas in 1888 and 1889, and elaborated by G. N. Calkins in a series of investigations begun in 1902. In general these studies on ciliates indicated that at conjugation there is initiated a cycle of reproductive activity. Thus after conjugation the rate of division rises for a considerable number of generations and then gradually wanes until death ensues unless the line is "rejuvenated" again by conjugation. This conclusion, if generally true, is of fundamental significance. But other work by various investigators has not only demonstrated that many species of Protozoa, in which fertilization normally occurs, can live under favourable environmental conditions in pedigreed cultures for many years and thousands of generations— apparently indefinitely— when fertilization is excluded, but also has revealed that there are others in which fertilization evidently does not occur at all in the life history. Therefore it is clear that basically fertilization is not a necessary phenomenon to counteract a general inherent tendency to degeneration and death in the Protozoa; and this is in agreement with the apparently limitless vegetative propagation of many plants and the greatly extended life of body cells of higher animals when cultivated in vitro.

Granting that fertilization in the Protozoa is not intrinsically indispensable, extensive experiments nevertheless have shown, particularly in the ciliates *Uroleptus* and *Spathidium*, that when conjugation does occur it actually produces a stimulation of the cell, especially evident in its rate of reproduction. Accordingly the dynamic aspect of conjugation may be of crucial importance— indeed have a survival value—when the organisms are exposed to unfavourable conditions. And the same result probably follows self-fertilization (autogamy), and also endomixis which involves nuclear reorganization without synkaryon formation.

Regeneration.— The power of replacing portions of the cell and specific organelles not carried over at the time of binary fission is, of course, universal in the Protozoa, but nearly equally so is the capacity to regenerate parts lost by mutilations of various kinds at other times in the life of the organism. Both processes are basically similar, involving dedifferentiation, growth, differentiation and reorganization. The animal may retain and remodel old structures, or discard and replace them in a great variety of ways. In some instances a very small amount of cytoplasm with a nucleus suffices for a complete restoration of form. Indeed, under favourable conditions in some of the ciliates, *e.g., Spathidium,* a complete individual capable of division may regenerate from a nucleated piece comprising less than 10% of the original volume of the individual, while much less than this amount may



FROM TURNER, "FERTILIZATION IN PROTOZOA," IN CALKINS AND SUMMERS, EDS., PROTOZOA IN BIOLOGICAL RESEARCH (COLUMBIA UNIV. PRESS)

FIG. 13.—GENERAL PLAN OF CONJUGATION IN CILIATES

1, two individuals joined ventrally, micronuclei in early mitosis; 2, first meiotic (equation) division; 3, second meiotic (reduction) division, macronucleus beginning to degenerate; 4, third division of one of the nuclei in each animal to form the gametic nuclei; 5, exchange of the male (♂) gametic nuclei; 6, fusion of gametic nuclei to form synkaryon and restore diploid condition; 7, conjugants separate, first division of synkaryon; 8, second division of synkaryon; 9, four nuclei produced by the two divisions of the synkaryon, the old macronucleus disintegrates; 10, two of the four nuclei develop into new micronuclei, two into new macronuclei; 11 and 12, first fission of the exconjugant distributes one micronucleus and one macronucleus to each daughter cell, re-establishing the vegetative condition.

suffice for restoration of form without the ability to reproduce. But many other factors besides size and the presence or absence of the nucleus influence the result; among them being the part of the cell involved, the relative amount of ectoplasm and endoplasm present, the phase in the life history, etc. Although a nucleus is necessary in all cases for complete regeneration followed by normal fission, enucleated fragments may survive many hours or until destructive metabolic processes gain ascendancy. In the ciliates either a micronucleus or part of the macronucleus must remain if complete regeneration and reproduction are to occur. Amicronucleate races which are commonly found in some species possess the same power of regeneration as do typical micronucleate individuals.

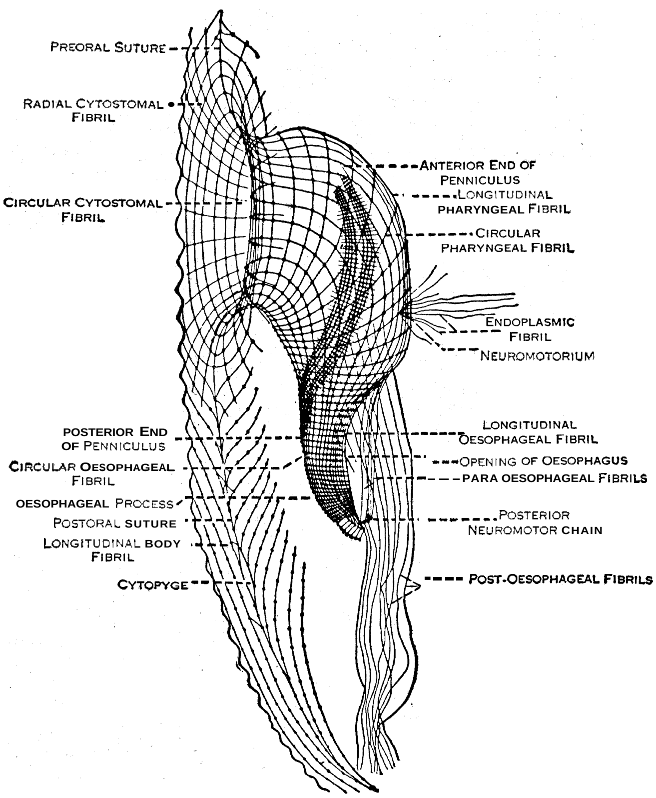
Behaviour.—All Protozoa, of course, respond to many environmental factors. The reception of stimuli occurs in general over the entire surface of the cell, but sometimes special receptors are also present. Apparently pseudopodia, flagella, cilia, cirri, etc., act as tactile organs and probably as chemical receptors, but the most specialized sensory structures are photoreceptors such as the stigma. or eye spot, of many chlorophyll-bearing flagellates, represented by the various species of *Euglena* and *Volvox.* In the latter the organelle consists of a cup of pigment surrounding a photosensitive substance, and a lenslike structure near the opening of the cup. Evidence indicates that the lens brings certain light waves to a focus on the photosensitive material. More remarkable still is the eyelike apparatus of certain Dinoflagellates which is provided with a large spherical lens.

The effect of stimulation in most cases is conducted by the entire cell, but at least in certain ciliates, such as *Epidinium* (*Diplodinium*), *Euplotes* and *Paramecium,* a so-called neuromotor system of conducting fibres is found. This system is integrated with the general supporting ectoplasmic fibrillar network and specifically comprises a complex of fibres that ramify from a focus, or motorium, near the gullet and terminate at the basal bodies of the cilia or cirri. Experiments indicate that the system has a conductile function, because severance of the relationship of the fibres with the motor organs results in the loss of co-ordinated movement by the latter. (Fig. 14.)

Motor responses to particular agents are referred to as chemotaxis, thermotaxis, phototaxis, galvanotaxis, etc., in accordance with the nature of stimulus involved. Apparently in actively motile forms the reactions to stimuli are of two general but related types, one involving the trial and error method and the other directive action. In the former type of motor reaction an animal when stimulated stops and retreats, then turns at an angle to its previous course and proceeds again. And this avoiding reaction, or shock reaction, is repeated until, if possible, the animal is removed from the stimulating agent. In general, unfavourable stimuli induce responses whereas favourable ones do not, and accordingly the animals tend to collect where optimal conditions prevail; the reactions, though negative, are in the long run adaptive. In contrast to such responses, directive reactions are relatively rare and, indeed, intrinsically may involve shock reactions although the organism moves toward or away from the stimulus. They are best exhibited in the response of some chlorophyll-bearing flagellates to light, and of various species to electric currents. Changes in the intensity or direction of light rays so affect the stigma that by a series of responses the organism becomes oriented with its long axis parallel with the beam of light. If the anterior end of the cell is oriented toward the source of light, progression is in that direction. Such positive phototaxis is usual in the green flagellates, but is subject to modification by various factors, such as abrupt changes in the intensity of the light or the chemical condition of the environment: as indeed are all reactions of the Protozoa. Most Protozoa exhibit galvanotaxis by directive responses to the passage of an electric current. Amoebae extend pseudopodia toward the cathode and move in that direction. Flagellates usually proceed toward the anode and ciliates toward the cathode, largely as a result of the direct action of the current on the locomotor organs. Accordingly, when certain flagellates and ciliates are intermingled on a slide under the microscope, they can be separated by the passage of a constant current —anodically galvanotactic flagellates moving to one pole and cathodically galvanotactic ciliates to the other. Then if the current is reversed the two groups rush toward each other, pass and again assemble at opposite poles.

But the behaviour of the Protozoa is not so stereotyped as might appear from the relatively simple reactions just mentioned. In certain cases these may be integrated so that the animals exhibit potentialities beyond those of mere automata. This condition may be glimpsed if a ciliate, *Stentor roeseli,* while sessile is stimulated by a tiny stream of carmine grains. In general, when the useless carmine first reaches the peristome no reaction occurs, but as the carmine continues, the animal bends over to one side. If this behaviour does not remove the stimulus, the ciliary beat is temporarily reversed so that the carmine momentarily does not reach the oral apparatus. And, if the stimulus still continues, the organism contracts more or less violently and, finally, becomes detached and swims away. Furthermore, when a *Stentor* which has reached the contraction stage in the series of reactions is stimulated again within a few minutes, it does not run the gamut of responses but immediately contracts. Obviously a series of different physiological states has been initiated, since the animal successively responds in a different manner to the same stimulus. Behaviour is modifiable.

Explosive Organelles. — Prominent among the various specialized organelles that contribute to the versatility of the protozoan cell are trichocysts and similar explosive structure. Trichocysts occur in many ciliates and have been most intensively studied in *Paramecium*, where they are quite evenly distributed



FROM LUND (UNIV. OF CALIF. PUBL. ZOOL., VOL. 39, P. 48, FIG. A)

FIG. 14—DIAGRAM OF THE NEUROMOTOR SYSTEM IN THE PERISTOMIAL REGION OF PARAMECIUM MULTIMICRONUCLEATUM VERY HIGHLY MAGNIFIED

just beneath the surface of the cell. Each trichocyst is a minute, spindle-shaped body which, on mechanical or chemical stimulation, ejects material that instantaneously forms a relatively long filament projecting from the cell. The function of the threads has not been determined but probably is protective. Exploded trichocysts may be replaced by new ones. More complex trichocysts, called cnidotrichocysts, occur in other species, for example the ciliate *Prorodon,* where they consist of a capsule containing a coiled tube which on discharge is everted and apparently passes material to the exterior. Indeed in some species it is evident that toxic material is secreted because free-swimming prey is paralyzed upon contact with the oral region to which the trichocysts are confined. Cnidotrichocysts closely approach in structure the nematocysts of coelenterates, as is evidenced by the fact that especially complex examples found in two genera of dinoflagellates were formerly regarded as ingested nematocysts. Again, an immense group of the Sporozoa is known as the Cnidosporidia because the highly specialized spores are characterized by so-called polar capsules, each containing a spirally-wound thread that evaginates and apparently serves as an anchor when the proper position is attained in a new host. The diversity of structure and function of explosive organelles makes it obvious that they have evolved independently in different groups of Protozoa. (Fig. 15.)

Encystment.—Many species of Protozoa have the ability to seal themselves in essentially impermeable cases, or cysts, to meet various exigencies of the environment or to carry on digestion and reproduction. So-called protective cysts enable the organism to withstand desiccation, lack of food and other conditions inimical to active life and are most common in fresh-water and parasitic forms. The general procedure of encystment in free-living species, such as many ciliates, involves a complex series of events. The animal becomes quiescent while cilia, flagella, and other organelles not absolutely essential for life are resorbed, and food and inert material are ejected. Contractile vacuoles function more and more slowly and finally disappear as water is eliminated and the body becomes a relatively small sphere. While this dedifferentiation is proceeding, the cyst wall is secreted which commonly consists of an outer gelatinous layer, or ectocyst, and an inner delicate membrane, or endocyst, but there is great variation in composition and structure. The ectocyst rapidly hardens and frequently has characteristic spines, warts, etc. Within this resistant case the dormant animal, with all life processes reduced to a minimum, can survive unfavourable conditions for long periods of time. Thus cysts in samples of dry soils, tightly bottled, have yielded the ciliate *Colpoda* after 38 years, and small amoebae and flagellates after 49 years, when supplied with culture fluid; but the evidence indicates that most ciliates encysted on dry hay rarely survive more than five years. The process of excystment is broadly the reverse of encystment and is initiated by the presence of moisture or, if the cysts are already in water, by the return of favourable temperature, chemical conditions and the presence of food. The endocyst is dissolved by enzyme action induced by the animal, which thereupon ruptures the ectocyst and escapes to assume its typical form.

The world-wide distribution of many of the Protozoa is probably dependent to a large extent upon their ability to encyst, which enables them to be transported in numerous ways, such as by adhering to the feet of birds or to dry grass, and by being wafted by air currents. However, results obtained from the exposure of sterile culture media to the atmosphere indicates that only a relatively few species are usually disseminated in the air: chiefly tiny amoebae and flagellates and the ciliate *Colpoda.* And, incidentally, there is no completely satisfying evidence that the cosmopolitan *Paramecium* encysts, in spite of the prevalent notion that a culture can be established by the infusion of dry hay in sterile water.

In many parasitic forms, notably the Sporozoa, cysts are crucial in order that the parasite may weather the outside world during chance transfer to a new host. Indeed, the absence of protected stages during a parasite's life history usually indicates that it is directly transferred by an intermediate host. Many of the highly specialized protective cysts of parasites are also reproduction cysts because spore formation and other types of multiplication occur in them. Encystment in such cases does not involve a dedifferentiation of the animal but rather its specialization for the reproductive process. Furthermore, various free-living species encyst for reproduction, fertilization or simply to digest a heavy meal. In the life history of the foraminiferan *Patellina corrugata* growth cysts, fission cysts and fertilization cysts occur in sequence. Obviously, then, protozoan cysts serve such various functions, sometimes several simultaneously, that it is often impossible to distinguish sharply among the many types.

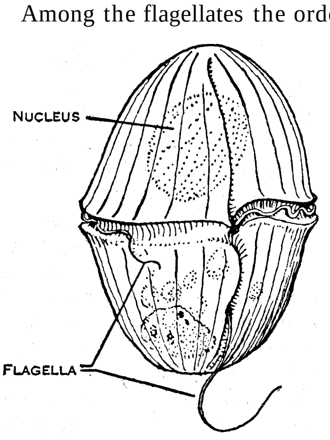
FIG. 15.—CNIDOSPORIDIAN SPORES WITH POLAR CAPSULES. VERY HIGHLY MAGNIFIED

DISTRIBUTION

Protozoa are essentially ubiquitous wherever moisture is available, but certain species are, of course, adapted to special habitats so that characteristic faunas develop. Excluding for the moment parasitic species that constitute highly specialized groups within nearly all higher animals and some plants, a few representative examples of marine and fresh-water faunas will serve as examples, but it must be borne in mind that each of these major faunas is, in turn, formed of numerous relatively local faunal groups.

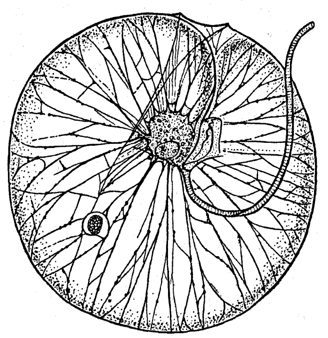
Among the flagellates the order Dinoflagellata stands pre-eminent in its contribution to the microscopic life of the sea. Typical dinoflagellates possess two flagella, usually lodged in grooves, one encircling the body and the other trailing posteriorly. Nutrition is commonly autotrophic through the presence of chromatophores, but many holozoic and parasitic species occur, and some ,of the zooxanthellae in the Radiolaria and Foraminifera are apparently symbiotic dinoflagellates. Although some species abound in fresh waters and are troublesome in municipal reservoirs, they are inconsequential in comparison with those constituting the marine fauna which plays an important part in the nutrition of oceanic life as a whole. This is chiefly because of photosynthetic activity that makes many species a first link in the nutritional chain and so an integral part of the so-called ocean pastures; but some species exist in such prodigious numbers that they directly constitute a significant part of the food of tiny invertebrates and so indirectly of higher animals. Vast areas of the sea may be discoloured by their presence; thus not infrequently the water appears orange like "tomato soup" from the presence of incalculable numbers of the cosmopolitan *Noctiluca miliaris,* and the same organism is responsible for much of the luminescence of marine waters. (Figs. 16, 17.)



FROM WOODRUFF, "FOUNDATIONS OF BIOLOGY" (MACMILLAN)

FIG. 16.— A DINOFLAGELLATE, GYMNODINIUM SP. MAGNIFIED ABOUT 500 TIMES

The great contributions of the rhizopods to the microfauna of the sea are made by the Foraminifera and the Radiolaria. Most species of the former are bottom-dwellers that creep on the surface of the mud and ooze or attach themselves loosely to foreign material, but pelagic species are represented by enormous numbers of individuals. The shells, composed chiefly of calcium carbonate, sink to the bottom and contribute to the Globigerina ooze, so called because of the predominance of members of the Globigerinidae and closely related forms. This and similar deposits cover vast areas—perhaps one third of all the ocean floor down to approximately 5,000 yd.—and have been computed to be accumulating in certain regions at the rate of about 12 mm. in 1,000 years. At greater depths other species with arenaceous shells persist. Deposits during the geologic past are represented today by' limestone, as seen in the chalk cliffs of England. Various types have rather definite geologic and geographic ranges and therefore are of significance in determining the age and characters of sediments and the general conditions under which they were laid down. Such knowledge is of great value in checking well-drillings and accordingly in locating oil-bearing strata. (Fig. 5.)



FROM PRATJE, "ARCHIV F. PROTISTENKUNDE" (FISCHER)

FIG. 17.—NOCTILUCA MILIARIS. MAGNIFIED ABOUT 50 TIMES

Although a few species of the Foraminifera inhabit fresh and brackish water, the Radiolaria are solely marine and adapted to a pelagic life. The body is typically spherical or conical and is usually supported by a silicious skeleton in a bewildering array of beautiful patterns. The distribution of the group as a whole is very extensive, both horizontally and vertically, and the skeletons accumulate in the great depths of the sea where calcareous shells of other forms become dissolved. Here in association with sponge spicules, diatom tests, and so on, they form the chief element of the Radiolarian ooze. And in the geologic past their skeletons have made large contributions to silicious rock. (Fig. 7.)

The ciliate fauna of ocean waters is by no means inconsequential, but it is not comparable in importance with those of the flagellates and rhizopods. Most typical is the wealth of marine species and individuals of the Tintinnidae, pelagic heterotrichous forms provided with vaselike protective cases consisting chiefly of a secreted organic material moulded into widely divergent but specific patterns.

As to the more varied conditions afforded by bodies of fresh water, it is impossible even to summarize the distribution of large groups of Protozoa in such broad terms. Members of the three free-living classes flourish everywhere in puddle, pond and lake, and some occur in hot springs and Arctic waters. Most of the common species abound in similar places the world over. Many species are remarkably adaptable, being equally at home in fresh or brackish water or even in the sea. Although this is true, very slight variations in conditions, particularly the type of available food and the chemical constituents of the environment, determine the presence or absence of certain species. For instance, *Paramecium* feeds chiefly on bacteria, and *Didinium* solely on .*Paramecium,* so that depletion of the bacteria eventuates in the encystment of *Didinium.* This interdependence seems relatively clear-cut, but it involves various other factors not immediately apparent.

The practical impossibility of analyzing many of the elements involved in the "web of life," even in a relatively restricted environment, is well exhibited by the general development of an infusion of a few wisps of hay and water. Here the obvious components merely supply the matter and energy for the interplay of various micro-organisms present in a dormant or active state on the hay or in the water. A microscopical examination of a newly-made infusion shows very few active organisms, but if the temperature is favourable countless bacteria arise in a day or so from the relatively small number originally present. Then during the period of bacterial ascendancy another factor intrudes itself: microscopic animals, chiefly Protozoa that have been multiplying with increasing rapidity as conditions became more favourable, soon become the dominant life phase in the infusion. Usually first to appear are various species of minute flagellates, some saprozoic and others holozoic, that employ the products of organic disintegration supplied by the activity of the bacteria and the bacteria themselves. Then tiny ciliates, such as *Colpidium* and *Colpoda* appear in countless numbers and feed on the bacteria. This dominance of small ciliates is terminated after a time by the ascendancy of larger ciliates which, though feeding to some extent on the now greatly depleted bacterial population, employ chiefly the smaller Protozoa as food. And so the general nutritional cycle in the infusion continues with attendant chemical changes; saprozoic species are gradually replaced in dominance by herbivorous types, and these in turn by others that are carnivorous. But clearly this sequence of events must sooner or later terminate; extermination faces the population unless chlorophyll-bearing organisms are present to entrap and store the energy of sunlight—to form food photosynthetically. If such occurs, the hay infusion world is, indeed, a microcosm in which the various Protozoa and other organisms are reciprocally adjusted so that essentially a stable equilibrium results. (Fig. 11.)

Most free-living Protozoa find larger and relatively stable bodies of water conducive to their welfare, but specialized conditions do not always exclude them. Thus various species inhabit the fluid in the traps of carnivorous plants, such as the bladders of *Utricularia* and the pitchers of *Sarracenia,* and others flourish in the water in holes in trees. Most of these species are incidental sojourners but some apparently are especially adapted to the microclimatic factors in such unique environments. Indeed, the examination of blades of grass moist with dew usually reveals certain species making the most of a brief opportunity for activity before returning to the encysted state. And within the soil an immense fauna of Protozoa contributes to soil microbiology in association with bacteria and other fungi, algae, and various lower animals. It appears that the majority of the Protozoa present are essentially cosmopolitan in distribution from the arctic regions to the tropics, though there are certain dominant types in nearly every soil. Most protozoan forms are found in the upper six inches of soil, but large numbers may be several feet below the surface. In general the number of species and individuals present is in direct proportion to the number of bacteria, being most numerous in rich, moist soils. Some idea of the size of the population may be gained from the fact that in one study it was estimated that at the maximum there were more than a million amoebae and flagellates per gram of soil. The view has been urged that the Protozoa may be inimical to soil fertility by destroying types of bacteria important for crop growth. This remains to be proved; but that the Protozoa form an important, active element in the soil microcosm is certainly true, even though many are in the encysted condition for considerable periods. Again here it seems clear that among the various species present some are mere casual inhabitants, while others constitute an endemic soil fauna. And in passing it should be noted that various Protozoa play a part in the so-called self-purification of streams by depleting the bacterial population, whereas others add to the contamination of municipal water supplies chiefly by liberating oily products of metabolism which impart odours to the water that may render it unpalatable. In brief, the adaptability of the Protozoa is so great that they have left hardly a niche in nature untenanted—not even in the bodies of other organisms.

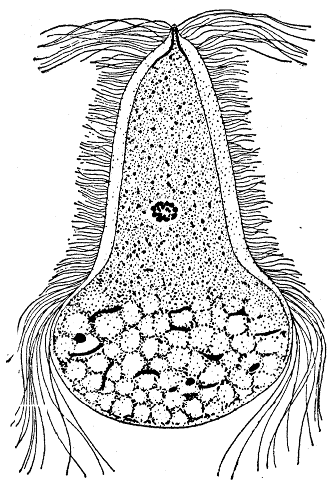
PARASITISM

The intimate association of Protozoa with other animals as commensals, symbionts, or parasites is widespread, but often it is difficult to distinguish between these types of relationship because one may grade into the other, or the same species may act in different capacities under varying conditions. Commensal associations incur no injury to either species involved, the protozoon merely gleaning food as a result of its position on the surface or in the interior of its host. Common ectocommensals among the ciliates are various vorticellids and suctorians attached to hydroids, and *Kerona* and *Trichodina* that crawl on *Hydra*. Endocommensals are more numerous, being widely distributed especially in the digestive tract of higher animals. Among them are most of the bizarre faunas of ciliates that inhabit the stomach or intestine of various herbivorous mammals, such as sheep, cattle and horses; and some of the flagellates and amoebae present in the human intestinal tract.

Symbiotic species, in which the relationship is mutually beneficial, are relatively few but include interesting examples. Thus the common *'Paramecium bursaria* harbours unicellular green forms, or zoochlorellae, in its endoplasm where they multiply and, in return for a relatively safe abode and waste products of metabolism, supply the products of photosynthesis when light is available. Again an immense number of highly specialized flagellates, such as the various species of *Trichonympha* and their allies, dwell in the intestines of certain termites and wood-feeding roaches where they secrete enzymes that digest cellulose and thus make the products available to their hosts. If the flagellates are removed the insects die of starvation. And at least a few of the ciliates mentioned above that inhabit the digestive tract of cattle apparently perform a similar function, although here digestion of cellulose is dependent chiefly upon bacteria. Furthermore, in these and other cases where the protozoan fauna is enormous it may well be that it directly affords an appreciable increment to the nitrogenous food supply of the host. (Fig. 18.)

Associations in which one organism, the parasite, secures the sole advantage at the expense of the hapless host are by far the most numerous. As already mentioned, protozoan parasites have been found in nearly all higher animals that have been investigated, and they also occur in some plants. Even the Protozoa themselves are not immune. Thus a species of amoeba infests the endoplasm of certain opalinid ciliates which, in turn, live in the frog—an example of hyperparasitism.

The most intensively studied protozoan parasites are naturally those which produce serious maladies in man, in particular the malarial organisms, trypanosomes, and endamoebae. The human malarial parasites are members of a large group of the Sporozoa that are known as Haemosporidia because a part of the life history is spent in the blood of vertebrates. Very closely related to the malarial forms in man are those that parasitize birds, and their study has contributed largely to the knowledge of malaria in general. Four species of human malarial parasites had been recognized by 1945, three of them being outstanding in importance: *Plasmodium vivax*, the cause of so-called benign tertian malaria, P. *falciparum* of malignant tertian malaria, and *P. malariae* of quartan malaria. P. *ovale* also produces a benign type of tertian malaria. The life histories of all four species follow a similar general basic plan with a mosquito of the genus *Anopheles* as the invertebrate host. Asexual stages (sporozoites) inoculated by a mosquito into the human blood stream multiply in the red blood cells and probably also in the reticulo-endothelial tissues. Eventually gamete-forming stages (gametocytes) arise which demand transfer from the peripheral blood to a mosquito for further development. If this hazard is met, gametes develop and fertilization occurs in the stomach of the mosquito and then the motile zygote enters the stomach wall and forms a large oocyst within which myriads of sporozoites are formed. Rupturing of the oocyst releases the sporozoites into the body cavity from whence they reach the salivary glands of the mosquito, ready to be inoculated into man. (Fig. 4.)



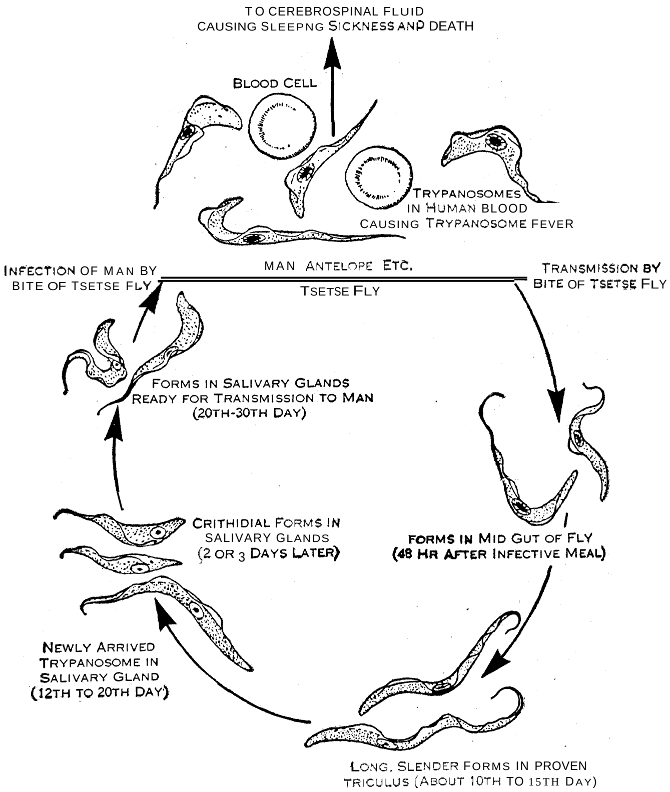
FROM CALKINS "BIOLOGY OF THE PROTOZOA" (LEA & FEBIGER), AFTER KOFOID & SWEZY

FIG. 18.—TRICHONYMPHA CAMPANULA. MAGNIFIED ABOUT 300 TIMES

The most important parasitic flagellates are members of the genus *Trypanosoma* that infest chiefly the blood stream of various vertebrates, including man, usually after a cycle of development in blood-sucking invertebrates. Trypanosomes show considerable change in form during the life history, but the typical "adult" phase found in the vertebrate circulatory system is an elongated bladelike organism, with the flagellum arising from a basal body near the posterior end of the animal and then passing forward as the edge of a delicate undulating membrane to emerge at the anterior end as a free flagellum.

The most important pathogenic forms in man are *Trypanosoma gambiensi*, the causative agent of typical African sleeping sickness, and T. *rhodesiensi*, which produces a similar but still more virulent effect. Both species are morphologically indistinguishable from each other and from *T. brucei*, which does not infect man but is the cause of "nagana" in domestic cattle of tropical Africa. All three are transmitted by tsetse flies and apparently are nonpathogenic in their natural reservoirs, certain antelopes and other wild mammals, and are essentially physiological races of one species. Another human trypanosome of high significance is *T. cruzi*, the cause of Chagas' disease, which is chiefly prevalent in Central and South America. The parasite is transmitted by triatomid bugs and multiplies in various organs of the human body. Most trypanosomes cause little disturbance in their natural hosts; for example, *T. theileri*, transmitted to cattle by tabinid flies and *T. lewisi*, to rats by fleas. The vectors of the trypanosomes of aquatic vertebrates are usually leeches, as in the case of *T. rotatorium* of the frog. (Fig. 19.)

Among the rhizopods that infest man the only true parasite is *Endamoeba histolytica*, formerly believed to be confined to tropical regions but now known to be cosmopolitan in distribution. The other five species are harmless commensals, although E. *gingivalis* of the mouth may take advantage of otherwise infected gums, and is apparently transmitted by contact because cysts are unknown. In the case of E. *histolytica*, encysted stages reach the human intestine, usually in contaminated water or food, where excystment occurs, and the amoebae multiply in lesions they produce in the wall of the colon. In many cases no observable pathological symptoms follow while the amoebae produce a continuous supply of cysts which pass to the outer world, ready to infect another host. The evacuation by the host of more than 40,000 cysts in one day has been recorded. But sometimes this



ADAPTED BY PERMISSION FROM "PARASITOLOGY" BY A. C. CHANDLER, PUBLISHED BY JOHN WILEY & SONS, INC.

FIG. 19.— GENERAL SCHEME OF THE LIFE HISTORY OF TRYPANOSOMA GAMBIENSI

relatively innocuous host-parasite relationship does not prevail, either because of the particular sensitivity of the host or the special virulence of the race of amoeba involved. Then the latter become highly destructive parasites that produce serious lesions in the tissues of the colon, resulting in "amoebic dysentery." In addition the parasites pass to other organs of the body, most often forming abscesses in the liver. Incidentally, this procedure is equally unfortunate for the amoebae, since the progeny are rarely able to encyst and make a getaway to another host. (Fig. 20.)

TAXONOMY

Classification of the Protozoa offers especial difficulties, chiefly because all the variations occur within the confines of a single cell or a series of cells comprising a life cycle, whereas in other animal phyla the numerous characters of multicellular bodies combine to afford more easily discernible diagnostic features. Accordingly, taxonomic systems are to a considerable extent more tentative in the Protozoa than elsewhere in the animal kingdom. However, it is believed that the following brief classification approximates the consensus of opinion of protozoologists and will serve to give a synoptic view of the phylum. It must be emphasized, however, that the versatility of the Protozoa is so great that only the most salient characters of representative types can be cited.

PHYLUM PROTOZOA. Typically unicellular animals that stand in contrast with the rest of the animal kingdom, the multicellular animals, or Metazoa. Four classes are recognized:

Class I. MASTIGOPHORA or FLAGELLATA. The most primitive of the four great classes of Protozoa, comprising animals with one to many flagella in the principal phase of the life history. The typical form is ovate or elongate with a cortex which maintains a definite shape, but there is immense variation and some species are even temporarily amoeboid. Division is almost always longitudinal, Habitats and methods of nutrition are highly diverse; most species are free-living, but many are parasitic.

Subclass PHYTOMASTIGOPHORA. A large assemblage of the most primitive members of the class, some of which can, with reason, be classified as plants. Many species assume a so-called palmella phase in which the cells lose their flagella, round up, and secrete a gelatinous matrix in which they reproduce. Nutrition is usually autotrophic, but many species are saprozoic and some are holozoic at various phases of their life history. They are widely distributed in fresh and salt water.

Order *Chrysomonadida.* Usually small, simple forms, with one or two apical flagella, yellow or brown chromatophores, and often a red stigma. Many are remarkably protean, readily assuming amoeboid and palmella phases. In some species the palmella state is dominant. Nutrition is usually autotrophic, but may be saprozoic or holozoic. Coverings of cellulose and silica are common. So-called coccoliths, common in ocean sediments, are plates of calcium carbonate from the tests of one widely distributed family of this order. Unique silicious cysts are characteristic of the group. Representative genera are *Chromulina, Mallomonas,* and *Dinobryon,* the last usually colonial, and *Synura* and *Uroglena,* both colonial.

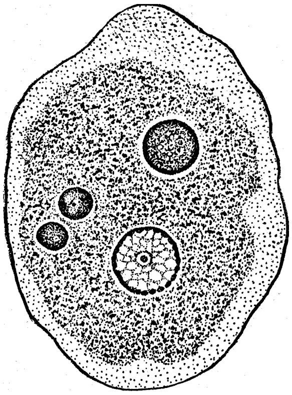
Order *Cryptomonadida.* Tiny flagellates with a relatively constant body form and one or two flagella, usually inserted at the anterior end of a furrow which in some species leads into a cytopharynx, Chromatophores may be yellow, brown, blue or green; but there are many colourless species that are either saprozoic or holozoic. Palmella stages occur. Some cryptomonads live as symbiotic zooxanthellae in other protozoons and in metazoons. Typical genera are *Cryptomonas* (with yellow chromatophores) and *Chilomonas* (colourless).

Order *Dinoflagellida.* A large but relatively circumscribed group; the characteristic type possesses two flagella, disposed in grooves, one of which forms a girdle while the other trails. Most species are provided with tests composed of one or numerous cellulose plates impregnated with inorganic material, but many are naked. Chromatophores are usually yellow or brown. Nutrition is autotrophic, saprozoic or holozoic. Departures from the typical body-plan are numerous, while symbiotic and parasitic species may lose all characteristic structure but form flagellated "dinospores." Representative genera are *Gymnodinium, Glenodinium, Peridinium, Ceratium* and *Blastodinium* (parasitic). The well-known *Noctzluca miliaris,* attaining about 1.5 mm. in diam., is an aberrant, floating, marine species with one small flagellum and a so-called tentacle. It was formerly assigned to a special group, the Cystoflagellata. (Figs. 16, 17.)

Order *Euglenida. A* wealth of common species, usually spindle-shaped, with one or two flagella emerging from a pit or pharynx into which a contractile vacuole discharges.. A red stigma is present in the chlorophyll-bearing forms. Some species are very plastic and exhibit "euglenoid movements." Nutrition is autotrophic, saprozoic or holozoic. Encystment commonly occurs, and palmellá phases are present in some species. Well-known genera include *Euglena* (green, one flagellum), *Astasia* (colourless, one flagellum), *Heteronema* and *Peranema* (colourless, two flagella). (Fig. 3.)

Order *Chloromonadida.* A largely artificial group comprising relatively rare and little-known species, usually with two flagella and small pale green chromatophores. Representative genera are *Gonyostomum* and *Vacuolaria.*

Order *Plzytomonadida.* Typically small, ovate or spindle-shaped cells usually with two flagella, a red stigma and green chromatophores. Many of the phytomonads are colonial. Sexual reproduction is general with isogamous or anisogamous gametes. Common representatives of the noncolonial forms are the many species of *Chlamydomonas,* in a few of which haematochrome develops abundantly under certain conditions so that the organisms impart a reddish tinge to melting snow, rain pools, etc. Some genera, such as *Polytoma,* comprise colourless, saprozoic forms. The family Volvocidae includes the highly interesting colonial types, represented, for example by various species of *Gonium, Pandorina, Eudorina, Pleodorinu* and *Volvox.* The individual zooids are, in general, Chlamydomonas-like in form and vary in number from 4 in *Gontum* to many thousands in *Volvox.* (Fig. 12.)



FROM DOBELL, THE AMOEBAE LIVING IN MAN" (WILLIAM WOOD & CO , 1919)

FIG. 20 —ENDAMOEBA HISTOLYTICA, SHOWING NUCLEUS AND THREE INGESTED RED BLOOD CELLS. MAGNIFIED VERY HIGHLY

Subclass ZOOMASTIGOPHORA. Flagellates without chlorophyll and unequivocally animal in nature, showing an immense structural range from simple to complex. Nutrition is holozoic or saprozoic. Many species are parasitic.

Order *Protomastigida.* Some of the simpler representatives, often referred to as monads, are tiny ovate forms, usually with one or two flagella, but with some amoeboid tendencies. Free, attached, and colonial species occur. Common genera include *Monas, Oicomonas* and *Anthophysa* (colonial). Members of the genus *Bodo,* with one flagellum directed anteriorly and the other trailing, are examples of somewhat more complex iorms, usually possessing a cytostome, multiple basal bodies and a parabasal body near the flagellar insertion. In the genus *Cercomonas* the trailing flagellum passes along the cell surface and becomes free merely at the posterior end, whereas in *Cryptobia* (*Trypanoplasma*) it forms the edge of an undulating membrane so that these parasites superficially resemble Trypanosomes. In one group, the Choanoflagellates, the animals have a delicate cytoplasmic collar about the base of the single flagellum that aids in catching food. The remarkable similarity of these flagellates to the collar cells of sponges and the fact that a colonial representative, *Proterospongia,* forms a gelatinous mass with both collar and amoeboid zooids suggest a possible point of origin of the Porifera, or sponges.

But by far the most significant members of the Protomastigida from the standpoint of human welfare are members of the family Trypanosomidae which comprises a remarkable series of parasitic species. In general they are fusiform or bladelike cells with or without an undulating membrane connecting a part of the single flagellum with the cell surface, but all are highly polymorphic. Three genera, *Leptomonas, Phytomonas* and *Leishmania,* are very similar in the flagellate phase, uith the flagellum arising from a kinetic complex at the anterior end. The leptomonads are confined to invertebrates and chiefly to insect hosts, but the phytomonads are transmitted by insects to the latex of certain plants and the leishmanias to vertebrates. In the vertebrate host leishmania loses the flagellum and rounds up as an intracellular parasite that gives rise to characteristic pathological symptoms; for example, one species produces in man the disease known as "kala azar," and another "Oriental sore." The members of the genera *Crithidia* and *Herpetomonas* are restricted to invertebrates and are similar in structure to the genera mentioned above, but with the flagellum arising further posteriorly and extending forward as the edge of a smal! undulating membrane. Finally, in the genus *Trypanosoma* the flagellum arises near the posterior end and proceeds forward as the edge of an extensive undulating membrane. Trypanosomes are blood-inhabiting parasites of man and other vertebrates, with an invertebrate, usually an insect or leech, as the intermediate host. The trend of evolution in the family is indicated by the progressive polymorphism exhibited by the several genera that reaches a climax in the trypanosomes whose life history recapitulates, as it were, the phases that are dominant in the other genera. (Fig, 19.)

Order *Polymastigida.* An assemblage of diverse forms usually with from three to eight flagella but sometimes with many. The majority of the species are parasites or commensals in the intestinal tract of animals. Among the simpler genera commonly represented by species in man are: *Trichomonas* with one nucleus and four anterior flagella and another flagellum which forms the edge of an undulating membrane; *Chilomastix,* with a single nucleus and four flagella, one of which undulates in a cytostomal cleft; and *Giardia,* with two nuclei and eight flagella arising from three parts of a bilaterally symmetrical body. It is not clear that any of the species are primarily pathogenic, though when present in large numbers they may aggravate abnormal conditions. The most complex polymastigotes live as commensals or symbionts in the intestine of termites and exhibit a reduplication of certain structures of the simpler species so that there may be many nuclei, each associated with several flagella, a parabasal body and other kinetic elements. Examples are *Calonympha* and *Stephanonympha.*

Order *Hypermastigida.* The acme of flagellate complexity is attained in this order, which includes a wealth of commensal and symbiotic forms chiefly in termites and cockroaches. They possess numerous flagella, either widely distributed or in tufts, and a multiplication of kinetic structures but only one nucleus. Regional differentiation of the cytoplasm is remarkable. The origin of the diversity and high specialization of the unique populations of hypermastigote and polymastigote flagellates in a restricted environment is of considerable evolutionary. interest. Common examples are *Lophomonas blattarum,* found in domestic cockroaches, and various species of *Trichonympha,* present in termites and wood roaches. (Fig. 18.)

Order *Rhizomastigida.* A heterogeneous group of species that may almost equally well be included under the class Sarcodina because they are essentially amoebae with one or more permanent flagella. The best-known genus is *Mastigamoeba.*

Class SARCODINA or RHIZOPODA. A huge assemblage of amoeboid animals formerly regarded as the most primitive class of the phylum. The chief general characteristic is the presence of pseudopodia for locomotion and obtaining food, though some temporarily develop flagella, and others produce flagellated gametes. Nutrition is usually holozoic.

Order *Amoebida.* The typical shell-less amoebae with pseudopodia varying from lobose to broad. Some of the simplest forms exhibit interchangeable amoeboid and flagellated phases. Among the larger fresh-water amoebae the best known is *Amoeba proteus* with lobose pseudopodia showing surface ridges, truncate bipyramidal crystals in the endoplasm, and a discoidal nucleus. Reproduction is apparently solely by binary fission. This species sometimes attains a length of more than 600 micra as it creeps along, but members of the genus *Pelomyxa* are very much larger and have many nuclei. One of the latter possibly was the amoeba observed by Rösel von Rosenhof as early as 1755 and named *Chaos chaos* by Linnaeus in 1767. In addition to the many free-living amoeba, large and small, there are numerous parasitic species, the one of outstanding importance being the widely distributed *Endamoeba histolytica,* the sole pathogenic amoeba inhabiting man. (Figs. 2, 20.)

Order *Testacea.* Amoebae with simple one-chambered tests of tectinous material in which foreign particles or secreted silicious plates are usually incorporated. The pseudopodia apparently consist solely of ectoplasm and are often threadlike. Reproduction is usually by the protrusion of a bud from the orifice of the test but, in certain cases, multiple division results in the liberation of many amoebulae that gradually assume the characters of the parent. Common representatives in fresh-water ponds and bogs are the many species of *Arcella* with yellowish, bowl-like tests, and *Difflugia* and *Euglypha* with pyriform tests. (Fig. 5.)

Order *Foraminifera.* An immense array of ,almost exclusively marine, shelled rhizopods of considerable importance. The shells may be tectinous, arenaceous, or silicious, but the majority are calcareous. They may consist of one or many chambers, and be imperforate or perforated by numerous tiny pores that afford, in addition to the mouth of the shell, exits for numerous fine branching and anastomosing pseudopodia. The multichambered (polythalamous) forms result from the addition to the initial chamber of one new chamber after another and, in general, their shape and the spatial relations they assume determine the various types of shells as linear, spiral, etc. The life history typically involves an alternation of asexual and sexual generations with characteristic differences in the shells, nuclear apparatus, etc. The asexual generation produces amoeboid spores that develop into sexual individuals, while the latter give rise to amoeboid or flagellated gametes and the resulting zygotes develop into asexual individuals. Nearly 50 families had been recognized by 1945. Well-known genera include *Globigerina, Elphidium* (*Polystomella*), *Peneroplis, Patellina,* and *Camerina (Nummulites),* the last solely fossil. (Fig. 5.)

Order *Proteomyxa.* A relatively small heterogeneous assemblage of indefinite relationships, usually with raylike pseudopodia that frequently branch or tend to anastomose. Most species are parasites on the lower algae, such as *Spirogyra.* Representative genera include *Nuclearia, Arachnula* and *Vampyrella.*

Order *Mycetozoa.* An immense group sometimes classified among the Fungi as Myxomycetes, or "slime moulds," chiefly because, in the typical free-living species, specialized structures are developed for the production and dissemination of air-borne spores. Although this characteristic may be regarded with some assurance as an indication of convergence rather than of relationship with plants, the Mycetozoa are evidently a borderline group where formal classification is difficult or fails entirely. The most prominent phase in the life history consists of a multinucleate sheet of flowing protoplasm, the plasmodium, with great networks of anastomosing pseudopodia. Eventually spores are developed and these produce tiny amoeboid forms, each with a flagellum, that multiply and form gametes. The zygote is an amoeboid cell which increases in size by growth and union with other similar plasmodia, in some cases becoming several centimetres in diameter and containing thousands of nuclei. Nutrition is saprozoic and holozoic as the plasmodium creeps over decaying wood, leaves, etc. Common genera include *Lycogala, Physarum* and *Fuligo.* In addition to the typical Mycetozoa there are usually included in the group various forms which may be only distantly related because they exhibit wide departures in structure and life history. One of the most common is *Plasmodiophora brassicae,* an intracellular parasite which produces the disease known as clubroot in cabbages and closely related plants.

Order *Heliozoa.* A rather circumscribed group of typically spherical fresh-water forms with raylike axopodia. Protective coverings of gelatinous material, silicious spicules, etc., are often present. Most so-called sun animalcules are free-floating but some are sessile. Nutrition is holozoic. Common genera include *Actinophrys* (uninucleate) and *Actinosphaerium* (multinucleate). (Fig. 6.)

Order *Radiolaria.* An enormous assemblage of marine species adapted for pelagic life, including some of the largest Protozoa. Most are spherical and are provided with complex skeletons of remarkable and beautiful designs. The skeletons are usually silicious, but in one group they are apparently composed of strontium sulphate. The most highly characteristic feature is the definite segregation of the body into intracapsular and extracapsular regions by a perforated membrane, the central capsule. The intracapsular protoplasm is relatively homogeneous and includes from one to many nuclei, oil droplets, etc., while the extracapsular region is differentiated into several zones. The outermost consists largely of axopodia and myxopodia which have their origin within or just outside the central capsule in the surrounding "matrix" and traverse the broad "calymma": a gelatinous zone apparently secreted by the protoplasm and characterized by fluid-filled vacuoles that give the animal a frothy appearance. So-called yellow cells (zooxanthellae) are usually present in the calymma and in certain cases, at least, are modified dinoflagellates and chrysomonads living as symbionts or parasites. Reproduction by division includes the central capsule and, when possible, the skeleton. Multiple division of the nucleus and centrai capsule without division of the extracapsular protoplasm may give rise to temporary forms with several capsules, a condition that is permanent in some colonial species. Reproduction by tiny flagellated spores also occurs, but the formation of gametes remains to be proved. Representative genera are *Collozoum* (without a skeleton, colonial), *Thalassicolla* (without a skeleton), *Acanthometron* (with a skeleton). (Fig. 7.)

Class SPOROZOA. A very large and heterogeneous assemblage of endoparasitic forms with hosts representing all animal phyla. Reproduction at some stage in the life history is by "spores," but these are not homologous throughout the class. In general, each species is limited to a specific host or to two hosts in each of which a part of the life history is spent. Transmission may be contaminative by resistant spores, or by inoculation of unprotected stages. Reproduction is usually by multiple fission (schizogony) followed by gamete formation and finally by sporulation (sporogony) to complete the life cycle. The alternation between the asexual and sexual phases is often associated with the change of hosts.

The class is sometimes divided into two subclasses, the Telosporidia and Neosporidia, with, in general, the following chief differences. In the former the production of spores terminates the life cycle, the sporozoites are vermicule in form, and the spores are without polar capsules; while in the latter, sporulation proceeds during the trophic phases of the life cycle, the sporozoites are amoeboid, and polar capsules are usually present in the spores. Though this division, suggested by Fritz Schaudinn in 1900, recognizes the natural assemblage of gregarines, coccidians and haemosporidians as Telosporidia, it fails to discriminate between the widely divergent forms included in the Neosporidia and, accordingly, it is customary to substitute for the latter group two subclasses: the Cnidosporidia with polar capsules, and the Acnidosporidia without such structures. But it is generally agreed that this is to some extent a temporary expedient awaiting further knowledge.

Subclass TELOSPORIDIA. The general characteristics are as stated above.

Order *Gregarinida.* A relatively homogeneous group of common parasites of invertebrates. For a brief period after the invasion of a host, development of the gregarine is intracellular, but most of the life history is extracellular with the parasites living in the intestine or various body cavities. Here the mature, wormlike forms (trophozoites) are either attached or move about by contortions of the body and by a characteristic gliding motion. Some gregarines are large enough to be readily visible to the naked eye. In general the body shows considerable differentiation and in some species is highly complex. In the cephaline type the body is divided into two parts (protomerite and deutomerite) by a transverse septum, and the protomerite itself may be capped by a special structure (epimerite) for attachment. The ectoplasm usually consists of several layers, including a region of myonemes which comprises both longitudinal and circular fibres, some of which may extend into the dense, granular endoplasm. Asexual reproduction by schizogony does not occur, the trophozoite proceeding directly to sexual phenomena and spore formation. The resistant spores usually pass from one host to another of the same species, but in some cases an alternate host is involved. Common examples of acephaline gregarines are the various species of *Monocystis* found in the seminal vesicles of earthworms. The more complex cephaline forms, chiefly inhabitants of the intestine of arthropods, are illustrated by members of the genus *Gregarina* that often parasitize meal beetles and cockroaches.

In addition to the eugregarines considered above, there is a small group of schizogregarines, so called because the life history includes a schizogonous cycle. The best known genera are *Ophryocystis* and *Schizocystis,* both with representative species that parasitize insects.

Order *Coccidia.* Intracellular parasites of many invertebrates and vertebrates, infesting chiefly the epithelial lining of the intestine and its derivatives, though some species invade the blood vascular system. The typical life history includes asexual multiplication by repeated schizogony followed by sexual phenomena and then sporogony involving the formation of resistant spores. Most members of the order are confined to a single host, but the blood-dwelling haemogregarines alternate between the circulatory system and other organs of vertebrates and the intestine of invertebrates such as mites and leeches, and are without resistant spores. Representative coccidians are the various species of *Eimeria* that infest in particular mammals and birds, *Adelea ovata* living in centipedes, and *Haemogregarina stepanowi* alternating between turtles and leeches. *Isospora hominis* occurs rarely in man.

Order *Haemosporidia.* Intracellular coccidialike forms that typically undergo schizogony chiefly in the red blood cells and reticulo-endothelial tissue of vertebrates, and fertilization and sporogony in the digestive tract of blood-sucking arthropods, particularly insects. Resistant spores are not formed. The most important genus is *Plasmodium,* which comprises the malarial parasites of man carried by anopheline mosquitoes, as well as parasites of various lower vertebrates, including birds. Other representative genera are *Haemoproteus* and *Leucocytozoon,* transmitted especially to birds by biting flies. Differing somewhat from the typical haemosporidians are the piroplasms carried by ticks and often the cause of serious diseases in domestic mammals. Of especial interest is *Babesia (Piroplasma) bigemina,* the cause of Texas cattle fever. This was shown by the work of T. Smith and F. L. Kilborne in 1893, which was the first demonstration of the transmission of a protozoan parasite by an arthropod vector. Closely related to the various species of *Babesia* are members of the genus *Theileria,* such as *T. parva* that produces East Coast fever in African cattle. (Fig. 4.)

Subclass Cnidosporidia. An assemblage of species characterized by resistant spores with polar capsules. The products of the spores are amoeboid forms that start early in the life history to produce spores by internal budding. Accordingly an alternation of asexual and sexual cycles is absent, sexual phenomena occurring in the trophic stages. Species with intermediate hosts are unknown. (Fig. 15.)

Order *Myxosporidia.* Almost exclusively parasites of fishes, in which they sometimes cause severe epidemic disease. Some species develop as free forms in cavities, such as the gall and urinary bladders, while others are actual tissue parasites that produce more serious pathological effects. Common genera with many species, some infecting economically important fishes, are *Ceratomyxa, Myxidium* and *Myxobolus.*

Order *Actinomyxidia.* A small group of little-known species which inhabit the coelom and intestinal epithelium of aquatic annelids. The spores are usually triradiate and have three polar capsules. Representative genera are *Triactinomyxon* and *Hexactinomyxon.*

Order *Microsporidia.* Minute intracellular parasites that chiefly infest various tissues of arthropods and fishes. The best known species are *Nosema bombycis* of the silkworm moth and *N. apis* of bees, the former producing the pébrine disease of silkworms investigated by Louis Pasteur in 1865.

Subclass Acnidosporidia. A provisional group comprising little-known forms with simple spores lacking polar capsules.

Order *Sarcosporidia.* This order includes one important genus, *Sarcocystis,* with several species that infest the muscles of vertebrates, chiefly mammals, including mice, pigs, cattle and rarely man. The parasites form large "sarcocysts" in which crescentic spores are formed and produce a toxin that may prove fatal when injected into small mammals.

Order *Haplosporidia.* Largely an artificial assemblage of diverse forms, with affinities still to be determined, though certain species are probably closely related to the Microsporidia. They inhabit body cavities and tissues of invertebrates and lower vertebrates. Representative genera are *Haplosporidium,* present in aquatic annelids and mollusks, and *Ichthyosporidium* in fishes. A species of *Coelosporidium* occurs in cockroaches.

Class Ciliophora or Ciliata. An immense and clearly differentiated class, often called the Infusoria, characterized chiefly by the presence of cilia, and by two types of nuclei except in the subclass Protociliata. Division is typically transverse. Most species are monomorphic and are free-swimming in fresh and marine waters, though some are temporarily or permanently attached. Colony formation occurs.

Subclass Protociliata. A small subclass comprising the so-called opalinids which are endocommensals or parasites almost exclusively of frogs and toads. The body is uniformly coated with cilia but otherwise shows little similarity to other members of the class. The nuclei, from two to many in number, are not differentiated into micronuclei and macronuclei and there is no cytostome or contractile vacuole. Fertilization is by anisogamous gametes. Four genera are recognized: *Protoopalina, Zelleriella, Cepedea* and *Opalina.*

Subclass Euciliata. A very large subclass that includes all of the typical ciliates. Micronuclei and macronuclei are present and fertilization is by conjugation. Most species are free-living but some are commensals or parasites. The classification of this highly organized group of the Protozoa is based chiefly on the plan of distribution and the specialization of the cilia.

Order *Holotrichida.* The holotrichs are usually provided with unspecialized cilia, either over the entire surface or restricted to certain regions of the body. The best known genus is *Paramecium,* represented by about ten clearly-defined species, some of which are among the most widely studied animals. Among other common genera are *Chilodonella, Colpoda, Colpidium, Spathidium* and *Didinium.* Most holotrichs are free-living, but many are commensal or endoparasitic, including a unique group of astomatous species. *Ichthyopthirius multifilius* is an ectoparasite of fresh-water fishes which sometimes causes serious epidemics in aquaria. (Figs. 1, 11.)

Order *Spirotrichida.* Species with a complex adoral zone of cilia united to form membranelles, and usually an undulating membrane, in addition to other ciliation. Included are the *heterotrichous* forms with relatively short cilia over the rest of the body, represented, for example, by the various species of *Stentor, Spirostomum, Blepharisma, Bursaria* and *Balantidium;* the *oligotrichous* forms with general body ciliation reduced or wanting, as in the genera *Halteria, Tintinnidium,* and *Epidinium;* and finally the *hypotrichous* forms with markedly flattened bodies provided with cirri on the ventral surface for creeping, etc., including such common genera as *Oxytricha, Stylonychia* and *Euplotes.*

Order *Peritrichida.* Members of this order are typically bell-shaped and attached by a stalk, and accordingly are commonly called bell animalcules. Ciliation is practically restricted to the rim of the bell and peristome, and includes an adoral zone. Representatives are the many species of *Vorticella* and the closely related colonial genera *Epistylis, Zoothamnium* and *Carchesium.*

Order *Chonotrichida.* A very small group of ciliates superficially similar but clearly unrelated to the peritrichs. All live attached to aquatic arthropods. The common genus is *Spirochona.*

Subclass Suctoria. A unique but widely distributed group of fresh-water and marine species in which the cilia are confined to the young, free-swimming stages which arise as buds. The adults are typically sessile and are provided with tentacles by means of which they adhere to the prey and withdraw its contents. Many species live attached to the surface of aquatic organisms, usually as commensals but sometimes as parasites, while others are highly modified endoparasites. Some species infest *Paramecium* and other ciliates. Common genera are *Tokophrya, Acineta* and *Ephelota.* (Fig. 10.)

Bibliography.—Standard treatises affording a survey of the Protozoa and an introduction to the immense literature in the field of protozoology include: Otto Buetschli, "Protozoen," in Bronn's *Klassen und Ordnungen des Tier-Reichs,* 3 vols. (Leipzig, 1880–89); C. M. Wenyon, *Protozoology* (London and New York, 1926); F. J. Cole, *History of Protozoology* (London, 1926); F. Doflein and E. Reichenow, *Lehrbuch der Protozoenkunde,* 5th Auflage (Jena, 1927–28); G. N Calkins; *Biology of the Protozoa,* 2nd ed. (1933); A. Kahl, "Ciliata," in *Die Tierwelt Deutschlands* (Jena, 1935); R. R. Kudo, *Protozoology,* 3rd ed. (1946); L. H. Hpman, *The Invertebrates: Protozoa through Ctenophora* (1940); G. N. Calkins and F. M. Summers (editors) *Protozoa in Biological Research* (1941).

PROUD, JOSEPH (1745–1826), English clergyman, was born in Beaconsfield, Buckinghamshire on March 22, 1745. He served as minister of the general baptist congregation at Knipton, Leicestershire beginning about 1772. and in 1775 accepted a similar position at Fleet, Lincolnshire, where he was ordained in 1780. In 1791 he mas ordained minister in the "new church" and opened the Birmingham "temple" in the same year. He continued to preach in various churches in Manchester and London where his oratory attracted large audiences. He wrote nearly 300 hymns and published numerous books, some of which went through several editions. He died at Handsnorth, near Birmingham on Aug. 3. 1826.

PROUD, ROBERT (1728–1813). U.S. educator and historian, was born near Yarm, Yorkshire on May 10, 1728. After attending a Friends' school he went to London in 1750 and continued his studies under the guidance of Dr. Fothergill. In 1759 he came to the United States and opened a boys' school in Philadelphia. In 1761 he became master of a Friends' school. a position he held until 1770, and later, from 1780 to 1790. His important work, *The History of Pennsylvania* (2 vols., 1797–98), contained much valuable material on the early history of the area. Proud died at Philadelphia on July 5, 1813.

PROUDHON, PIERRE JOSEPH (1809–1865), French moralist and advocate of social reform. was born on Jan. 15, 1809, at Besançon, in the traditionally rebellious Jura mountain district of France. He came of a poor family and at 19 became a working compositor; later, as a proofreader, he acquired knowledge of theology; Latin and Greek, as well as Hebrew. Although he subsequently won academic scholarships, he spurned formal training and remained a self-educated man. His interests turning to economics and politics. he published. in 1840. *Qu'est-ce que la propriété?* His answer. "Property is theft," does not, however, mark him a socialist. Proudhon voices, instead, the typical middle-class objection to concentrated economic power and the consequent difficulty that small businessmen have long experienced in raising capital even when the security offered was perfectly sound. So far from demanding the abolition of private property in means of production, Proudhon urged that productive property be widely dispersed among owner-producers who operate as individuals or band together in mutual benefit associations. Proudhon argued that the government should preserve an open door for investment in small and locally or mutually owned businesses. To this end the government should establish a semipublic exchange and capital bank to take the place of the Bank of France and the stock exchange. This "people's bank" would furnish currency and credit at a low rate of interest, or none at all, against: (1) written orders for payment drawn by sellers of goods on the purchasers (acceptance bills); (2) payment bills issued to wage-earners by their employers; (3) credit bills presented by buyers of residential housing. industrial or agricultural property, who have been judged eligible for home loans or business loans. Thus Proudhon aimed to universalize the bill of exchange: an instrument of credit whose familiar use was in connection with the shipment of finished goods in commerce rather than in relation to home ownership or business-property transactions. Proudhon wished to divorce money and credit from any basis of gold or specie, so that the economy would constitute a universal credit union, with productivity rather than specie as the basis of credit. Labour and every product of labour would in effect be ready and exchangeable money. Because money in the form of goods or services cannot be hoarded, the aggregate supply of goods and services creates its own sufficient aggregate demand, hence unemployment caused by overproduction would be banished. With money based on productivity rather than specie, market competition would regulate prices so that consumers might buy goods at nearly their real costs of production; prices would not be burdened by surcharges of interest, rents and capital gains realized by absentee capitalists, landlords and speculators. Nor can the government create money or manipulate its supply to favour politically powerful special-interest groups. For in Proudhon's scheme, money is only th'e reflection of productive transactions whose terms are negotiated by private producers without the intervention of government.

Besides his monetary reform proposals, Proudhon projected the concept of associations of owner-producers. Each association forms its internal rules; the members surrender individual advantages for the common good of the organization. A spirit of give-and-take also characterizes, in Proudhon's vision, the relations among the separate organizations of businessmen. workers and farmers. Thus mutualism nithin groups joins with mutuality between groups to yield an economy of justice—economic justice not stipulated by the government but justice emanating from the ranks of the producers.

Proudhon's economic reform program was early attacked by Karl Marx (*q.v.*), in 1847. on the ground that finance capitalism. which Proudhon sought to abolish, and industrial capitalism, which Proudhon wished to strengthen, are inextricably intertwined. In the Marxist view, the unplanned nature of capitalist production sets the stage for economic instability under which speculation thrives. as well as for concentration of economic power and exploitation of labour, so that Proudhon's desired working harmony among producers cannot be realized. This controversy—with Proudhon writing *The Philosophy of Misery* and Marx countering with *The Misery of Philosophy*—is of current interest. It exhibits the roots of the continuing difference between middle-class reformers and the would-be socialist transformers of capitalism.

A prolific and passionate writer. Proudhon analyzed in the manner of an unprofessional philosopher. and his writings frequently lapse into merely perceptive journalism, especially those in the field of national and international political affairs. Proudhon portentously combined a rebellious peasant provincialism with a global grandiosity—thus he presaged in his thoughts and deeds the persistently conflicting tendencies of French capitalist democracy, toward anarchy on the one hand and despotism on the other.

Proudhon's works in English translation include: *What Is Property? System of Economic Contradictions: or the Philosophy of Misery; General Idea of Revolution in the Nineteenth Century.* His complete works were published in Paris (1923–52). See also ANARCHISM; SOCIALISM.

PROUST, JOSEPH LOUIS (1754–1826), French chemist, whose great contribution to chemistry was his experimental establishment of the principle of the constant composition of compounds. Born at Angers on Sept. 26, 1754, he mas the son of an apothecary. He studied chemistry under the direction of G. F. Rouelle, and became chief apothecary at the Salpêtrière hospital in Paris. In his lifetime he attained eminence in chemistry in both France and Spain. In France he lectured at the Palais Royal, and in Spain he taught at the Academy of Artillery at Segovia, at the seminary at Vergara and at the newly established Royal laboratory at Madrid. The latter had notably excellent facilities, which enabled him to conduct (1799–1806) skilled researches on the composition of many substances, finally proving—beyond doubt that then existed—that pure compounds were strictly definite in composition by elements, no matter what their source. Thus his celebrated controversy with Claude Louis Berthollet (1748–1822) was resolved in Proust's favour. Proust did not formulate the law of definite proportions (John Dalton, 1808), but his work furnished the necessary experimental evidence for its acceptance. After his election in 1816 to the French Academy of Sciences he returned to Angers where he died July 5, 1826. Proust, a Frenchman, is frequently confused with William Prout (1785–1850), an Englishman. The latter was the proponent of the hypothesis in 1815 that the atomic weights of the elements are exact multiples of the atomic weight of hydrogen.

PROUST, MARCEL (1871–1922), French man of letters, was born in Paris on July 10, 1871. His father was a professor of medicine, and his mother was of Jewish extraction. He was educated at the *lycée* Condorcet, and about 1892 he was for some time associated with Léon Blum, Louis Mirhlfeld and Tristan Bernard on the *Revue Blanche,* a periodical conducted by a select group of intellectuals, mostly Jewish. Becoming a favourite in the salons—especially those of Mme. de Caillavet and Madeleine Lemaire—he wrote a number of society love stories (collected in 1896 under the title Les *plaisirs* et *les jours*) distinguished by their psychological subtlety. He also attained reputation as a clever writer of pastiches. He became an enthusiastic admirer of John Ruskin and translated several of his works into French, including the Bible of Amiens, to which he contributed a valuable preface.

In 1902 Proust's health began to fail. Thenceforward he was reluctantly obliged to lead an extremely retired and careful life, and for many years it looked as if he had altogether abandoned literature, in which his name hitherto had not been known outside a small circle of friends. He was reading and writing a great deal, however. The interminable discursiveness of Ruskin, which French readers do not suffer gladly, was to him a constant source of delight, and Saint-Simon, ever one of his favourite authors, exerted a powerful influence upon him at this time. Thus it came about that, having unlimited time at his disposal, he embarked upon a long and leisurely work, full of minute detail, in which was imprisoned, as in a net, his whole experience of life; in which the salon life he loved was revived in all its details and observances like the court life in Saint-Simon's memoirs; in which the people he had known provided the materials for new, fuller and richer characters (M. de Charlus, for example, is a blending of three different people of Proust's acquaintance), and in which the author sought out and lived the past over again. Hence the general title given to the 15 volumes of the series, A la recherche du temps perdu (1913, etc.).

This lengthy work had almost been completed when Proust published the first part, *Du côté* de *chez Swann,* in 1913. The freshness and minuteness of the recollections of childhood attracted some attention, but nonetheless Proust, who had had to publish the first part at his own expense, had difficulty in finding a publisher for the second, *A* l'ombre des *jeunes filles* en *fleurs.* When it did appear its qualities were at once appreciated by Léon Daudet, whose enthusiastic articles, followed by the award of the Prix Goncourt in 1918, brought Proust's name prominently before the public, and he was read, discussed and criticised everywhere. Two more parts appeared during Proust's lifetime—Le *côté* de *Guermantes* and *Sodome* et Gomorrhe, both in 1921. When he died in Paris. Nov. 18, 1922. he left three parts still in manuscript—La *prisonnière,* published in 1924, Albertine *Disparue* (1926) and Le temps *retrouvé* (1926).

Proust's influence, especially after his death, has been considerable. He introduced into the novel an analytic method which has a superficial resemblance to that of Meredith, but is more properly comparable with that of Freud. That the name and notion of time should appear in the general title of his great work is not without significance. By a curious coincidence he was related by marriage to Bergson, the philosopher of "creative time," and the term "creative time" aptly describes the psychological time which Proust explores, seeks and recovers. His people are never given as "characters" in the fashion of La Bruyère or Balzac; they are always in process of development, change and continual creation.

Part of Proust's success was due to the very thing that is likely to tell against his lasting reputation. viz. the fact that his characters, beginning with the "I" of the book, are exceptional, an erotic and mysterious group having little in common with, the generality of mankind. This is true not only of *Sodome* et Gomorrhe and Proust's emphasis upon homosexuality, but also of the idle life and ultimate nothingness of the people of his world, their lack of all interests other than those of social life, and the indifference that the ordinary reader must always feel as to their fate. On the other hand, there will be a taste for Proust so long as there is a taste for psychology as an end in itself, and so long as the play of memory, the searching and brooding that pertain to the conquest of the past, afford to some men a sufficient reason for living or a romantic manner of not living. The authorized translation by C. K. Scott Moncrieff appeared with the series title Remembrance of Things Pest (1922–1930), the final part. Past Recaptured (1932), being translated by F. A. Blossom, the whole appearing in 4 vol. in 1934. (A. T.; X.)

PROUSTITE, a mineral consisting of silver sulfarsenite, known also as light red silver ore, and an important source of the metal. It is closely allied to the corresponding sulfantimonite, pyrargyrite (*q.v.*), or dark red silver ore, from which it was distinguished by the chemical analyses of J. L. Proust in 1804, after whom the mineral received its name. The composition is Ag_3AsS_3. The colour is scarlet-vermilion and the lustre adamantine; crystals are transparent and very brilliant, but on exposure to light they soon become dull black and opaque. The streak is scarlet, the hardness 2.5, and the specific gravity 5.57.

The mode of occurrence is the same as that of pyrargyrite, although proustite is less common, and the two minerals are sometimes found together. Magnificent groups of large crystals have been found at Chafiarcillo in Chile; other localities which have yielded fine specimens are south Lorrain, Ont., and Freiberg and Marienberg in Saxony. It is mined as an ore in Mexico and is found in small amounts in the United States in California, Colorado, Idaho and Nevada.

PROUT, SAMUEL (1783–1852), English water colourist, born at Plymouth, Devon, Sept. 17, 1783. was educated at Plymouth grammar school. He went on sketching expeditions with B. R. Haydon, at whose father's house he met John Britton, publisher of The Beauties of England and Wales. He worked for Britton in London, and exhibited at the 1803 Royal Academy. He also painted marine pieces for T. Palser, received pupils, and in 1813 published The Rudiments of Landscape, With Progressive Studies, the first of his several handbooks for art students. From 1815 he exhibited regularly at the Water-Colour society, becoming a member four years later. A visit to France in 1819 distinguished him from previous English topographers by his choice of foreign townscapes as subjects, and that same year he attempted the recently discovered process of lithography. His Illustrations of the Rhine (1824) comprised the first of many lithographs resulting from frequent visits to France, Germany, the Netherlands and Italy. He died at Camberwell, Feb. 10, 1852. Prout's success was due to his fine draftsmanship, skillful composition and ability to seize upon some strikingly picturesque quality.

PROUTY, CHARLES AZRO (1853–1921), U.S. lawyer, was born in Newport, Vt., on Oct. 9, 1853. He graduated at Dartmouth college, Hanover, N.H., in 1875 and subsequently became principal of Newport academy. He was admitted to the bar in 1882 and practised law in Newport until 1896. In 1888 he was a member of the Vermont house of representatives and from 1888 to 1896 served as a reporter of decisions of the state supreme court. He was appointed to the U.S. Interstate Commerce commission in 1896, holding office until 1914 and serving as chairman in 1912–13.

In 1914 Prouty was made director of valuation for the commission and from 1918 to 1920 was director of public service and accounting in the U.S. Railroad administration. He died at Newport on July 8. 1921.

PROVENCAL LANGUAGE is one of the Romance languages (*q.v.*). In its narrow meaning the term refers to the speech, or the dialects, of the region called Provence. But more often it is the collective term for all southern dialects of France. Similarly the alternative name *langue* d'oc (oc "yes." as compared with northern oil, modern oui) refers generally to all idioms of the Midi (the south), although Languedoc as a politico-geographic term signifies only part of the region. In literary history, however, Provencal is the name given to the artificially homogeneous standard language employed by the troubadours (*q.v.*) of the 12th, 13th and 14th centuries.

The boundary separating Provencal (in the widest sense) from northern French runs from the estuary of the Gironde eastward along the northern edge of the Massif Central, crosses the Rhone between Vienne and Valence, and moves toward the Alps; but in the middle ages the frontier lay much farther to the north, being anchored in the west at the mouth of the Loire and in the east in the southern Vosges mountains.

This linguistic boundary. which is so trenchant as to be one between languages rather than dialects, resulted from differing historic and cultural developments. The Midi, or at least part of it, mas conquered by the Romans in 122 B.C., about 70 years before the rest of Gaul. A flourishing and rich province, it was quickly and profoundly romanized. Moreover. the Germanic invasions of the middle ages were culturally less effective than they were in the north; even that of the Franks (so decisive elsewhere as to give their name to the whole country) exerted. little influence. The southern dialects in comparison with the northern, are therefore more conservative in their retention of Latin traits and less affected by the Germanic superstratum.

The medieval history of the Midi is that of many small feudal holdings, in constant dispute among themselves and with outsiders. The country never attained national independence, but it was officially united with the rest of France in 1486. The greatest single catastrophe to befall the south was the crusade against the Albigenses (*q.v.*) early in the 13th century. What began as a religious expedition under the aegis of the church against the Xlbigensian heresy ended as political suppression of the south and its feudal lords by northern competitors. This calamity brought about the end of the independent flourishing of the Midi's native culture, particularly of its troubadour literature; it was assuredly responsible for the end of Provenqal as an interregional standard idiom. for the re-emergence of local dialects, and for the spread. albeit slow, of standard northern French, in particular Francien, the dialect of the Île-de-France, as the literary and official language of the whole region.

Henceforth the southern dialects. bereft of a southern standard language in competition with Francien, sank to the level of patois of strictly local and familiar currency. The present dialects may be classified as follows: (1) Provencal (in the narrow sense as idioms of the Provence proper); (2) Xuvergnat and Limousin; (3) Gascon (see below). Each of these larger divisions can of course be subdivided into smaller dialects, in the past as much as, or even more than. now.

This dialectal fragmentation of the south raises the question of which of the southern dialects was employed in troubadour poetry, or which formed the core of their fairly homogeneous language. The main obstacle to a satisfying answer, apart from the insufficient knowledge of the medieval dialects of the Midi. is that Provenqal, even in the works of the oldest troubadours (Guilhem IX. Marcabrun. Cercamon), is already fully developed and standardized, so that the history of its formation escapes linguistic scrutiny. On the whole. it seems to represent a central rather than a peripheral southern speech area. The history of the Provençal language largely deals nith the language of the troubadours

Late spoken Latin	Old Provençal	Old French	Modern French

securu(m)	*segur*	*seür*	*sûr*
matura(m)	*madura*	*meür*	*mûr*
laudare	*lauzar*	*lower*	*louer*

since little else is known until recent times. It is convenient to compare it with the northern Francien standard in order to show its peculiarities. See also FRENCH LANGUAGE and, especially for earliest developments from Latin, ROMANCE LANGUAGES.

Where northern dialects nasalize a vowel before a following *m* or *n,* nith eventual absorption of the consonant (*pontem* > *põ*), Provencal may not nasalize at all, or may nasalize the vowel with retention of the consonant (*pontem* > pon, *põn*).

Gascon has certain peculiarities which set it apart from other southern dialects. For example, Latin medial -11- appears as *-r-* (*appellare* > *apera[r]*), final *-l* as *-t* (*bell[um]* > bet), initial *r-* as *arr-* (*ramu[m]* > *arram*), initial f- as h- (*femina* > *hemna, henno*). For these and other reasons some do not include Gascon among the Provencal dialects (in the wider sense). But then the only alternative is to establish it as a separate Romance language, as some linguists do with Catalan or Franco-Provencal or both.

In morphology, the declension of Old Provencal retains, as does Old French, a two-case system. one for the subject and one for the nonsubject case. In the modern dialects, a one-case (that is, no-case) system prevails.

The Provenqal verb partakes of all the changes from Latin to Romance in general; but the typically Provençal features relate it more to Ibero-Romance (Spanish, Portuguese, Catalan; *q.v.*) than to French.

A renascence of southern speech ways was unsuccessfully attempted during the 19th century, mainly through the efforts of Frédéric Mistral (q *v.*), who attempted to create a new literary standard language for the Midi, based chiefly on several patois of the Bouches-du-Rhône district.

PROVENCAL LITERATURE. Provenqal literature is much more easily defined than is the Provencal language (*q.v.*). Starting in the 11th and 12th centuries in several centres, it gradually spread out, first over the greater portion, though not the whole, of southern France, then into the north of Italy and Spain. It never felt the influence of the neighbouring literatures. At the time of its highest development (12th century) the art of composing in the vulgar tongue did not exist, or mas only beginning to exist, to the south of the Alps and the Pyrenees. In the north, in the country of French speech, vernacular poetry nas in full bloom; but between the districts in which it had developed—Champagne, Île-de-France. Picardy and Normandy—and the region in which Provencal literature had sprung up. there seems to have been an intermediate zone formed by Burgundy. Bourbonnais. Berry. Touraine and Anjou which, far on in the middle ages, appears to have remained almost barren of vernacular literature. In its rise Provenqal literature stands completely by itself. It presents at several points genuine analogies with the sister literature of northern France; but these analogies are due principally to certain primary elements common to both and only in a slight degree to interaction.

Provencal literature can be clearly divided into three periods: the first covers the middle ages from the 11th to the 13th century; the second extends from its first renaissance over the classical age. covering the 17th and 18th centuries; and the third begins mith its second renaissance in the 19th century, the age of the Félibrige and their successors.

FIRST PERIOD

Origin.—The new vernacular literature took a poetic form, and its oldest monuments show a virtuosity and a variety that indicate that poetry had already been practised for some time. The oldest piece of Provencal verse extant is said to belong to the 10th century: it is a refrain attached to a Latin poem in a Vatican ms. (text in the *Zeitschrift* fzir deutsche *Philologie,* 1881, p. 335). More important, however, is a 257-line fragment of didactic verse preserved in an Orléans ms. and frequently edited since F. J. Raynouard first printed it in his *Choix* des *poésies* originales des troubadours. It is the beginning of an adaptation of A. Boethius' treatise De Consolatione Philosophiae by an anonymous clerk, whose use of the poetic form in the vulgar tongue shows that his illiterate contemporaries must at least have been already accustomed to such poetry. The handwriting of the manuscript is that of the period A.D. 1000–50, the language seems to belong most probably to the Limousin or to La Marche. Boethius' ideas are developed with a Christian colouring of which there is no trace in the Latin original; for instance, from some verses in which Boethius contrasts his happy youth with his afflicted old age. the clerkly author draws a lengthy homily on the necessity of laying up from early years a treasure of good works. A little later on, at the close of the 11th century, we have the poems of William IX, duke of Aquitaine (Guilhem VII of Poitiers). They consist of 11 very diverse strophic pieces and were meant to be sung. Several are love songs; one relates a *bonne* fortune in very free terms; and the most important of all—the only one which can be approximately dated, being composed at the time when William was setting out for Spain to fight the Saracens (about 1119)—expresses in touching and often noble words the writer's regret for the frivolity of his past life and the apprehensions which oppressed him as he bade farewell, perhaps forever, to his country and his young son.

There is no reason to believe that William created the type of poetry of which he is to us the oldest representative: it may have been his high rank that saved some of his work from oblivion while that of his predecessors and contemporaries disappeared. The contrast in form and subject between the Boethius poem and the stanzas of William IX is an indication that by the 11th century Provençal poetry was being rapidly developed in various directions. Whence came this poetry? How and by whose work was it formed? That it has no connection whatever nith Latin poetry is generally admitted. The view which seems to meet with general acceptance (even if a slight influence from Arabic poetry can nom be admitted) is that Romance poetry sprang out of a popular poetry quietly holding its place from Roman times Yet, as regards the substance, the poetic material, we find nothing in the earliest Provencal which is strictly popular. the extremely personal compositions of William IX have nothing in common with folklore. At least the poets must have found themselves obliged to compound with the refinement of an aristocracy that had become. from century to century, more and more delicate, not to say learned.

From what class of persons did this poetry proceed? Latin chroniclers of the middle ages mention ioculares, *ioculatores,* men of a class not very highly esteemed whose profession consisted in amusing their audience either by what we still call jugglers' tricks, by exhibiting performing animals, or by recitation and song. They are called joglars in Provencal, jonglers or jongleurs in French; and they were the first authors of poetry in the vernacular both in the south and in the north of France. In the north, where manners mere not so refined and where the taste for warlike adventure prevailed, those of the jongleurs who composed verses produced chansons *de* geste full of tales of battle and combat. In the courts of the southern nobles, where wealth was more abundant and life more civilized, they produced love songs.

The Provençal love songs reflect the social conditions obtaining in the Midi under feudalism. The daughters of territorial lords, who might well become rich heiresses, were married for political reasons, not to satisfy their own inclinations; but, once married, they seem to have enjoyed a very generous measure of personal liberty. Consequently, they welcomed the attentions of their husbands' dependents, who, as courtiers, would address flattering songs of love to them. As the poets were usually far beneath the ladies in social status. they wrote in a most guarded and respectful style, as though they had very little hope of having their love requited. This profession of "courtly" or "chivalrous" love became a matter of convention; but it would be a mistake to assume that the real sentiments or experiences of the poets were invariably as platonic as the expression given to them.

The Troubadours.—By the end of the 11th century, then, a clear distinction had been drawn between the lower sort of *joglars* and the refined poets; and it is to the poets as such that the name troubadour (*q.v.*) belongs, comprising as it does not only accomplished poets of the lower ranks of society but also some of the great nobles who wrote poetry. In the Limousin lived a viscount of Ventadour, Eble. who early in the 12th century seems to have been brought into relation with William IX of Aquitaine and, according to a contemporary historian, Geffrei, prior of Vigeois, erat valde *gratiosus* in cantilenis. We possess none of his compositions; but under his influence Bernart de Ventadour was trained to poetry. Bernart gained the love of the lady of Ventadour and. when on the discovery of their amour he had to depart elsewhere. received a gracious welcome from William IX's granddaughter Eleanor of Aquitaine, consort (from 1152) of Henry II of England. Of Bernart's compositions we possess about 50 songs of elegant simplicity; some of which may be taken as the most perfect specimens of Provencal love poetry. At the same period, or earlier, flourished Cercamon, a Gascon, who composed, says his old biographer, "pastorals according to the ancient custom" (*pastorelas* a la *uzansa* antiga). Among the earliest troubadours is hfarcabrun, a pupil of Cercamon's, from whose pen we have about 40 pieces, those ahich can be approximately dated ranging from 1135 to 1148 or thereabout. His songs, several of which are historical. are free from the commonplaces of their class, and contain curious strictures on the corruptions of the time. Jaufre Rudel of Blaye, the singer of the *amor* de lonh (far-away love), is scarcely less famous.

Only a few of the troubadours can be cited here. They include Peire d'Alvernha (Peter of Auvergne), who in certain respects must be classed with Marcabrun; Arnaut Daniel, remarkable for his complicated versification, the inventor of the sestina; Arnaut de Mareuil (Marueil or Maroill) who, while less famous than Arnaut Daniel, surpasses him in elegant simplicity of form and delicacy of sentiment; Bertran de Born. famous for the part that he is said to have played both with his sword and with his *sirventess* in the struggle between Henry II of England and his rebel sons; Peire Vidal, of Toulouse. a poet of varied inspiration who grew rich with gifts bestowed on him by the greatest nobles; Giraut de Borneil (Guiraut de Bornelh), lo *maestre* dels trobadors and at any rate master in the art of the so-called "close" style (*trobar clus*), though he has also left us some songs of charming simplicity; Gaucelm Faidit, from whom we have a touching lament (*planh*) on the death of Richard Coeur de Lion; Folquet de Marseilla, a ponerful thinker who from being a troubadour became first a monk, then an abbot and finally bishop of Toulouse (d. 1231); the chivalrous Raimbaut de Vaqueyras (Provence); the truculent monk of Montaudon (Auvergne); the satirical Peire Cardenal (Velay); and "the last troubadour," Guiraut Riquier.

The troubadours who nere not themselves great feudatories could hardly expect to obtain a livelihood from any other quarter than the generosity of the great. It will consequently be well to mention the most important at least of those princes who are known to have been patrons and some of them practisers of the poetic art. They are arranged approximately in geographical order, and after each are inserted the names of those troubadours with whom they were connected.

France.—ELEANOR OF AQCITAINE, Bernart de Ventadour (Ventadorn); HENRY CURTMANTLE, son of Henry II of England, Bertran de Born(?); RICHARD COEUR DE LION. Arnaut Daniel, Peire Vidal, Folquet de Marseilla, Gaucelm Faidit; ERMENGARDE OF NARBONNE (1143–92), Bernart de Ventadour, Peire Rogier, Peire d'Alvernha; RAYMUND V. count of Toulouse (1143–94), Bernart de Ventadour, Peire Rogier, Peire Raimon, Uc Brunet, Peire Vidal, Folquet de Marseilla, Bernart de Durfort; RAYMUND VI, count of Toulouse (1194–1222), Raimon de Miraval, Aimeric de Pegulhan. Aimeric de Belenoi, Ademar lo Negre; ALPHONSO II, count of Provence (1196–1209), Elias de Barjols; RAYMUND BERENGAR IV, count of Provence (1209–45), Sordel; BARRAL DE BAUX, viscount of Marseilles (d. *c.* 1192), Peire Vidal, Folquet de Marseilla; WILLIAM VIII, lord of hfontpellier (1172–1204), Peire Raimon, Arnaut de Mareuil, Folquet de Marseilla, Guiraut de Calanson, Aimeric de Sarlat; ROBERT, dauphin of Auvergne

(1169–1234), Peirol, Perdigon, Pierre de Maensac, Gaucelm Faidit; GUILLAUME DE BAUX, prince of Orange (1182–1218), Raimbaut de Vaqueyras, Perdigon; SAVARIC DE MAULÉON (1200–30), Gaucelm de Puicibot, Uc de Saint-Circ; BLACATZ, a Provençal noble (1200?–36), Cadenet, Joan d'Albuzon, Sordel, Guilhem Figueira; HENRY I, count of Rodez (1208–22?), Uc de Saint Circ; perhaps HUGH IV, count of Rodez (1222?–74) and HENRY II, count of Rodez (1274–1302), Guiraut Riquier, Folquet de Lunel, Serveri de Girone, Bertran Carbonel; NUÑO SANCHEZ, count of Roussillon (d. 1241), Aimeric de Belenoi; BERNARD IV, count of Astarac (1249–91), Guiraut Riquier, Xmanieu de Sescas.

Spain.—ALPHONSO II, king of Aragon (1162–96), Peire Rogier. Peire Raimon, Peire Vidal, Cadenet, Guiraut de Cabreira, Elias de Barjols, the monk of Montaudon, Uc Brunet; PETER II, king of Aragon (1196–1213), Raimon de Miraval, Aimeric de Pegulhan. Perdigon, Ademar lo Negre, Uc de Saint Circ; JAMES I, king of Aragon (1213–76), Peire Cardenal, Bernart Sicart de Marvejols, Guiraut Riquier. At de Mons; PETER III. king of Aragon (1276–85), Paulet de Marseilla, Guiraut Riquier, Serveri de Girone; ALPHONSO VIII or IX, king of Castile (1158–1214), Peire Rogier, Giraut de Borneil, Aimeric de Pegulhan, Uc de Saint Circ; ALPHONSO X, king of Castile (1252–84), Bertran de Lamanon, Bonifaci Calvo, Guiraut Riquier, Folquet de Lunel, Xrnaut Plages, Bertran Carbonel.

Italy.—BONIFACE I, marquis of Montferrat (1192–1207), Peire Vidal, Raimbaut de Vaqueyras, Elias Cairel, Gaucelm Faidit (?); FREDERICK II, emperor (121s–so), Joan d'Albuzon, Afmeric.de Pegulhan, Guilhem Figueira; Azzo VI, marquis of Este (1196–1212), Aimeric de Pegulhan, Rambertin de Buvalelli; Azzo VIII, marquis of Este (1215–64), Aimeric de Pegulhan.

The decline and fall of troubadour poetry was due mainly to political causes. When in the first decades of the 13th century the Albigensian War had ruined a large number of the nobles and reduced to lasting poverty a part of the Midi, the profession of troubadour ceased to be lucrative. It was then that many of these poets went to spend their last days in the north of Spain and Italy, where Provencal poetry had for more than one generation been highly esteemed. Following their example, other poets who were not natives of the Midi began to compose in Provencal; but from the middle of the 13th century, they began to abandon the foreien tongue and took to singing the same airs in the local dialects. About the same time in the Midi itself the flame of poetry had died out save in a few places — Narbonne, Rodez, Foix and Astarac — where it kept burning feebly for a little longer. In the 14th century composition in the language of the country was still practised; but the productions of this period are mainly works for instruction and edification. The poetry of the troubadours was dead.

For a further account of the art of the troubadours, with lives of individual exponents and a bibliography, *see* TROUBADOURS.

Chansons de Geste and Historical Poems. — Northern France is *par excellence* the country of the *chanson de geste* (*q.v.*); but Provençal literature has some highly important specimens of the class. The first place belongs to *Girart de Rossillon,* a poem of 10,000 lines, which relates the struggles of Charles Martel with his powerful vassal Gerard oi Roussillon. The existing recension seems to have originated on the borders of Limousin and Poitou; but it is a recast of an older poem no longer extant, probably either of French or at least Burgundian origin. To Limousin also seems to belong the poem *Aigar e Maurin* (end of the 12th century). Of less heroic character is the poem *Daurel e Beton* (first half of the 13th century).

Midway between legend and history may be classified the Provenqal *chanson* on the siege of Antioch, a mere fragment of which, 700 verses in extent, has been recovered in Madrid and published in *Archives de l'Orient latin,* vol. ii. This poem (*see* G. Paris, in *Romania,* xxii, 358) is one of the sources of the Spanish compilation La *Gran Conquista de Ultramar.* To history proper belongs the *chanson* of the crusade against the Albigensians, which, in its present state, is composed of two poems, one tacked to the other: the first, containing the events from the beginning of the crusade till 1213, is the work of a cleric named Guilhem de Tudela, a moderate supporter of the crusades; the second, from 1213 to 1218, is by a vehement opponent of the enterprise. The language and style of the two parts are no less different than the opinions. The second part is certainly one of the masterpieces of Provenqal literature. Finally, about 1280, Guilhem Anelier, a native of Toulouse, composed a poem on the war carried on in Navarre by the French in 1276 and 1277, a historical work of little literary merit. All these poems are in the form of *chansons de geste;* viz., in stanzas of indefinite length, with a single rhyme. *Girart de Rossillon, Aigar e Maurin* and *Daurel e Beton* are in lines of ten, the others in lines of 12 syllables. The peculiarity of the versification in *Girart* is that the pause in the line occurs after the sixth syllable and not, as is usual. after the fourth.

Narrative Poems.—We possess but three Provencal romances of adventure: *Jaufre* (composed in the middle of the 13th century and dedicated to a king of Aragon, possibly James I), *Blandin de Cornoalha* and *Guillem de la Barra.* Connected with the romance of adventure is the novel (in Provençal *novas,* always in the plural), which is originally an account of an event "newly" happened. Some of the extant novels may be ranked with the most graceful works in Provençal literature. Two are from the pen of the Catalan author Raimon Vidal de Besalu: one, the *Castia-gilos,* is an elegant treatment of the story of the husband who disguises himself as his wife's lover in order to trap her and receives with satisfaction blows intended, as he thinks, for him whose part he is playing; the other is the recital of a question of the law of love, departing considerably from the subjects usually treated in the novels. Mention may also be made of *Novas del Papagai* by Arnaut de Carcasses, in which the principal character is an eloquent parrot, who assists the amorous enterprises of his master. Novels came to be extended to the proportions of a long romance. *Flamenca,* which belongs to the novel type, still runs to more than 8,000 lines, though the only ms. of it has lost some leaves both at the beginning and at the end. This poem, composed in all probability in 1234, is the story of a lady who by very ingenious devices, not unlike those employed in the *Miles gloriosus* of Plautus, eludes the vigilance of her jealous husband. No book in mediaeval literature betokens so much quickness of intellect or is so instructive in regard to the manners and usages of polite society in the 13th century. From the south of France the novel spread into Catalonia, where we find in the 14th century a number of novels in verse' very similar to the Provenqal ones, and into Italy, where in general the prose form has been adopted.

Didactic and Religious Poetry. — The more important works are: the Boethius poem (unfortunately a mere fragmentj, already mentioned as one of the oldest documents oi the language; an early (12th-century?) metrical translation of the *Disticha de moribus* of Dionysius Cato (*Romania,* xxv, 98, and xxix, 445): Daude de Prades (early 13th century), *Auzels cassadors,* one of the best sources for the study of falconry; and a translation by Raimon d'Avignon (*c.* 1200) of Rogier de Parme's "Surgery" (*Romania,* x, 63 and 496). More original are some compositions of an educational character known under the name of *ensenhamenz* and comparable in some respects to the English nurture books. The most interesting are those of Garin le Brun (12th century), Arnaut de Mareuil, Arnaut Guilhem de Marsan, Amanieu de Sescas. Their general object is the education of ladies of rank. Of metrical lives of saints we possess about a dozen, among which two or three deserve a particular attention: the life of St. Fides (ed. by A. Thomas and by E. Hoepffner), written early in the 12th century; the life of St. Enimia (13th century), by Bertran of Marseilles (ed. by C. Brunel) and that of St. Honorat of Lerins by Raimon Feraut (about 1300), which is distinguished by variety and elegance of versification but is almost entirely a translation from Latin. Lives of saints (St. Andrew, St. Thomas the Apostle, St. John the Evangelist) form a part of a poem, strictly didactic, which stands out by reason oi its great extent (nearly 35,000 verses) and the somewhat original conception of its scheme — the *Breviari d'antor,* a vast encyclopaedia on a theological basis, composed *c.* 1288–1300 by the Minorite friar Matfre Ermengaut of Béziers.

Drama. — The dramatic literature of the Midi consists of mysteries and miracle plays seldom exceeding 2,000 or 3,000 lines, which never developed into the enormous dramas of northern France, whose acting required several consecutive days. Generally those plays belong to the 15th century or to the 16th. Still, a few are more ancient and may be ascribed to the 14th century or even to the end of the 13th. The oldest appears to be the *Mystery of St. Agnes* (edited by K. Bartsch, 1869), written in Arles. Somewhat more recent, but not later than the beginning of the 14th century, are a mystery on the Passion of Christ and another on the Marriage of the Virgin; the latter is partly adapted from a French poem of the 13th century (see *Ronzania,* xvi, 71). A manuscript printed by A. Jeanroy and H. Teulié 1893, contains not less than 16 short mysteries, 3 founded on the Old Testament, 13 on the New. They were written in Rouergue and are partly imitated from French mysteries. At Manosque (Basses Alpes) was found a fragment of a *Ludus sancti Jacobi,* inserted in *a* register of notarial deeds (printed by C. Arnaud, Marseilles, 1858). The region comprised between the Rhône and the Var seems to have been particularly fond of representations of this sort, to judge by the entries in the local records (see *Romania,* xxvii, 400). At the close of the 15th and the beginning of the 16th centuries many mysteries were played in that part of Dauphine which corresponds to the present *département* of Hautes-Alpes. Five mysteries of this district, composed and played about 1500 (the mysteries of St. Eustace, of St. Andrew, of St. Pons, of SS. Peter and Paul and of St. Anthony of Vienne) have come down to us. The influence of the contemporary French sacred drama may to some extent be traced in them.

Prose. — In the 12th century we find in Languedoc sermons whose importance is more linguistic than literary (*Sermons du XII^{e} siecle en vieux provençal,* ed. by F. Armitage, Heilbronn, 1884). About the same time, in Limousin, were translated ch. xiii–xvii of St. John's Gospel (K. Bartsch. *Chrestomathie provençale*). Various translations of the New Testament and of some parts of the Old were made in Languedoc and Provence during the 13th and 14th centuries (see S. Berger, "Les Bibles provençales et vaudoises," *Romania,* xviii, 353;

and "Nouvelles recherches sur les Bibles provençales et catalanes," ibid., xix, 505). The Provencal prose rendering of some lives of saints made in the early part of the 13th century (*Revue* des *langues romanes,* 1890) is more interesting from a purely linguistic than from a literary point of view. To the 13th century belong certain lives of the troubadours intended to be prefixed to, and to explain, their poems. Many of them were written before 1250, when the first anthologies of troubadour poetry were compiled; and some are the work of the troubadour Uc de Saint Circ. Some were composed in the north of Italy, at a time when the troubadours found more favour east of the Alps than in their own country. Considered as historical documents these biographies are of a very doubtful value. To the same period must be assigned Las *Razos* de trobar of the troubadour Raimon Vidal de Besalu (an elegant little treatise touching on various points of grammar and the poetic art), the *Donatz proensals* of Uc Faidit and the "life" of St. Douceline, who died in 1274, near Marseilles, and founded an order of Beguines.

The leading prose work of this period is the treatise on grammar, poetry and rhetoric known by the name of Leys *d'amors,* composed in Toulouse c. 1350. The decay of Provencal literature, caused by political circumstances, arrived too soon to allow of a full development of prose. Nor did anything remain, in the second quarter of the 14th century, of what had been the first Provençal classicism, except the stale School of the Gai Savoir.

SECOND PERIOD

Yet Provenqal literature never died out entirely. The Academy of Toulouse, founded in 1324, was flourishing, mith the School of the Gai Savoir, at the end of the Hundred Years' War and, after many vicissitudes, is flourishing still. The poets crowned by this body between 1324 and 1498 stand in the same relation to the troubadours as the Meistersinger do to the Minnesanger: academic correctness takes the place of inspiration. The institution flourished, even to the extent of establishing branches in Catalonia and Majorca; and in 1484, when its prosperity was threatened, a seinifabulous person, Clémence Isaure, is said to have brought about a revival by instituting fresh prizes. The town of Toulouse never ceased to supply funds of some kind. In 1513 French poems were first admitted in the competitions, and under Louis XIV (from 1679) these were alone held eligible. This arrangement held good till 1893, when the town very properly transferred its patronaqe to a new Escolo *moundino;* but it soon restored its support to the older institution, on learning that Provençal poetry was again to be encouraged. In the two centuries that followed the glorious mediaeval period we have a succession of works, chiefly of a didactic and edifying character, which served to keep alive some kind of literary tradition. Religious mystery plays, which, though dull to us, probably gave keen enjoyment to the people, represent a more popular genre; the latest that have come down to us may be placed between the years 1450 and 1515.

In the 16th century there are not only signs of a revival, but a strong movement toward what might be called a Provenqal Renaissance. The Gascon Pey de Garros (d. 1585), author of the famous Eglogues, raised his native dialect to the rank of a literary language with his translation of the Psalms of David (1565) and inserted in his Poesias *gasconas* (1567) a maniiesto that might be compared to the Declaration of Font-Ségugne, launched four centuries later by the Felibres (see below, Third Period). As early as 1579, G. de Salluste du Bartas, in his trilingual *Salut,* followed the example of Pey de Garros. The Rabastens wheelwright, Augié Gaillard (1530–95), started the movement in Languedoc, and Louis Bellaud de la Bellaudière (1532–88) in Provence proper.

After Garros, in Gascony, came Guillaume Ader (Lou Catounet gascoun, 1605; Lou *Gentilome gascoun,* 1610), Louis Baron (b. 1612), who celebrated with great tenderness his native village of Pouyloubrin, Geraud Bedout (Lou Parterre gascoun, 1642), and J. G. d'Astros who, about the same time, with his remarkable Trinfe de la lengouo gascouo proved a most elegant and witty verse writer. But the most conspicuous among the poets of the Midi between Pey de Garros and Jacques Jasmin is certainly Pierre Goudelin (Goudouli; 1579–1649) of Toulouse, called "the hlalherbe of Oc." who, had he written in French, would have been given rank with the best of the times. Nicolas Sabolv (1614–75) excelled in the popular form known as the noel.

Other 17th-century writers worth mentioning, outside Gascony, are Claude Brueys (1570–1650), remarkable chiefly for comedies dealing with duped husbands (*Jardin deys musos* provensalos, 1628); Gaspar Zerbin (La *Perlo* deys *musos* et *coumedies provensalos,* 1655); Jean Michel de Nimes who wrote the picturesque *Embarras* de la *Fieiro* de Beaucaire; Daniel Sage of Montpellier (Las Foulies, 1650); the *avocat* Bonnet, author of the best among the open-air plays that mere annually performed at Béziers on Ascension Day (a number of these, dated 1616–57, were eubscquently collected, but none can compare with the opening one, Bonnet's *Jugement* de Paris); Nicolas Fizes, of Frontignan, whose vaudeville, the *Opéra* de *Frontignan* (1670), dealing with a slight love intrigue, and an idyllic poem on the fountain of Frontignan, show a real poetic gift. A number of Toulouse poets, mostly *laureats* of the academy, may be termed followers of Goudelin: of these, Franqois Boudet. who composed an ode, Le Trinfe del *Moundi* (1678), in honour of his native dialect, deserves mention. The classical revival that may be noted about this time is also generally ascribed to Goudelin's influence. Its most distinguished representative was Jean de Valks, of Montech, who made excellent translations from Virgil and Persius and wrote a brilliant burlesque of the former in the manner of Scarron (Virgile deguisat, 1648).

The best of the pastoral poets was François de Cortkte (1571–1655), of Prades, whose comedies, Rnnzounet and *Miramoundo* (published, unfortunately with alterations, by his son in 1684), are written with such true feeling and in so pure a style that they can be read with real pleasure. A comedy of his dealing with Sancho Panza in the palace of the duke has been edited. Arnaud Daubasse (1664–1727), of Qnercy, who belonged to the working classes, was patronized by the nobility in exchange for panegyrics.

In the 18th century the number of authors is much larger, but the bulk of good work produced is not equally great in proportion. The priests are mainly responsible for the literary output of Languedoc. The chief of the band is the abbe' J. B. Favre (1727–83), whose *Sermoun* de *Moussu* Sistre, delivered by a drunken priest against intemperance, is a masterpiece. He also wrote a successful mock-heroic poem (Sidge de Cadaroussa), travesties of Homer and Virgil, a prose novel depicting the country manners oi the time (*Histouèro* de *Jean-l'an-prés*) and two comedies which likewise give a vivid picture of the village life that he knew so well. Two genuine poets are the brothers Rigaud of Montpellier: Auguste (1760–1835) was the author of a deservedly famous description of a vintage; and Cyrille (1750–1824) produced an equally delightful poem in the Amours de Mounpeie'. Pierre Hellies of Toulouse (d. 1724), a poet of the people, whose vicious life finds an echo in his works, has a certain rude charm, at times distantly recalling Villon. In Provence, Toussaint Gros (1698–1748), of Lyons, holds undisputed sway. His style and language are admirable, but unfortunately he wasted his giits largely on trivial *pièces* d'occasion. J. B. Coye's (1711–77) comedy, *Lou* Novy para, is bright and still popular, while J. B. Germain's description of a visit paid by the ancient gods to Marseilles (Bourrido dei Dious, 1760) has considerable humour. In Gascony the greatest poet is Cyrien Despourrins (1698–1755).

THIRD PERIOD

The Revolution produced a large body of literature, but nothing of lasting interest. When it was over, scholars like F. J. Raynouard (1761–1863), of Aix, occupied themselves with the brilliant literary traditions of the middle ages; newspapers sprang up (the Provençal *Bouil-Abaïsso,* started by Joseph Désanat, and the bilingual Lou *Tambourin* et le menestrel, edited by Pierre Bellot, both in 1841); poets handed together and collected their pieces in volume iorm (*e.g.,* the nine *troubaire* who published Lou Bouquet *prouvençaou* in 1823). Much has been written about the "iorerunners of the Felibrigr," and critics are sorely at variance as to the writers that most deserve this appellation. We shall not go far wrong if we include in the list Hyacinthe Morel (1756–1829); Louis Aubanel (1758–1824); Auguste Tandon, "the troubadour of Montpellier"; Antoine Fabre d'Olivet (1767–1825); J. J. M. Diouloufet (1771–1840); Jacques Azaïs (1778–1856); Léon d'Astros (1780–1863); F. H. J. Castil-Blaze (1784–1857); the marquis de Fare-Alais (1791–1846). While these writers were all more or less academic and appealed to the cultured iew, four poets of the people addressed a far wider public: Antoine Verdié (1779–1820), of Bordeaux, who wrote comic and satirical picces; Jean Reboul (1796–1864), the baker of Nimes, who never surpassed his first effort, *L'Ange* et l'enfant (1828); Victor Gelu (1806–85), relentless and brutal but undeniably powerful of his kind (*Fenian* et *Grouman;* dix chansons *provençales,* 1840); and, greatest of them all, the true and acknowledged forerunner of the Felibres, Jacques Jasmin (*q.v.*).

The Advent of the **Felibrige.**—In 184j Joseph Roumanille (1818–91) of Saint Remy became usher in a small school at Avignon, which was attended by Frédéric Mistral (*q.v.*). Roumanille had composed some pieces in French; but, finding that his old mother could not understand them, he determined thenceforth to write in his native dialect only. These poems revealed a new world to young Mistral and spurred him on to the resolute that became the one purpose of his life: de *remettre* en *lumière* et conscience de sa gloire cette noble race *qu'en plein '89 Mirabeau nomme* encore la nation *provençale.* There is no doubt that Mistral's is the more puissant personality or that his finest work towers above that of his fellows; but in studying the Provençal renaissance, Roumanille must not be overlooked: his claims, indeed, were put forward with great force by Mistral himself (in the preface of Lis Isclo d'or). Roumanille's secular verse (Li Margaritedo, 1836–47; *Li Sounjarello,* 1852; Li Flour de Sauvi, 1850–59, etc.) moves the reader with the sincerity of its poetry, his *noëls* are second only to those of Saboly, his prose works (such as Lou Mege de *Cucugnan,* 1863) sparkle with delightful humour. He it was who in 1852 collected and published *Li Prouvençalo,* an anthology in which all the names yet to become famous and most of those famous already (such as Jasmin) are represented. In 1853 he was one of the enthusiastic circle that had gathered round J. B. Gaut at Aix and whose literary output is contained in the *Roumavagi deis* troubaires and in the shortlived journal Lou Gay Saber (1854). At the same time the first attempt at regulating the orthography of Provenqal was made by him (in the introduction to his play, La Part *dou* bon *Dieu,* 1853). In 1854 he was one of the seven poets who, on May 21, foregathered at the castle of Font-Ségugne, near Avignon, and founded the Felibrige.

The other six were Mistral, Aubanel, A. Mathieu (a schoolfellow of Mistral's at Avignon), E. Garcin, A. Tavan and P. Giera (owner of the castle). Of these, Théodore Aubanel (1829–86; of Avignon, son of a printer and following the same calling) alone proved himself worthy to rank with Mistral and Roumanille. "Zani," the girl of his youthful and passionate love, took the veil; and this event cast a shadow over his whole life and determined the character of all his poetry (*La Miougrano entredubaerto,* 1860; *Li Fiho d'Avignoun,* 1883). His is, without a doubt, the deepest nature and temperament among the Felibres, and his lyrics are the most poignant. His powerful love drama *Lou Pan dou pecat* was received with enthusiasm at Montpellier in 1878.

The Felibrige after Roumanille, Aubanel and Mistral.—The Felibrige increased considerably in Mistral's time and the subsequent period. The names of A. B. Crousillat, J. Brunet, L. Roumieux and of the "Muse" Antoinette de Beaucaire should be added to those of the signatories of the Font-Ségugne declaration. In Catalonia, V. Balaguer (1824–1901) lent his glory to the development of the Felibrean movement, before joining it. Among the poets of the next generation the most illustrious is certainly Félix Gras (1844–91) who settled down at Avignon as a young man. His rustic epic, *Li Carbounié* (1876) is full of elemental passion and abounds in fine description and scenery. Among his other works are *Li Roumancero Provençal* (1887) and a collection of prose tales, *Li Papalino* (1891). Gascony, which had been less closely associated with the Felibrige, then admitted the Landais writer Isidore Salles among the heirs of Despourrins and of the earlier 19th-century author Xavier Navarrot. Quite independent were Auguste Fourès in Languedoc and Clovis Hugues and Auguste Marin at Marseilles. The Latin Felibrean movement developed in Montpellier with A. Roque-Ferrier (1844–1907) and the Federalist movement with T. Amouretti (1863–1903) and Marius André (*La Glòri d'Esclarmoundo,* 1894; *Eme d'arantge un cargamen,* 1924). We should also mention, among the wider heritage of the first Felibres, the Irishman Bonaparte Wyse (*Li Piado de la Princesso,* Plymouth, 1882), the popular songwriter Charles Rieu, or Charloun (1845–1924), and, coming with a number of poets, born in Gascony, Rouergue and Languedoc, the somewhat artificial Joseph Roux (*La Chansou lemousina,* 1889) and the Auvergnat Arsène Vermenouze who proved with *Flour de brousso* (1895) and *Jous la cluchado* (1909) one of the poets most evocative of his homeland. Among those who attained fame during the first half of the 20th century, we should note the names of Valère Bernard (1860–1936) of Marseilles, author of *La Legenda d'Esclarmonda,* a masterpiece comparable to Mistral's best work, Antonin Perbosc (1861–1944), the Languedocian poet of *Lo Got occitan* and of *Lo Libre dels ausels,* Michel Camelat of Bigorre, Simin Palay of Béarn, and the Pyrenean *trobairitz* Philadelphe de Gerde. Contemporary with them were the *meynadiers* of the Camargue in Provence proper: Joseph d'Arbaud (1872–1950), who is less famous as the poet of *Lou Lausié d'Arle* than as the author of short stories such as *La Bestiou dou Vacarès,* written in an epic vein; Folco de Baroncelli (1869–1943) and Marius Jouveau (1878–1949). A curious case is that of S. A. Peyre, writing in Provençal, in French and in English. If Paul Froment (1875–98) had not died so young, he would doubtless have been the great poet of Quercy. P. L. Grenier (1879) was a notable artist who revived the classical language of Limousin. Albert Pestour, also a native of Limousin, with a fine command of the vernacular language, was the inspired poet of the *Rebats sus l'Autura* and of *L'Autura enviblada.* Among authors writing in the 1950s, mention should be made also of J. S. Pons (Roussillon), Louise Paulin (Languedoc) and of P. Eyssavel (Provence). They had, moreover, a regiment of young followers who bore witness to the permanent vitality, not so much of the Felibrige (a notion that was by that time somewhat out-of-date) as of Occitanian poetry.

Bibliography.—For a general bibliography, *see* D. C. Haskell, *Provençal Literature and Language* (New York, 1925), a list of references in the New York public library. On the whole of Provençal literature there is only one work: C. Camproux, *Histoire de la littérature occitane* (Paris, 1953). On the first and second period, viewed as a whole, *see* A. Jeanroy, *Histoire sommaire de la poésie occitane, des origines à la fin du XVIIIe siècle* (Toulouse, 1945).

On the first period, for general surveys, *see* J. B. de La Curne de Sainte-Palaye, *Histoire littéraire des troubadours,* 3 vol. (Paris, 1774); A. Restori, *Letteratura provenzale* (Milan, 1891); J. B. Beck, *Die Melodien der Troubadours* (Strasbourg, 1908); J. J. Salverda de Graves, *De Troubadours* (Leyden, 1917); J. Anglade, *Pour étudier les troubadours,* 2nd ed. (Paris, 1930); A. Pillet, *Bibliographie der Troubadours* (Halle, 1933); A. Jeanroy, *La Poésie lyrique des troubadours* (Paris, 1935); P. Belperron, *La Joie d'amour: contribution à l'étude des troubadours* (Paris, 1948). For general surveys with selections, *see* F. J. Raynouard, *Choix des poésies originales des troubadours,* 6 vol. (Paris, 1816–21); K. Bartsch, *Chrestomathie provençale,* 4th ed. (Elberfeld, 1880); C. Appel, *Provenzalische Chrestomathie,* 3rd ed. (Leipzig, 1903); V. Crescini, *Manualetto provenzale,* 2nd ed. (Verona, 1905); A. Kolsen, *Dichtungen der Trobadors* (Halle, 1916–19); J. Beck, *Les Chansonniers des troubadours et des trouvères, publiés en facsimilé et transcrits en notation moderne* (Philadelphia, 1927); A. Jeanroy, *Anthologie des troubadours* (translations only; Paris, 1907); J. Anglade, *Anthologie des troubadours* (Paris, 1927); J. Audiau and R. Lavaud, *Nouvelle anthologie des troubadours* (Paris, 1929); A. Berry, *Florilège des troubadours* (Paris, 1930); M. de Riquer, *La Lirica de los trovadores* (Barcelona, 1948). For special studies and selections, *see* Manuel Mila y Fontanals, *Los Trovadores en España* (Barcelona, 1861, 1889); P. Meyer, *Les Derniers Troubadours de la Provence,* 2 vol. (Paris, 1869–71); C. Chabaneau, *Poésies inédites des troubadours du Périgord* (Paris, 1885); F. de la Salle de Rochemaure and R. Lavaud, *Les Troubadours cantaliens* (Aurillac, 1910); A. Jeanroy, *Jongleurs et troubadours gascons des XIIe et XIIIe siècles* (Paris, 1923); H. J. Chaytor, *The Troubadours and England* (Cambridge, 1923); J. Audiau, *Les Troubadours et l'Angleterre* (Paris, 1927); J. Anglade, *Les Troubadours de Toulouse* (Paris, 1928) and *Actualité des troubadours de l'Aude* (Toulouse, 1941); A. Basset, *Les Troubadours limousins* (Limoges, 1949). For individual troubadours, *see* Troubadour: *Bibliography.* There are modern editions of *Girart de Roussillon* by P. Meyer (Paris, 1878), of *La Chanson de la croisade contre les Albigeois* by P. Meyer (Paris, 1875–79), of *Flamenca* by P. Meyer, 2nd ed. (Paris, 1901) and of *Las Leys d'Amors* by J. Anglade (Paris, 1919–20); there is also an important study of *Flamenca* by G. Millardet (Paris, 1936). The ancient *Biographies des troubadours* have been republished by J. Boutière and A. Schutz (Toulouse, 1950). *See* also A. Jeanroy, *Les Joies du Gay Savoir* (Paris-Toulouse, 1914); J. Anglade, *Les Origines du Gay Savoir* (Paris, 1919); and *Las Flors del Gay Saber* (Barcelona, 1926).

On the second period *see* J. B. Noulet, *Essai sur l'histoire littéraire des patois du Midi de la France aux XVIe et XVIIe siècles* (Paris, 1859) and *Histoire littéraire des patois du Midi de la France au XVIIIe siècle* (Montpellier, 1874–77).

On the third period, *see* P. Mariéton, *Les Félibres* (Paris, 1885); G. Jourdanne, *Histoire du Félibrige* (Avignon, 1897); E. Ripert, *La Renaissance provençale, 1800–60* (Paris, 1918) and *Le Félibrige* (Paris, 1924), the latter with an excellent bibliography; J. Salvat, *Le Félibrige* (Castelnaudary, 1940).

On Gascon literature, viewed separately, *see* G. Millardet, *Le Domaine gascon* (Brussels, 1909), for bibliography; G. Bastit, *La Gascogne littéraire depuis le moyen-âge jusqu'à nos jours* (Bordeaux, 1894); F. Sarran, *Poètes gascons du Gers* (Auch, 1904); G. Guillaumie, *Anthologie de la littérature et du folk-lore gascons,* 7 vol. (Bordeaux, 1941–45); I. Girard, *Anthologie des poètes gascons* (Toulouse, 1942).

(A. A. F. B.)

PROVENCE, a province in the southeast of ancient France, bounded on the north by the Dauphiné, on the east by the Alps and Italy, on the west by the Rhône and on the south by the Mediterranean sea. About 600 B.C., according to tradition, some traders from Phocaea founded the Greek colony of Massalia (Marseilles). Other colonies in the neighbourhood, such as Antibes, Agde and Nice, originated in this settlement. During the wars which followed, the inhabitants of Massalia asked assistance from the Romans, who thus made their first entry into Gaul (125 B.C.) and conquered the territories between the Alps, the sea and the Rhône (with the province of Narbonne on the right bank of this river). These lands formed the Provincia Romana, and the name was retained by Provence. The town of Aix (Aquae Sextiae) was founded to form the capital of this conquered land. Under the empire the territory of the former Provincia was divided into the new provinces of Narbonensis II, of the Maritime Alps and of Viennensis and formed an important centre of Roman learning and civilization. Arles was made the chief town of the province, becoming after the capture of Trier by the barbarians (A.D. 418) the capital of Gaul. By the 5th century bishoprics had been founded in all the cities of Provence.

At the beginning of that century Provence was attacked by the Visigoths. In 476 Arles was captured by Euric I, and the country south of the Durance thus came definitely under Visigothic rule. The more northern cities, such as Orange, Apt and Trois-Châteaux, were joined to the kingdom of Burgundy. About 510 Visigothic Provence was ceded to Theodoric, king of the Italian Ostrogoths; and soon afterward the Ostrogoths extended their lands in the north as far as Gap and Embrun. Witigis, king of the Ostrogoths, ceded Provence to the kings of the Franks about 537, when the northern cities and those on the coast (Arles, Marseilles, Toulon, Antibes, Nice) were given back to Burgundy, while a narrow strip of territory, with Avignon, Apt, Cavaillon, Riez, etc., extending from the west to the east as far as the Alps, was added to the kingdom of Austrasia.

In the 8th century western Provence was for a time conquered by Arabs from Spain. In 739 they were expelled by Charles Martel, who brought the country definitely under Frankish rule. Under Charlemagne and Louis the Pious the history of Provence was incorporated with that of the rest of the empire and became more and more subject to the incursions of the Saracens. **After** the partition of Verdun (843) it fell to the portion of the emperor Lothair. Later it went to his son, the emperor Louis II; and finally in 875 it passed to Charles the Bald, who handed it over to his brother-in-law Boso (879). The latter bore the title of king, and thus arose the kingdom of Provence (Provence, Viennois, Lyonnais and Vivarais), sometimes called Cisjuran Burgundy.

After some years of trouble the kingdom was given, in the 10th century, to Rudolph II of Burgundy, so that the kingdom of Burgundy now extended from the Aar to the Mediterranean. But under Rudolph's successors control became weaker and weaker, until Provence passed to the German kings, who then took the title of king of Arles (see ARLES, KINGDOM OF).

Local Countships. — At the beginning of the 10th century Provence was in a state of complete disorganization. All the real power was in the hands of local counts. It is probable that from the 9th century' several of the Provençal countships were united under one count and that the count of Arles had the title of duke, or marquis, and exercised authority over the others. In the middle of the 10th century this position was held by another Boso, of unknown origin, who left it to his two sons William and Roubaud (Rotbold).

From the end of the 10th century the descendants of the two brothers, without making any partition, ruled over the different countships of Provence; only one of them, however, bore the title of marquis. The counts of Provence had, from about the middle of the 11th century, a tendency to add the name of their usual residence after their title, and thus the lordships, known later under the names of the countships of Provence, of Nice and of Venaissin grew up. At last, by the marriage of Douce, the heiress, in 1112 to Raymund-Berengar III (Ramón Berenguer), count of Barcelona, the marquisate of Provence with the overlordship of this region passed to the house of Barcelona. The definite establishment of the countships of Provence, Venaissin and Forcalquier belongs to this period.

After the death of Raymund-Berengar IV (II of Provence) in 1162, his son Alphonso II, king of Aragon, took the title of count of Provence. His succession was disputed by the count of Toulouse, Raymund V. Most of the lay and ecclesiastical lords of Provence recognized Alphonso, who in 1176 signed a treaty with his competitor, by which Raymund V sold his rights to the king of Aragon.

Alphonso was represented in Provence by his brothers Raymund-Berengar III (of Provence) and Sancho, in turn, and in 1193 by his son Alphonso, who inherited Provence but not Aragon on his father's death in 1196. This Alphonso gave Aragon and Catalonia to his brother Peter (Pedro) and kept only Provence for himself; but on the death of his father-in-law, Count William II, in 1208, whose son had been disinherited, he added to it the county of Forcalquier. It was not until after his death (1209), during the minority of his son Raymund-Berengar IV, that Provence was involved in the struggle of the count of Toulouse against Simon de Montfort, when the part played by the city of Avignon in the Albigensian movement finally led to the expedition of Louis VIII of France against the town (see ALBIGENSES).

Raymund-Berengar had also to fight against Raymund VII, count of Toulouse, who had received from the emperor in 1230 the countship of Forcalquier. The intervention of St. Louis, who in 1234 had married Margaret, the eldest daughter of the count of Provence (the second, Eleanor, married Henry III of England in 1236), put an end to the designs of the count of Toulouse. Raymund-Berengar died in 1245, leaving a will by which he named as his heiress his fourth daughter, Beatrice, who shortly afterward, in 1246, married the celebrated Charles of Anjou (see CHARLES I, king of Kaples), brother of the king of France. After her death, in 1267, Charles still maintained his rights in Provence. The countship of Venaissin was left to him by his sister-in-law, Joan, countess of Toulouse. but in 1272 King Philip III took possession of it, giving it up in 1274 to Pope Gregory X, who had claimed it for the Roman Church in pursuance of the treaty of 1229 between Raymund VII of Toulouse and St. Louis.

Charles of Anjou was continually occupied with his kingdom of Naples. His government of Provence was marked by his struggles with the towns. In the first part of the 12th century the towns of Provence began to form municipal administrations and consulates, independent of the viscounts, who in theory represented the authority of the count in the towns. Marseilles, Arles, Tarascon, Avignon (whose consulate laws ddte from the 12th century), Brignoles and Grasse had become self-governing and elected their magistrates, sometimes negotiating with the count, as a power with a power, and concluding political or commercial treaties without consulting him. The city of Nice, which was joined to Provence in 1176. had retained its freedom. This state of affairs was in direct opposition to the arbitrary policy of Charles of Anjou. In 1251 he seized Arles and Avignon and placed them under a viguier (vicar) nominated by himself. In 1257 Marseilles was also subdued, and ministers nominated by the court performed their duties side by side with the municipal officials.

Annexation to France. — The successors of Charles of Anjou were chiefly interested in maintaining their rights over the kingdom of Naples. Charles II (-ruled 1285–1309) lived in Provence during the latter years of his reign and tried to introduce reforms into the administration of justice and finance. Robert of Calabria (1309–43), his son, was succeeded by his granddaughter Joanna I, widow of Andrew of Hungary, who sold her rights over the city of Avignon (where the popes settled from 1309 to 1377 and subsequently during the great schism) to Clement VI in 1348 to raise money to continue the struggle against the house of Aragon in Naples. The emperor Charles IV visited Avignon and had himself crowned king of Arles in 1365. He gave up his claims to Louis I, duke of Anjou, brother of Charles V of France. but the expedition which this prince made to take possession of Provence only resulted in the seizure of Tarascon and failed before Arles (1368).

Joanna had first nominated as her heir Charles of Anjou-Gravina, duke of Durazzo, her nephew by marriage: but when he took sides against her claim to the kingdom of Kaples she nominated instead Louis of Anjou as her eventual successor (1380). Louis took possession of Provence, while Charles of Durazzo made the queen prisoner at Naples and gave orders for her to be put to death (1382). Louis of Anjou also made an expedition to Naples, but did not arrive till after her death; he died in 1384. His son Louis II (ruled 1384–1417), only resident in Provence toward the end of his life, established a *parlement* in 1415. The wars carried on by his successor, Louis III (ruled 1417–34), against the kings of Aragon, his rivals at Naples, were the cause of the temporary ruin of Marseilles by the Aragonese fleet. René I (*q.v.*), duke of Anjou and Lorraine, Louis's brother and successor, after an unsuccessful attack on Naples (1460–61) retired to France, but after 1471 generally resided in Provence, where he built the castle of Tarascon and interested himself in art, literature and pastoral amusements. In 1474 he left his territories by will to his nephew Charles, count of Maine, who on his death in 1481 bequeathed Provence to Louis XI, king of France. Under Louis's successor, Charles VIII, Provence was definitely annexed to France. though even then it preserved a certain individuality. In laws relating to this country the sovereigns added to their title of king of France "and count of Provence and of Forcalquier," and Provence preserved a separate administrative organization.

Religious Troubles. — In the 16th century Protestantism made its appearance in Provence. A sentence passed in 1540 by the parlement of Provence against the heretics was carried out with great severity in 1545 by the president Jean de Maynier, baron d'Oppède, and the baron de la Garde. The movement drew a fair number of followers from the ranks of the lesser nobles. Charles IX's journey in Provence in 1567, followed by the establishment in the *parlement* at Aix of a court (*chambre*) in which Catholics and Protestants had an equal number of seats; led to a momentary cessation of hostilities. These were resumed between the Carcistes (Roman Catholics) and Razats (Protestants) but were again interrupted by the peace of 1576, which gave some guarantees to the Protestants, with La Seyne as a place of security, and also by the plague of 1579, which affected the whole country. The

League, on the other hand, made rapid progress in Provence. and the governor Bernard de Nogaret de La Valette and his brother Jean-Louis, duc d'Epernon (afterward governor also), vainly tried to pacify the country. La Valette and the party of the *Politiques* or Bigarrats mere finally more or leas reconciled to the Protestants; and at the time of the death of Henry III, the struggle was no more than a question of local politics. In 1596 the religious wars in Provence were definitely ended by the capitulation of Marseilles.

Under Rrchelieu the restriction of local freedom led to a rising which Condé suppressed in 1630–31. At the time of the Fronde additional taxes were levied by the *parlement* at Aix, and a period of local unrest began which culminated in an insurrection at Marseilles in 1660 followed by the abohtion of the last remaining municipal liberties of the town.

Provence was severely tried by the imperial invasions of 1706 and 1746 and the great plague of 1720.

Economic Development. — Throughout the middle ages, Provence was continually changing from the economic point of view. At the end of the ancient period and in Merovingian times it was a busy region with an important transit trade, the port of Marseilles being a commercial focus that connected Provence with the Italian ports and with the east. From the 7th century, however. trade undernent a serious crisis, caused in part by Arab expansion along the Mediterranean and by plundering of the Saracens, who blockaded the port and often attacked the coast of Provence But as early as the 12th century trade came to life again and the inland towns became local fairs. These fairs, however, did not enjoy so much prosperity as did those of other regions, because the important commercial roads — from Italy to Champagne and Flanders — did not cross this region. Nevertheless, Marseilles and Aigues-Mortes were ports in relation with Italy and the Latin east. At the beginning of the Angevin period (the end of the 13th century) the ports were busiest. Moreover, the tonns acquired a considerable pohtical importance dnd became great commercial and banking centres as well; such was the case with Avignon, where the papacy settled in the 14th century, and with Beaucaire, famous for its fairs. But later internal disturbances brought about a considerable falling off of these activities.

Administration.—Provence, with its own language and its law so closely related to Roman law, was quite separate from the other French provinces. Until 1639 it retained its provincial estates, the origin of nhich has been traced back to the 12th century They met annually and included representatives of three orders for the clergy, the archbishop of Aix, president ex officio of the tstates, the other bishops of Provence and the abbots of St Victor at hlarseilles, of Montmajour and ot Thoronet; for the nobility, all the men of noble birth until 1623. when this privilege was restricted to actual holders of fiefs; for the third estate, the members of the 22 chief towns of the *vigueries* (divisions corresponding to the *prévôtés* of the rest of France) and 15 other privileged places, among which were Arles and Marseilles. There nere theoretically no taxes, but only supplies given freely by the estates and assessed by them. The administrative divisions of Provence were constantly changing. At the end of the *ancien régime* tire government (*gouvernement*) of Provence, which corresponded to the *généralité* of Aix, was made up of eight *sénéchaussées:* those of lower Provence—Aix, Arles, Marseilles Brignoles, Hyères, Grasse, Draguignan, Toulon; and four of upper Provence—Digne, Sisteron, Forcalquier, Castellane. For judicial purposes the *parlement* of Aix had replaced the former *conseil e nment* or *cour souveraine*. There was a *chambre des comptes* at Aix and also a *cour des aides*. A decree dated Dec 22, 1790 divided Provence into the three departments of Bouches-du-Rhône, Basses-Alpes and Var; and in 1793 Vaucluse, the former county of Venaissin, which belonged to the pope, was added to these

The boundaries of Var were modified in 1860 after the annexation of the county of Nice when the department of the Alpes Maritimes was formed.

PROVERBS, BOOK OF. This Old Testament book falls into nine sections. Each of these has its special stylistic and other characteristics. some of them containing evident traces of compilation from earlier collections, one (as has only lately been recognized) being almost completely paralleled in an extant Egyptian hook, while individual proverbs are found to bear traces of the "international" character of their origin and are variously related to the culture of Egypt, Babylonia, Greece, etc. *(see* Wisdom Literature).

Moreover, the tradition preserved in the book itself which ascribed certain parts of the book to Solomon (x. 1, xxv. 1), the "sages" (xxii. 17, xxiv. 23), Agur (xxx. 2), King Lemuel's mother (xxxi. 2) militates against the view that any one author was responsible for the composition of these various sections of the book: the ascription to Solomon in i. 1 probably referred originally to chapters i.–ix.—though this was probably the last section to be compiled.

Wellnigh the only characteristics common to all sections of the book may be summed up under three heads and these are not confined to the Book of Proverbs but are to be found in nearly all the extant gnomic literature of the Hebrews—the presuppositions that "wisdom" comes from Jehovah, that wisdom is, or should be, the guiding principle of life, and that cardinal social virtues such as industry, thrift, discretion, truthfulness, honesty, chastity, thought for others, including the lower animals, should be inculcated. Consequently in its present form the book represents the last stage in a long compilatory history and provides many useful examples of Hebrew proverbial and gnomic thought at various stages of its development. The date of each section and subsection must be alternately determined by the character of its contents, the relation in which the latter stands to the extant gnomic literature of other peoples, and the stage or stages of moral and theological development reflected in it.

Chapters i.–ix.—The first section serves as an introduction to the whole book, but in origin it is of late date and its contents suggest that, like the book as a whole, it was compiied from more than one source. At times, for instance, the motive advanced for good conduct is moral and religious (*e.g.*, ii. 5–8): at times it is frankly utilitarian (*e.g.*, vi. 1–5). Instead of a series of unrelated proverbial couplets, such as those in the following section, comparatively long discourses follow on each other. The sage addresses his remarks to young men. Though not confining his warnings to these two offenses, he warns them more especially against highway robbery and adultery — unless indeed the latter is an only too thinly veiled warning against Hellenism (*cf.* "Madam Folly" in ch. ix. 13–18) conceived of as a prostitute enticing the uninstructed ("ye simple ones") from their allegiance to their true love, the "wisdom" which comes from Jehovah, incarnate, as it were, in His religion, Judaism. Somewhat similar warnings against woman's wiles are given by Egyptian sages such as Amenophis and Ptah-hoteph, and by the Mesopotamian author of the Wisdom of Ahikar. The section is chiefly remarkable for the developed thought contained in viii. 1–31 as to "wisdom," its relation to God, the universe and man. It is perhaps more developed than, not only Eccles. xxiv. 1–19, but also the descriptions of it in the Book of Wisdom. "Wisdom" claims to have existed prior to the universe *(cf.* "in the beginning" with the first words of Gen. i. 1 and Jolin i. 1) as a possession of God (viii. 22 sff.), to have witnessed the creation of the universe, and even to have acted as a clerk of the works or architect in the process of the creation, unless, as the parallelism of the verse makes probable, the vocalization of the Hebrew word translated "master workman" should be altered to justify the rendering "nursling." But it is questionable whether even here the Hebrew author does more than poetically *Personify the principle* of wisdom: he scarcely gives it a real *hypostasis* and does not go so far in this direction as did Philo in his description of the Logos as "a second god."

It is not, however, outside the bounds of possibility that the author of the prologue to the Fourth Gospel was considerably influenced by this description of wisdom rather than by Philo's descriptions of his Logos, even though he substituted the latter term for "wisdom." This advanced thought as to wisdom is not confined to ch. viii., but seems to be more or less presupposed throughout the section. The author's philosophy of life otherwise shows little of a pronouncedly modern character. Righteousness and wickedness are rewarded in this life (*e.g.,* ii. 21) ; the sacrificial worship is inculcated (ii. 9, iii. 9); the words "law" and "commandment" are used now of the Mosaic system, now of parental injunctions, now of the sage's advice. It is the language and philosophy of life characteristic of Deuteronomy which are most prominent; suffering is divine chastisement administered, however, in love (iii. 12).

Chapters **x.–xxii.**—The second section illustrates earlier stages in the literary productions and ideals of the exponents of wisdom. Each proverb is confined to two lines, antithetical in form if we except a few in which synonymous parallelism occurs. The utilitarianism of the compiler of this section is often overemphasized: it contains, on the contrary, sentiments which anticipate some of the highest ideals expressed in the New Testament and to which the latter owe their literary form (*e.g.,* x. 12 cf. I Cor. xiii. 7, I Pet. iv. 3, James v. 20; xiv. 31; xvii. 5, cf. Matt. xxv. 40, 45; xx. 11, cf. Matt. vii. 16; xx. 22, *cf.* Matt. v. 39, Rom. xii. 17, 19, etc.). It reflects, moreover at times the "prophetic" revolt against the hollowness of merely external sacrificial worship (xv. 8, xxi. 3) cf. the emphasis on the national virtue demanded by Amos (xiv. 34) and on inner purity (xx. 9) and on the omniscience of Jehovah (xv. 3, 11). Thus, in date, the section shows no trace of the developments of religious, theological and philosophical thought for which the latter post-exilic Judaism was responsible; on the other hand, along with much which might be the product of any period, it presupposes, at least in the above respects, the very latest products of pre-exilic piety.

Chapters **xxii. (17) to xxiv.** (22) — The third section bears the title "words of the wise." Its contents are presented to the reader in a strophic form, forming a miniature discourse, and having four lines to a strophe, as in the newly deciphered Egyptian "Teaching of Amenophis." It is the remarkable similarity of the section to this latter book which has especially concentrated attention upon it since 1924. The similarity between the two continues, with certain exceptions, throughout a considerable portion of the section and creates a problem which is scarcely solved by the theory that both reflect gnomic sayings which were common to all nations of the orient. Indeed so close is the relationship that it is possible to emend with a fair degree of certainty, on the basis of the Egyptian tradition, passages in which the Hebrew text is manifestly corrupt: thus "excellent things" (xxii. 20) without any change in the consonantal text, should be read as "thirty (sayings)," the exact number of the "chapters" into which *The* Teaching of Amenophis is divided. It would appear unlikely that the Egyptian sage borrowed from the Hebrew, and we are therefore compelled to suppose that either a copy of the Egyptian book penetrated into Palestine and its contents gradually became "Hebraised," its Egyptian theology slowly yielding to that of the Hebrews and proverbs from. other sources gradually attaching themselves to it; or a Hebrew sage, visiting or living in Egypt, became acquainted with it, expurgated its Egyptian polytheism and made it acceptable to those who saw in Jehovah the only God who ruled every department of life. Either of these alternatives can best be visualised as happening in pre-exilic rather than late post-exilic days, but to dogmatise as to the exact date, whether the reign of Hezekiah, the early years of the exile or otherwise is to substitute guesswork for reason. An outstanding one among the many sayings common to the Hebrew and Egyptian gnomic writers occurs in the next section (xxiv. 23–34, an appendix to the present one) as well as already in the preceding one (xx. 22) : it is the earliest extant form of "the golden rule," later extolled by Hillel and Jesus, which is thus proved to be in its origins Egyptian rather than Hebrew or Jewish.

Chapters **xxv.–xxix. (27).**—The fifth section, attributed traditionally to Hezekiah's scribes (xxv. 1), contains, like the second section, chiefly short independent proverbial aphorisms; but it has some of two or more verses in length, and advances from the consideration of worldly matters in chs. xxv.–xxvii. to matters of more specifically religious import in chs. xxviii., xxix.. where the observance of "the law" in particular is emphasized, and prophecy is specified as a sine qua non of popular self-restraint (xxix. 18). In spite of the presence in this section of proverbs which occur elsewhere, it contains several of considerable interest. It reflects a somewhat hostile attitude to the monarchical form of government, but attempts to deflect criticism from the person of the king to his courtiers. Whether "the king" is a native Jewish ruler, Davidic or Maccabaean, or a Ptolemaic or Seleucid overlord, or merely figures impersonally in a set of proverbs of international vogue cannot be decided: consequently it gives no real help in fixing the date of the section. In at least two respects this collection provided the inspiration for practical and ethical advice too often supposed to have originated in Christian circles namely xxv. 7 which evidently inspired Luke xiv. 8–11, and xxv. 21 which is quoted in Rom. xii. 20.

Chapter **xxx. (1–16).**—The sixth section has the cryptic and not very convincing title "The words of Agur, the son of Jakeh, of Massa (R. V. mg.)," followed by a line which has defied all efforts to translate it. This, like xxxi. 1, though a frank confession by the Jewish sages that they were prepared to welcome aphorisms of foreign origin, and having done so, openly to ascribe them to a foreign author, really throws no light upon the origins and background of the present section. It would appear to date from a period when problems of theology and philosophy were being discussed ad nauseam and to emanate from an author who found little comfort, but much disturbance of faith in speculations of this nature. Consequently confessing his own limitations of intellect (v. 2 seq.), he plaintively asks who in point of fact has ever penetrated into the supra-mundane sphere to return with a knowledge adequate to justify him in propounding such riddles (v. 4). And so he takes refuge in the revealed "word" of God and utters a warning against human endeavours to supplement it or detract from it in self-confidence or insolence. He ends by pointing out the shortcomings of his generation (vv. 5–14). It is the answer of a religious obscurantist rather than, as is too commonly supposed, of a pious agnostic.

Final Section. — The seventh section, chap. xxx. 15–33, consists of miscellaneous dicta introduced by an unintelligible line and bound together by their "numerical" form of introduction In these few words is concentrated a wealth of insight into the normal and abnormal, the obvious and mysterious in life and nature, which, as it were in a nut-shell, illustrates the keenness and the breadth of observation to which the "wisdom" writers, the humanists of Israel, trained themselves.

The eighth section, chap. xxxi. 1–9, purports to be a further instance of foreign wisdom, again from "Massa," and indeed an illustration of a king's instruction by his mother. The vices against which he is warned include impurity, drink and maladministration of justice. These vices were prevalent in most oriental courts of the period during which the section could have been written, and do not necessarily presuppose the vices which Hellenism in particular communicated to the petty kings of oriental states into which it penetrated.

The ninth and last section, chap. xxxi. 10–31, is perhaps the masterpiece of this remarkable collection of the literary output of the humanists of Israel. Incidentally it is an "alphabetical" poem, each verse beginning with a letter of the Hebrew alphabet, and each letter appearing in its correct sequence. The lie is here given to the depressing picture, though one too often fully justified, which is mostly drawn in the Old Testament, of woman's personal and economic position among the Hebrews as the slave and chattel of her husband who was legally free to possess not one but many wives. But practice reinforced by economic necessity. probably rose in this respect above precept. At any rate, in the wealthy and prosperous household here depicted monogamy is presupposed and the poet depicts the wife as its master-mind as well as its mainstay. To what extent such a régime pressed heavily on the female slaves and other underlings we do not know since no literature emanating from them has survived.

Next to their passion for the highest morality of their day. and their unswerving loyalty to their ancestral faith, certain of the Hebrew gnomic writers whose work has survived in the Book of Proverbs will be held in honour most of all for their ability, which, as stated at the outset, is only now beginning to be realized, to master the gnomic literature of Egypt and of Mesopotamia, of Edom and of Massa, to expurgate from it what was unworthy, and to transform it into an instrument for the instruction of successive generations of the worshippers of Jehovah. Only a study of the Book of Proverbs in the light of the comparative study of gnomic literature can make the reader realize this; for instance in addition to close relationship with the Egyptian Teaching of Amenophis, there are more than 70 dicta in the Wisdom of Ahikar and of these more than half find an echo in this book.

BIBLIOGRAPHY.—For the literature, which is considerable, *see* the commentaries of Toy (1898), and especially W. O. E. Oesterley, *The Book of Proverbs* (1928) in the *Westminster Commentaries*, who gives striking parallels and references to the latest literature. *See* also Cheyne, *Job and Solomon* (1887) ; id., in *Sem. PROVIDENCE, the capital of Rhode Island, U.S., is located at the head of Narragansett bay on the Providence river, about 43 mi. S.W. of Boston and 180 mi. N.E. of New York city. It is an active seaport as well as an important industrial and commercial centre.

Providence is built on three hills College hill, on which Brown university is located, rises most sharply to the east of the central business district; it was at the foot of this rise and on its slope that the first houses and shops were built. The total land area of the city is only 17.9 sq.mi. and the density of population is high (1.159 in 1960). Most of the city is closely built-up with many sections where multiple-dwellings are common. The population remained nearly stationary at around 250,000 persons from 1930 to 1950, declining to 207,498 in 1960. Meanwhile. moderate growth took place in the Providence-Pawtucket standard metropolitan statistical area. This area increased 9% from 1940 to 1950 and 7.4% from 1950 to 1960, its total population in 1960 being 816,148. The metropolitan area as defined by the census bureau includes, in Rhode Island, all of Bristol county; Warwick city, East Greenwich and West Warwick towns in Kent county; Central Falls, Cranston, Pawtucket. Providence and Woonsocket cities and Cumberland, East Providence, Johnston, Lincoln, North Providence, North Smithfield and Smithfield towns in Providence county; North Kingstown town in Washington county; and in Massachusetts, Attleboro and North Attleboro, Seekonk, Bellingham, Franklin, Plainville, Wrentham, Blackstone and Millville towns. Important manufacturing centres in the metropolitan area, in addition to Providence, include Pawtucket, Central Falls, Cranston, Bristol, Woonsocket and East Providence. The remaining communities are primarily residential and, except for the city of Warwick, are smaller in size. (For comparative population figures see table in RHODE ISLAND: Population and MASSACHUSETTS: *Population.)*

Among these communities only Woonsocket and Pawtucket have well-developed separate business centres and all are dependent on Providence for many services, retail, wholesale and financial. Local bus lines operate to most of the suburbs and a network of major highways centres on Providence from all directions. Besides the English and the Irish, the major ethnic groups represented are the Italians, followed by Canadians (both English- and French-speaking) and Russians.

History. — After his banishment from Plymouth colony for his unorthodox religious beliefs, Roger Williams made his way slowly to the banks of the Seekonk river and thence by canoe to a point at the foot of what is now known as College hill, where he and his five dissenter companions found a spring with abundant water. On the way he is said to have been hailed by a friendly Indian with the words, "What cheer?" — perpetuated in the names of several businesses. From the Narragansett chieftains Canonicus and Miantonomi, Williams secured a grant of land which he named in gratitude for "God's merciful providence" and which he dedicated as "a shelter for persons distressed for conscience."

The site was a favourable one and the promised freedom of conscience appealed to many. By 1675 about 1,000 persons made up the population. Further growth was only momentarily halted by King Philip's War when 29 homes were burned by the Indians. More important in the long run was the erection of the city's first wharf in 1680 by Pardon Tillinghast; in the years which followed Providence developed into a major commercial centre. Its sailing ships to the West Indies, Africa, India, China and coastal ports carried home molasses, slaves, rum and other items in exchange for colonial exports; this trade was the basis for the development of several wealthy and powerful families whose great mansions filled with expensive furniture and art objects rose along College hill.

Providence took a leading part in the rebellion against Great Britain which led to the colonies' independence. In 1772 a British revenue vessel, the "Gaspee," was ^burned off Warwick while aground. In 1775 occurred a Providence Tea Party as an attack upon the idea of taxation without representation. Revolutionary forts were built and manned and French troops were quartered in what is now University hall at Brown university. The city was the scene of the signing of the Rhode Island Independence act on May 4, 1776, two months in advance of the country's Declaration of Independence.

In the post-Revolutionary period, Providence's crippled trade and commerce gradually recovered. The city's prosperity was augmented by new industrial development, starting with the establishment in adjacent Pawtucket in 1790 of Samuel Slater's textile mill, the first in the U.S. The town grew in size and status during the first half of the 19th century, incorporating as a city in 1832. Several notable buildings were erected, including the Arcade, an imposing covered building of many separate shops built in 1828 and designed after an Athenian temple, and the Providence Athenaeum (1836), a private library on College hill.

In the second half of the 19th century the city's industrial activities became of prime importance, supplanting but not diminishing its commerce and trade. The first important industry in Providence was the textile industry, starting with cotton factories and later expanding to include a woolen and worsted industry. Next came the jewelry industry, beginning with the little shop in which Seril Dodge made silver shoe buckles in 1786 and expanding after 1850 into a major industry. By 1880 the state was first in the nation in jewelry manufacture; 142 of its 148 plants were in Providence.

In addition to textiles and jewelry, other industries have developed to places of importance in the city and its metropolitan area, especially the machine tool and metal, rubber and electronics industries. In the second half of the 20th century Providence continued to be of major importance as the centre of the nation's most highly industrialized state.

Historic Sites. — One of the oldest cities in the U.S., Providence contains much of historic interest. The names of many streets are reminders of its trade and commerce and its early search for religious toleration; Benefit, Benevolent, Hope, Friendship, Dubloon, India and Ship streets and many others remain. Other points of historic interest in the city include the First Baptist meetinghouse, oldest of the denomination in the U.S.; First Unitarian church, its bell the largest cast by Paul Revere; the Old State house; the present capitol; and the Rhode Island Historical society, with extensive collections on Rhode Island history. The city contains dozens of old and historic homes and public buildings, many of which are open. The Old Slater mill in adjacent Pawtucket is a museum.

Education and Cultural Activities. — Despite its emphasis on industrial activity, Providence is an educational, cultural and recreational centre. The oldest of its several colleges is Brown university, founded in Warren in 1764 as Rhode Island college, moved to Providence in 1770 and renamed Brown university in 1804 in honour of Nicholas Brown, a treasurer of the college and a principal benefactor. Its women's college is Pembroke, organized in 1891.

John Hay library, erected as a memorial to John Hay secretary of state under Presidents McKinley and Theodore Roosevelt and a Brown graduate in the class of 1858, and other college libraries contain about 850,000 volumes and many special collections. On the campus are the John Carter Brown library, containing the world's foremost collection of Americana printed prior to 1801, and the Annmary Brown memorial, with a world-famous collection of incunabula from the period 1460 to 1500 Brown's Haffenreffer museum, located at Bristol. has a growing collection of Indian and other anthropological materials.

The Rhode Island School of Design is a private, coeducational college, founded in 1877 and providing four-year degree programs in the fine arts, architecture, design and related fields. The school's museum is notable for its collections of early furniture and early American crafts. There are comprehensive collections of paintings and sculpture of various periods and an oriental collection.

Other institutions of higher learning in Providence include the Rhode Island college, a state college chartered in 1854 and now offering teacher training on a handsome 48-ac campus opened in 1958; Providence college, a liberal arts college for men under the auspices of the Dominican Order, founded in 1917; and Roger William: Junior college, incorporated in 1956.

The Providence Public library facilities were approximately doubled in 1954 by the opening of a new wing to the main building, erected in 1900. There are several branch libraries and one or more libraries in each of the towns in the metropolitan area

Recreational Facilities. — The city maintains several parks and playgrounds and a municipal golf course. The largest park is Roger Williams park, with 453 ac. of lakes, flower gardens, walks, animal and bird houses, a museum of natural history, Betsey Williams cottage and a small amusement area for children.

Several state parks and picnic grounds are located in the metropolitan area. Yacht clubs and marinas are found in several waterfront communities and sailing and other forms of boating are common on Narragansett bay and adjacent waters. A ski slope and tow are operated by the state in Cumberland in winter. Dozens of ocean resorts lie just beyond the metropolitan area on the bay and the Atlantic ocean. (V. H. Wh.)

PROVINCE, a term applied in ancient Rome (Lat. *provincia*) to the sphere of duty assigned to one of the higher magistrates, the consuls and praetors (*qq.v.*). Only those magistrates who had military power (*imperium*) had a province. When the province of a quaestor is mentioned it refers to the province of the consul or praetor to whom the quaestor is subordinate.

When the government of conquered countries grew to be one of the most important duties of the higher magistrates, the term province, from designating the government of a conquered country as one particular duty of a Roman magistrate, came to be used generally as a designation of the country itself.

The provinces paid tribute to Rome, for it was a recognized principle that they were the estates of the Roman people and were to be managed for its benefit. The constitution of a province was drawn up by the victorious Roman general, assisted by ten commissioners appointed by the senate, and the province was governed on the lines laid down in this constitution or charter (*lex provinciae*). For administrative purposes the province was divided into districts, each with its capital, for judicial purposes into circuits (conventus) and in the chief town of each circuit the governor of the province held assizes.

The lands of cities captured by force of arms were turned into Roman domains, and were let out by the censors to private persons. Royal domains, such as those of Macedonia and Cyrene, were also confiscated. Communities which surrendered were usually allowed to retain their personal freedom and private property; but all the lands were subjected to a tax, consisting either of a payment in kind (*vectigal*) or of a fixed sum of money (tributum, stipendium). It is to this class of communities (the *civitates* vectigales or stipendiariae) that the majority of the provincial states belonged. In a better position were those states whose freedom was guaranteed by Rome on the ground of old alliances or special loyalty. Their freedom was recognized either by a treaty or by a decree of the Roman people or senate. As a decree of the people or senate could at any time be recalled, the position of the free states without a treaty was more precarious than that of the treaty states (*civitates foederatae*). The latter enjoyed internal freedom, retained their lands, paid no taxes, and were bound to render those services only which were expressly stipulated for in the original treaty. Amongst such treaty states were Massilia (Marseille), Athens, Rhodes and Tyre. The privileges of the free states without a treaty were somewhat similar. All political distinctions, save that between slave and freeman. disappeared when Caracalla bestowed the Roman franchise on the whole empire (A D. 212).

Provincial Diets. — Every province had, under the empire, a provincial assembly or diet of its own (concilium or *commune*), and these diets are interesting as the first attempts at representative assemblies. The diet met annually, and was composed of deputies (legati), from the provincial districts. It arranged for the celebration of religious rites and games, especially for the worship of the emperor. The celebration was under the conduct of the high priest of the province. The diet also passed votes of thanks to the outgoing governor, or forwarded complaints against him to Rome; and it had the right of sending embassies direct to the senate or the emperor.

The Provincial Governor.—The provinces were administered by governors from Rome, who held office for a year. From the formation of the first provinces in 227 B.C. down to the time of Sulla (82 B.C.) the governors were praetors (*see* PRAETOR); from the time of Sulla to that of Augustus the praetors remained in Rome during their year of office, and at the end of it assumed the government of a province with the title of propraetor. A province which was the seat of war, or was in a disturbed state, was committed to the care either of one of the consuls for the year, or of a commander specially appointed for the purpose, with the title of proconsul. The senate determined which provinces were to be governed by consuls and which by praetors and the consuls arranged between themselves which of the provinces each should have, and similarly with the praetors. The Sempronian law of 123 B.C. provided that the senate should nominate the two consular provinces before the election of the consuls, and that the consuls should, before their entry on office, arrange which of the two provinces each should have. The Pompeian law of 53 B.C. enacted that no one should hold the governorship of a province till at least five years after his consulship or praetorship. This law was repealed by Caesar, but was re-enacted under Augustus; it setered the connection between an urban magistracy and the governorship of a province, and turned the latter into an independent office. A provincial governorship was regularly held for one year; but it could be prolonged by a vote of the people or a decree of the senate. The necessary supplies of men and money were voted to the governor by the senate. His staff included one or more lieutenants (legati) and a quaestor (*q.v.*). Besides these the governor took with him young men of the upper classes to assist him in the government. These were known as the companions (*comites*) or suite of the governor They were chosen by the governor himself, but they were maintained at the expense of the state, and under the empire, received regular pay. In addition there was a crowd of subordinates. Before setting out for his province the governor, clad in the purple military robe of his office, offered sacrifice on the Capitol; then immediately after receiving the *imperium* or military command he marched out of the city (for the *imperium* could only be exercised outside of Rome and was forfeited by staying in the city), preceded by his lictors and accompanied by his suite. His year of office began from the day he set foot in his province. In the hands of the governor all powers military and civil were united. He commanded all the troops in the province, and had power to raise levies of Roman citizens as well as of provmcials. and to make requisitions of war material. He possessed both criminal and civil jurisdiction; as criminal judge he had the power of life and death, and from his sentence none but Roman citizens could appeal; as civil judge he was guided partly by the charter of the province (*lex* provinciae), partly by the edict which it was customary far him to issue before his entrance on office (see PRAETOR).

Condition of the Provinces under the Republic. — The Roman people regarded the provinces as so many estates from which they were to derive revenue. Hence agriculture and commerce were encouraged, settlements were made, roads and aqueducts were constructed; in short, the Roman aimed at exploiting his empire by a system of prudent economy. But the Roman governors were apt to look on their provinces as their own peculiar prey; they had usually bought their way to office at vast expense, and they now sought in the provinces the means of reimbursing themselves for the expenditure they had incurred at Rome. Redress was to be had by a complaint to the senate; after 149 B.C. there was a court established at Rome for the trial of cases of extortion (*repetundae*) by provincial governors. But, even when the provincials had arraigned their oppressor, it was difficult to secure his condemnation at the hands of juries composed of men who had a fellow-feeling for the offender because they had themselves committed, or hoped for means of committing. similar offences Besides the governor, two classes joined in wringing the uttermost farthing from the unhappy provincials. These were the publicani (*q* v.) or farmers of the taxes, and the money-lenders (negotiatores). Both these classes were recruited from the *equites* (*q.v.*) and, since from 122 B.C. the juries were drawn at first exclusively and after 70 B.C. partially from that order, the provincial governor could not check their excesses without risking a condemnation at the hands of their brethren. Accordingly he generally made common cause with them.

The Provinces under the Empire. — Under the empire the provinces fared better. Romans and provincials were reduced to a common level of subjection to the emperor, who meted out equal justice. The first centuries of the Christian era were for some of the countries included in the Roman empire the happiest of their history.

Augustus, in 27 B.C., divided the provinces into imperial and senatorial. Those which required the presence of an army were placed under the direct control of the emperor; those which needed no troops were left to the senate. (1) The senatorial provinces were ruled by annual governors called proconsuls. Their poners were much the same as they had been under the republic, except that they had now no troops. or only a handful to maintain order. (2) The imperial provinces were governed by imperial lieutenants (legati *Caesaris*), who were nominated by the emperor and held office at his pleasure; all of them had the power of the sword (*ius* gladii). For the administration of the finances these lieutenants had procurators under them, while the governors of the senatorial provinces continued to have quaestors. Certain other possessions were regarded as domains of the emperor, and were managed by a procurator or praefect (see PREFECT (ROMAN), responsible to the emperor.

PROVINCETOWN, a town of Massachusetts. U.S., situated among extensive sand dunes within a fishhook-shaped harbour at the northern end of Cape Cod, is a noted artists' colony. fishing port and tourist centre. Discovered by explorers Bartholomew Gosnold and Henry Hudson in 1602 and 1609, it was the first landing place of the Pilgrims before they founded Plymouth. The birth of Peregrine White. the first white person born in New England, and the signing of the Mayflower Compact both occurred on shipboard in Provincetown harbour. Settled by lawless traders and fishermen before 1700 on lands owned by the Province of Massachusetts Bay (hence its name), the village was first a precinct of the town of Truro and in 1727 became a separate township. Its exposed position, subject to repeated attacks by sea, forced its abandonment during the French wars and the American Revolution. Its magnificent harbour was used as a naval base by British blockading squadrons in the Revolution and the War of 1812. In the 19th century it was an active maritime and whaling port, and its Portuguese descendants still maintain there the most prosperous fishing industry on Cape Cod. Until 1900 its communications with the mainland were mostly by boat because of the wind-blown loose sand that swept across its highways.

Modern Provincetown was for some time the home of Eugene O'Neill, whose first produced play, Bound East for Cardiff, was staged there in 1916 by the Provincetown Players. The top of the great Pilgrim monument, 350 ft. above the sea, affords a superb view of the cape and Massachusetts bay. Drives along the sand dunes, buried forests and shipwreck-littered beaches are popular with tourists. The close-packed streets and wharves of the old maritime town are annually explored by thousands of visitors. The resident population is about 3,500. (H. F. Ho.)

PROVINCETOWN PLAYERS, an experimental theatrical group, was organized in 1915 at Provincetown, an artists' colony in Massachusetts. Its program, the creation of a vital American drama, derived philosophical support from the hypotheses of Jane Ellen Harrison and Gilbert Murray (*qq.v.*). In 1916 they staged *Bound East* for *Cardiff*, the first of Eugene O'Neill's plays to be produced. That minter they moved to New York's Greenwich Village where, calling themselves the Playwrights' theatre, they encouraged playwrights, actors and stage technicians to "work out their ideas in freedom." The result was to provide an impetus to the individual artists and playwrights (particularly O'Neill), who were responsible for the renaissance of the American theatre after 1920, and to demonstrate to the commercial theatre that its patrons were as ready for provocative treatment of contemporary themes as patrons of museums or novel readers. The group disbanded in 1929. (A. S. DR.)

PROVING GROUND, an area set aside and usually specially modified and equipped to "proof test" military devices and military and commercial vehicles. The purpose of such testing is to show up, by excessive or distorted operation, the weaknesses of an item or any of its components; to determine whether the item's operation fits into a standard pattern; or to determine the life expectancy of any product. In many instances, items are tested to destruction; in the case of ammunition the test is actually an expenditure of sample quantities from each lot made. In all cases, data are collected, evaluated and used in further development or in making engineering or production improvements.

Vehicle proving grounds, whether military or commercial, have a wide variety of roads and road surfaces to cause the vehicle under test to be strained or overworked in one manner or another. Corduroy tracks twist the car frame to determine its stamina; steep slopes shon whether the engine can develop sustained power under unusual demand; braking power is tested when a stop is made on the slope. Tires are tested on many types of cobbles and broken stones and in sand and deep mud. Engines and brakes are proof tested by running the vehicle through deep water; brakes and tire traction are put to the test by passing through deep mud.

Military proving grounds also have special facilities and instruments for proofing guns of all sizes, from small arms to the largest cannon. Rifles or machine guns may be fired from stands in indoor ranges to test the gun barrel's resistance to wear when fired at excessive rates, to determine its ability to operate at extreme ranges of temperature or in dust or rain, or to allow studies of bullet flight by flash photography. Some artillery weapons are also fired indoors, but more often the firing is in the open against various types of targets, including different thicknesses of armour plate. Prominent on the artillery test range are tall towers supporting large metal rings. These rings are solenoids ('electrical coils affected magnetically by the presence of moving steel objects) through which shells are fired to study their behaviour.

Guided missile proving grounds are distinctive primarily because of the much greater ranges involved. They are usually located in sparsely settled areas where missiles may be fired distances of 100 mi. or more; sometimes they are on coasts so that firing may be out to sea.

Notable proving grounds in the United States are several commercial vehicle test areas maintained by manufacturers of motor vehicles near Detroit, Mich.; the U.S. army ordnance corps' Aberdeen proving ground near Baltimore, Md., for guns, ammunition and combat and transport vehicles; and the U.S. army's

White Sands missile range in New Mexico, for rockets and missiles. Aberdeen's area is more than 70.000 ac., but shells may be fired as far as 30 mi. out over Chesapeake bay. White Sands is a desert valley 40 mi. wide and about 100 mi. long. Very long range missiles for the army and the air force are fired southeastward into the Atlantic ocean from the Atlantic missile range at Cape Canaveral, Fla.

Germany's great proving ground at Hillersleben before and during World War II resembled Aberdeen proving ground in that it permitted the proof testing of many types of weapons ana other material at one place. The United Kingdom, hoaever, spreads the proof testing or try-out operations to different areas. For example, tanks are tested at Castle Douglas in Scotland; artiliery at Holyhead in Anglesey and at Lark Hill in Wiltshire; infantry weapons and ammunition at the small arms school at Hythe. Kent. Long-range rockets and missiles developed within the British Commonwealth are tested at the Woomera range in Australia.

(F. D. McH.)

PROVINS, a town of northern France, capital of an arrondissement of the *département* of Seine-et-Marne, at the junction of the Durtain with the Voulzie (an affluent of the Seine), 59 mi. E.S.E. of Paris by rail. Pop. (1954) 8.288. Provins began to figure in history in the 9th century. Passing from the counts of Vermandois to the counts of Champagne, it quickly became prosperous. Cloth and leather were its staple manufactures, and its fairs were attended by traders from all parts of Europe, throughout which its money had currency. Plague and famine reduced the population in the 14th century and the Hundred Years' War completed its ruin. During the religious wars it sided with the Catholic party and the League, and Henry IV obtained possession of it in 1592 only after thirteen days' siege. The town has mineral waters and a trade in roses. Provins is divided into two quarters —the ville-haute and the less ancient *ville-basse*—which in the 13th century were surrounded by fortifications. In the *ville-haute* stands the large tower known as the king's, Caesar's or the prisoner's tower. The tower serves as belfry to the church of St. Quiriace, which dates from the 12th century. The old tithe-barn is a building of the 13th century with two fine vaulted chambers, one of which is below ground. The church of St. Xyoul dates from the 12th to the 16th centuries. St. Croix belongs partly to the 13th century. There is an active trade in grain, livestock and wool, and the industries include nursery-gardening, brickmaking and the manufacture of porcelain, gas and petrol engines, agricultural implements and sugar.

PROVISION, in ecclesiastical law, signifies the conferring of an office or benefice. With King John's submission to the pope in 1213, presentations of this sort previously made by English patrons were gradually appropriated by Rome to finance the increasingly costly centralized church administration. To secure papal aid in international affairs, English kings tolerated this system, resented by commons because so many foreigners were granted English benefices by the pope, until the coincidence of the Hundred Years' War with France and the Avignon papacy led to the enactment of the Statutes of Provisors (1351) and of Praemunire (1353) which outlawed the practice. Nevertheless, despite this and subsequent legislation, papal provision continued. abetted by the king, who eventually managed to secure virtual control over the pope's nominations. Provision was finally eliminated with the death of Mary Tudor. Though papal provision was legally sound, its abuses, condemned alike by satirists and saints, provoked such mass indifference toward the church that it must be considered one of the prime causes of the collapse of Catholicism in the 16th century.

Maitland, *Roman Canon Law in the Church of England* (1898) ; J. R. H. Moorman, *Church Life in England in the Thirteenth Century* (1955). (P. A. Be.)

PROVISIONAL ORDER, in Great Britain, a direction by a government department sanctioning some project otherwise unattainable without private bill legislation. The procedure generally involves: (1) preliminary local enquiry and report by a departmental inspector; (2) departmental decision as to the framing of the order; and (3) inclusion of the order in a provisional order conformation bill introduced into parliament by the minister concerned. Such bills, if opposed, are referred to a select committee; they also go before examiners who see that the contents comply with standing orders. An early instance is the Inclosures act of 1845 whereby commissioners could provisionally order the enclosure and regulation of commons. Gradually the system was extended to the varied purposes of local government. The early enactments were later superseded and the process of devolution progressively developed.

Two railway acts in 1864 initiated the provisional certificate which embodied schemes for railway construction or working agreements, and, unless the schemes were opposed, required no express parliamentary sanction. Later a special order procedure was evolved whereby a draft of the proposed order was published and (on objection) a local enquiry was held, but a confirmatory act of parliament was not required. The National Health Insurance act of 1928 authorized a "provisional special order." Under this variant the appropriate minister, instead of waiting for criticisms of his draft orders, could bring them into force forthwith provided that he certified the expediency of such action. (C. T. C.)

PROVO, a city of Utah, U.S., the seat of Utah county, is situated 45 mi. S. of Salt Lake City between Utah lake and Wasatch peaks, at an altitude of 4,549 ft. An amalgam of weathered gray adobes and modern structures of frame or brick set amid trees and gardens, Provo has a dual modern identity as college town and steel centre.

The city takes its name from the Provo river, named for the trapper Étienne Provost (c. 1782–1850), who penetrated to Utah from New Mexico in 1824. Brigham Young sent a Mormon colonizing mission to the site in 1849 and the next year what had been Ft. Utah by legislative fiat became Provo. Incorporated in 1851, Provo was Utah's second city until the Pacific Railroad gave Ogden predominance in 1869.

Decisive in Provo's early fortunes was the founding in 1875 of Brigham Young academy, a Mormon institution which in 1903 became Brigham Young university. After 1923, steel plants were built in northern and southern suburbs; the Geneva plant, erected during World War II, became the largest integrated steel plant in the western U.S. and Utah's largest single manufacturing enterprise. The city has some other industry and is the trading centre for a rich agricultural area. It has a council-manager form of government, in effect since 1956.

The population of the Provo-Orem standard metropolitan statistical area (Utah county) in 1960 was 106,991. For comparative population figures see table in Utah: Population.

(D. L. M.)

PROVOOST, SAMUEL (1742–1815), first bishop of the Protestant Episcopal Church in New York, was born in New York city on Feb. 26, 1742. After graduating from King's college (later Columbia university) in 1758, he went to England for further study, becoming a fellow-commoner of St. Peter's college, Cambridge, in 1761. Though of Reformed background, he united with the Church of England in his college days, if not earlier. He was ordained deacon on Feb. 23, 1766, and priest on March 25, 1766. Returning to America, he was elected assistant minister of Trinity church, New York, in Dec. 1766, resigning in 1771 because of ecclesiastical and political differences with the vestry. Though strongly sympathetic to the American cause in the Revolution, he took no active part in the dispute, living in retirement on a farm in Dutchess county until the end of the war. After the British evacuated New York, the Whig party gained control of the parish of Trinity church and elected Provoost rector. He was appointed a regent of the University of the State of New York in 1784 and served as chaplain to congress in 1785. He took an active part in the organization of the Protestant Episcopal Church after the Revolution and was elected bishop of New York on June 13, 1786. With Bishop William White of Pennsylvania he was consecrated in England on Feb. 4, 1787. They were the first two Americans to be consecrated by English bishops. Provoost was elected chaplain of the U.S. senate in 1789. Ill-health compelled him to retire from all active duty in 1801. He died on Sept. 6, 1815.

(W. W. Ms.)

PROVOST, a title attached to various ecclesiastical and secular offices. In ecclesiastical usage the word *praepositus* was at first applied by the church fathers to any ecclesiastical ruler or dignitary. It early, however. gained a more specific sense as applied to the official next in dignity to the abbot of a monastery, or to the superior of a single cell. In England the title provost has thus everywhere given way to that of "dean"; in Germany, on the other hand, "*Probst*" is still the style of the heads of certain chapters. The name *praepositus* was also sometimes used for the secular *advocatus* of a monastery. With the ecclesiastical use of the title is connected its English application to the heads of colleges; "provost" is still the style of the principals of Queen's, Oriel and Worcester colleges at Oxford. of King's college at Cambridge, of Trinity college at Dublin and of Eton college.

As a secular title *praepositus* is also very old; we need only instance the *praepositus sacri cubiculi* of the late Roman empire, and the *praepositus palatii* of the Carolingian court. The important developments of the title in France are dealt with below. From France the title found its way into Scotland, where it survives in the style (provost) of the principal magistrates of the royal boroughs. and into England, where it is applied to certain officers charged with the maintenance of military discipline. A provost marshal is an officer of the army appointed when troops are on service abroad for the prompt repression of all offences. He may at any time arrest and detain for trial persons subject to military law committing offences! and may also carry into execution any punishments to be inflicted in pursuance of a court-martial (Army act, 1881, *s.* 74). A provost sergeant is an officer responsible for the maintenance of order when soldiers are in Great Britain.

The Provost in France. — The word *prévôt* (provost) in old French law had many applications. In conformity with its etymology (*praepositus*) it could be applied to any person placed at the head of a branch of the public service, a position which, according to the old principles, habitually carried with it a right of jurisdiction. It is thus that there was at Paris the provost of Paris, who was a royal judge, and the provost of the merchants (*prévôt des marchands)*, the head of the Paris municipality. There were besides — to mention only the principal provosts — the provosts of the marshals of France (*prévôts des maréchaux de France*), of whom more below; the provost of the royal palace (*prévôt de l'hôtel du roi)* or grand provost of France *(grand prévôt de France)*, and the provost general (*prévôt général*) or grand provost of the mint (*grand prévôt des monnaies*). But the most important and best known provosts, who formed part of a general and comprehensive organization, were the royal provosts (*prévôts royaux*), the lower category of the royal judges. It must be borne in mind, however, that the magistrates belonging to the inferior category of royal judges (*juges subalternes*) had different designations in many parts of France. In Normandy and Burgundy they were called *châtelains,* and elsewhere—especially in the *south — viguiers.*

Some time in the 11th century the provosts replaced the viscounts wherever the viscounty had not become a fief, and it is possible that in creating them the crown was imitating the ecclesiastical organization in which the provost figured, notably in the chapters. The royal provosts had at first a double character. In the first place they fulfilled all the functions which answered locally to the royal power. They collected all the revenues of the domain and all the taxes and dues payable to the king within the limits of their jurisdiction. Doubtless, too, they had certain military functions, being charged with the duty of calling out certain contingents for the royal service; there survived until the end of the *ancien régime* certain military provosts *prévôts d'épée* (provosts of the sword)·who were replaced in the administration of justice by a lieutenant. Finally, the provosts administered justice, though certainly their competence in this matter was restricted. Their second characteristic was that their office was farmed for a time to the highest bidder. It was simply an application of the system of farming the taxes. The provost thus received the speculative right to collect the revenues of the royal domain in the district under his jurisdiction; this was his principal concern, and his judicial functions were merely accessory. By these short appointments the Crown guaranteed itself against another danger: the possible conversion by the functionary of the function into a property. Very early,. however, certain provostships were bestowed *en garde; i.e.,* the provost had to account to the king for all he collected. The *prévôtés en ferme* were naturally a source of abuses and oppression, the former seeking to make the most of the concession he had bought. They disappeared in the 16th century, by which time the provosts became regular officials, their office being purchasable.

Other transformations had previously taken place. The creation of the royal *baillis* reduced the provosts to a subaltern rank. Each *bailli* had in his district a certain number of provosts, who became his inferiors in the official hierarchy. When appeals were instituted (and this was one of the earliest instances of their introduction) the provost, the sphere of whose competency was limited, was subject to an appeal to the *bailli,* though his judgment had hitherto been without appeal.

Moreover, in the 14th century they had ceased to collect the revenues of the royal domain, except where the *prévôté* was *en ferme,* and royal collectors (*receveurs royaux*) had been appointed for this purpose The summoning of the feudal contingents. the *ban* and *arrière-ban*, had passed into the hands of the *baillis*. Thus the provosts were left for their sole function as inferior judges for non-nobles.

The "provosts of the marshals of France," mentioned above, were non-legal officials (*officiers de la robe courte)* forming part of the body of the *maréchaussée* which was under the *ancien régime* what the *gendarmerie* was after the Revolution. Their original function was to judge offences committed by persons following the army, but in the course of the 14th and 15th centuries they acquired the right of judging certain crimes and misdemeanours, by whomsoever committed. They became stationary, with fixed spheres of authority, and the oifences falling within their competency came to be called *cas prévôtaux.* These were the worst crimes of violence, and all crimes and misdemeanours committed by old offenders (*repris de justice)*, who were familiarly known as the *gibier des prévôts des maréchaux* (gaol-birds).

(J. P. E.)

PROXY (short for "procuracy"), a term denoting either (1) a person who is authorized to stand in place of another; (2) the legal instrument by which the authority is conferred. Proxies are now principally employed for certain voting purposes. A proxy may in law be either general or special. A general proxy authorizes the person to whom it is entrusted to exercise a general discretion throughout the matter in hand, while a special proxy limits the authority to some special proposal or resolution. Formerly a peer could give his vote in the British parliament by proxy, by getting another peer to vote for him in his absence, temporal peers only voting for temporal and spiritual peers for spiritual. However, on March 31, 1868, on the recommendation of a committee, a new standing order was adopted by which the practice of calling for proxies on a division was discontinued. In English and American bankruptcy proceedings creditors may vote by proxy, and every instrument of proxy, which may be either general or special, is issued either by the official receiver or trustee. Under the English Bankruptcy Act of 1914 and the American Bankruptcy Act of 1898 a creditor may still vote by proxy in the manner prescribed. A shareholder in a limited liability company may vote by proxy, and regulations to that effect prescribing the requirements are usually embodied in the articles of association. In England a proxy to vote at a meeting must bear a revenue stamp.

PRUDENTIUS, AURELIUS CLEMENS (348–*c.* 410), the most remarkable of the earlier Christian poets in the West, was probably born at Tarraco. The meagre autobiographical preface, which he affixed to the complete edition of his works when he was fifty-seven years old, makes it clear that he received a liberal education — being of noble family — practised as a lawyer and entered official life, and finally held some high office under Theodosius. At the age of fifty-seven he retired to a monastery, but died shortly afterwards.

Bentley calls Prudentius "the Horace and Virgil of the Christians," but his diction is stilted and his metre often faulty. The list of his works given in the preface mentions the hymns, poems against the Priscillianists and against Symmachus and *Peristephanon.* The *Diptychon* or *Dittochaeon* is not mentioned. The twelve hymns of the *Cathemerinon liber* ("Daily Round") consist of six for daily use, five for festivals, and one intended for every hour of the day. Prudentius shows Ambrose as his master here, but gives to Ambrose's mystic symbolism much clearer expression. The *Apotheosis* and *Hamartigenia* are polemic, the first against the disclaimers of the divinity of Christ. the latter against the gnostic dualism of Marcion and his followers. In them Tertullian is the source of inspiration. Of more historical interest are the two books *Contra Symmachum,* of 658 and 1.131 hexameter verses respectively, the first attacking the pagan gods, the second directed against the petition of Symmachus to the emperor for the restoration of the statue of Victory which Gratian had cast down.

The *Peristephanon* consists of fourteen hymns to martyrs. These were mostly Spanish, but some were suggested to Prudentius by sacred images in churches or by the inscriptions of Damasus. This book, with the *Cathemerinon liber* and the *Psychomachia,* mas among the most widely read books of the middle ages. Its influence on the iconography of mediaeval art was great. The *Psychornachia* is aesthetically inferior, but had the greatest influence of all of Prudentius's writings. In it he depicts the struggle of Christendom with paganism under the allegory of a struggle between the Christian virtues and the pagan vices. The *Dittochaeon* is a series of quatrains, probably intended to explain forty-nine pictures of a basilica. The work is more interesting for archaeology than for literature.

PRUD'HON, PIERRE PAUL (PIERRE PRUDON) (1758–1823), French painter, born at Cluny on April 4, 1758, was the 13th child of a mason. By the aid of the bishop of Mâcon he was placed with Devosge, director of the art school at Dijon. In 1778 Prud'hon went to Paris armed with a letter to Willie, the celebrated engraver, and three years later he obtained the triennial prize of the states of Burgundy, which enabled him to go to Rome, where he became intimate with Canova. He studied the work of Correggio and the affinity of his style with that of the great Italian gave him the title of the French Correggio. He returned to Paris in 187. The illustrations which he executed for the *Daphnis and Chloe* published by Didot brought him into notice, and his reputation was extended by the success of his decorations in the Hôtel de Landry (now Rothschild), his ceiling painting of "Truth and Wisdom" for Versailles (Louvre), and of "Diana and Jupiter" for the Gallery of Antiquities in the Louvre. In 1808 he exhibited "Crime Pursued by Vengeance and Justice" (Louvre), which had been commissioned for the assize courts, and "Psyche Carried off by Zephyrs." These two compositions brought Prud'hon the Legion of Honour; and in 1816 he entered the Institute. Consoled for the misery of his marriage by the devoted care of his pupil, Mlle. Mayer, Prud'hon's situation seemed enviable; but Mlle. Mayer's tragic suicide in 1821 brought ruin to his home, and Prud'hon died two years later on Feb. 16, 1823.

PRUSSIA, a former German kingdom, became the largest and most important *Land* of the Third German Reich. It included the whole of Germany north of Saxony, Thuringia, Bavaria and Hesse, except Mecklenburg and Oldenburg, and some small enclaves, such as Brunswick. In 1938 the *Land* of Prussia comprised the provinces of East Prussia, Berlin, Brandenburg, Pomerania, Grenzmark, Silesia, province of Saxony, Schleswig-Holstein, Hanover, Westphalia, Hesse-Nassau, Rhine province and Hohenzollern. In 1945 East Prussia passed in part to the U.S.S.R. and the remainder to Poland. Poland also absorbed all Prussian territory as far as the Oder-Neisse line, expelling the German population and replacing it by Poles. The main part of the rest of Prussia was subdivided into the new *Lander* of Brandenburg and Saxony-Anhalt in eastern Germany, and Schleswig-Holstein, Lower Saxony and North Rhine-Westphalia in western Germany. Berlin was divided between the two republics. Lesser areas of Prussia were included in the *Länder* of Mecklenburg in eastern Germany, and of the Rhineland-Palatinate, Hesse and Baden-Württemberg in western Germany. Though the boundaries of the new *Lander* usually followed the former political pattern, some regard was also paid to their economic character. Prussia was formally liquidated by a law of the Allied Control council on Feb. 25. 1947.

Physical Features. — The greater part of Prussia belongs to the Great European plain, though its surface is more varied than that bare statement suggests. The plain is narrowest in the west, being only 75 mi. wide between the Weser uplands and the North sea. It includes three divisions, markedly different in character: (1) west of the lower Elbe, a region of reclaimed *Marschen* along the coast, of *Moor* or ill-drained peat bogland behind it, and of dry, sandy *Geest* lands further inland; (2) east of the Elbe, with the low Baltic heights next the coast and the belt of *Urstromtaler,* wide marshy valleys, to the south; (3) the fertile *Borde* strip along the edge of the uplands and with wide "bays" (Cologne, Miinster, Leipzig and Silesia) reaching south into the mountainous country. In the southwest, most of the Rhine plateau country, the Harz and Weser uplands and part of the Triassic hill country (with the volcanic Vogelsberg and Rhon) fall within the Prussian area. The borderlands between Silesia and Czechoslovakia are also mountainous. The lowland courses of all the north German rivers are thus within the Prussian frontiers.

Prussia contains a large proportion of woodland, the most extensive forests being in East Prussia, Silesia and Brandenburg where conifers prevail. In the Rhenish and Hessian lands oaks and beeches are most prominent. The northwestern lowlands had few trees but in recent years large plantings of conifers have been made on the drier sandy lands.

Climate. — The climate of Prussia is transitional between the rainy and changeable type of western Europe and the more stable but more extreme type of eastern Europe. Rainfall decreases from west to east but temperature ranges increase, mainly because winters are colder.

Area and Population. — In 1939 Prussia had a total area of 113,410 sq.mi. and, according to the census of 1939, a population of 41,467,089. The six new *Lander,* with a total area of 55,814 sq.mi., had in 1939 a population of 28,269,000, increased to 30,766,000 by 1946. World War II and the postwar years saw considerable movements of population throughout the Prussian area. The North Rhine-Westphalian districts continued to have the densest populations (1,007 per sq.mi. in 1950) but the largest increases were in the eastern sections of west Germany. During the war there was a tendency to place new industrial establishments there rather than in the Rhine districts, where they were more accessible to Allied bombing. The *Auslands-deutsche* recalled between 1939 and 1944 were mainly settled in the eastern portions of Prussia. The still larger migration of about 9,000,000 people expelled from Poland and Czechoslovakia added to this westward movement. After the war the movement was continued by the refugees passing from east to west Germany. Large population increases, especially in rural districts, have been caused in this way, notably in Schleswig-Holstein and Lower Saxony.

Agriculture. — Except in Westphalia and the northern Rhinelands, and along a narrow belt from Münster to Silesia, where there was a slight predominance of industry, agriculture was everywhere the main occupation of the people of Prussia. The chief arable areas were along the Baltic coast and on the loess soils of the *Borde.* In Brandenburg and Lusatia arable land was mixed with woodland, on the geest with sandy waste. The reclaimed marshlands were either under the plow or meadow. Grasslands dominated the area from Schleswig-Holstein to the lower Rhine. Rye was the main grain crop everywhere (about 75% of the grain-growing area), especially prominent between the lower Ems and the Weser, and in Brandenburg and Posen. Wheat and winter barley were restricted to the better soil areas of the *Borde*, the drained marsh soils of the Eibe and Vistula, and the Lower Rhine. Oats became an important crop on the northwest lowlands, especially near the sea. The potato was widely grown, with heavy production east of Berlin and the middle Elbe. On the Rhenish plateau it took the place of grain as the main food crop. In later years sugar beet had become of very great importance as a crop on the *Borde* in Hanover and Saxony! and west of Cologne. In normal years there were surpluses of rye, oats and sugar.

The production of livestock did not meet the demand before World War II, nor was there a sufficiency of dairy produce. Cattle were most numerous in Schleswig-Holstein, and pigs were raised and fattened in great numbers, particularly on the lowland between Hamburg and the Ruhr. The numbers of sheep showed a long-continued decrease. Stall feeding of cattle was general except on the North sea *Märschen* where all-year outdoor grazing of dairy cattle was possible. Forage crops were widely grown and there was considerable import of animal foodstuffs,though the spread of sugar beet, with the use of the tops and the pulp from the scgar factories, had lessened the need for this. The value of animal products far exceeded that of crops.

Most of the land east of the Elbe and in Silesia was in large holdings of more than 250 ac., that in the western lowlands and the Rhine lands in holdings of 12 to 50 ac. The farms of the *Borde* were of intermediate size. During the nazi period steps were taken to divide some of the larger holdings and to consolidate the smallest. Under Soviet direction all holdings of more than 250 ac. were to be eliminated and subdivided into farms of 20 ac. About half the farms in the eastern zone were of this size by 1952.

Before World War II western Germany imported about 40% of its food and the east German area lacked some foods (*e.g.* meat, formerly secured from Schleswig-Holstein, and supplementary grain from Silesia). The lands taken over after the war by the U.S.S.R. and Poland formerly provided nearly a quarter of Germany's agricultural production. Since the population of the German Federal and Democratic republics is roughly equivalent to the prewar population of the whole Reich the loss of these Prussian areas created a serious problem.

The principal wine-growing districts of Prussia are the Rheingau and the Rhine province. The vineyards are terraced on the stony, southward-facing slopes of the Rhine and its tributaries, especially the Saar and the Moselle. The harvest is so uncertain that the industry can be maintained only by concentration on high-grade wines.

Mining and Power Production. — Prussia was far the largest producer of minerals in the Reich. Seventy per cent of German coal (127,000,000 tons in 1938) was mined in the Ruhr and a further 13% (26,000,000 tons) in Silesia. The high-grade coking coals of the Ruhr were of special importance in the metal industries. The Silesian field came entirely into Polish hands after World War II. The utilization of the Prussian lignite (brown coal) deposits was greatly extended after 1919, the output increasing to more than 250,000,000 tons in 1943. Two-thirds of this came from Brandenburg and the area between Magdeburg and Leipzig, the one-third from the Ville field west of Cologne. Oil is found near Hanover but the output of the wells is far exceeded by the synthetic production from coal and lignite. Most of the home-produced iron ore, only a small fraction of that consumed, was mined in the Hanover area and the Siegerland. Small quantities of ores of copper and of lead and zinc are still obtained from the Harz. Before it lost the Silesian mines in 1919 Germany ranked first in Europe as a zinc producer. The Stassfurt deposits are still an important source of salt, of potash for the chemical industry and of magnesium for the making of aluminum alloys. Before World War II Germany had a larger production of electricity than any other country in Europe, nearly all from thermal stations on or near the lignite (40%) and coal (36%) fields.

Industry. — Of the 14,500,000 people employed in German industry in 1939 about 9,000,000 were in Prussian factories and workshops. The main concentratioris were on the Ruhr coal field and along the Rhine front within easy reach of it, on the lignite field of the middle Elbe, and in Berlin and the North sea ports. The iron and steel industry was located on the Ruhr field because of its coke supplies. From its first development until 1919 it used principally the Lorraine ores but since that date has depended on imported (mainly Swedish) ores. Heavy engineering was closely situated around the steelworks but fabrication and light engineering were more widely dispersed; *e.g.*, shipbuilding at Bremen and Hamburg, railway material at Essen and Berlin, motor cars at Frankfurt. The largest manufacturers of electrical machinery had their works in Berlin. The heavy chemical industry, using coal, lignite and potash as basic materials, naturally developed on the Ruhr and the middle Elbe. Finer chemicals were manufactured around Frankfurt. The chief area for textiles was the Wuppertal, south of the Ruhr.

The dismantling of industrial plants and the breakup of the large cartels were prominent features of Allied policy immediately after World War II. The resulting widespread unemployment soon led to a reversal of the former and the latter was applied less drastically than was originally planned. In the German Federal Republic the production of electricity was in 1953 about double the prewar level, lignite exceeded the prewar level, and coal and textiles had reached it. Steel production was still limited to about two-thirds of the old level. In the German Democratic Republic where dismantling was carried much further and a large part of the remaining products were taken by the U.S.S.R. as reparations, output was still low though increasing as earlier restrictions were withdrawn.

Communications. — Prussia was excellently provided with internal means of communication. Its railway network included about 17,000 mi. of track. The main trunk route was from west to east, through Aachen, Cologne, Diisseldorf, Hanover, Berlin, Danzig and Konigsberg. Important lines followed the Rhine in the west and radiated from Berlin to link the North sea and Baltic ports with southern Europe. In the years immediately before World War II they were supplemented by the through motor roads (*Autobahnen*). All the rivers are navigable across the plain and these were connected by an extensive canal system. The great Mittelland canal, opened in 1938, joined the Elbe with the Rhine, and the Dortmund-Ems system served the Ruhr area, while the Kiel ship canal gave a short route from Hamburg to the Baltic sea. The division of western and eastern Germany gravely disrupted the whole transport system, cutting off Hamburg from most of its hinterland and Berlin from its North sea ports.

HISTORY

The state of Prussia, which has played so great a part in the history of Germany, came into being gradually, being formed out of wholly dissimilar components. The chief of these mere the mark of Brandenburg and the state of the Teutonic Order in Prussia (*i.e.*, the country originally inhabited by Prussians, Prusi or Borussi. a Baltic people speaking a language akin to Lithuanian and Latvian). The history of each of these, up to their union, must be treated separately.

The Teutonic Order. — In 1226 the Polish duke Conrad of Mazovia invited the Teutonic knights into his territory to combat the heathen Prussians. After a difficult struggle, the order conquered the territory, exterminated most of the native population, and invited German peasants and townspeople into the country as settlers. In the 14th century the state ruled by the knights was a power in northeastern Germany. In 1308 it conquered Polish Pommerellia and for a time the Neumark also, and through its connection nith the Order of the Sword. of Livonia, extended its influence as far as Estonia. A string of flourishing cities sprang up along its coast. In Marienburg, since 1309 the seat of the

grand master of the order, the splendid castle was built which to this day testifies to the past glories of the order and formed the centre of its admirably organized administrative system. But even in the 14th century the order was beginning to decline owing mainly to the fact that once the struggle against the heathen was ended. it lost its original spiritual character. occupied itself only with purely mundane tasks, and thus lost touch with its original purpose. The rule of the knights. who admitted none of the local nobility into their ranks, came to be felt by the inhabitants as a foreign rule. When Poland and Lithuania united into a powerful state at the end of the 14th century, and the rulers of this state began to plan the recovery of the Baltic coast, the order could not rely fully either on the nobles or on the towns in its territory. After the defeat of their army at the battle of Tannenberg (1410) the knights were forced to cede part of their territory to Poland. In a second war the Poles took Marienburg, and at the peace of Thorn (1466) forced the order to cede them West Prussia and Ermeland, with Danzig and Thorn, and to acknowledge the suzerainty of the Polish king for the rest of their territory. At the beginning of the 16th century, the Reformation began to penetrate these regions also, and the grand master of the day, Albert of Brandenburg, a grandson of the elector Albert Achilles, proceeded, with the consent of the king of Poland. to take the decisive step which was tantamount to the end of the order's rule He went over to Protestantism, at the same time proclaiming himself hereditary duke of Prussia (152j). As his only son, Albert Frederick (1568–1618), was an imbecile, the power passed almost wholly to the estates. Albert Frederick's eldest daughter, Anna, married the elector John Sigismund, and through her Prussia passed in 1618 to the electors of Brandenburg. As Anna was also coheiress through her mother of the great territories which had been united under the rule of the dukes of Jiilich, Cleve and Berg on the lower Rhine, and as this ducal house had become extinct a few years previously (1609), the electors of Brandenburg could hope to acquire not only Prussia, but also considerable domains in west Germany. (See BRANDENBURG.)

Frederick William I.—Frederick William I (1713–40), the son and successor of Frederick I, has long been unjustly represented as a crude tyrant. He mas a sober-minded man, without any strong intellectual interests, but a first-class organizer and imbued with a stern sense of duty, based on religious sentiment. and he devoted his whole soul to the service of the state. He resumed the work begun by his grandfather, the Great Elector, and is the true father of the Prussian administrative system and Prussian officialdom He created a new central administrative service in the shape of the general directory, for which he drew up the instructions himself (1723). This organ acted as a general ministry, in which the agenda was distributed to the several members, partly by subject, partly on local lines. while all important measures were decided in general conference. The king reserved to himself the final decision. Each official received a commission stating his duties, emoluments and exact official regulations. All official bodies had to keep a record of, and send in a weekly report on, their activities. In most cases officials were nominated by the king at his discretion; only in the selection of the Landrate, who were in charge of the provincial districts (Krezse) the nobles still had a certain voice. Officials and magistrates were obliged to pass through a definite course of training, and could not be appointed unless they had passed the prescribed examination. The king organized a regular procedure of judicial appeal, making the *Kammergericht* in Berlin the supreme judiciary instance for the whole state. Judicial procedure was also simplified and improved in important respects. In the financial administration he introduced the strictest economy. He succeeded in increasing the revenue from the royal domains and prerogatives and from the indirect taxes to a considerable degree. and in achieving an annual surplus. This he put into a state exchequer, which contained 7,000,000 thaler at his death. He made special efforts to encourage trade and industry, following the principles of the mercantile system (*q.v.*), which at that time were everywhere accepted. As the country was thinly populated, he encouraged the immigration of efficient labour. Just as his grandfather had admitted a large number of the Huguenots expelled from France after the repeal of the Edict of Nantes by Louis XIV. so Frederick William allowed the Protestants expelled by the archbishop of Salzburg to enter his kingdom, settling most of them in East Prussia. Foremost a soldier, the king devoted particular attention to the training of the standing army, the numbers of which he raised from 40,000 to 80,000. It was still a mercenary army, recruited from volunteers at home and abroad. He took pains, however, to ensure that as high a proportion as possible should be composed of his own subjects and divided the whole Prussian territory into recruiting districts. the so-called "cantons"; each district was obliged to supply the men for one specified regiment. The recruiting was often done in a very arbitrary fashion, which gave rise to many complaints. Definite instructions were draan up and regular inspections carried through to ensure uniformity of training; the army thus created was superior to those of most other states. It was Frederick William who first gave Prussia the characteristic stamp of a military and bureaucratic state.

For all his military inclinations, Frederick William was a peaceable man by nature, and in his foreign policy always avoided military entanglements. When he came to the throne. Prussia was embroiled in the Northern War; at the conclusion of peace he succeeded in securing Western (Hither) Pomerania up to the Peene, which had formerly been in the hands of Sweden, with the important commercia! town of Stettin. He failed, hen-ever, to secure support for his claims, which were based on old succession treaties, to further portions of the Cleve-Julich heritage and to parts of Silesia. As a loyal German, he thought it his duty to maintain as good relations as possible with the emperor; but encountered profound mistrust in Vienna, where the growing strength of the Prussian state was watched with concern. and toward the end of his life was forced into an increasingly sharp opposition to the house of Habsburg.

Frederick the Great.—Frederick William died in 1740. He was succeeded by his son, Frederick the Great (1740–86), who was at that time 28 years of age. He had had violent conflicts with his father in his younger days, as his passionate and freedom-loving nature revolted against the severe discipline which his father thought necessary. Furthermore, the younger man's inclinations led him toward the new ideas of the Aufklarung, while the old king was a strict Calvinist. The crown prince's attempted flight (1730) brought this conflict to a head. The king had his son imprisoned. and even had an idea of excluding him from the succession; Frederick was only able to buy a reconciliation at the price of complete submission to his father's will. He was obliged to pass through a strict training in the administrative service and the army, a training which did much to prepare him for his later career.

For Frederick's conflicts with Maria Theresa in the first half of his reign, see AUSTRIA, EMPIRE OF; AUSTRIAN SUCCESSION. WAR OF; GERMANY; SILESIA. They ended in the acquisition of Silesia, with the exception of a few small districts south of the Riesengebirge. which remained in the hands of Austria. Frederick's successful resistance in the Seven Years' War against Austria, France and Russia raised his prestige enormously. From this time onward his state was recognized as a European great power. In addition to Silesia, he had also acquired East Frisia which came to him in 1744 on the extinction of the old princely house, through a succession treaty. At the first partition of Poland (1772) he also acquired West Prussia (except Danzig and Thorn), a particularly important district because it bridged the gap between East Prussia and the Brandenburg family dominions. Frederick carried on the internal development cf the Prussian state on the lines laid down by his father. He instituted a general civil code for his state in the shape of the Prussian Landrecht—a work not completed until after his death; accelerated judicial procedure, abolished torture, and introduced the principle that the crown should not interfere with the course of justice. In administrative matters, he sought to pay special consideration to the local peculiarities of the different provinces, and made frequent journeys of inspection to satisfy himself that his orders mere being carried out. The fiscal system was further developed; but an attempt to introduce the farming of taxes, on the French model (1766), proved unsuccessful and had to be abandoned. Under his rule the state revenue increased largely; on his death he left 55,000,000 thaler in the state exchequer. He had the low-lying country of the Oder and the Warthe drained, settled villages of colonists in the Pomeranian forests, arranged for the plantation of hops and potatoes, and founded factories. He left several detailed exposés of his administrative and political principles, notably in his political testaments of 1752 and 1767, which were designed to serve as a guide to his successor. Like his father, he considered himself the first servant of the state, and said that the prince should govern as though he had to render account to his subjects for all his measures. It did not, however, occur to him to do so. He rarely consulted with his ministers in person; he called for reports from them in writing, and dictated the answers, which he sent to them in writing. His liberal views in matters of religion led him to adopt the policy of toleration, on principle, toward the different churches: a policy which was also naturally dictated by practical considerations in a state which included a Protestant majority and a Catholic minority. His lively interest in all intellectual questions led him to take measures to improve the level of public education. In the upper schools the classics were made the principal subject of instruction. The king wished to establish compulsory primary education for all children from 5 to 13, but lack of means made it impossible to carry this out. Although Frederick was deeply influenced by the humanitarian ideas of the *Aufklärung,* and considered the furtherance of the people's welfare and of popular education to be among the monarch's essential duties, yet his guiding thought remained always to raise the forces of his comparatively small, weak state, by better organization, so as to maintain the position of power which he had won.

Collapse and **Reform.**—As Frederick left no issue from his marriage, contracted at his father's orders, with a princess of Brunswick, and as his younger brother, Augustus William, had predeceased him, the latter's son, Frederick William II, succeeded him on the throne (1786–97). He was indolent and dissipated, squandered the state exchequer and left the cares of government to his favourites. Under his reign no progress was made in the domestic organization of the state. In foreign affairs his participation in the war against revolutionary France brought him only losses, while the large accessions of territory that the second and third partitions of Poland (1793 and 1795) brought him were gains of but doubtful value. For the Prussian state! which after 1795 extended as far as Warsaw, thus received so large a percentage of Polish blood that had these frontiers proved permanent, its German character would have been endangered.

His son, Frederick William III (1797–1840), was a man of the best intentions, but pedantic, vacillating and narrow. The government fell more and more into the hands of the cabinet councillors who, under the system introduced by Frederick the Great, formed the sole channel of communication between the king and the ministers. But while under Frederick the councillors had been only executive organs of the king's will, under his weak successors they became the all-important personal advisers of the monarch. The Prussian state still kept the outward form given it by Frederick William I and Frederick the Great; but the living spirit was gone from it, and its swift and complete collapse after the first great military reverse (Jena, 1806), is easily comprehensible. Under the peace of Tilsit (1807) Frederick William was obliged to cede his entire territory west of the Elbe and the greater part of his acquisitions in Poland; he retained only Brandenburg, Pomerania, Prussia and Silesia. This fearful collapse, however, also released the forces of reconstruction which still lived on within the state, and during the so-called "period of reform" a complete reconstruction of the state was begun. The king himself always remained disassociated from, and at heart hostile to, these efforts, which appeared to him as a concession to Jacobinism; but as he knew no plan of his own for reconstructing the shattered state! he was forced to let the apostles of the new ideas have their way.

Heinrich, baron vom und zum Stein became the leading figure in the administration. He had long been urging reforms, but before 1806 without success. His fundamental idea was that in a modern state the people itself must be required to help in the conduct of public affairs because the state cannot exist unless it can count upon the willing co-operation and devotion of its citizens. The most important measures which he carried through mere the liberation of the peasants from serfdom, the reintroduction of municipal self-government under the Municipal act of 1808, and the abolition of cabinet government. He also planned to introduce self-government in the rural districts and participation of representatives of the people in the provincial administration and the central government. He was unable, however, to carry these measures into practice, being dismissed in the autumn of 1808 at Napoleon's order. The reforms were taken up again by Karl, prince von Hardenberg, in 1810, on his appointment as head of the ministry, although on lines rather different from those intended by Stein. Hardenberg really inclined more to enlightened despotism than to Stein's idea of self-government. His principal achievements were the reorganization of the finance and of the administrative system, the abolition of restrictions in industrial life, and the edict of 1811 which made the peasants free proprietors of their holdings, in return for the cession of a part of them to the former landlords. The peasants were thus required to buy their ownership at the price of giving up part of their holdings. Moreover, as the smaller holdings were excluded from the measure, the landlords could now take full possession of them, and their former cultivators sank to the position of agricultural labourers without property.

These years also saw a great reorganization of the army, carried through by Generals Gerhard von Scharnhorst and Hermann von Boyen. The underlying principle was the transformation of the mercenary army into a national army. Universal service was introduced, degrading punishments abolished, admission to the corps of officers revised and the internal organization of the army rearranged in more practical form. But for these reforms in all directions, the little state would have been incapable of the great achievements which it performed during the War of Liberation.

The Congress of Vienna. — After Napoleon's defeat in Russia, the Prussian General Hans Yorck von Wartenburg took his forces over to the Russian side and Frederick William III reluctantly followed his lead. The Prussian army played a principal part in the overthrow of Napoleon and Prussia re-emerged as a great power. At the Congress of Vienna, Prussia did not recover its Polish lands lost in 1807, which now went to Russia. In compensation it received Western Pomerania, the northern half of the kingdom of Saxony, Westphalia and the Rhineland. Its population was increased from under 6,000,000 to 10,000,000. Prussia ceased to be a northeastern German state and straddled across Germany. For the first time also it counted a large number of Roman Catholics amongst its people.

In the excitement of liberation the king had promised a constitution; after 1815 the promise was ignored. All that remained of it was the assurance that the state would not raise any new loan without the consent of an elected body. Meetings of the estates mere introduced for the individual provinces, but they were given only an advisory voice in local affairs. Prussia continued to be run by the old nobility and bureaucracy, who were increasingly out of touch with the liberal sentiment of the western provinces. The only striking advance in the reign of Frederick William III was the creation of the *Zollverein* (virtually complete by 1834) which brought all the German states except Austria under Prussian economic leadership.

The 1848 Revolution. — On the death of Frederick William III, his eldest son Frederick William IV (1840–61) ascended the throne. He had grown up in an age when the theories of romanticism had dominated Germany; these theories swayed him, and, like his father, he was averse at heart to the modern political demands. After long consideration, however, he determined in 1847 to convoke the members of all provincial diets to a united diet at Berlin. This body, however, immediately put forward a demand to be convoked at regular intervals, and to be recognized as a partner, with equal rights, in the legislation. The king refused to admit such claims, and the dellberations led to no practical result. Nevertheless, it was an event of no small importance that representatives of all parts of the Prussian state had, for the first time, met for common parliamentary debates.

Soon after this. revolution broke out all over Germany. Although the military remained the victors in the street fighting of March 18 in Berlin, the king nevertheless decided to give way and withdraw the troops from Berlin. He agreed to the convocation of a constituent national assembly. which was to meet in Berlin and collaborate with him in drawing up a constitution. But as democratic elements gained the upper hand in this assembly, the king dissolved it and enacted a constitution (Dec. 5, 1848), with the proviso that a freshly elected parliament should negotiate further on its final form. These negotiations proving very protracted, the parliament was again dissolved in the spring of 1849, and it was only when a chamber was elected on the three-class franchise that agreement was at last reached on a definitive constitution, to which the king took the oath on Feb. 4. 1850. Prussia now received a parliament. consisting of two chambers; the first chamber. called the *Herrenhaus* after 1854, was composed of representatives of the large landed proprietors and of the larger towns, and of members nominated by the king. either for life. or as hereditary members. The second chamber was elected by all taxpaying citizens, but as the electors were divided into three categories, according to taxes paid, electors with larger incomes were given much greater influence than the poorer classes. Yet, despite the limited franchise, this was a genuine constitution. The chambers had defined rights and were entitled to meet regularly. The budget was to be agreed annually between the chambers and the crown—a phrase which seemed to imply, though it did not, a large measure of parliamentary sovereignty. Inadequate as the constitution appears by democratic standards, without it there would have been later no constitutional conflict at all.

During the revolution of 1848 Frederick William IV hoped to lead the movement for unification. He said in a famous phrase: "Prussia is merged in Germany." His conservative principles soon reasserted themselves. On April 3. 1849. he refused the imperial crown, when it was offered to him by the Frankfurt national assembly; he would only accept it. he said, from the German princes. He and his friend Joseph Maria von Radowitz attempted to build a lesser German union, on conservative lines. known as the Erfurt union. In 1850 this was challenged by Austria; and as Frederick William shrank from war, Prussia was obliged to abandon its ambitions by the agreement of Olmiitz or Olomouc (Nov. 2, 1850).

William I and William II.—A period of reaction followed in Prussia. Frederick William IV appointed an extremely reactionary government. which remained in power until he became insane in 1857. His brother, William, prince of Prussia, acted as regent until his death (Jan. 2, 1861) and then ascended the throne as William I. The new ruler took at first a more liberal line than his brother. In 1858 he appointed a liberal ministry under Prince Hohenzollern, and for nearly four years Prussia experienced "the new era." William and his minister of war. Albrecht, count ron Roon, disagreed. however, with the chamber over the reorganization of the army. Roon wished to increase the army establishment, which had remained stationary since 1815, so that every Prussian should perform his military service. The lomer chamber were ready to agree with this, but insisted in return that the period of service be reduced to two years and that the *Landwehr*, or reserve, should play a more independent part. The struggle which followed was a conflict over the character of the Prussian army, not its size. By the constitution, the taxes were imposed permanently. The chamber could not cut off supplies. It could only refuse to authorize the expenditure of money already collected. In 1861 they authorized the additional expenditure for a single year. In 1862, as their demands were still refused. they refused authorization altogether. William first thought of abdicating. At the last minute Roon persuaded him to appoint Otto von Bismarck minister president (Sept. 23, 1862).

As the lower chamber refused to accept the budget which the king and the upper chamber had put forward, Bismarck argued that there was "a hole in the constitution"; and he governed without a budget for the next few years. The liberals were helpless. It would have been unconstitutional to refuse the taxes. They could only protest and wait for Bismarck to fail in his foreign policy. Instead he succeeded, and his defeat of Austria in 1866 led many liberals over to his side. He in turn was willing to confess the illegality of his actions. He asked for and received an Act of Indemnity (Sept. 1866).

Campaigns of 1864–71 which led to union of Germany under Prussia's leadership cannot be told here. (*See* SCHLESWIG-HOLSTEIN QUESTION; GERMANY; AUSTRIA, EMPIRE OF; FRANCO-GERMAN WAR.) The acquisition of Hanover, Kurhesse, Nassau and Frankfurt-am-Main after the war of 1866, gave Prussian territory a wholly new aspect. Its eastern and western halves, which up to this date had been separated by these districts, mere now linked up into a single great north German state, containing nearly two-thirds of the total population of Germany (in 1914, 40,000,000 out of a total population of 67,800,000).

With the unification of Germany in 1871 the king of Prussia became German emperor, in supreme command of all German armed fo ces. The Prussian army was, in fact, the main instrument by mhich Prussian power mas extended throughout Germany. Bismarck also combined Prussia and Germany in his own person. He mas both political head oi the empire as *Reichskanzlrr* and Prussian minister president. Roon was Prussian minister president for a short period in 1872–73; hut when he fell ill Bismarck resumed the office and kept it until 1890. His successor Georg Leo von Caprivi gave up the position of Prussian minister president; but this led to a conflict of policy between the two offices and ultimately to his resignation. The two posts were then reunited until the end of the empire in 1918.

The alliance concluded by Bismarck with the liberals at the time of the foundation of the empire had important effects. The Local Government act of 1872 increased the autonomy of the rural districts, thus linking up with the traditions of the age of Freiherr von Stein. The so-called *Kulturkanzpf—the* struggle against the Roman Catholic Church which was waged in the '70s—was also in accord with liberal ideas. It ended, however, finally, with the state restoring to the church its control over the preliminary training of the clergy, and retaining only a right of veto over appointments to ecclesiastical posts.

During the short reign of Frederick III (March–June 1888) and under William II, the situation remained in essence unchanged. The new Rural Districts act (*Landgemeindeordnung*) of 1892 carried existing institutions a step further. The fiscal reform carried through about the same time by J. von Miquel made self-assessment the basis of taxation, and provided relief for the poorer classes and heavier contributions from large incomes,

Reiorm of the franchise was often discussed, to give Prussia the same universal suffrage as the reich; but these proposals never came to anything, and the three-class franchise survived until the revolution of 1918.

Republic of **Prussia.**—The revolution ended the Prussian monarchy. It also severed the connection between the Prussian prime minister and the imperial chancellor. Prussia became a *Land* of the Weimar republic, with the same universal suffrage. Since Prussia was the most industrialized part oi Germany, its parliament had always a left-wing majority. Prussia was ruled between 1918 and 1932 by the Social Democrats, sometimes alone. sometimes in coalition with the Centre. The most outstanding personality was Otto Braun, the prime minister. Since the *Land* controlled the police, the Social Democratic government of Prussia was the essential defense of German democracy.

In 1932 the coalition of Centre and Social Democrats lost their majority. Franz von Papen, then chancellor, used this excuse to overthrow Prussian democracy. He was nominated imperial commissioner ior Prussia by Pres. Paul von Hindenburg and expelled the democratic government. This made easier Hitler's accession to power on Jan. 20, 1933. Soon afterward Hermann Goring took Papen's place as ruler of Prussia. The Prussian constitution was set aside by the National Socialists, its legislature was abolished but it still led a nominal existence as a component part of the reich. (*See* also BRANDENBURG; GERMANY.)

(E. BRA.; A. J. P. T.)

PRUSSIA, in the original sense, a territory of Germany, stretching along the Baltic coast for about 220 mi. and occupying an area of 24,083 sq.mi. The eastern part formed the duchy of Prussia, conquered and colonized by the Teutonic Order and acquired by the elector of Brandenburg in 1618, furnishing his successor with his regal title in 1701. The western part, severed from the eastern half and assigned to Poland in 1466, was not annexed to Prussia until the partition of Poland in 1772, while Danzig and Thorn remained Polish down to 1793. The two districts were temporarily (1824–78) united to form a single province.

PRUSSIC ACID, also known as hydrocyanic acid or hydrogen cyanide, is a highly volatile, colourless liquid of extremely poisonous character. It was discovered in 1782 by K. W. Scheele, who obtained the compound from prussian blue. Prussic acid (HCN) and its compounds are used for many chemical processes, including the manufacture of pigments and dyes; the casehardening of iron and steel; electroplating; and fumigation. The acid is employed in the preparation of acrylonitrile, which is used in the production of acrylic fibres, synthetic rubber and plastics. In some states of the U.S. the legal method of inflicting capital punishment is by dropping pellets of cyanide into sulfuric acid, thus releasing the highly toxic prussic-acid gas, which causes death when inhaled. In variable but generally small proportions it is widely distributed among plants in the form of glycosides; *i.e.,* in combination with sugars. Amygdalin, which is present in bitter almonds, is an example of such glycosides; it yields prussic acid upon hydrolysis. Cyanides are the salts of prussic acid.

Preparation.— A convenient method of obtaining prussic acid in the laboratory is to add a cold mixture of 100 c.c. concentrated sulfuric acid and an equal volume of water slowly to 100 g. of coarsely granular potassium cyanide in a large flask connected to two U-tubes filled with anhydrous calcium chloride. The vapours emerging from these U-tubes are condensed by passing downward through a condenser and collected. Brine cooled to $-10°$ C. is circulated through the jacket of the condenser. A fully anhydrous product is made by adding phosphorus pentoxide to the liquid thus prepared, shaking for a short period and distilling once more.

Prussic acid is made commercially from sodium cyanide in a continuous manner by bringing together a 23% aqueous sodium cyanide solution and concentrated sulfuric acid in a lead-lined generator and condensing and collecting the vapours evolved. The sulfuric acid is kept slightly in excess over the cyanide in the course of the reaction. The residual prussic acid in the liquid, which forms 20% of the total, is recovered by boiling the solution, the vapours being condensed after a partial enrichment in a special "cooler." Prussic acid of 97.5%–98% strength is made from the combined crude condensate by fractional distillation. Large quantities of the acid are also prepared from commercial calcium cyanide by a similar process.

Important quantities of prussic acid are made in Germany from "Schlempe," a by-product of the sugar industry resulting from the treatment of beet molasses with strontia for the purpose of recovering the sugar present in this product. Schlempe contains 4% of nitrogen in the form of betaine, $(CH_3)_3N^+-CH_2-CO_2^-$, in addition to decomposition products of vegetable proteins. It is first distilled, the tarry matter carried over by the vapours being condensed and separated; the gases escaping the condenser are next preheated by passage through a tunnel in an externally heated chamber and are then conducted through the cyanizing chamber. This chamber is filled with firebrick checkerwork and is previously heated by direct gas fire to a temperature somewhat in excess of 1,000° C. The cyanized gas contains about 7% prussic acid, 7% ammonia and 24% carbon dioxide by volume. It is freed of ammonia by scrubbing with hot, dilute sulfuric acid. The prussic acid in the emergent gases is absorbed in water and the aqueous solution thus obtained, which contains 2%–3% prussic acid, is fractionally distilled to recover the prussic acid. The acid is condensed to liquid and further refined or it is directly converted to sodium cyanide.

Synthetic Methods.— Several possible methods for the synthesis of prussic acid have been investigated. Tmo such methods developed into successful commercial processes and became employed for the preparation of the compound on a very large scale. A brief description of these processes follows.

Synthesis by Controlled Oxidation *of* a Hydrocarbon Ammonia Mixture.— Prussic acid is formed when a mixture of methane and ammonia, containing an insufficient amount of oxygen for complete combustion, is passed through a glowing platinum gauze. The reaction giving rise to the compound may be expressed as $2NH_3 + 2CH_4 + 3O_2 \rightarrow 2HCN + 6H_2O$. Leonid Andrussow, who discovered this method, developed it into a successful technical process. Methane and ammonia are mixed in the approximate ratio 11:10 and sufficient air is added to the mixture to give an oxygen content of about 15.5%. The mixture is passed through two or more layers of incandescent platinum iridium gauze with 3% to 5% iridium. The gauze is constructed of 0.16-mm. wire. The several layers of the gauze, resting on a special support, are held between ceramic rings inside a short tube, the whole constituting the converter. The cold gases enter the converter usually at a linear velocity of 103 cm. per second, emerging at a temperature of 1,000°–1,030° C. at a little over 500 cm. per second. The heat generated by the reaction is sufficient to maintain the gauze at the desired temperature. The gases emerging from the converter may be passed through sodium hydroxide solution after being cooled sufficiently. The prussic acid is quantitatively absorbed and may be recovered as sodium cyanide. Alternatively, the ammonia is removed by scrubbing with dilute acid and the prussic acid is absorbed in cold water in special towers and recovered by distillation. Of the total ammonia fed into the converter approximately 63% is utilized in the formation of prussic acid and 10% to 20% is lost by complete combustion. Platinum losses resulting from catalyst deterioration amount to about 1 g. per metric ton of hydrocyanic acid produced.

Aliphatic hydrocarbons other than methane are capable of undergoing the reaction. Methane receives preference, however, since higher hydrocarbons tend to deposit carbon and cause what is known as spotting of the catalyst. This results in loss of efficiency and a greater rate of deterioration of the gauze.

Synthesis by Dehydration of *Formamide.*—In this process formamide is dehydrated in the vaporized condition by passing it, in admixture with a large proportion of ammonia, over an aluminum phosphate catalyst heated to 360° C. The reaction expressing the change is $HCONH_2 \rightarrow HCN + H_2O$. The original formamide ammonia mixture contains 3%–5% of formamide. Dehydration is carried out at atmospheric pressure and proceeds very rapidly. The prussic acid formed is absorbed in sodium hydroxide solution and may be recovered as sodium cyanide.

Formamide is prepared through the reaction of anhydrous ammonia with methyl formate at 30°–60° C. under a pressure of 15 atm.: $HCOOC_2H_5 + NH_3 \rightarrow HCONH_2 + CH_3OH$. It is purified to analyze 99.7% by fractional distillation. Methyl formate is made by the reaction of carbon monoxide with methyl alcohol in the presence of 1% sodium as sodium methoxide: $CO + HOCH_3 \rightarrow HCOOCH_3$. The reaction is carried out at 110° C. under 100 atm. and proceeds quite readily with evolution of heat. The product is freed from the dissolved sodium methoxide by distillation and the mixture of methyl formate and methyl alcohol thus obtained is used directly for the preparation of formamide. The methyl alcohol recovered in the distillation step contains a small amount of unreacted methyl formate and is used for the preparation of additional quantities of methyl formate. The process is, therefore, essentially a complete synthesis of prussic acid, utilizing ammonia and carbon monoxide as the starting materials.

The yield of prussic acid based on ammonia exceeds 92%; it is somewhat more than 85% when calculated on the basis of carbon monoxide used. Approximately 5.5 lb. of methyl alcohol are lost in the process for every 100 lb. of prussic acid produced. The catalyst, if it should become deactivated by a coating of carbon, is reactivated by blowing air through the heated mass. It can be used for several years before it becomes necessary to replace it.

Physical and Chemical Properties.— Prussic acid boils at 25.7° C. and freezes to a snowlike, white mass melting at $-14.9°$ C. It is highly volatile even in the frozen condition. The dielectric constant of prussic acid is the second highest known, indicating the strongly polar character of its molecule. In this respect the compound bears a great resemblance to water, and like water it is a strongly ionizing solvent. The abnormally high heat of evaporation of the liquid is also ascribable to the highly polar character of the molecule. Prussic acid is miscible in all proportions with water and most organic solvents. The vapours of prussic acid are combustible and mixtures with air containing 7%–40% prussic acid by volume are explosive. The products of combustion are carbon dioxide and nitrogen.

The elements in the molecule of prussic acid may be combined in one of two possible ways, $H-C\equiv N$ or $H-N=C$, designated respectively as the normal (nitrile) and the iso (carbylamine) forms. The fact that both methyl cyanide, CH_3-CN, and methyl isocyanide, CH_3-NC, result from the reaction of prussic acid with diazomethane, CH_2N_2, would seem to indicate that both forms coexist in liquid prussic acid, possibly in a state of dynamic equilibrium (see ISOMERISM: *Tautomerism*). Evidence indicates that the molecules of normal structure largely predominate in the liquid. The dissociation constant of prussic acid in aqueous solution at 18° C. is 1.3×10^{-9} or $\frac{1}{230}$ that of carbonic acid, which is itself a weak acid. The degree of acidity developed in aqueous solution is, for this reason, too small to affect the colour of most indicators. The vapours of prussic acid react with remarkable rapidity, nevertheless, with solutions of alkalies, which can therefore serve effectively for the elimination of the compound from a stream of air containing prussic acid.

Polymerization of Prussic Acid.—Prussic acid in the pure form is stable and can be kept unchanged almost indefinitely in sealed glass containers. The acid gradually polymerizes in the presence of minute amounts of substances of basic character such as ammonia, sodium cyanide, etc. The polymer is a black solid of approximately the same empirical composition as prussic acid. Polymerization is accompanied with the evolution of considerable heat and is greatly accelerated as the temperature rises. For this reason the polymerization of comparatively large quantities, which may cause a great rise in temperature with the consequent rise in pressure, may result in an explosion. The addition of small quantities of a strong acid, or of compounds giving rise to acids by gradual reaction with water, effectively stabilizes the commercial acid.

Chemical **Behaviour.**—Prussic acid cannot be esterified directly. Its esters, $R-CN$ (*i.e.*, the nitriles), are usually obtained through the interaction of an alkali metal cyanide with an organic halide or sulfate. Methyl cyanide can, for example, be prepared by heating methyl iodide with an alcoholic solution of potassium cyanide according to the equation: $KCN + ICH_3 = CH_3CN + KI$. The fact that nitriles, $R-CN$, may be prepared through the dehydration of the amides of the corresponding acids, $R-CONH_2$, definitely demonstrates that these compounds are normal cyanides, $R-C\equiv N$. The reaction of organic halides with silver cyanide or mercuric cyanide leads to the formation of isonitriles, $R-N=C$, which differ in their properties from normal nitriles. Prussic acid combines with aldehydes and ketones in the presence of small quantities of substances of basic character, such as potassium cyanide or amines, generally at room temperature, forming cyanohydrins. Acetaldehyde cyanohydrin results, for example, from the reaction of acetaldehyde with prussic acid: $CH_3CHO + HCN = CH_3CH(OH)CN$.

Prussic acid is capable of reacting with ethylene oxide under pressure in the presence of a basic catalyst at a moderately high temperature to form ethylene cyanohydrin:

$$CH_2-CH_2O + HCN \rightarrow HOCH_2CH_2CN$$

This compound is readily dehydrated on distilling in the presence of certain catalysts to acrylonitrile, $CH_2=CHCN$. This is the basis of one of the technical preparations of the latter compound, which has assumed great importance. Acrylonitrile, together with butadiene, is used in the preparation of the acrylic type of synthetic rubber. In the polymeric form it is used for the manufacture of an important synthetic fibre; another synthetic fibre is made from the copolymer of acrylonitrile and vinyl chloride.

Chlorine, reacting with prussic acid in dilute aqueous solutions, gives cyanogen chloride, $ClCN$: $2HCN + Cl_2 = ClCN + HCl$. Bromine reacts similarly, forming cyanogen bromide.

The cyano group, $C\equiv N$, present in prussic acid, is capable of various transformations because of the reactive or "unsaturated" character of the nitrogen-to-carbon bonds. The addition of water, or hydrolysis, can take place in steps, the formation of formamide, $HCONH_2$, being the first stage and that of ammonium formate, $HCOONH_4$, the second stage of the reaction. Hydrolysis takes place readily in the presence of concentrated hydrochloric acid or moderately concentrated sulfuric acid. Concentrated sulfuric acid destroys the ammonium formate, the final products of the reaction being ammonium sulfate and carbon monoxide. Four atoms of hydrogen may be added to the molecule of prussic acid to obtain methylamine, $CH_3.NH_2$. Addition may be brought about by passing a mixture of prussic acid with a large excess of hydrogen over platinized asbestos heated above 150° C.

Metallic Cyanides.—The cyano group or radical behaves in many respects like an element and, combining with metals, gives the metallic cyanides which resemble the metallic halides. This resemblance is particularly marked in the case of alkali metal salts. The radical shows a marked power, on the other hand, of forming complex salts such as potassium ferrocyanide, $K_4Fe(CN)_6$. In these compounds, usually one metal atom forms part of the complex cyanide anion. For example, potassium ferrocyanide dissociates into the potassium cations, K^+, and ferrocyanide anions, $Fe(CN)_6^{4-}$. Ferrous ions, F^{++}, and cyano ions, CN^-, are present in the solution in such minute quantities, in this instance, that ordinary analytical tests fail to reveal their presence; and the stability of the complex is such that the addition of a mineral acid yields the corresponding free ferrocyanic acid, $H_4Fe(CN)_6$. This behaviour is common to many, but not by any means all, of these complex salts. Some, like potassium zinc cyanide, $K_2Zn(CN)_4$, are easily decomposed by acids with the liberation of prussic acid.

The tendency to form complex cyanides is most marked in the metals of Group VIII and contiguous metals (transition elements, see PERIODIC LAW, THE). Most complex cyanides are of the following types: $K[R(CN)_2]$, where R is Cu, Ag, Au; $K_2[R(CN)_4]$, where R is Zn, Cd, Hg, Ni, Pd, Pt; $K_4[R(CN)_6]$, where R is Cr, Mn, Fe, Co, Ru, Os, Ir; $K_3[R(CN)_6]$, where R is Cr, Mn, Fe, Co, Rh, Ir; $K_4[R(CN)_8]$, where R is Mo or W.

Sodium Cyanide is one of the two commercially most important salts of prussic acid. It is prepared in a pure form, analyzing 96%–98% NaCN, by the Castner process, which utilizes the reaction of metallic sodium with ammonia and charcoal. A less pure form of the compound is made from prussic acid. In Germany a large portion of the prussic acid obtained from Schlempe is converted to sodium cyanide.

The Castner Process.—Metallic sodium is melted with charcoal in a steel vessel and dry ammonia is blown into the liquid, while the temperature is gradually raised to 600° C.; the mass is finally heated to about 850° C. in order to complete the conversion of the last remaining portion of sodium cyanamide into cyanide. The molten mass is filtered through iron turnings, after being cooled to some extent, and is cast in molds in the form of spheroids of convenient size. The reaction proceeds in three steps: sodium amide is the first product, $Na + NH_3 = NaNH_2 + H$; the amide reacts rapidly with charcoal forming sodium cyanamide, $2NaNH_2 + C = Na_2CN_2 + 2H_2$; and this finally combines with an additional atom of carbon to form sodium cyanide, $Na_2CN_2 + C = 2NaCn$.

Preparation From Prussic Acid.—Prussic acid is absorbed in aqueous sodium hydroxide solution of such strength that a saturated solution of sodium cyanide (45% by weight) is produced. The use of an excess of prussic acid is avoided, since otherwise a dark product is obtained because of the polymerization of the free acid. The solution is evaporated in *vacuo* to a paste, which is centrifuged to give a product containing 10% water. The remaining water is removed by drying this product on heated trays in vacuo. The dried powder, which analyzes 90%–92% NaCN, is compressed into rectangular cakes of convenient size.

Properties of Sodium *Cyanide*.—Sodium cyanide is a colourless solid crystallizing in the cubic system. It forms a dihydrate, $NaCN.2H_2O$, which crystallizes in large colourless plates decomposing above 34.7° C. Sodium cyanide is soluble in water, alcohol and anhydrous ammonia: it melts at 563.7' C.

In aqueous solution sodium cyanide is partially hydrolyzed to prussic acid and sodium hydroxide: $NaCN + H_2O = NaOH + HCN$. When aqueous solutions of sodium cyanide are heated hydrolysis of the cyano group takes place at an appreciable rate and ammonia and sodium formate result: $NaCN + 2H_2O = HCOONa + NH_3$. This reaction also takes place at ordinary temperatures, although at an extremely slow rate.

Calcium Cyanide has acquired considerable commercial importance since the introduction of its preparation from cyanamide: a mixture of 10 parts commercial calcium cyanamide, 8 parts common salt and 0.5–1 part calcium carbide is fed into an electric furnace of the arc-resistance type with conducting hearth and a single suspended graphite electrode. Alternating current passing through the charge heats this to 1,200°–1,400° C., and the fused mass overflows to a pan in which an internally water-cooled rotating drum picks up a thin layer of the melt. The cyanide is thus chilled rapidly in the form of a thin sheet which breaks into flakes as it is scraped off and collected. The product analyzes more than 45% $Ca(CN)_2$ and contains impurities derived from the coal and coke used in the manufacture of cyanamide and from the salt. Calcium cyanide is formed through the combination of calcium cyanamide with carbon. The carbon is present in the commercial product in the required amount because of its mode of formation from carbide: $CaC_2 + N_2 = CaCN_2 + C$. Rapid cooling of the fused cyanide is essential for the prevention of reversion to cyanamide, which takes place rapidly between 400° and 700° C.

Calcium cyanide in the pure form is a white powder which melts at 640° C. ± 30° C., when heated rapidly, to a clear liquid. The melt soon becomes turbid and finally solidifies as it reverts to calcium cyanamide. An important property of calcium cyanide is its reaction with atmospheric moisture which takes place according to the equations:

$$Ca(CN)_2 + H_2O \rightarrow Ca(OH)CN + HCN$$
$$Ca(OH)CN + H_2O \rightarrow Ca(OH)_2 + HCN$$

The reaction takes place rapidly if the cyanide is finely ground and the relative humidity is in excess of 35%. It forms the basis of the use of calcium cyanide as a fumigant.

Heavy Metal Cyanides.—The simple cyanides of heavy metals are insoluble in water, with the notable exception of mercuric cyanide. Cuprous, silver and zinc cyanides have acquired some commercial importance.

Cuprous Cyanide, CuCN, the only stable cyanide of copper, is made by adding a solution of sodium cyanide to one of cuprous chloride in saturated aqueous sodium chloride. It is soluble in solutions of alkali metal cyanides. The complex salts obtained through the combination of cuprous cyanide with alkali cyanides are used in the electrodeposition of copper on iron. Cuprous cyanide is also important as a reagent for the introduction of the CN radical into aromatic compounds by reaction with aromatic diazo compounds.

Silver Cyanide, AgCN, separates as a white flocculent precipitate when hydrocyanic acid is added to an aqueous solution of a soluble silver salt. It dissolves in sodium cyanide solution, forming the complex salt $NaAg(CN)_2$, which is used in the process of electrodeposition of silver.

Zinc Cyanide, $Zn(CN)_2$, may be prepared by adding hydrocyanic acid to a solution of zinc acetate in water. It separates as white crystals which dissolve in solutions of alkali cyanides, with the formation of a complex cyanide.

Potassium Ferrocyanide, $K_4Fe(CN)_6$, together with the corresponding sodium salt, finds wide use in the preparation of Prussian blue, in the dye industry for the fixation of aniline black dyes and in the casehardening of iron by the "cementation" process. It may be prepared through the reaction of ferrous sulfate and potassium cyanide in aqueous solution. It is obtained more economically from commercial calcium cyanide. Commercial calcium cyanide is dissolved in water and treated with the calculated quantity of ferrous sulfate. To the filtered solution potassium chloride is added, thus precipitating the nearly insoluble potassium calcium ferrocyanide, $K_2CaFe(CN)_6$; this is filtered, washed and then boiled with the required quantity of aqueous potassium carbonate solution. The solution is filtered and concentrated by boiling in cast-iron vessels, and the salt is allowed to crystallize during 14 days on wires or strings suspended in the liquid. The sodium salt may be prepared similarly by the use of sodium chloride and sodium carbonate in the process in place of the potassium salts.

Potassium Ferricyanide, $K_3Fe(CN)_6$, is prepared by oxidizing potassium ferrocyanide in aqueous solution electrolytically or with chlorine. Electrolysis is carried out in diaphragm cells with nickel electrsdes. Potassium ferricyanide crystallizes out from the anode liquor on cooling, and the mother liquor is replenished with fresh ferrocyanide and returned to the cell. The reaction may be represented ionically as follows: $Fe(CN)_6^{4-} = Fe(CN)_6^{3-} + e$; $H_2O + e = OH- + 1/2H_2$.

Oxidation with chlorine is carried out by conducting gaseous chlorine into a cold 10% solution of ferrocyanide. The reaction is represented by the equation: $2K_4Fe(CN)_6 + Cl_2 = 2K_3Fe(CN)_6 + 2KCl$. The passage of chlorine is discontinued when the conversion of the ferrocyanide is just completed. The solution is evaporated to the crystallizing point, a little caustic potash is added to eliminate the small amount of prussian green formed, which is precipitated as ferric hydroxide and removed by filtration. The ferricyanide is recovered by crystallization in an 85%–90% yield. Potassium ferricyanide, used in combination with hypo, is a common photographic chemical (Farmer's reducer).

Iron Cyanide Blues form an important group of pigments. They may be prepared directly through the interaction of ferric salts with alkali ferrocyanides or of ferrous salts with alkali ferricyanides in neutral or acid solution. They are amorphous substances containing variable quantities of combined water. Depending upon the procedure followed in their preparation, soluble or insoluble varieties may be produced. The soluble types, which may be represented by the formula $K\ Fe[Fe(CN)_6]aq.$ and contain a maximum of four molecules of water, may be prepared by mixing cold neutral solutions of ferric chloride and potassium ferrocyanide, the latter being used in excess. Insoluble blues conform to the formula $Fe_4[Fe(CN)_6]_3aq.$ and contain a maximum of 10–11 molecules of water. They are formed when an excess of a ferric salt solution is added to a neutral or slightly acid solution of potassium ferrocyanide.

Blues prepared by the direct method lack the desirable brilliancy of colour; they are generally known as Prussian blue. Fine qualities can be prepared only by an indirect process depending upon the oxidation of potassium ferrous ferrocyanide or of mixtures of this substance with ferrous ferrocyanide:

$$6K_2Fe[Fe(CN)_6] + 3H_2O + 3O = Fe[Fe(CN)_6]_3 + 3K_4[Fe(CN)_6] + 2Fe(OH)_3$$
$$3Fe[Fe(CN)_6] + 3H_2O + 3O = Fe_4[Fe(CN)_6]_3 + 2Fe(OH)_3$$

Paris blue, also called chinese blue. is the finest of iron blues. It is made as follows: a solution of 66 kg. ferrous sulfate (120 kg. of commercial product) in 600 1. water and one of 7j kg. potassium ferrocyanide (83 kg. of commercial product) in 1.000 1. of water are added simultaneously to 600 1. of water with vigorous agitation. The precipitate is washed by decantation, the wet paste is brought to the boiling temperature and a solution of 44 kg. ferric chloride (80 kg. of commercial product) in zoo 1. of water heated to 70° C. is added in the course of one to one and one-half hours. The liquid is boiled with stirring for one-half hour and diluted with boiling water to 4.000 1.; the precipitate is then washed six to eight times with hot water by decantation and finally filtered and dried first at 40°–45° C. then finally at 70° C. It is important that the ferrous sulfate solution be free of ferric sulfate; sufficient purity is assured by allowing the solution to remain in contact with iron filings for one to two days.

Five main varieties of iron blues are recognized in commerce:

prussian blue, paris blue, bronze blue, milori blue and steel blue. In chemical composition they are nearly identical. Milori blue is a special quality, showing a bright colour and a reddish tint. It is distinguished by exceptional softness and is largely used for printing inks.

Detection and Estimation. — The presence of prussic acid in an aqueous solution may be demonstrated by a variety of methods; one that is most commonly employed depends upon the conversion of the acid into prussian blue: one or tuo drops of moderately concentrated sodium hydroxide solution and of freshly made ferrous sulfate solution are added to the liquid, and the whole is boiled. The liquid is cooled and acidified and a drop of ferric chloride solution is added; a precipitate of prussian blue then forms if prussic acid was present in the original solution. One of the most satisfactory methods for the quantitative determination of prussic acid is titration of the acid in the form of its alkali metal salt with standard silver nitrate solution. with a few drops of 10% potassium iodide solution as an indicator. The end point is reached when a permanent opalescence is observed in the solution; at this point the reaction $2NaCN + AgNO_3 = NaAg(CN)_2 + NaNO_3$ is just complete. It can be seen that every formula weight (see MOLECULE, CHEMICAL) of silver nitrate used is equivalent to two formula weights of prussic acid.

Toxic **Action.**—Hydrocyanic acid is highly toxic through inhibition of cellular oxidative processes. Acute poisoning from hydrocyanic acid or its salts, the cyanides, is manifested by dizziness, nausea, staggering and loss of consciousness if the amount absorbed is sufficient. Death ensues rapidly if lethal quantities are absorbed through ingestion of the cyanides or through the inhalation of HCN gas in sufficient amounts. In sublethal poisoning recovery is usually complete within a few hours and there are no permanent aftereffects. In sublethal doses the CN radical is rapidly detoxified by the body through combination with sulfur, which forms nontoxic sulfocyanides. Man can withstand 50–60 parts of HCN per 1,000,000 parts of air for one hour without serious consequences. while exposure to concentrations of 200–500 parts per 1.000.000 parts of air for 30 minutes is usually fatal.

First-Aid Treatment for Cyanide Poisoning. — Carry patient to fresh air and have him lie down and keep warm. Call a physician. If the patient is breathing, break an amyl nitrite pearl in a cloth and hold lightly over the nose for not more than 15 to 20 seconds or have him inhale aromatic spirits of ammonia. Repeat every five minutes for 2j minutes if recovery is not forthcoming. This poison is rapid in action and few patients survive.

If the patient has stopped breathing give artificial respiration until breathing starts; then administer amyl nitrite as above.

If cyanides have been swallowed and the patient is conscious give one pint of 1% sodium thiosulfate solution (or soapy water or mustard water) by mouth every 1j minutes until vomiting occurs Never give anything by mouth to an unconscious person. During World War II p-am~nopropiophenone, administered orally, was found by the medical division, chemical narfare service, U.S. army, to have value in the prophylaxis of cyanide poisoning.

Pest Control. — The use of prussic acid for the control of insect and other pests has become quite general since D W. Coquillet first employed the compound in 1886 for the control of scale insects of citrus trees in California. Prussic acid is extensively used as a fumigant for the control of insects in stored goods, of household pests and of insect and rodent pests occurring in ships and railuays cars and for a variety of other purposes as well as for the control of agricultural pests. The liquid is available in stout steel cylinders for shipment over long distances. A product consisting of prussic acid absorbed in wood-pulp disks or in granular diatomaceous earth in sealed tins is also available.

Periodic general fumigation of flour mills has become common practice in the U S. Liquid in cylinders is used for this purpose. It is sprayed at each floor from special spray nozzles attached to a permanent piping system or to rubber hose reaching all parts of the floor. The liquid is ejected with compressed air. This method of application is also utilized in the fumigation of other large buildings and ships The most effective and economical method of flour-mill fumigation consists in injecting the liquid into the various machines, thus producing the highest concentration of the fumigant at the sources of infestation. An elaborate, permanent machinery piping system forms an essential part of this method.

The pressure of demand for effective measures directed at the prevention of insect damage to stored goods led to the development of vacuum fumigation technique. Specially constructed large cylindrical or rectangular airtight chambers are used for this purpose. The commodities to be fumigated are introduced into the chamber on special trucks, the chambers are sealed tight and evacuated and the prussic acid is then injected in the form of vapours. The doses required may vary, according to the commodities fumigated and the magnitude of the load, between $1\frac{1}{2}$ and 3 lb. or more per 1,000 cu.ft. of space.

A convenient method of fumigation of dwelling houses and commercial establishments of moderate size utilizes disks of wood pulp impregnated with liquid prussic acid. The disks are contained in sealed metal cans which are opened just before use by means of a special cutter. The disks are evenly scattered throughout the various floors of the building on heavy paper placed on the floor.

The introduction of calcium cyanide made possible the satisfactory solution of a number of difficult pest-control problems. The mode of action of this product depends upon its reaction with the moisture in the atmosphere, generating vapours of prussic acid. In the finely ground form it is the most effective agent known for the destruction of burrowing animals such as rats, rabbits, ground hogs, etc. It is also one of the best fumigants for the control of ants and termites in their nests. A granular form is best suited for this purpose; it is applied on the walks in a thin layer in quantities corresponding to $\frac{1}{8}$ to $\frac{1}{4}$ oz. per 1,000 cu.ft. of space. Application is begun an hour after sunset and the house is allowed to remain closed overnight. The temperature within the house should be rising and preferably between 60° and 70° F. and the air should be calm. Several applications at weekly intervals are recommended. An important use of calcium cyanide is in the fumigation of grain in storage, for which a granular form of the product is used. It is applied to the grain at a controlled rate by a special device at the time the grain is run into the bin. A dosage of 10 to 20 lb. per 1,000 bu. of wheat gives satisfactory control of insects without damage to the grain.

Casehardening.—Casehardening of iron or steel articles by immersion in a fused cyanide bath came into general use, especially in the United States and Canada. after its introduction in 1910. The bath material usually consists of 60% sodium cyanide mixed with other salts such as sodium carbonate or sodium chloride. It is fused-in mild steel or chromium-steel pots and the temperature is raised to a point above 760° C. The cyanide gradually decomposes and the resulting carbon combines with, and penetrates into, the metal. The rate of penetration of carbon into mild steel is about 0.01 in. per hour and about 50% greater when nickel steel is used. Casehardening usually implies a case depth of 0.015–0.060 in.; cases of smaller depth, in some instances only 0.005 in. thick, are produced for surface hardening. Sodium cyanide is added to heat-treating baths to prevent decarburation of the treated pieces. A concentration of 10% is usually regarded sufficient for this purpose, but lower or higher concentrations may be used in connection with low and high carbon steels.

Electroplating. — A solution containing the double cyanide of sodium and silver, $NaAg(CN)_2$, or the corresponding potassium salt, and a molecular excess of the alkali cyanide serves for electroplating metal articles with silver. The article to be plated, its surface thoroughly cleaned, and a sheet of silver are suspended in the solution a few inches apart; and a direct current is passed through at a rate of three amperes per square foot of surface. The article to be plated is made the cathode, the silver the anode. As electrolysis proceeds, the silver anode gradually dissolves, and an equal quantity of the metal is deposited out of the solution upon the surface of the article. The concentrations of the double salt commonly used correspond to two ounces to four ounces silver per imperial gallon. The solution improves with use. Plating with gold. gold-silver or gold-copper alloys is done in a similar way. Cyanide solutions are also used in deposition of copper, zinc, brass and cadmium. more especially on iron.

Flotation.— In the flotation process of ore concentration, separation of metal sulfides is effected by a rising current of air bubbles through the vigorously agitated water suspension of the ore containing a little oil or other flotation agents. The metal sulfides rise with the froth and are obtained in a concentrated form by collecting the froth. G. E. Sheridan and G. G. Griswold discovered in 1922 that the addition of a small amount of sodium cyanide to the suspension of ore previously made faintly alkaline with soda ash prevents the flotation of zinc and iron sulfides without affecting that of lead and copper sulfides. By making use of this effect the sulfides of zinc and iron may be separated from those of lead and copper. The iron and zinc sulfides may be separated by a second treatment in more strongly alkaline solution, the zinc alone floating.

Sodium and calcium cyanides are used extensively in the process of gold and silver extraction. *See* CYANIDE PROCESS.

PRUTZ, HANS (1843–1929), German historian, son of Robert Eduard Prutz (1816–1872), the essayist and historian. was born at Jena on Nay 20, 1843, and studied at Jena and Berlin. His *Preussische Geschichte* (4 vols., Stuttgart, 1899–1902) is an attempt to apply scientific rather than patriotic canons to a subject which has been mainly in the hands of historians with a Prussian bias. In 1902 Prutz resigned the chair of history in the university of Konigsberg, which he had held since 1877.

His other works include: *Aus Phonicien,* a collection of historical and geographical sketches (1876); *Quellen-beitrage zur Geschichte der Kreuzzüge (1876)*; *Kulturgeschichte der Kreuzziige (1883)*; *Staatengeschichte des Abendlandes im Mittelalter* (1885–87); *Geheimlehre und Geheimstatuten des Tempelherrenordens* (Danzig, *1879)*; *Entwickelung und Untergang des Tempelherrenordens (1888)*; *D. geistl. Orden,* (1907).

PRYNNE, WILLIAM (1600–1669), English Parliamentarian and scholar, son of Thomas Prynne, was born at Swainswick near Bath, and educated at Bath grammar school and at Oriel college, Oxford. He was called to the bar at Lincoln's Inn in 1628. In 1629 Prynne came forward as the assailant of Arminianism in doctrine and of ceremonialism in practice, and thus drew down upon himself the anger of William Laud. *Histrio-mastix,* published in 1632, was a violent attack upon stage plays in general, in which the author pointed out that kings and emperors who had favoured the drama had been carried off by violent deaths, and applied a disgraceful epithet to actresses, which, as Henrietta Maria was taking part in the rehearsal of a ballet, was supposed to apply to the queen, After a year's imprisonment in the Tower Prynne was sentenced by the Star Chamber on Feb. 17, 1634, to be imprisoned for life, and also to be fined £5,000, expelled from Lincoln's Inn, rendered incapable of returning to his profession, degraded from his degree in the University of Oxford, and set in the pillory, where he was to lose both his ears. The latter portion of the sentence was carried out on May 7, and the rest of his punishment inflicted except the fine and part of the imprisonment.

In 1637 he was once more in the Star Chamber, together with John Bastwick and Henry Burton. In *A Divine Tragedy Lately Acted* he had attacked the Declaration of Sports, and in *News from Ipswich* he had assailed Matthew Wren and the bishops generally. On June 30 a fresh sentence, delivered on the 14th, was executed. The stumps of Prynne's ears were shorn off in the pillory, and he was branded on the cheeks with the letters S.L., meaning "seditious libeller," which Prynne, however. interpreted as "*stigmata laudis*." He was removed to Carnarvon castle, and thence to Mont Orgueil castle in Jersey, where he occupied himself in writing against popery.

Immediately upon the meeting of the Long parliament in 1640 Prynne was liberated and on April 20, 1641, reparation was voted by the house of commons, at the expense of his persecutors. Prynne now attacked the bishops and the Roman Catholics and defended the taking up of arms by parliament. He showed a vindictive energy in the prosecution of Archbishop Laud. He prepared the evidence against him, and, having been entrusted with the search of Laud's papers. he published a garbled edition of the archbishop's private "Diary!" entitled *A Breviate of the Life of Archbishop Laud.* He also published *Hidden Works of Darkness brought to Light* in order to prejudice the archbishop's case. Prynne supported a national church controlled by the state, and issued a series of tracts against independency. He denounced John Milton's pamphlet in favour of divorce, was answered in the *Colasterion,* and contemptuously referred to in the sonnet "On the New Forcers of Conscience." He also opposed violently the Presbyterian system, and denied the right of any church to excommunicate except by leave of the state (*e.g., Four Serious Questions* [1644]; *A Vindication of Four Serious Questions* [1645]). He was throughout an enemy of individual freedom in religion.

Prynne took the side of parliament against the army in 1647, supported the cause of the 11 impeached members, and visited the University of Oxford as one of the parliamentary commissioners. In 1648 Prynne was returned as member for Newport in Cornwall. He at once took part against those who called for the execution of Charles I; the result was his inclusion in "Pride's Purge" on Dec. 6, when, having resisted military violence, he was imprisoned. After recovering his liberty Prynne retired to Swainswick. On June 7, 1649, he was assessed to the monthly contribution laid on the country by parliament. He not only refused to pay, but published *A Legal Vindication of the Liberties of England,* arguing that no tax could be raised without the consent of the two houses. He was imprisoned in various places from 16jo to 1653, and on his release renewed his pamphleteering activities.

On the restoration of the Rump parliament by the army, on May 7, 1659, 14 of the secluded members, with Prynne among them, claimed admittance. He was prevented from taking his seat, and another attempt in December also failed. He was returned for Bath to the Convention parliament and to the parliament of 1661. During 1663 he served constantly on committees, and was chairman of the committee of supply in July, and again in April 1664. The last time he addressed the house appears to have been in Nov. 1667.

Prynne was more notable as a scholar than as a politician. His voluminous writings, though devoid of style and orderly arrangement, derived a lasting value from the historical materials, and especially from the original records, printed in them. His knowledge of the national archives, unrivalled in that age, was fittingly acknowledged by his appointment in 1661 as keeper of the records in the Tower. In that office he not only continued his publications but also did much to rescue the records from the neglect into which they had fallen and to secure their proper and orderly preservation. Prynne died unmarried on Oct. 24, 1669.

See E. W. Kirby, *William Prynne* (Cambridge, Mass., London, 1931), which contains a bibliography of his writings.

PRYOR, ROGER ATKINSON (1828–1919), U.S. soldier and jurist! was born near Petersburg, Va., on July 19. 1828. He graduated at the law school of the University of Virginia in 1848, and in 1849 was admitted to the bar. He served'as a Democrat in the national house of representatives. 1859–61, and was re-elected for the succeeding term, but owing to the secession of Virginia did not take his seat. He served in the provisional Confederate congress (1861) and also in the first regular congress (1862) of the Confederate constitution. He entered the Confederate army as a colonel: became a brigadier-general (April 16, 1862), and took part in the battles of Williamsburg, Seven Pines, second Bull Run and Antietam. Owing to a disagreement with President Davis he resigned his commission in 1863, and entered Gen. Fitzhugh Lee's cavalry as a private. He was taken prisoner Nov. 1864. but was released on parole by order of the president. In 186j he removed to New York city, where he practised law. He was judge of the New York court of common pleas, 1890–94, and of the New York supreme court: 1894–99, when he retired from the bench. He died in New

York city on March 14, 1919.

PRYTANEUM AND PRYTANIS. 1. In ancient Greece, each State, city or village possessed its own central hearth and sacred fire; the fire (*cf.* at Rome the fire in the temple of Vesta) was kept alight continuously, tended by the king or members of his family. The building in which this fire was kept was the Prytaneum (Πρυτανεῖον), and the chieftain (the king or prytanis) probably made it his residence. The word prytanis is applied to those who, after the abolition of monarchy, held the chief office in the State. Rulers of this name are found at Rhodes as late as the 1st century B.C. The Prytaneum was regarded as the religious and political centre of the community. When colonists went out they took with them a brand from the Prytaneum altar to kindle the new fire in the colony; the fatherless daughters of Aristeides, regarded as children of the State at Athens, were married from the Prytaneum as from their home; foreign ambassadors and citizens who had deserved especially well of the State were entertained in the I'rytaneum as public guests. In Achaea, this central hall was called the *Leïton* (town-hall), and a similar building is known to have existed at Elis. The site of the Prytaneum at Athens cannot be definitely fixed. The Prytaneum mentioned by Pausanias, probably the original centre of the' ancient city, was situated somewhere east of the northern cliff of the Acropolis. Curtius places the original Prytaneum south of the Acropolis in the old Agora, and regards that of Pausanias as a building of Roman times (*Stadtgesclzichte,* p. 302). Many authorities hold that the original Prytaneum of the Cecropian city must have been on the Acropolis. From Aristotle's *Constitution of Athens* (ch. 3) we know that the Prytaneum was the official residence of the archons, but, when the new Agora was constructed they took their meals in the *Thesmotheteion* for the sake of convenience. There was also a court of justice called the court of the Prytaneum; it tried murderers who could not be found, and inanimate objects which had been the means of causing death.

2. For the PRYTANEIS of the Boule see BOULE.

PRZEMYSL, a town of Poland, in the province of Rzeszów, 60 mi. W. of Lvov, Soviet Union, by railway. Pop. (1960) 46,000. It is situated on the river San, and is the seat of a Roman Catholic and a Greek Catholic bishop. the cathedral dating from the 15th century. The industries comprise the manufacture of machinery, the refining of naphtha, corn-milling and the sawing of timber. On the hill above the town are the ruins of an old castle, said to have been founded by Casimir the Great.

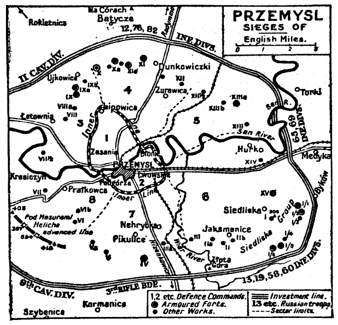
Przemysl was founded at an early date on the borderland between Poland and Russia. Russian princes founded a state there in the 11th century which became absorbed in the principality of Galich or Halicz and was annexed by Casimir the Great after 1330. It was occupied by Austria from 1773 to 1915. Polish after 1918. it was occupied by the U.S.S.R. in 1939 and Germany during World War II.

BRZEMYSL, SIEGES OF. In 1914 Przemysl was protected by a ring of forts 36 m. in circumference. Some of the forts were of recent construction. but the fortress as a whole was not strictly up-to-date. To clear the foreground in front of the fortified line no fewer than 18 villages and some five miles of forest were levelled to the ground on mobilization. The armament of the fortress included four large modern howitzers of about 12in. calibre and some 9in. and 6in. howitzers of older pattern. There were in all about 1.000 guns in the fortress, hut more than half of these were old. short-range weapons of little value except for close defence. There were 114 machine-guns, of which two-thirds were mobile.

The eventual garrison left in the fortress when the Austrian armies retreated from the San on Sept. 18, 1913. consisted of: $61\frac{1}{2}$ battalions (of which $40\frac{1}{2}$ were Landsturm)! seven squadrons. four field batteries, 33 fortress artillery companies. 48 Landsturm artillery brigades. eight sapper companies, and various technical and administrative units. The total strength was approximately 130.000 men and 21,000 horses.

The First Siege.—The Austrian armies withdrew from the San on Sept. 18; by Sept. 24 the investment of the fortress was 'complete. On the south-west front the garrison held a line a mile or two in advance of the ring of forts; elsewhere the line of the forts was held. The siege of the fortress was undertaken by Radko-Dimitriev's III. Army.

While arrival of the siege artillery material was still delayed by the state of the communications, the Austrians renewed the offensive early in October. In the hope of capturing Przemysl by a *coup de main* before the progress of the enemy offensive compelled the raising of the siege, Radko-Dimitriev carried out several violent assaults between Oct. 5–8 against the Siedliska group of works to the south-east of the town. These assaults broke down with heavy loss, and the approach of the Austrian III. Army necessitated the withdrawal of the investing forces.



BY JOHN BARTHOLOMEW & SONS

The fortress was entered by Austrian infantry of the field armies on Oct. 11, on which date Radko-Dimitriev's III. Army retreated to the east bank of the San.

Period Between the First and Second Sieges.—During the Austrian attempts to force the San line, which lasted throughout October, the fortress lay in the centre of the battle line and its garrison took an active part in the operations. Its reserves of supplies and material were also largely drawn on by the field armies to make good the deficiencies caused by the poor working of the lines of communication. During their retreat the Russians had systematically destroyed the railways and bridges, and the continued wet weather had rendered the roads almost impassable. Thus it was natural that the reserves of Przemysl should be used for the benefit of the field armies, from whose operations, great results were expected at the time. But when the offensive proved fruitless and Russian pressure necessitated a retirement which would leave the fortress again isolated, special efforts mere made hastily to reprovision it. They were so far successful that the fortress was enabled to hold out for $4\frac{1}{2}$ months in the second siege.

Second Siege, **Nov.** 6,1914–March **22, 1915.—**The strength of the garrison was approximately the same as in the first siege, but a detachment of aeroplanes had been added. Kusmanek had now laid out new entrenched positions from one to two miles in advance of the line of forts, to give ,more depth to the defence and to keep the Russian siege artillery at a greater distance. On Nov. 9 the investment of the fortress for the second time was complete. The siege was now undertaken by a specially formed XI. Army under General Selivanov, consisting of four divisions of second-line troops. It had been decided to reduce the fortress by blockade rather than by assault. During November and December such fighting as occurred was initiated rather by the sorties of the garrison than by the attacks of the besiegers.

During February and the first half of March the Austrian field armies made repeated efforts to advance to the relief of the fortress, but unsuccessfully.

Meanwhile the Russians had gradually closed in and had commenced a systematic bombardment of the fortress. On March 13 they carried the advanced positions on its north front. Kusmanek's situation was now desperate; his supplies and munitions were almost exhausted, and the final effort of the field armies to come to his rescue had definitely been abandoned. He determined on an attempt to save a portion of the garrison by a breakthrough to the east. The effort was made on the morning of the 19th, but was soon brought to a stand. The fate of the fortress was now sealed. On the morning of March 22 Kusmanek surrendered, after destroying the works and military stores as far as possible. The numbers of the garrison then amounted to about 110,000.

Recapture of the Fortress.—The Russians did not hold the fortress for long. At the beginning of May, Field Marshal Mackensen's offensive on the Dunajec broke through the Russian line and drove their armies back to the San. On May 30 the

Austrians attacked on the south-west and the Germans on the north of the fortress. The former made little progress, but the German heavy artillery, which included 42 cm. howitzers, made short work of the northern group of forts. On the night of June 2 the Russians abandoned the fortress.

Conclusions.—Przemysl was the only land fortress of World War I which stood a prolonged siege after complete investment, but the length of its resistance was seemingly due to the Russians' lack of efficient siege artillery, as is confirmed by the speed with which Mackensen's heavy guns reduced the forts at the time of its recapture. Nor can it be admitted that the fortress served any strategical aim commensurate with the efforts expended on its defense and attempted relief. It is true that its resistance during the first siege was of value to the Austrians when their armies again advanced to the San, in assuring to them a bridge-head over the river. But during the second seige Przemysl was an embarrassment rather than a source of strength and led to several ill-considered efforts at relief which cost the Austrian field armies dearly. The fortress did not control any line of supply vital to the Russian armies operating west of it toward Cracow, since there was a railway available through Jarostow. The Russians could therefore afford in the second siege to resort to a simple blockade by second-line troops, so that the fortress did not even weaken their field armies to any appreciable extent.

PSALMANAZAR, GEORGE (*c.* 1679–1763), French adventurer. After various escapades, including a pilgrimage to Rome in the guise of a Japanese convert, he came to London, where he imposed on many people, notably on the bishop of London, who employed him to translate the Catechism into what was supposed to be Japanese. In 1704 and 1707 he published fictitious works on Formosa. Eventually he confessed to his imposture.

He died in London on May 3, 1763.

His *Memoirs of . . . known by the name of George Psalmanazar* (1764) do not disclose his real name or the place of his birth. His fictitious publications include: *Historical and Geographical Description of Formosa* (1704); *Dialogue between a Japanese and a Formosan* (1707); *An Enquiry into the Objections . . . with George Psalmanazar's Answer* (undated).

See P. W. Sergeant, *Liars and Fakers* (London, 1926).

PSALMS, the first in order and importance (*cf.* Luke xxiv. 44) of the third division of the Hebrew Old Testament, known as the "Writings." The Hebrew name of the Psalms is *tehillim,* or "praise-songs," which expresses a predominant, though by no means the entire, character of the collection. This anthology of Hebrew poetry also includes petitions (iv.), laments (xliv.), imprecations (lviii.), meditations (cxix.), historical reviews (cvi.), and even a marriage ode (xlv.). But there can be no doubt that the purpose of the collection was to gather the sacred poetry of Israel for use in the *post-exilic* worship of the temple. This is shown by the technical and professional titles of the psalms, as well as by their general character and their occasional references (note the definite allusions to the destruction of Jerusalem, the exile or the dispersion in li. 18, lxxxix. 38, 44, cvi. 47, cxxvi. 1, cxxxvii. 1, cxlvii. 2).

As the book lies before us, it is a collection of collections, being divided into five books, which themselves contain certain smaller distinguishable groups of psalms. The first four books are each closed by a doxology, at least as old as the Septuagint version (second half of 2nd century B.C.). In Bk. I. (i.–xli.) practically all the psalms are ascribed to David (the exceptions can be explained). In Bk. II. (xlii.–lxxii.) there is more variety, xlii.–xlix. being ascribed to "the sons of Korah," l. to Asaph, li.–lxv. to David, lxvi., lxvii. simply to "the chief musician" or choir-conductor, lxviii.–lxx. to David, lxxii. to Solomon (lxxi. is anonymous). The editorial note at the end of this book, "Finished are the prayers of David the son of Jesse," shows there was once a collection of "Davidic" psalms, and that there has been a rearrangement of material bringing psalms of other groups above the rubric. In Bk. III. (lxxiii.–lxxxix.) there is an "Asaph" group (lxxiii.–lxxxiii.) followed by a miscellaneous appendix (Korah, David, Ethan). We have clear evidence of other editorial work in the overwhelming predominance of the name "Elohim" for God in Psalm xlii.–lxxxiii. as compared with the personal name, "Yahweh" (the occurrences are 200:43; in Psalms, i.–xli. 15:272); this is confirmed by the fact that Ps. xiv. of the first Book reappears as Ps. liii., with its fourfold "Yahweh" changed into "Elohim" (so also in Pss. xl. 13–17 and lxx.). In Bks. II. and III. alone do we get psalms ascribed to guilds of temple-singers. Bks. IV. and V. are divided by the doxology of cvi. 48 (*cf.* 1 Chron. xvi. 35, 36, where a liturgical formula has been transformed into a historical statement). But the division seems artificial (perhaps made to get five books of psalms corresponding with the five books of the law), since Psalms cv.–cvii. are closely related in subject-matter. If, therefore, we take Bks IV. and V. together, we find in them a distinct group of "Pilgrim" psalms (cxx–cxxxiv.), and a scattered one of "Hallelujah" psalms (civ.–cvi., cxi.–cxiii., cxv.–cxvii., cxxxv, cxlvi.–cl) largely liturgical. Ps. cviii. seems to have been made by combining lvii. 7–11 and lx. j–12, which again proves the existence of separate collections, since the same material would not originally appear twice in the same collection.

The Hebrew psalms are in rhythmical, but unrhymed verse, the most frequent type being that of the three-beat line. The other characteristic of Hebrew poetry is its parallelism ("synonymous," li. 2; "antithetic," i. 6; "synthetic," cxxi. 4). The musical accompaniment was melodic unison, not the harmonies of modern music, so that its chief use, beyond support to the singers, was to synchronize the beats, as by cymbals (1 Chron. xv. 19, xvi. 5). Six distinct instruments are named in Ps. cl. (*see* Wellhausen, *Psalms,* Appendix, "Music of the Ancient Hebrews"). The singing was by professional choirs with a response ("Amen," "Hallelujah") from the worshippers (1 Chron. xvi. 36, 2 Chron. xxix. 27, 28). For a glowing description of the ritual see Ecclus. l. 11–21.

At first sight, the contents of the Psalter may seem to occasion relatively little difficulty to the exegete, as compared with the prophecies. The psalms are for the most part simple and often conventional in language, and without those references to obscure historical events which make the writings of the prophets so difficult. But the apparent gain is really a great loss to historical exegesis. Whilst the absence of reference to contemporary events makes the psalms much more capable of use then than now in worship and devotion — it was in some measure due, we may suppose, to elimination and adaptation — yet it also makes the investigation of the original meaning more difficult. Thus it is usually impossible to give a precise historical background to a particular psalm. The titles professing to do this, and to ascribe authorship, are of little use for critical purposes, and represent a late and usually worthless conjecture. Scholars have now generally abandoned the earlier attempts to ascribe particular psalms to precise events from the Davidic down to the Maccabean age; there is considerable variety of opinion as to the nature, date, authorship and origin of the psalms considered individually.

Four main questions arise: (1) to what extent are the psalms primarily and originally "cultic," more or less officially composed for use in public worship, and to what extent are they private religious lyrics, gathered from many sources, and subsequently adapted to use in the temple-services? (2) In close relation with this question comes another as to the significance of the speaker in many of the psalms; does the "I" mean the whole community, or is it an individual person who is speaking? (3) To what period of the religious history of Israel do the psalms chiefly belong, and to what extent are they pre-exilic in origin, though admittedly post-exilic in present adaptation and arrangement? (4) Are they a native product or are they dependent on Babylonian or Egyptian models, as the creation stories of Genesis are dependent on Babylonian mythology? It will be seen that these are not merely academic questions, for each of them may affect the exegesis of a particular psalm. A quarter of a century ago, the answers to these four questions generally given by critical scholarship were as follows: (1) the psalms are chiefly poems of the individual, though some were intended from the outset for use in the temple; (2) the "I" of the psalms usually represents the community; (3) the psalms are almost wholly post-exilic in origin; (4) they are native products. All these answers are now being met with vigorous criticism. At the present moment the protagonists in this criticism are the German scholar, Gunkel, and the Norwegian scholar, Mowinckel. Some account of their views must be given, as they cannot be neglected by the modern student of the psalms.

Gunkel's leading principle is that the psalms should be studied in their "classes" (Gattungen) or types, of which he finds four of chief importance, viz., "hymns" (*e.g.*, cxlv., cxlvii., cxlviii., cl.), "national laments" (*e.g.*, xliv., lxxix., lxxx., lxxxiii), "individual laments" (iii., xiii., liv., lxxxviii.) and "individual thanksgivings" (xxx., lxvi., 13 seq.). These classes are differentiated by the use of regular formulae, such as "Deliver us, Yahweh," or "I will thank Yahweh," and by more or less regular forms of composition. so that we are not left to subjective impressions only when deciding as to what class a particular psalm belongs. On the basis of this differentiation Gunkel constructs a general history of the "classes," partly from internal evidence, such as the greater length, individualization, or composite character of the later representatives of the class, and partly from the parallels with psalm-like compositions found elsewhere in the Old Testament, which it is possible to date with confidence, such as the Song of Miriam (Exod. xv. 21), the song of the seraphim heard by Isaiah in the temple (vi. 3), the lyrics of Jeremiah and the "Psalms of Solomon" (1st century B.C.). Gunkel's general conclusion is that hymns of praise and national laments were found at an early date, whilst individual laments arose later, but prior to Jeremiah. He admits that prophecy influenced the language, eschatological outlook and spirituality of the Psalms, but claims that this influence was exerted before as well as after the exile. He argues that the existence of similar compositions in Babylonia and Egypt at a much earlier date confirms the intrinsic evidence that "Psalm-composition belongs to the earliest periods of Israel's history."

Mowinckel, whilst recognizing and using the classification of psalms by their type, throws his emphasis on their cultic character, and indeed barely admits the existence of any psalms not cultic in origin (his exceptions are i., cxii., cxxvii.). The psalms were composed by the temple-singers, whom he regards as existing from the early days of the temple. The class of psalms to which he gives primary attention is that containing references to the enthronement of Yahweh as king (xlvii., xciii, xcv.–c., with which many others are to be linked). These he connects with an alleged festival of the New Year (originally beginning in the autumn), a festival after the analogy of that celebrated at Babylon in honour of Marduk. The cultic acts of this festival (*e.g.*, the procession bringing the ark into the temple) were realistically conceived, *i.e.*, they were supposed to help in bringing about that which they "dramatized." Thus they anticipated the future (eschatology) while recalling the past (mythology). There is a similar "realism" in Mowinckel's interpretation of the numerous petitionary psalms, which are held to attribute misfortune and sickness to magicians and sorcerers, who are the original "workers of iniquity" so frequently mentioned. Such psalms were employed, with suitable accompanying rites, as part of the temple-cult; they counteracted adverse magic by exorcisms and imprecations of these "enemies." There were prophets as well as priests, or priest-prophets, attached to the temple, who gave oracles; thus the petition of Ps. lxxxv. 1–7 is answered by the oracle of vv. 8–13. It should be said that a "cultic" interpretation of the psalms as a whole has been independently urged by other scholars, *e.g.*, by J. P. Peters, who further conjectures that the "Elohistic" psalms belonged to northern temples (cf. the northern "Elohistic" saga-writers), the Korahite to Dan, the Asaphite to Bethel, and were afterwards incorporated in the liturgy of Jerusalem.

It will be seen, therefore, that there is considerable division of opinion at the present time in regard to our first quesrion, the cultic element in the Psalter, Mowinckel regarding practically the whole Psalter as cultic in origin, whilst Gunkel regards the majority of the psalms as of private and occasional origin, though subsequently introduced into the cult. On this point Gunkel's view seems more convincing, from the intrinsic evidence and from the general probabilities. Like a modern hymn-book, the Psalter seems to contain many poems not originally intended for use in worship, but subsequently adapted to it—indeed, the religious wealth of the Psalter seems largely due to this variety of origin. On the other hand, Mowinckel does make a strong case for the special interpretation of the psalms of the enthronement of Yahweh, even though he brings far too many under this head. His explanation of the "eschatological" features is also attractive; less so seems his too sweeping connection of sickness and misfortune with magic, though there is probably an element of real truth in his contentions (the tendency of those who discover some neglected truth is to generalize to excess on the basis of it). In a collection so extensive and varied as the Psalter we need not regard any one explanation or theory as necessarily applicable to more than a part of the material. Variety of origin almost follows from variety of date, and their issue is most naturally variety of meaning, even where the same conventional phrases may be used.

In regard to the closely linked question as to the collective or individual interpretation of the speaker in the psalms, Gunkel follows Balla in reaction from the view that was general a quarter of a century ago (*e.g.*, Smend, Cheyne), *i.e.*, that the "I" of the Psalms is collective, personifying the nation. Mowinckel agrees with Gunkel so far as the "individual laments" are concerned, but recognizes a primitive "corporate personality" finding utterance through the leader or king as its representative. We may ask whether this principle does not admit of a wider application than even Mowinckel allows. It seems to go a long way towards explaining the puzzling combination of "collective" and "individual" elements in such a psalm as the xxii., and the rapid transitions so often found (cf. xliv. 5–7 and 14, 15). The same phenomena occur in relation to the Servant of Yahweh in Deutero–Isaiah, and admit of the same explanation—thzi the primitive mind draws no such hard and fast limits between the individual and the community as we do (see The Cross of the Servant, by H. Wheeler Robinson, pp. 32–36; The Psalmists, ed. D. C. Simpson, pp. 82 seq.). We may often find it impossible to decide whether a psalm is collective or individual—because the ancient category was neither one nor the other, but a third category including both.

In regard to dating the composition of individual psalms, there seems to be some danger of a similar excessive reaction from the view associated with the name of Wellhausen, open as that is to criticism. The arguments of Gunkel and Mowinckel, amongst others, do show in their different ways that psalms were composed in the pre-exilic period, a fact which has been too grudgingly admitted. The intrinsic evidence of some of the psalms, such as the reference to a human king, or the processional features of the second part of xxiv. ("Lift up your heads, O ye gates"), or the primitive cosmology of the first part of xix., confirms the probability that some of these pre-exilic productions would survive in a post-exilic Psalter, So long as we are thinking of the origin and original meaning of a particular psalm, we must always be prepared to admit that it may go back to a relatively early date, however much modified in its present adaptation to the needs of the second temple. On the other hand, we use any psalm in its present form as an early document only at considerable risk; we may conjecture, but we cannot prove. The main reasons for regarding the contents of the Psalter as largely post-exilic remain unaffected by recent criticism, *i.e.*, those that spring from the general relation of the religion of the psalms to the prophetic religion. If with Gunkel we regard the majority of the psalms as the expression of individual piety, we have to ask whether such wide-spread piety is conceivable before the work of the great prophets. The psalms represent a partial fulfilment of the prophecy of the New Covenant made by Jeremiah; is it likely that they preceded it? We cannot reasonably doubt that the prophets of the 8th and 7th centuries were pioneers, and that they taught truths that were new to their cbntemporaries, even though they may have used forms of expression and even of thought which were more or less conventional. Nor can there be any doubt that the religion of the Psalter as a whole is closely related to the prophetic teaching. We seem to have parallel phenomena in the formulation of Israel's laws (Deuteronomy, the Law of Holiness, the Priestly Code) and in the Wisdom Literature; in all three cases ancient elements are given a new setting, but the new setting gives them a new meaning. Laws, proverbs and psalms are alike reinterpreted and restated in the light of the prophetic teaching, which had certainly taken time to permeate the nation's religion. Nothing has come to us through the editorial sieve that could not be given a plausibly orthodox meaning according to post-exilic standards. Thus the psalms as a whole must still be treated as a post-exilic book. This might be confirmed by the subtler test of psychological usage, hardly to be simulated; the word "spirit," for example, is used of man in the psalms with psychical predicates in a way not found elsewhere in the pre-exilic literature of the Old Testament.

As for the relation of the psalms to the similar compositions of Babylonia, we find many interesting and instructive parallels of form, language and thought, but not less striking differences which must not be ignored, due to the far higher religious standpoint of Israel, and the suppression of magic in the interests of religion (though some of the older forms and expressions doubtless continued to be used). The resemblances may be partly explained by the independent development of closely related peoples (G. R. Driver, in *The Psalmists*, pp. 109 seq.), and partly by the entrance of the Hebrews into a land dominated by Mesopotamian influence (as the Tell el-Amarna tablets prove); but it is quite possible that there was some direct influence also, even prior to the exile. This possibility also applies, but in a much smaller degree, to the influence of Egypt; there is the well-known parallelism of the "Hymn to the Sun" of Ikhnaton with Ps. civ., which matches the close relation of the "Teaching of Amenophis" to our canonical Book of Proverbs. But whatever contributions came directly or indirectly from without, there is good ground for holding that in all that really matters the Psalter is a native product, and that to Israel still belongs the undiminished glory of carrying the religious lyric to its highest point of development.

Any attempt to characterize the teaching of this anthology must be made with the full consciousness of its variety of authorship, purpose and date. It is the most varied of the books of the Old Testament, and offers many unreconciled antitheses. Devotion to the sacrificial system and ritual of the temple is found side by side with prophetic protests against the popular reliance on them. Faith in the exact retributive justice of God within the limits of earthly life does not exclude the perplexities of those who could not be blind to the sufferings of the innocent and the prosperity of the wicked. The nationalistic demand for supremacy over, and even for vengeance on, enemies is neighbour to the universalistic sense of Israel's missionary stewardship for all the world. The recoil from the shadow of death, which leaves no light of Yahweh's presence beyond the grave, does not wholly prevent the conviction of a fellowship with God that virtually conquers death. But certain comprehensive truths may be usefully remembered in the study of the Psalms.

The central religious principle is, of course, the idea of God. The monotheism is sometimes implicit rather than explicit, for there are a number of references to other "gods" (lxxxvi. 8, lxxxix. 6, xcv. 3, etc.); yet these are perhaps no more than the survival of ancient phraseology. The general standpoint of the psalms is that of an exalted and imageless monotheism (cxv.), unlimited in power, universal in range. The most prominent attributes of Yahweh are "lovingkindness" (chesedh) and "righteousness" (*ṣedhek, ṣedhakah*), combined in cxlv. 17, expanded in xxxvi. 6–11; they are complementary, not antithetical. To these must be added the mystery and majesty of God—the quality which we have come to call "the numinous," best expressed in Ps. xc.; the wrath of God cannot be measured by human norms of right and wrong. This great God is omnipresent (cxxxix. 7–12), and eternal (xc. 1, 2; cii. 26–28). Around this great and exalted personal centre in heaven, but on the lower level of earth, we may trace a series of concentric circles in nature, history, human society, the temple, narrowing at last to the personal religion in which man can look right up to God. Nature is directly controlled in all its detail by God, and no "laws of nature" come between Him and His creation. The cosmology of the "nature" psalms (viii., xix. 1–6, xxix., lxv., civ., cxlviii.) is crude; man walks on a flat earth, with the "shades" of Sheol beneath his feet, and Yahweh with His angels above his head, on the solid firmament; round about the earth is the primaeval ocean and its monsters, overcome long since by Yahweh's creative power. The great facts which emerge from this primitive setting of man's life are the dignity and glory of his high place (viii.) amid the glories of Yahweh's creation (xix. 1–6) and His universal providence (civ.). The power of the enthroned Yahweh is manifest in the majesty of the thunderstorm which sweeps the earth, whilst in the heavenly palace His angels glorify Him (xxix.).

The peculiar providence of God is, however, best seen in the redemptive history of Israel (lxxxi. 10). At great crises, Yahweh has intervened to save His chosen people (cxiv.). The God of the past (cv., cvi.) will be the God of the future, when His rule shall be proved supreme over all (xlvii., and the other "enthronement" psalms). A prince of the house of David shall be his vicegerent (lxxxix. 3 j seq.; cf. ii., lxxii.) and the final judgment of men shall vindicate His righteousness (i. 5). This is the essential faith of the righteous, the company of those who fear Yahweh and are remembered by Him (cf. Mal. iii. 16), the group to whom we seem to owe the most "spiritual" of the psalms. They live in a society of mingled elements, and have many enemies, without and within, for there are imprecations against unworthy Israelites (lxix., cix.) as well as against the ungodly heathen (cxxxvii., lxxxiii., lix., lviii.), and they may be under unjust rulers (lii.). Their great problem is that which troubled the best minds and hearts of Israel, and found no solution within the Old Testament, *i.e.*, the strange and perplexing prosperity of the wicked and the adversity of the righteous in a world governed by an omnipotent and righteous God (xlix., xxxix., xxxvii., lxxiii.).

The sacramental centre of this faith is the Temple in Jerusalem, to which the exile turns with passionate longing (xlii., xliii.—originally a single psalm). (The devotion to the "Law" came later, except for i., xix. 7–14, cxix.) To the temple come the pilgrims from afar (cxx.–cxxxiv.), full of pride in the holy city (xlviii.), the spiritual home of many proselytes as well as of Jewish exiles (lxxxvii.). The temple is Yahweh's earthly dwelling-place (cxxxii. 13, 14) to which His "guests" may come (xv., xxiv.); its sacrifices (lxvi. 13–1j, cxvi. 13) and processions (lxviii. 24–27, cxviii., xxvi. 6j mark supreme moments of religious experience. This is the normal attitude of the Psalmists towards the temple; but the emphasis of the Book is prophetic rather than priestly, and this finds utterance sometimes in the contrast of "spiritual" religion with external rites (xl., l., li., except for the added verses, li. 18, 19). The personal religion of the psalmists is marked by trust in Yahweh based on history and experience (xvi., xxiii., xci., ciii.), by the consciousness of "righteousness" (xviii. 20–24), not divorced from fundamental ethical qualities (xv., xxiv., ci., l.), by the awakening to a sense of sin and of the need of forgiveness, usually, it would seem, through misfortune, sickness, the fear of death (xxxii., li., cxxx.), and in the highest examples, by a victorious conviction of fellowship with God (lxxiii. 23–26) which even death will not be able to break. This last is the more noteworthy, because there does not seem to be either here or elsewhere in the psalms any explicit teaching of immortality or resurrection (some have found the hope in xvi., xvii., xlix.).

Such is the relatively simple faith of the most influential book of the Old Testament, which has claimed so supreme a place in the public worship and private devotion of Jew and Christian. Its magical secret lies in its simple and concrete expression of universal religious experience. Its value is altogether independent of our enquiries into its sources; indeed, it has won its place by its lowly submissiveness to reinterpretation in order to meet the ever-changing needs of the unchanging human heart.

PSALTERY, PSALTERION or SAWTRIE, an ancient stringed instrument twanged by fingers or plectrum, and mentioned many times in the English Bible, though precisely what form of instrument is implied by these various references is doubtful. In its mediaeval form it consisted of a shallow box sound chest over which strings varying in number were stretched, being fastened at one side to pegs and at the other to wrest pins. In the early rectangular form the strings, numbering 10 to 12, were of uniform length, the pitch being varied by their thickness and tension. When the triangular form succeeded the rectangular, the stringing was that of the harp, pitch being dependent on the length. The psaltery was held in an upright position against the chest of the performer, until, owing to the increasing number of strings, it grew too cumbersome, when it was placed flat on a table or on the knee. From the psaltery descended the spinet and the harpsichord.

THE PSALTERY, A MEDIAEVAL INSTRUMENT PLAYED BY FINGERS OR PLECTRUM

PSAMMETICHUS (Egypt. PSAMMETK), the name of three kings of the Saite, 26th dynasty, called by Herodotus respectively Psammetichus, Psammis and Psammenitus. The first of these is generally considered to be the founder of the dynasty; Manetho, however, carries it back through three or four predecessors who ruled at Sais as petty kings under the 25th, Ethiopian, dynasty. It is known from cuneiform texts that 20 local princelings were appointed by Esar Haddon and confirmed by Assur-bani-pal to govern Egypt. Kiku (Necho), father of Psammetichus, was the chief of these kinglets, but they seem to have been quite unable to hold the Egyptians to the hated Assyrians against the more sympathetic Ethiopians. The labyrinth built by a king of the 12th dynasty is ascribed by Herodotus to the Dodecarchy, or rule of 12, which must represent this combination of rulers. If the dynasties were numbered thus before Manetho, the numeral may be the cause of Herodotus' confusion.

After his father's death Psammetichus I (664–610 B.C.) was able to defy the Assyrians and the Ethiopians, and during a long reign marked by intimate relations with the Greeks restored the prosperity of Egypt. The short reign of the second Psammetichus (594–588 B.C.) is noteworthy for the graffiti of his Greek, Phoenician and Carian mercenaries at Abu Simbel. The third of the name was the unfortunate prince whose reign terminated after six months in the Persian conquest of Egypt (525 B.C.). It has been conjectured that the family of the Psammetichi was of Libyan origin; on the other hand, some would recognize Negro features in a portrait of Psammetichus I, which might connect him with the Ethiopian rulers. (F. LL. G.)

PSELLUS, MICHAEL CONSTANTINE (1018–after 1078), Byzantine author, scholar and statesman, whose writings are of fundamental importance for the understanding of his period, was born in Constantinople. After an excellent education, he became a civil servant; he then entered the imperial secretariat and under Constantine IX (1042–55) he was prominent at court. He was also distinguished for his scholarship and in 1045 became head of the faculty of philosophy in the reorganized University of Constantinople. After an unsuccessful retreat in 1055 to a monastery on Mt. Olympus in Bithynia, he returned to public life and was exceedingly influential during the years 1056–78, particularly under the regime of his friends the Ducas, the last of whom, Michael VII, had been his pupil.

His *Chronographia*, a lively and highly individual history based on his own experiences, is an invaluable source. The *Chronographia* was edited with French translation in the Budé series by E. Renauld, 2 vol. (1926–28); English translation by E. R. A. Sewter (1953). Other works were edited in J. P. Migne, *Patrologia Graeca*, vol. 122 (1864); K. N. Sathas, *Bibliotheca medii aevi*, vol. 4–5 (1874–76); E. Kurtz and F. Drexl, 2 vol. (1936–41). The extensive corpus of his works (some unedited) ranges from philosophy and theology to letters, orations, poems and incursions into demonology and Chaldean lore. He has been condemned as a timeserving and unstatesmanlike politician but, apart from the encyclopaedic nature of his knowledge which gained him fame in his own day, he also stands out as a distinguished historian and keen philosopher.

PSEUDO-CODINUS: *see* CODINUS, GEORGIUS.

PSEUDONYM, a false or invented name, particularly the fictitious name under which an author produces his work in order to conceal his identity. The same end is gained by publication without any name, or anonymously. The body of works thus produced either without the author's name or under a fictitious name became known as anonymous and pseudonymous literature. Many books affording a key to the identity of the various writers have been published. Though Fredericus Geisler published a short treatise on the subject entitled *Larva detracta*, etc., in 1669, the chief early work was that of Vincent Placcius (1642–99), whose *Theatrum anonymorum et pseudonymorum* was published in 1708 edited by L. F. Vischer; supplements were published in 1711 and 1740.

Other works included *Dictionnaire des ouvrages anonymes et pseudonymes* (1806–09), by Antoine A. Barbier; *Deutsches Anonymen-Lexikon, 1501–1850* (1902–07) and *Deutsches Pseudonymen-Lexikon* (1906), by M. Holzmann and H. Bohatta.

In English, R. Thomas' *Handbook of Fictitious Names* appeared in 1868. *Dictionary of the Anonymous and Pseudonymous Literature of Great Britain*, by S. Halkett and J. Laing, was revised and published posthumously in four volumes in 1882–84. Other English works were W. Cushing, *Initials and Pseudonyms*, 2nd series (1886, 1888), and *Anonyms* (1890); and F. Marchmont, *A Concise Handbook of Literature issued under Pseudonyms or Initials* (1896).

PSICHARI, ERNEST (1883–1914), French author, grandson of Ernest Renan, and son of Jean Psichari, director of studies at the École des Hautes Etudes in Paris, was killed on the western front on Aug. 22, 1914. He was one of the leaders of the young generation before World War I who sought to "rationalize" war and the defense of their country; he sought to provide the psychological basis for heroic action.

His work is that of an intellectual who must justify the "great sacrifice." In the year before World War I *L'Appel des armes* had a powerful moral effect among young intellectuals. It is the story of a captain in the Algerian army who converts to the military ideal the antimilitarist son of an internationalist, who finds mental peace in military obedience.

This was followed by *Les Voix qui crient dans le désert. Le*

Voyage du centurion appeared as the finished form of this work. In 1917 Jean Psichari presented to the Luxembourg library 25.000 volumes on mental subjects, in memory of Ernest.

See Henri Massis, *La Vie d'Ernest Psichari (1916)*; *L.* Aguettant, *Ernest Psichari* (1920); *A.* M. Goichon, *Ernest Psichari* (1925).

PSILOMELANE, an ore of manganese, is one of a group of hydrated manganese oxide minerals, with very similar appearances and properties, which are difficult to distinguish. They frequently occur in hard black botryoidal or stalactitic masses with a smooth surface, hence the name from the Greek *psilos,* "smooth," and *melanos,* "black." However, they may also be soft and earthy, in which case they are known as wad (*q.v.*). They are distinctly crystalline, and not amorphous as once supposed. The name psilomelane was originally applied to material from Schneeberg, Saxony, which has the formula $BaMnMn_8O_{16}(OH)_4$, and should be restricted to this composition. The other manganese minerals of similar appearance are referred to as being of the psilomelane type. See also PYROLUSITE. (L. S. RL.)

PSITTACOSIS, an infectious disease of world-wide distribution, is caused by a virus and is transmitted to man from various birds. The infection has been shown in about 70 different species of birds, but parrots and parakeets (Psittacidae, from which the disease is named)! pigeons, turkeys and a few other species have been the principal sources of human infection.

The disease is also called ornithosis, especially when seen in nonpsittacine birds.

History. — The association between the human disease and sick parrots was first recognized in Europe about 1880, but it was not until 1929–30 that a thorough study of the disease was made. In those years outbreaks of severe cases, attributed to contact with imported parrots, occurred in 12 different countries of Europe and America. During the investigations conducted at that time in Germany, England and the United States, experimental transmission was accomplished and the causative agent was revealed. Strict regulations followed concerning importation of psittacine birds, which doubtlessly reduced the incidence of the disease but did not prevent the intermittent appearance of cases. The infection was later found in domestic stocks of parakeets and pigeons and subsequently in other species. An increase in number of cases in Great Britain and the U.S. appeared in 1952, following relaxation of regulations concerning commerce in psittacine birds and increase in the popularity of parakeets as pets. Infected turkeys have also accounted for many cases. In 1954, a peak year in the U.S., 563 cases were reported, 200 of them related to poultry-dressing plants.

The Disease in Man. — Psittacosis is an acute febrile illness in which some degree of inflammation of the lungs (pneumonitis) occurs, sometimes detectable only by X-ray examination. It tends to be severe in older persons. The duration is two to three weeks, and convalescence often is protracted. Before modern chemotherapeutic drugs were available the case fatality rate was approximately 20%, but penicillin and the tetracycline drugs reduced this figure almost to zero. Diagnosis can be rendered more accurate by examination of specimens of the patient's blood serum taken early in the illness and during the second or third week. A rise in antibody content in the later specimens, detected by the complement fixation test in which inactivated (noninfectious) psittacosis virus is used, confirms the diagnosis.

Virus. — The infectious particle, or elementary body, of psittacosis virus is spherical in shape and is one of the largest of the viruses. being 200–300 $m\mu$ (.0002–.0003 mm. or .000008–.000012 in.) in diameter. Like all viruses, these particles invade tissue cells of the animal they attack, multiply within the cell, eventually destroying it, and are thus released to invade other cells of the same or another host. Unlike most viruses, those causing psittacosis and related infections are susceptible to chemotherapeutic drugs, as indicated above. Viruses of this type, in addition to occurring in birds, have been found in mice, hamsters, cats, opossums, sheep and cattle, but as far as is known these do not infect man. A similar virus that is transmitted from man to man directly is that of lymphogranuloma venereum. The generic name *Miyagawanella* has been suggested for this entire group, commemorating the work of the Japanese scientist Y. Miyagawa on lymphogranuloma venereum. An English bacteriologist, S. P. Bedson, during the 1930s contributed basic information on the psittacosis virus, and, in the U.S., K. F. Meyer made extensive studies over several decades on the epidemiologic aspects of the disease

Transmission and Control. — Psittacine birds apparently acquire the infection in the nestling stage and may become carriers of the virus even though they remain in good health. When such birds are crowded or chilled, as during shipping, or placed under other adverse conditions, the latent infection may be aggravated and become acute. The bird then shows obvious signs of illness and the virus is discharged in excess nasal secretions or in a watery diarrhea. After such infectious material is dried it readily infects other birds or men, in the form of an inhaled dust. When psittacosis occurs in poultry plants it is seen especially in the personnel exposed to dust or feathers. In a few outbreaks transmission from man to man has occurred, especially from a severely ill patient to nursing or medical attendants, but this is exceptional.

Although it has been impossible to control psittacosis completely on a national scale, some parakeet aviaries have been maintained free of infection by scrupulous care in keeping the birds isolated from disease sources and by practising good husbandry. Chemotherapeutic measures also offer promise. To protect himself and his household, the individual bird owner should avoid contact with sick birds, purchase birds if possible only from known healthy stock and strive to keep his pet in sound condition. (F. B. G.)

PSKOV (German. PLESKAU). a town of U.S.S.R. in the Pskov district of the Leningrad oblast, in 57° 48' N.. 28° 22' E., situated on both banks of the Velikaya river, 9 mi. S.E. from Lake Pskov. Pop. (1956 est.) 69,000. The chief part of the town, with its kremlin on a hill, occupies the right bank of the river, to which the ruins of its old walls (built in 1266) descend. The old cathedral in the kremlin has been four times rebuilt since the 12th century; the present edifice (1691–99) contains some very old shrines, and also the graves of the bishops of Pskov and of several Pskov princes. The church of Dmitriy Solunskiy dates originally from the 12th century; others are of the 14th and 15th centuries.

History.—Pskov, formerly the sister republic of Novgorod and one of the oldest cities of Russia, maintained its independence and its free institutions until the 16th century, being thus the last to be brought under the rule of Moscow. It already existed in the time of Rurik (9th century); and Nestor states that in the year 903 Olga, wife of Igor. prince of Novgorod, was brought from Pleskov (*i.e.,* Pskov). The Velikaya valley and river were from a remote antiquity a channel for the trade of the south of Europe with the Baltic coast. Pskov being an important strategic point, its possession was obstinately disputed between the Russians and the Germans and Lithuanians throughout the 11th and 12th centuries. It became in the 12th century a *prigorod* of the Novgorod republic; *i.e.,* a city having its own free institutions, but included in certain respects within the jurisdiction of the metropolis, and compelled in time of war to march against the common enemy. Pskov had, however, its own prince (defensor municipii); and in the second half of the 13th century Prince (Timotheus) Dovmont fortified it so strongly that the town asserted its independence of Novgorod, with which, in 1348, it concluded a treaty wherein the two republics were recognized as equals. Its rule extended over the districts of Pskov, Ostrov, Opochka and Gdov (farther north on the east side of Lake Peipus). The vyeche or council of Pskov was sovereign, the councils of the subordinate towns being supreme in their own municipal affairs. The council was supreme in all affairs of general interest, as well as a supreme court of justice, and the princes were elected by it; these last had to defend the city and levied the taxes. which were assessed by 12 citizens. But while Novgorod constantly showed a tendency to become an oligarchy of the wealthier merchants, Pskov figured as a republic in which the influence of the poorer classes prevailed. Its trading associations, supported by those of the working classes, checked the influence of the wealthier merchants.

Its strong walls and its 40 large and wealthy churches bear testimony to the wealth of the inhabitants, who then numbered about 60.000. As early as the 13th century Pskov was an important station for the trade between Novgorod and Riga. A century later it became a member of the Hanseatic league. Its merchants and trading associations had factories at Narva. Reval and Riga, and exported flax. corn, tallow, skins. tar, pitch, honey and timber for shipbuilding. Silks, woolen stuffs and all kinds of manufactured wares were brought back in exchange. In 1399 the prince of Moscow claimed the privilege of confirming the elected prince of Pskov in his rights; and though, 50 years later, Pskov and Novgorod concluded defensive treaties against Moscow, the poorer classes continued to seek at Moscow protection against the rich.

After the fall of Novgorod (1475) Pskov was taken (1510) by Basil Ivanovich. prince of Moscow, and a *voyvode* or deputy was nominated to govern the city. Moscow, at the end of the 17th century, abolished the last vestiges of self-government at Pskov, which thenceforward fell into rapid decay. Near this city the Teutonic knights inflicted a severe defeat upon the Russians in 1502. Pskov became a stronghold of Russia against Poland, and was besieged (1581) for seven months by Stephen Báthory during the Livonian War. and in 1615 by Gustavus Adolphus of Sweden. Under Peter the Great it became a fortified camp. Under the tsarist regime the province of Pskov extended from Lake Peipus to the sources of the western Dwina, and after the 1917 revolution the province of Pskov, though much diminished, remained an administrative unit. In 1927 it was incorporated in the newly created Leningrad area (*q.v.*).

PSOCOPTERA (CORRODENTIA), an order of insects, the best known of which are book-lice, pale flightless insects about 1 or 2 mm. long, found among old papers, on dusty shelves or in cereals. Outdoor species, called bark lice, are mostly winged and occur on the bark and foliage of trees. sometimes under stones or in ground litter. The outdoor species are not economically important. but book-lice often are a considerable nuisance. Psocid is a general term for any member of the order.

Psocoptera usually are not more than $\frac{1}{4}$ in. long, and the wing venation of flying species is distinctive. Tarsi are two- or three-segmented and cerci are absent; mouth parts are for chewing, with the lacinia of the maxilla usually elongate and chisellike. Metamorphosis is gradual, and occasionally the gregarious nymphs of outdoor species form conspicuous clusters on tree trunks. Psocids eat molds, cereals and organic debris.

About 150 species of psocids have been found in the United States, but neither this figure nor the estimate of 1,250 described world species approaches the total number that exist, because the group. now arranged in over 20 families, has been rather neglected by entomologists.

See also INSECT.

See D. J. Borror and D. M. DeLong, *An Introduction to the Study of Insects,* ch. xiv, pp. 169–179 (1954). (A. B. GU.)

PSORIASIS. — Psoriasis is a moderately common disease of the skin, of great chronicity. It may begin at any age, and a familial history of psoriasis is common. Individuals affected by the disease are ordinarily otherwise healthy; the only exception to this is arthritis in some patients. The lesions of psoriasis are usually characteristic. consisting of sharply outlined dull red patches of varying size, with thickening of the skin, and a heavy rough scale which is silvery or asbestoslike in colour.

Psoriasis has a characteristic distribution over the body in a majority of cases, involving principally the scalp, the elbows, the front of the knees and the trunk. It does not cause loss of hair. Involvement of the nails is quite common. and this may be mistaken for a ringworm infection. The disease varies a great deal in severity and in many patients it will show periodic flareups. In general, nervous tension will make psoriasis worse. There is no regular relation of the disease to any type of diet. Sunlight is usually very helpful, and a considerable variety of local treatments are effective temporarily. Most of the proprietary medicines sold for the treatment of psoriasis contain organic compounds of mercury or various types of tars. Arsenic internally was formerly used in the treatment of psoriasis. but is now rarely employed. X-ray therapy is used with decreasing frequency; it carries definite risks if used in excess. No infectious agent has ever been isolated regularly from lesions of psoriasis. and there is no evidence that the disease is in the least contagious. Compounds such as cortisone or ACTH have been employed successfully in some patients, but are variable in their effects and are justified only in the most severe cases, particularly those with associated arthritis. (D. M. P.)

PSOROSPERMIASIS, a term formerly applied to infection with any one of several groups of Protozoa. including the Cnidosporidia, Myxosporidia, Gregarinida, Coccidia or Sarcosporidia, all of which have in common a resistant spore or cystic stage, which develops in the intestines, liver, kidneys, ureters, musculature or other tissues of the host. (E, C. F.)

PSYCHE, in Greek mythology. the personification of the human soul. The importance, in Platonic philosophy, of love (in the highest sense) as an agent of the soul's progress leads, in art from the 4th century B.C., to representations, allegorical or playful, of Psyche (generally represented as a winged girl, a relic of the old conception of the soul as a bird or insect) in company with Eros (*q.v.*), usually in amatory scenes. The tale of Cupid and Psyche, in the *Metamorphoses* of Apuleius, is interesting as the only ancient fairy tale which is told as such. In it Psyche, the youngest daughter of a king, arouses the jealousy of Venus, who orders Cupid to inspire her with love for the most despicable of men.

Cupid, however, falls in love with her and carries her off to a secluded spot, where he visits her by night, unseen and unrecognized by her. Persuaded by her sisters that her companion is a hideous monster, and forgetful of his warning, she lights a lamp to look upon him while he is asleep; in her ecstasy at his beauty she lets fall a drop of burning oil upon the face of Cupid, who awakes and disappears. Wandering over the earth in search of him, Psyche falls into the hands of Venus, who forces her to undertake the most difficult tasks. The last and most dangerous of these is to fetch from the world below the box containing the ointment of beauty. She secures the box, but on her way back opens it and is stupefied by the vapour. She is only restored to her senses by Cupid, at whose entreaty Jupiter makes her immortal and bestows her in marriage upon her lover.

See O. Waser in W. Roscher, *Lexikon,* iii, 2327 *et seq.* (3924) ; *L.* C. Purser, ***The*** *Story of Cupid and Psyche* (1910).

PSYCHIATRY is the branch of medicine which specializes in the study and treatment of illnesses causing various kinds of behavioural disturbances. These disorders include: disturbances of mood, as seen in depressive states and anxiety; excessive or inadequate affective responses or inadequate social control of emotions; conditions characterized by disorganized thinking and perception, such as phobias, obsessions, delusions, hallucinations; transient as well as irreversible impairments in intellectual activities; and certain physical disturbances which simulate diseases associated with malfunctioning of body organs.

Psychoanalysis, to be distinguished from psychiatry, is both a particular theory of personality development and functioning and a particular method of psychotherapy used in psychiatry. Strictly defined, psychology is the scientific study of the mind; it is not a medical specialty. *(See* PSYCHOANALYSIS ; PSYCHOLOGY; PSYCHOTHERAPY.)

Questions of symptomatology and diagnosis, and those concerning etiology, treatment and prevention, are the problems of psychiatry. Sometimes the sufferer's condition is manifested in behaviour that is so grossly inappropriate that the existence of an illness is easily recognized. At other times, the difficulty may be known only to the sufferer. Irrational violence or the striking immobility of severely depressed persons are obvious pathological conditions. On the other hand. states of apprehension, obsessive thoughts and unreasonable fears may exist for prolonged periods without recognition. In the latter instance, the conditions become known only through the subjective reports of the ill. or when the symptoms intrude upon ordinary routine activities and force a general awareness of a mental illness.

In explaining the genesis of behavioural disorders, modern psychiatry emphasizes the patient's genetic predisposition; the influence of anatomical, physiological and biochemical processes; and the determining effect upon the nervous system of the recording of the person's ongoing series of life experiences, beginning with the prenatal period and extending through childhood experiences in the family to the environmental and cultural pressures. To the psychiatrist, the sum of these factors determines personality. A human being's personality is recognized as his characteristically recurring patterns of behaviour in response to life experiences, to and with other persons. (See PERSONALITY.)

This article is organized as follows:

I. HISTORY

A. EARLY HISTORY

Many modern scientific concepts regarding psychiatric disorders are derived from the historical past. References to mental disorders in early Egyptian. Indian, Greek and Roman writings show great insight, but for the most part the philosophers, physicians and theologians who contemplated and wrote about the problems of human behaviour regarded psychiatric illnesses as a reflection of the displeasure of the gods or as evidence of demoniac possession. Only a rare few realized that behavioural problems were not separable from physical illnesses and that the sufferers should be treated humanely rather than exorcised, banished or punished. Although progress was slow in banishing the belief in supernatural causes, as early as 860 B.c., some Greek priests supplemented their incantations and exorcisms for the mentally disturbed with recommendations for kindness and physical and recreational activities such as walking, riding and listening to soothing music.

A significant advance toward scientific understanding of mental disorders occurred in the 6th century B.C. when the Greek healers turned to observation and interest in experimentation. At this time: Alcmaeon made the first dissection of the human body and observed the connection of sense organs, such as the eye and the ear, to the brain. Searching for the seat of reason and of the soul, Alcmaeon decided that they were located in the brain.

Shortly after Alcmaeon reported on his experimentation, the problem of mental disorders gained the attention of Greek philosophers. Empedocles spoke about the significance of emotions and the possibility that love and hate were the fundamental sources of change in behaviour. Plato incorporated concepts of Empedocles in his consideration of the role of Eros in the personal and social life of man. This medical and philosophical thought was not recaptured until Sigmund Freud (*q.v.*) presented his theories and clinical studies in the late 19th century.

Hippocrates (*q.v.*), a sensitive! perceptive observer of clinical phenomena, described many mental disorders found in modern times, including psychosis after pregnancy, delirious states associated with infections such as tuberculosis and malaria and the acute confusion which follows severe hemorrhage. He flatly rejected the idea that mental disturbances were caused by the intervention of the gods or by possession. He also took an unequivocal position concerning the legal rights and responsibilities of the mentally disturbed. Athenian lam recognized the rights of the mentally disturbed in civil affairs, but gave no special consideration to the mentally disturbed when they became involved in capital crimes. Through the vast respect accorded him, Hippocrates was able to provide this consideration. In the Athenian courts, if it could be proved that the person on trial suffered from a condition which Hippocrates designated as paranoia, the court would appoint a guardian for the accused.

Hippocrates classified mental disorders into three categories: mania, melancholia and phrenetis. His descriptions reveal many of the classical symptoms which are recognized in epilepsy, mania, melancholia and paranoia. To Hippocrates, hysteria mas a mental disease, but it was limited to women. As he saw it, hysteria was caused by the wandering of the uterus through the body and symbolized the body's pining for the production of a child; he thought that marriage was the best remedy for hysteria.

Hippocrates and his followers were the first group of physicians who approached mental illness scientifically. Their understanding of mental disorders emphasized natural causes, clinical observations and brain pathology. They were the first to describe and examine empirically the clinical materials of psychiatry. In establishing a movement toward the biological study of mental illness, Hippocrates challenged and won people away from the theological interpretations. Many physicians after Hippocrates contributed substantially to psychiatry. notably Asclepiades, Celsus, Aretaeus and Soranus (*qq.v.*). Soranus, in his instructions for the treatment of disturbed patients, prescribed the use of tact and discretion; he stated that the patient's attention must be tactfully directed to his difficulties; he advised the physician to observe the mental patient's tolerance to sedation and warned of the need to supervise the patient through his period of convalescence.

The high point in medical thought of this period was reached in the work of the Roman physician Galen (2nd century A.D.), who, through a scientific approach to the study of the anatomy of the nervous system. drew attention to the role of the brain in mental functioning. He discovered that the existence of a symptom did not necessarily mean that the organ or the part of the body which expressed the symptom was the affected portion. As a consequence of his experimental work and his studies of mental disorders, Galen developed a theory of the rational soul as divided into an external and an internal part. The external part consisted of the five senses. The soul's internal functions were imagination, judgment, perception and movement. On the basis of his experimentation, Galen concluded, as Plato had thought and Aristotle had denied, that the brain, not the heart, was the seat of the soul. His observations had shown him that compression of the heart affected only the function of the arteries. Galen rejected the idea that hysteria resulted from the wandering of the uterus about the body, but he considered it to be caused by a local engorgement of the uterus.

In the period following the death of Galen, primitive thinking about mental illness re-emerged. Witchcraft and demonology dominated medical thought of medieval times and continued to exert an influence into the 19th century. However, beginning with the 16th century, signs of scientific questioning began to appear again. Among the physicians who challenged demoniacal explanations of mental disturbances were Paracelsus, Agrippa and Johann Weyer. Beginning with Francis Bacon in the 17th century, a number of philosophers, recognizing that the functions of the mind were a part of their concern with the natural order of the universe, began to exert an effect on medical thought. Notable among those who contributed to the modern science of psychopathology were Descartes, Hobbes, Locke, Condillac and Hume.

B. 19th Century

1. Humanitarian Movement. — Paralleling the reappearance of scientific questioning and the development of medical science was an improvement in the public attitude toward the mentally ill. These combined factors resulted in the establishment of mental hospitals and in more humane treatment methods. The humanitarian movement received its initial impetus through the efforts of the great French physician Philippe Pinel (*q.v.*), who after the French Revolution was placed in charge of the Bicêtre, the hospital for the mentally ill in Paris. Under Pinel's supervision, a completely new approach to the handling of mental patients, as well as a new concept of mental hospital operation, was introduced. Chains and shackles were removed from the patients. In place of dungeons, the patients were provided with sunny rooms and permitted to exercise on the hospital grounds. The reforms which Pinel sponsored and their gratifying results placed France in the forefront of psychiatry.

In England, several generations of the Tuke (*q.v.*) family supported the humanitarian movement. Through the efforts of William Tuke and his son Henry, aided by the Society of Friends, York Retreat was opened (1796) for the humane care of the mentally ill. In the United States, an energetic and courageous Kew England woman, Dorothea Dix (*q.v.*), between 1841 and 1881 carried on a campaign to arouse the people and the legislators to an anareness of the inhumanities which prevailed in all of the country's mental hospitals. Not only was Miss Dix the leading spirit in improving the care of mentally ill in the United States, but she also helped in promoting the reform movement in Canada and in Scotland. The modern mental hospital in North America and in western Europe aims at providing a friendly, encouraging, therapeutic atmosphere. The hospital staff attempts to provide a variety of activities designed to help the patients regain mental health. While there is still a large gap between practice and theory in many hospitals, the modern mental hospital is moving in the direction of the "open-door" policies initiated in England. The term open-door symbolizes the trend away from the locked ward toward freedom of the patient to move about the hospital and recognition of the therapeutic effects of a sheltered, supportive environment where all the staff help the patients and patients help each other to health. (See also Hospital.)

2. Biological Movement. — Along with humanitarian reform in hospital practice and treatment methods during the late 18th and the 19th centuries, there was a resurgence of medical and scientific interest in psychiatric theory and practice. Great strides were made during this period in establishing a scientific basis for the study of mental disorders. A long series of observations by brilliant clinicians in France. Germany and England culminated in Emil Rraepelin's (*q.v.*) classification of mental disorder. Kraepelin's integration of a mass of descriptive clinical data into meaningful symptom categories was a major contribution to psychiatry, and his classification system served as the basis of all subsequent nosologies.

Rapid advances in studies of anatomy, psychology, pathology, chemistry and bacteriology led to the expectation of discovering specific brain lesions for the various forms of mental disease. While this search did not attain the results desired, the scientific emphasis was productive in that it did elucidate the gross and microscopic pathology of many brain disorders which produce psychiatric disability. In addition. the research effort illuminated the role of infectious and metabolic disturbances in the production of mental diseases. One of the notable achievements of this period was the discovery of Treponema *pallidum* (Spirochaeta *pallida*), the organism causing syphilis, as the basis of the brain pathology producing general paresis (*q.v.*). Other discoveries were the causation of pellagra psychosis in a vitamin deficiency and the recognition of delirious reactions caused by malnutrition and pernicious anemia. Significant observations also were made on the cellular changes in the brain which accompany the presenile and senile psychoses, and a number of pathological conditions associated with mental retardation were identified. The advances made in the 20th century toward establishing the biochemical correlates of mental disturbances and in developing the tranquilizing agents represent the moving fringe of the earlier search for etiological specificity in disordered body organs and systems.

3. Psychological Movement. — Certain of the major psychotic states, notably schizophrenia and manic-depressive reactions, frustrated the effort to find in cellular pathology the principal causative agent of mental disease. Other explanations were needed for the many puzzling aspects of these conditions, and these explanations emerged in a wave of psychological viewpoints, beginning with the study of hypnosis in relation to hysteria. The arrival of Franz Anton Mesmer (*q.v.*) in Paris dated the beginning of broad scientific interest in psychological factors as influencing or altering human behaviour. Advancing the belief that the distribution of a universal magnetic fluid in the body was the basis of health and disease, Mesmer opened a clinic in Paris where he treated all kinds of diseases, including hysterical paralysis, in a ceremonial setting in which he "magnetized" the patients by applying to their bodies iron rods treated with various chemicals. Mesmer's therapy was a group method of treatment; he moved among his patients touching each of them with his hand and waving a wand over them.

Mesmer's own personal success was short-lived, and he was branded a charlatan. His work was studied by a committee of the Academy of Sciences whose members included Jean Sylvan Bailly, Benjamin Franklin, Lavoisier and LeRoi. The committee was unable to find any evidence of animal magnetic fluids, but it was impressed with the results produced by Mesmer's touching of the patients. It advised against the use of mesmerism and warned of potential dangers from harmful imitations. Outside France the recommendations of the academy went unheeded, and mesmerism spread throughout the world. A French magnetizer, Charles Poyen, introduced séances of magnetism in the United States from which the watchmaker P. P. Quimby (*q.v.*) obtained his first conceptions of faith healing and successfully treated Mary Baker Eddy for hysterical paralysis. Use of mesmerism as an anesthetic during surgery was advocated by several physicians, but this practice passed quickly with the introduction of nitrous oxide and chloroform.

The first physician to be attracted by scientific curiosity to the serious study of mesmerism was the English surgeon James Braid, who provided a descriptive formulation of the condition and introduced the term hypnotism. After Braid, the scientific study of hypnotism lagged until a French country doctor, A. A. Liébault, resumed interest in the subject and learned to use hypnosis for the induction of sleep. Liébault subsequently made wide use of hypnotism in his medical practice, and he also taught the technique to the French physician Hippolyte Bernheim, the English neurologist J. M. Bramwell and the renowned French neurologist Jean Martin Charcot (*q.v.*).

Questioning the view that psychological factors could cause hysteria, Charcot conducted, at the Sâlpetrière hospital in Paris, an extensive and detailed study designed to determine the organic factors associated with the condition. On Feb. 13, 1882, Charcot presented a report of his findings to the Academy of Sciences. He convinced the academy members that the phenomena of hypnotism were manifestations of abnormality and that the characteristics of the hypnotic state could be observed only in patients with hysteria. The same academy that earlier had condemned research on animal magnetism was thus won to a new point of view. Charcot's success prepared the way for the harvest of psychological insights that followed. Among his many students was Freud.

Charcot's views were not accepted by all French physicians, however. Bernheim, who was professor of medicine at Nancy, vigorously challenged Charcot's conclusion, maintaining that the phenomena observed at the Sâlpetrière took place only when conditions of suggestion were set up by the hypnotist. He stressed the study of the process of suggestion and the characteristics of suggestibility, and rightly claimed that the latter were not restricted to hysterical persons. Bernheim's work, apart from pro-

viding a new perspective on hypnosis, had other implications; some psychiatrists have regarded it as the first attempt to evolve a general understanding of human behaviour. Developing out of his studies, for example, were new questions concerning, the legal responsibility of criminals and the causes of criminal behaviour; Bernheim, by advancing the belief that mechanisms of suggestion underlay the endless variety of normal and abnormal behaviour, chailenged the concept that the will was the agent of crime and evil. Along with Charcot, Bernheim put to final rest the persisting concern with demoniac possession.

Pierre Janet (q.v.) also studied hysteria and furthered rhe acceptance of psychological causation. Recognizing the neurotic components of hysteria (fixed ideas and inner conflict with reality), Janet insisted upon psychological treatment for the condition. His psychotherapy was founded primarily on the use of persuasion and of techniques for altering the patient's environment. The work with hypnotism and hysteria opened the door for further recognition of the psychoneuroses. (See also HYPNOSIS; *HESTERIA.)*

C. MODERN SCHOOLS

Freud took the first steps toward providing the theoretical structure upon which much of modern psychiatry rests. Adoli Meyer (q.v.) also played a prominent role in the development of modern psychiatry through his pluralistic and interactional concepts of human behaviour; he drew attention to the multiple biological, psychological and social factors that influence personality. Both Freud and Meyer were greatly aided in the construction of their theories by knowledge of the work of the great English theoretical neurologist John Hughlings Jackson (q.v.).

Drawing from the genius of Charles Darwin and Herbert Spencer, Jackson set forth an evolutionary theory to explain the function and development of the nervous system. In the development of his theory, Jackson drew from his extensive and careful clinical observations of epilepsy and other diseases of the brain. He concluded that the functions of the nervous system were integrated at progressively more complex levels, with mentation, the highest level of iunction, located within the cerebral cortex. Jackson viewed the symptoms accompanying impaired brain function as representing both the disappearance oi the most recently acquired functions of the brain, and the reappearance oi earlier and more primitive functions that had become submerged during the evolutionary process. According to Jackson, when injury to the brain produced a permanent defect in the functioning of the nervous system, in addition to symptoms caused by loss of function and symptoms representing re-emergence of more primitive functions, the organism also produces another type of symptom to compensate or substitute for the loss. Jackson's theoretical position inherently postulates that the understanding of any behavioural disturbance is dependent upon knowledge of the progressive development of a particular type of behaviour in a given organism as well as knowledge of the presentation of such behaviour in other living species. Such assumptions are basic ior both the psychoanalyst and psychobiologist.

1. *Psychobiological School.— The psychobiological school of psychiatry, established by Meyer represents in broad outline the theoretical structure of the general field of modern psychiatry. Meyer, who moved to the United States in 1892 from Switzerland, received his training in Switzerland and in other countries of Europe; his training in many ways paralleled that of Freud. Throughout his career, Meyer emphasized that the understanding of human processes and the problems of human behaviour lie in the utilization of knowledge from biology, psychology and sociology. The explanation of the total personality requires study of the physical attributes of the individual as well as the many social, cultural and emotional influences to which he has been exposed. Meyer stressed the importance of early parental influences in the development of the personality of the child and conceived of mental disturbances as progressive habit formations. The techniques he developed for psychiatric examination are the basis of all those used in English-speaking countries. Meyer insisted that understanding of maladaptive behaviour required a comprehensive study of the life history of the individual, tracing the development of the personality through each progressive and unfolding stage to the present life situation. To Meyer, the individual was both a product and a victim of his life experiences. Meyer emphasized that each individual personality had its assets and its liabilities. The existence of faulty habit patterns implied possibilities of teaching healthy ones. To the psychiatrist he appealed for careful study of the development of symptoms, and cautioned that symptoms should not be attributed to a, specific cause. Meyer's orientation departed markedly from that of theorists and practitioners who explained mental phenomena solely on a physical basis.*

The weakness of Meyer's psychiatry lies in its failure to work through the study of intrapsychic processes and their origin in family life; recognition of the importance of these forces represents some of the most significant thought of the psychoanalytic school. The psychobiologists emphasize that psychiatric disabilities are reactions rather than disease processes with established courses.

2. *Psychoanalytic School.— The psychoanalytic movement originated in the perceptions and meticulous clinical observations of Freud. After studying with Charcot, Freud returned to Vienna, where he was associated with Josef Breuer in studies of neurotic patients under hypnosis. Freud and Breuer observed that their patients tended to relive earlier life experiences, which could be associated with the symptomatic expression of the illness. When the sources of the patients' ideas and impulses were brought into consciousness during the hypnotic state, the patients showed improvement. Although the collaboration was proceeding well, Breuer became disturbed by the responses which the patients made to him (a phenomenon later defined by Freud as the transference relationship) and discontinued the study; Freud pursued it alone.*

Observing that most of his patients talked freely without being under hypnosis. Freud evolved the technique of free association (see ASSOCIATION, MENTAL). *In treatment! he advised the patient to speak freely and to say anything that came into his mind, without regard to its assumed relevancy or propriety. Noting that patients sometimes had difficulty in making free associations, Freud concluded that certain painiul, anxiety-ridden (traumatic) experiences were repressed from conscious awareness. Freud noted that in the majority of the patients seen during his early practice the events most frequently repressed were concerned with disturbing sexual experiences. Thus he hypothesized that anxiety was a consequence of the repressed energy (libido) attached to sexuality; the repressed energy took expression in various symptoms that served as psychological deiensive mechanisms.*

Freud later modified his concept of anxiety. His new concept regarded anxiety as the emotion generated by the threat of some fearfuloccurrence or of impending danger. In later years, Karen Horney (q.v.) and other psychiatrists extended Freud's concept of a threatening event leading to the arousal of the anxiety. The more recent theories of anxiety included not merely feelings of fear, guilt and shame consequent to sexual fantasies that the person regards as reprehensible; anxiety is conceived also as resulting from the arousal of fantasies of aggression and hostility and from fears of loneliness caused by separation from a person on whom the sufferer is dependent.

Freud's free-association technique provided him with a tool for studying the meanings of dreams, slips of the tongue, forgetfulness and other mistakes and errors in everyday life. From these investigations he was led to a new conception of the structure of personality: the id, ego and superego. (1) The id is the reservoir of drives and impulses derived from the genetic background and concerned with the preservation and propagation of life. Freud regarded the drives resting in the id as the prime sources of the sexuality and aggressive impulses that are needed to perpetuate the race and to satisfy the biological needs ior food, water, oxygen and warmth. The impulses of the id are seen as operativ beyond conscious awareness. (2) The ego (q.v.), in contrast to the id, operates in the conscious and preconscious levels of awareness. It is the portion of the personality concerned with perception, cognition and executive actions. (3) The third portion of the personality structure, Freud called the superego. In this rests the individual's accumulated ideals and values and the mores of his family and society; the superego serves as a censor on the ego functions.

In the Freudian framework, conflicts among the three structures of the personality are repressed and lead to the arousal of anxiety. The person is protected from experiencing his anxiety directly by the development of various psychological defensive mechanisms. The defensive mechanisms (described in the article DEFENSE MECHANISMS) are adaptive mechanisms learned through the family and the cultural influences to which the growing child is exposed. They become pathological when they interfere with the capacity of the adult to pursue the satisfactions of living in a society. The existence of these patterns of adaptation or mechanisms of defense are quantitatively but not qualitatively different in the psychotic and neurotic states.

One of Freud's fruitful contributions was his concept of transference. In the course of his work with his patients, Freud became aware of the deep attachments they formed for him. Learning that the patients of other analysts reacted similarly. he concluded that these emotional attachments represented a repetition of the relationship the patient previously had with his parents or their substitutes. The love or hatred which the patient felt for his parents and which he unconsciously projected to the analyst influenced the patient's capacity to make free associations. By objective treatment of these responses and the resistances they evoked, as well as by bringing the patient to analyze the origin of his feelings, Freud concluded that the analysis of the transference and the patient's resistance to its analysis were the keystones of psychoanalytic therapy. Psychoanalytic therapy contrasts with all other forms of psychotherapy in its emphasis on transference. Recognition of the transference relationship has been of major importance to the entire field of psychiatry, however, and to medicine generally.

Freud described the development of personality as a psychosexual evolution that begins at birth and continues through childhood. In the framework of Freud's libido theory, the personality develops through a series of stages: oral, anal, urethral, oedipal and genital. The implication of these stages to personality development is that various body zones have the capacity for pleasurable sensation. As the child grows, the centres of body gratification pass progressively from one area to another. See also PSYCHOANALYSIS.

3. Interpersonal Schools.—The U.S. psychoanalyst Harry Stack Sullivan emphasized the careful study of the interaction between the developing child and his parents and his later relations with others as providing a more significant operational method of understanding human behaviour than that of the libido theory. Sullivan's conceptions, which represent a blend of psychoanalysis and psychobiology are represented in the interpersonal school of psychiatry.

4. Psychosomatic Medicine.—The term psychosomatic medicine does not properly refer to a school in psychiatry; rather it describes the directed interest of a growing group of psychiatrists who, in close collaboration with other colleagues in medicine, are concerned with the study of reactions to anxiety as expressed through physiologic disturbances. In these instances responses of bodily organs rather than inappropriate symbolic behaviour are the defenses against threat. Psychosomatic disorders comprise not only the "organ neuroses" noted in early psychiatric classifications but also many other physiologic disturbances known to be precipitated by emotional stress. Bodily reactions to stress take expression in cardiovascular disorders: respiratory ailments such as certain forms of asthma and attacks of hyperventilation; gastrointestinal disturbances leading to belching, flatulence, anorexia, obesity, constipation and diarrhea; migraine and tension headaches; pelvic pain; dysmenorrhea; dyspareunia (in women, difficult or painful coitus); and impotence and frigidity. Psychosomaticists also study and treat the stress-induced responses contributing to modifications of the diabetic metabolism, the neurodermatoses, gastric and duodenal ulcers and ulcerative colitis.

Psychosomatic medicine is concerned not only with describing the nature of conflict- or stress-induced physiologic disturbances but also with defining the conditions under which disturbances of internal organs take place. Much emphasis is placed on the fact that emotional problems aggravate all illness and that denial of the existence of an emotional disturbance provokes greater disability.

In determining proper treatment, the psychosomaticist is interested in learning the kinds of situations and thoughts that produce personality disturbances. This knowledge is essential to understanding and preventing many conditions, such as the hallucinations and delusions that some patients have when they are deprived of sight during cataract operations. The gynecologist and obstetrician seek information about the patient's feelings concerning contraceptive practices. artificial insemination, therapeutic abortion and other emotionally laden areas of medicine. The surgeon can be assisted by knowledge of the patient's fears of mutilation or disfigurement; a patient's negative response during convalescence or unwillingness to undertake rehabilitative measures may be a consequence of his emotional attitudes to physical illness. All these conditions, as well as many others, require the attention of either a psychiatrist working in the medical service of a hospital or with a group of physicians who have understanding of psychosomatic interaction.

II. DIAGNOSIS AND CLASSIFICATION OF MENTAL DISORDERS

A. DIAGNOSIS

The psychiatric diagnosis is based on examination of the patient and history of his illness. Information is obtained concerning possible hereditary influences, the patient's physical maturation and his emotional and social development. taking into account experiences in both the family and community environment. Physical as well as neurological examinations are made and, when indicated, supplemented by psychological tests and other special examinations such as electroencephalographic or biochemical and serological tests. Together these procedures provide data upon which the psychiatrist makes his diagnosis and formulates the determinative factors that explain the reaction patterns of his patient.

1. Symptomatology.—The actions of the mind cannot be isolated and separated into independent functions, such as the senses, memory, imagination, reason, desire or perception. Nor do the symptoms of mental disorders represent disease of a particular area of the brain. Psychiatric symptoms are expressions of loss or impairment of some function or of failure in development of that function. Loss of function may arise from psychological conflict, or it may occur secondary to a structural disturbance of the brain. For example. a defect in memory could be the consequence of an inherited defect; it could result from a blow to the head or from a growing brain tumour; or it could be the expression of a psychological conflict.

For most psychiatrists, anxiety and its control represent the central problem in psychopathology. Although many stressful experiences and conditions give rise to both fear and anxiety, these emotional reactions are usually differentiated. In general, fear is temporary and is directly related to some external event. Anxiety, in contrast is aroused by any threat to the person's wholeness or his self-concept. It is a pervasive sense of apprehension or tension, the source of which is not consciously recognized. Anxiety has its antecedent in the tensions of early infantile life, and it is aroused in the growing child and in the adult in relation to actual or fantasied interpersonal conflicts.

When fear or anxiety is aroused, the person attempts to adapt and bring about a state of equilibrium or condition without tension. Rightly or wrongly, in actuality or in fantasy, the anxious person expects to receive an unfavourable reaction or estimate of his personal worth or conduct from someone whom he respects or whom he considers to be in authority. Through learning, the expressions of anxiety tend to be disguised or converted into various socially adaptive mechanisms; thus, most people are unaware of anxiety or of the circumstances that provoke it. When the person becomes anxious, however. the anxiety interferes with his capacity to recognize, evaluate and manage properly the situations associated with it. The ability to learn or profit from experience is impaired and capacity to adapt to new situations is limited because only a restricted range of stereotyped and repetitive responses is available.

Hostile and aggressive attitudes, expressed both overtly and covertly, are among the commonest psychiatric symptoms. Such impulses are often repressed in the psychological sense; by reaction formation they may re-emerge as pathologically excessive solicitousness and gentleness. Sometimes the hostile impulses are projected onto other persons; this is a common occurrence with paranoid types, who ascribe their destructive impulses to others. It should be noted that aggressive trends are utilized constructively in certain sports and work.

Pathological disturbances of motility are recognized in the behaviour of hyperactive, nonproductive persons. In these conditions, there may be a tremendous drive to action or to speech, often leading to what is designated as a stream or flight of ideas. Constant repetition of speech or of body movements is an expression of a motility disturbance underlying a compulsive drive. Various mannerisms may occur in which the person grimaces, repeats gestures, shows peculiar types of gait or repeats meaningless words or phrases.

Healthy affect, or the feeling tone of a person's life, is e ident in ability to make controlled and variable responses to daily life experiences. Affectivity penetrates and colours the psychological life and influences the thought and action of every person. Disturbances of affect may lead to disturbances of consciousness, motility and intellect. Affective state can modify a person's judgment and ideas to the extent of distorting his capacity to evaluate reality, and thus it may lead to delusional and hallucinatory thinking.

Pathological elation, a condition seen in the manic behaviour of some psychotics, is an affective state of abnormal confidence and enjoyment. It is also recognized with certain brain syndromes such as general paresis, brain tumours and multiple sclerosis. A less frequently observed pleasurable state is that of ecstasy. The opposite of elation and ecstasy is depression, varying from mild downheartedness and indifference to feelings of despair and hopelessness.

Disturbances in perception and thought are seen in hallucinations and illusions, phobias, obsessional thinking and delusions; in apparently disconnected or loose associations; and in unusual retardation or flights of ideas.

2. Predisposing and Precipitating Factors.—Diagnosis of a psychiatric illness requires consideration of the predisposing and precipitating factors. These include a wide range of situations and conditions: hereditary background; effects of previous illnesses; presence of physical defects; use of drugs such as alcohol and narcotics; existence of nutritional and vitamin deficiencies; vocational, sexual or economic stress; and exposure to particular kinds of privation. Numerous studies have been and are being conducted to determine the precise correlates of mental disorders.

Heredity.—The exact role of heredity in the development of mental and emotional disorders is still a matter of conjecture. Evidence indicates that certain inborn errors of metabolism transmitted through recessive genes underlie some forms of mental retardation. Based on studies of the incidence of schizophrenia among persons with various relationships to a schizophrenic patient, F. J. Kallmann postulated that schizophrenia is transmitted by recessive genes in the form of a predisposition; the schizophrenic reaction develops when a biologically vulnerable person is placed under particular stress. Kallmann reported a concordance rate for schizophrenia of 86% of identical twins and of only 14.5% among fraternal twins and siblings. Criticisms of attributing mental disorders solely to genetic factors rest largely upon the potentiality that parents have for transmitting their emotional difficulties to the next generation through the prolonged social learning that takes place in the course of family living.

Age.—Mental and emotional illnesses tend to make their appearance at certain ages. Adolescence, the middle years and senescence are associated with periods of major physiological changes and psychological stresses involving problems in family, vocational and social roles. During adolescence, the incidence of psychotic reactions rises rapidly. The young person must deal with the stresses arising from sexual maturation, the decisions to be made in the selection of a vocation and the conflicts that ensue in becoming emancipated from parents and assuming independent status. For women, the middle years are particularly critical, as they terminate the opportunity and hope for child bearing. This period also often brings emotional stress with the departure of children from the home and the need for the mother to find satisfactions in new roles and activities. Men at this age often have emotional problems associated with waning sexual energies and failure to attain to aspired goals. In old age, psychiatric disability tends to be precipitated with the mounting limitations of physical incapacities, the loss of satisfactions from work life and the emptiness of the retirement years, the loneliness that comes through the death of old friends and associates and other stresses.

Sexual Factors.—While sexual behaviour in itself does not appear to be a source of mental disturbance; attitudes toward sexual acts and emotions aroused in relation to sexual strivings contribute to psychiatric illness or influence the content of the illness. No sexual act is in itself a cause of mental illness, but the unremitting anxiety and guilt that some persons experience over such acts may be a cause.

Married persons appear to be considerably less susceptible to mental disorders than the widowed,-single and divorced, but marriage in itself will neither cure nor prevent mental illness. In a marriage from which no sense of security is derived, the emotional disturbance of a partner may be aggravated.

No specific psychiatric disability is aroused by pregnancy or the postpartum period. The mental disturbances which occur sometimes with pregnancy and childbirth arise from the emotional significance these events have to the mother. For a woman who is psychologically unprepared and emotionally immature. the bearing of a child may arouse unconscious and repressed conflicts toward her own parents and siblings. Approximately one-half the psychiatric reactions to pregnancy are schizophrenic; rhe other half are manic-depressive or psychoneurotic.

Alcohol.—Alcohol plays an important role in producing mental disease; there is a direct correlation between the amount of alcohol consumed in a community and the incidence of observed alcoholic psychoses. Underlying the habituation to alcohol usually is a primary personality disturbance. The same personality defect occurs with narcotic addiction.

Disease *and Injury*.—In western countries wnere the diet generally is adequate. cerebral impairment resulting from vitamin and other nutritional deficiencies is seen most often as a secondary complication in the elderly or seriously psychotic. Of infectious processes, syphilis was once the source of the most serious disturbances, but general paresis (*q.v.*) caused by syphilis became infrequent after the development of penicillin treatment.

Congenital or acquired physical defects often play an important role in creating personality disturbance. Acceptance of one's body and its acceptance by others represent a nuclear issue in the development of a secure personality. Children born with defects or children whose physical characteristics are unattractive to their parents often develop self-disparaging and self-defeating attitudes. The consequence is frequently a defect in the ability to make social adaptations that may be severe enough to cause psychiatric disability. Adults who suffer a disruption of their body image through injury, surgery or illness also are liable to personality disturbance. Among the commonest precipitants of psychiatric disability are head injuries, which may lead either to organic brain syndromes or to neuroses.

At one time overwork was considered a cause for mental illness. In the modern view the person who works long hours and excessively does so in order to fulfill a personal need—to reduce anxiety or as an outlet for energy or creativity. Work is also a means of maintaining human contacts in an otherwise withdrawn person. When a breakdown does take place in relation to vocation, usually a disruption of some important human relationship is threatened or has taken place. No evidence exists that mental efforts, in the absence of anxiety, produce psychotic or neurotic illness.

B. Classification

Kraepelin's classification system for mental disorders, established in 1883, was in general use until 1917, when the American Psychiatric association introduced the system that became the basis of that recommended in 1948 by the association in the fourth edition of Standard *Nomenclature* of Diseases and Operations. This classification system is more comprehensive and more flexible than the earlier schemes, and it also can be applied to the practice of psychiatry in general hospitals, in out-patient clinics and in private office practice, as well as in mental hospitals. According to this system, mental disturbances may be classified into three general categories representative of physical and psychological pathology: (1) acute and chronic brain disorders caused by or associated with impairments of brain tissue function; (2) mental deficiency; and (3) psychogenic disorders having no clearly defined physical or structural change in the brain. The psychogenic disorders, the major group, comprise the psychoneuroses, the majority of psychotic reactions, psychosomatic disorders and personality disorders.

1. Brain Disorders.—Acute.—Acute brain disorders are organic brain syndromes, usually temporary, from which a patient recovers. Although they generally involve reversible impairments in brain function, some of these disturbances may result in permanent changes in brain tissue, which can be detected by modern micropathological techniques. For the most part, they are the result of a serious disruption of the metabolism of the brain, particularly its capacity to metabolize glucose, its basic energy source. The symptoms of these disorders have been known under the general term of delirium.

Delirious reactions are characterized by varying degrees of disturbances in consciousness and impaired awareness of surroundings. Some persons have the capacity to develop these reactions more readily than others, and the form and content of the delirium tend to be related to the underlying personality and the life experiences. The delirious person may show variable states of cloudiness, bewilderment, periodic somnolence, stupour or, in the deepest stages, coma. Usually, in states of confusion or bewilderment, the sufferer is anxious or apprehensive. Upon being questioned, he shows impairment in his ability to grasp meaning and to comprehend correctly the environment as to place, time or person. He is disoriented. Along with delusions, some persons experience frightening hallucinations (*q.v.*).

Deliria are commonly associated mith febrile illness, toxic states, metabolic disturbances (such as uremia, pellagra or pernicious anemia), states of cardiac decompensation and trauma following head injury. The best known of the acute brain syndromes is the delirium tremens of the alcoholic. See also Delirium.

Chronic.—Chronic brain disorders result from a permanent impairment of cerebral tissue and are characterized particularly by disturbances in memory, judgment and affect (any experience of emotion or feeling). General paresis was once the most prevalent of these conditions, accounting for 8% to 10% of the patients committed to public mental hospitals. The use of penicillin for the treatment of syphilis greatly reduced the incidence of this disease.

At mid-20th century, the most frequently encountered chronic brain disorders are those suffered by large numbers of elderly presenile persons or those that occur as a consequence of cerebral arteriosclerosis in later life. Both these conditions are most prevalent in the U.S. and in western European countries which have expanding aged populations. In the U.S. chronic brain syndromes due to senile and arteriosclerotic psychoses account for approximately 40% of the hospitalized mentally ill.

2. Mental Deficiency.—This, the second large category of mental disorders, is defined as an impoverishment in intellectual competency which results either from an innate fault in the individual's developmental potentiality or from arrested development. Thus, the mentally defective person is not equipped with intellectual capacities, judgment, social skills and foresight that are possessed by the average person. This condition is discussed in the article Mental Deficiency.

3. Psychogenic Disorders.—Psychogenic disorders are defined as conditions whose causes or origins are not clearly traceable to a physical cause or to structural damage of the brain and the nervous system. These disorders include the major psychoses, such as the schizophrenic, paranoid, manic-depressive and involutional reactions; psychophysiological (psychosomatic) reactions; psychoneurotic reactions; and personality disorders. They are characterized by varying degrees of personality disturbances, ranging from catastrophic to minor interference in interpersonal relations. Distinctions are easily made between the psychoses and psychoneuroses when the symptoms are well-defined, but these illnesses can be very difficult to differentiate at their early stages or in the borderline states. Symptomatology most commonly is the basis of distinction, but the disorders are also distinguished on legal and social grounds.

Psychosis.—The diagnosis of psychosis usually implies a greater severity of personality disturbance than that occurring in psychoneurosis. In the psychotic person the inner emotions and experience are so disturbing that he is frequently unable to carry on ordinary social functions. The psychotic has a limited capacity for differentiating his own subjective experiences, *i.e.*, describing what he is, has actually observed, tried or known; his capacity to interpret and respond to his environment therefore is gravely impaired. In other terms, he is unable to deal with reality; he creates his own special environment in which his perceptions are distorted or falsified in the form of delusions or hallucinations. The thought processes of the psychotic are often so disorganized that his thinking appears disrupted and irrational. (*See* also Psychoses.)

Psychoneurosis.—Unlike the psychotic, the psychoneurotic presents personality traits which are regarded as a socially acceptable adaptation against anxiety. In psychoneurosis, the inner experiences do not bring about a gross disturbance of external behaviour. The neurotic has the ability to maintain contact and good testing of the external environment. Although his thinking may be restricted or distorted by his overvalued and limited ideas, he does not suffer delusions and hallucinations. Moreover, he is not excessively withdrawn socially, and he usually retains his interest in the people and the world about him.

The question as to whether a neurosis may become a psychosis has been argued for years, but there is no certain or definitive knowledge. Psychiatrists who consider the psychotic reaction as a disease process usually reject the idea that progression can occur. On the other hand, most psychiatrists recognize a large number of borderline states, particularly with schizoid personalities, where the social adaptation of the patient is very precarious. The multiplicity of neurotic symptoms that certain patients suffer, the ambivalence they demonstrate, their disturbed psychosexual iife and their poorly developed self-concept have given rise to the classification by some psychiatrists of "pseudoneurotic schizophrenics." (*See* also Neuroses.)

Personality Disorders.—Personality disorders are a group of conditions in ahich there are persisting patterns of inadequate or antisocial behaviour rather than of predominantly psychological or emotional disturbances that cause suffering and a sense of distress. Persons who always react mith undue excitability and ineffectiveness in the presence of minor stress or who regularly display judgment that is not dependable are among those classified as having personality disorders. Such persons have little control over their hostile feelings, are fickle in their relations with others and are unable to form enduring or satisfactory relationships. Vocationally and socially these persons do poorly, even though they may be of normal or superior intelligence and physically well-endowed. Also included in the group with personality disorders are persons who exhibit extreme emotional instability characterized by explosive outbursts of rage upon minor provocation. At times, these personalities may be blustering and threatening; at other times they can be despairing and inaccessible. Two other common forms of personality disorder are seen in persons exhibiting either passive dependence reactions or passive aggressive reactions. The former are generally helpless, indecisive and clinging. When faced with minor problems, they show anxious and panic-stricken behaviour. In contrast, the passive aggressive person expresses his hostility in stubbornness. procrastination and inefficiency.

One of the most complex groups of the personality disorders is the category of sociopdths. Persons with sociopathic tendencies act out their hostility on the rest of the world. As a group, they make up the mass of the criminals and delinquent elements of society. Their symptomatology may also include various kinds of pathology expressed in sexual deviations. The commonest expression of this is homosexuality, but there are other forms, such as exhibitionism, voyeurism, masochism and sadism. (See also HOMOSEXUALITY; SEXUAL DEVIATIONS.)

Psychophysiologic Disorders. — In the psychophysiologic disorders, also designated psychosomatic conditions, anxiety produces a dysfunction in bodily organs through inappropriate activation of the involuntary nervous system and the glands of internal secretion. Thus the psychosomatic symptom emerges as a physiological concomitant of an emotional state. For example, in a state of rage, the angry man's blood pressure is likely to be elevated and his pulse and respiratory rate to be increased. When the anger passes, the heightened physiologic processes usually subside. However, if the man had a persistent inhibited aggression (chronic rage) which he was unable to express overtly, the emotional state remains unchanged, though unexpressed in the overt behaviour, and the physiological symptoms associated with the angry state persists. With time, such a person becomes aware of the physiological dysfunction. Very often he develops concern over what appears as an inappropriate activation of body organs, but he will deny or be unaware of the emotions which evoke the reactions. See above, History: *Modern Schools:* Psychosomatic Medicine.

III. TREATMENT OF MENTAL DISORDERS

1. Psychopharmacology.—One of the most striking advances in the symptomatic treatment of mental illnesses in the first half of the 20th century was the development of the series of pharmacological agents commonly known as tranquilizers. These drugs contrast sharply with the hypnotic and sedative drugs that formerly were in use and that clouded the patient's consciousness and impaired his motor and perceptual abilities. The tranquilizers can allay the symptoms of anxiety and reduce agitation with much less disturbance of consciousness. However, valuable as the tranquilizing substances have been, there is need for further study of their effects alone and in combination with other drugs; also drugs with extended and improved properties should be developed. Occasionally the tranquilizing drugs have toxic side effects, giving rise to such conditions as jaundice or a parkinsonianlike reaction; both these symptoms are reversible upon withdrawal of the drug. The drugs produce other minor symptoms because of their action on the autonomic nervous system.

Tranquilizers are used in treating many different kinds of disturbances but are particularly effective in relieving the symptoms of tension, overactivity, agitation, impulsiveness, explosive outbursts and destructive behaviour. Since they are prescribed for symptoms, they are not specific to the treatment of any diagnostic category. They have been more useful in treating the various psychotic states than in psychoneurotic reactions and personality disorders. The drugs also have been used in the treatment of toxic delirious states resulting from overuse of alcohol and in mental conditions resulting from brain damage.

Because of their ability to modify the behaviour of even the most disturbed patients, these agents have affected greatly the management of the hospitalized mentally ill. They have been responsible for dramatic changes in the behaviour of many psychotic patients. The noisy, untidy, crowded and unpleasant atmosphere that formerly pervaded the wards of many mental hospitals has largely disappeared; in the absence of the destructiveness. apathy and untidiness formerly exhibited by many patients, hospitals can be maintained more attractively. Because of the quieting effects of the tranquilizers, hospital staffs are able to devote more of their attention to other therapeutic efforts, and patients have been given greater freedom to move about and much more rehabilitative assistance. (See also NEUROPHARMACOLOGY AND PSYCHOPHARMACOLOGY; TRANQUILIZING DRUGS.)

2. Shock Therapy. — In 1933. Manfred Sakel of Vienna presented the first report of his work with insulin shock. Until the discovery of the superiority of the tranquilizing agents, variations of insulin shock therapy (also called insulin coma therapy) were commonly used in the treatment of schizophrenia and other psychotic conditions. With insulin shock treatment, the patient is given increasingly large doses of insulin which reduce the sugar content of the blood and bring on a state of coma. Usually the comatose condition is allowed to persist for about an hour, at which time it is terminated by administering warm salt solution via stomach tube or by intravenous injection of glucose. Insulin shock had its greatest effectiveness with schizophrenic patients whose illness had lasted less than two years (the rate of spontaneous recovery from schizophrenia also is highest in the first two years of the illness). Insulin shock therapy also had more value in the treatment of paranoid and catatonic schizophrenia than in the hebephrenic types.

Electroconvulsive therapy, introduced in Rome in 1938 by U. Cerletti and L. Bini, has been widely used in treating disturbance5 in which severe depression is the predominant symptom. It has been particularly recommended for manic-depressive psychoses and other types of depression. The technique is essentially the passage of alternating currents through the head between two electrodes placed over the temples The passage of the current causes an immediate cessation of consciousness and the induction of a convulsive seizure. In general, electroconvulsive treatments are given three times a week for a period ranging from two to six weeks; some acutely disturbed patients, however. have been given as many as two or three treatments in a single day. Following a course of treatment there is usually an impairment of memory, varying from a slight tendency to forget names to a severe confusional state. The memory defect diminishes gradually over several months. Electroconvulsive therapy, like insulin shock, declined in use after the tranquilizing drugs were introduced.

3. Psychosurgery.—The first treatment of mental disturbances by means of brain surgery was developed by the Portuguese neurologist Antonio de Egas Moniz (*q.v.*), the first operation being performed by Egas Moniz' colleague Almeida Lima, in 1935. The operation, called prefrontal lobotomy or leucotomy mas based on experimental studies demonstrating that certain neurotic symptoms induced in chimpanzees could be modified by cutting brain fibres. Egas Moniz' original operation consisted of cutting two openings in the skull, one on each side above the temple. and then severing the nerve fibres connecting the thalamus with the frontal lobes of the brain.

Prefrontal lobotomy has come to be generally regarded as a radical procedure to be followed only after all other forms of treatment have proved ineffective, and since the introduction of the tranquilizing agents the condition of only a very few patients warrants such a drastic measure. Patients selected for this operation usually show chronic agitation and severe distress, persistent depression, emotional aggressiveness and excited and impulsive behaviour. Phobias, obsessions, hallucinations and delusions not of long-standing duration have been relieved by this procedure. On the other hand, psychosurgery has had relatively little effect in modifying behaviour that characteristically expresses cruelty, avoidance of responsibility, excessive use of alcohol or pathological sexuality; it also has proved generally ineffective in the treatment of the chronic and withdrawn psychotic. The procedure tends to accentuate difficult personality traits by lowering inhibitory controls and by leading to development of facetious and tactless social behaviour. Many patients after the operation tend to shoa Increase in self-esteem coupled with lack of self-criticism.

The effect of lobotomy on intellectual functions has been a subject of much controversy. Ordinary psychological tests and observations reveal little change in the patient's psychological functioning in the months immediately following the operation.

It is believed, however, that lobotomy results in significant deterioration in intellect over the course of years. Patients who prior to their illness possessed the ability to perform tests requiring a high degree of abstraction showed great impairment in these capacities after lobotomy. Also, close observation of performance of persons with high intellectual capacity indicates a reduction in such capacity after surgery.

4. Psychotherapy. — Psychotherapy is the treatment of personality disturbances by psychological means. The essential factor in the many different techniques of psychotherapy is the establishment of an understanding and accepting relationship between therapist and patient. In this relationship, the therapist does not deprecate, censure or judge the patient, and the patient is encouraged to discover and speak of his emotional life. This is necessary if the aim of treatment is greater insight into the sources of the patient's difficulties and his achievement of greater personal satisfactions. There are many types of psychotherapy, and the indications for their use depend upon a number of variables, including the nature of the illness, age and intellectual capacity of the patient, estimate of his motivation and his capacity to face anxiety. These are discussed in the separate entries PSYCHOTHERAPY; PSYCHOANALYSIS; and PSYCHOLOGY, APPLIED: *Clinical* Psychology.

IV. CHILD PSYCHIATRY

The increasing recognition of the crucial influence of parent-child relationships on the child's personality development has provided a strong impetus to the study of psychiatric disorders of childhood. The approach to the diagnosis and treatment of children's mental and emotional disturbances is necessarily different from that with adult patients. The child is living through the most active and critical phases of his development. His personality is constantly being molded and changed as he moves from one developmental stage to another. In assessing the healthy or unhealthy patterns of a child's personality development, the psychiatrist must have extensive knowledge of the ever-changing patterns of personality, particularly at the various age levels through adolescence.

Although many of the general principles relating to therapy of adult psychiatric disorders apply to child psychiatry, a number of special problems arise with children which require special techniques. Usually the parents of the child bring him for treatment, or he is referred to the psychiatrist by a community agency — the school or the juvenile or family court. Because much of the essential information on the child's behaviour and other medical, psychological and social factors must be obtained from the parents, the pediatrician, psychologist, teacher or social workers, child psychiatrists work closely with the parents and other specialists who have been in frequent or close contact with the child. Thus, in the field of child psychiatry, the working relationship between the psychiatrist and the related social and medical disciplines is closer and more essential than it is in adult psychiatry, where the patient usually can provide much of the pertinent and necessary information on his life and his condition.

For the most part, child psychiatry is concerned with the study and treatment of the different neurotic reactions or problems of emotional maladjustment that affect children. The emotional maladjustments of children frequently are manifested in behaviour difficulties, unpleasant character traits or psychosomatic disturbances. Neurotic reactions include habit spasms. stammering, overactivity and phobias. Ticlike movements of the face and other parts of the body are common. Among infants, deprivation of mothering or problems in the infant's relationship with the mother may lead to withdrawn behaviour, continuous crying, inability to eat, insomnia and physical or mental retardation or both. Older children are often seen for such habit disturbances as persistent nail biting, thumbsucking, bedwetting and temper tantrums. Children also are referred for treatment because of conduct problems or propensities for disobedience, lying, stealing, destructiveness, fighting, fire setting, cruelty and running away from home.

As in the treatment of adult patients, psychiatric treatment of children requires determination of any genetic, constitutional or physical factors that have contributed to the disturbance. Also, it is essential that the relationship between the child and the parent be assessed for its contribution to the disturbed behaviour. Where there are disturbing influences that can be associated with parental dissension, alcoholism, hostility, cruelty, neglect, overprotection of the child, excessive ambitions for and expectations of the child, it is common to find behavioural disorders. The existence of neurotic, psychotic or psychopathic illness in the parents also contributes to a faulty parent-child relationship. The parents' unconscious feelings about the child and the kinds of conflicts which disturb the parent-child relationship also must be determined. (It must be recognized that the emotional behaviour of the parents is sometimes the result rather than the cause of the child's misdemeanours.) Another important source of personality problems is the child's relationship with brothers and sisters. In addition, the death or loss of a parent often has a profound and lasting effect, as it reduces the child's opportunity for healthy growth through continuing identification with or differentiation from the absent parent.

School experiences also can create personality problems. Many children exhibit conduct and learning disturbances because they have been unable to cope with modern methods of instruction. Children with perceptual difficulties, for example, may fail to learn to read or may not develop the reading skills appropriate to their age level, because of the scanning method of teaching reading without phonetic sounds or spelling out the letters in a word. As a consequence, they often become anxious over their failure to meet the standards of their family and their class. When these emotions are aroused, conduct disturbances may ensue.

V. PSYCHIATRIC TRAINING AND ORGANIZATION

A. TRAINING

1. United States. — In the United States, to qualify as a specialist in psychiatry, a physician must complete a period of training in an accredited or qualified hospital or other institution. Usually the physician enters a psychiatric residency training program after one year of medical internship, which followed his obtaining the degree of doctor of medicine from an accredited medical school. Residency training in psychiatry provides supervised experience in the diagnosis and treatment of mental and emotional illnesses. It includes opportunities for using all the varieties of treatment in specialized psychiatric hospitals and institutions, out-patient departments, various kinds of children's services and general hospitals. The resident physician in psychiatry also is required to take formal course work in such fields as psychobiology, psychopathology and psychodynamics, neuroanatomy, neurophysiology and neuropathology. Upon completion of this training, the physician may apply for examination by the American Board of Psychiatry and Neurology. The certificate of the board indicates that the physician has completed his general training; it does not measure his level of competence in the performance of special therapies.

The clinical psychologist, in contradistinction to the specialist in psychiatry, is not trained in medicine. He has the degree of doctor of philosophy in psychology and has been trained in the theory and practice of psychological testing of mental patients. In some institutions he may, under supervision, receive training to do certain forms of psychotherapy. The training of the clinical psychologist, unlike that of the psychiatrist, does not equip him to diagnose, to prescribe drugs and medicine, or to administer shock therapy and other psychiatric diagnostic and treatment procedures.

For the most part, the psychoanalyst in the United States has obtained the degree of doctor in medicine and has completed a residency in psychiatry. In addition, he has completed the requirement of a personal psychoanalysis and has conducted the analysis of several patients under the supervision of a qualified training analyst. Also he has undertaken and completed certain other didactic and clinical training. The majority of qualified psychoanalysts in the United States are members of or candidates for membership in the American Psychoanalytic association.

A small group of clinical psychologists, social workers and others also have been trained to do psychotherapy and psychoanalysis. These persons were trained largely in the past by psychoanaiysts in England and other western countries of Europe. The U.S. medical profession generally believes that clinical psychologists, social workers and lay analysts who practise psychotherapy or psychoanalysis should do so in collaboration with a psychiatrist or a physician. This position is based on the belief that proper psychiatric diagnosis requires a physical and neurological examination; only those trained in medicine are able to decide whether the somatic symptoms of an illness are due to an underlying physical process or are representative of an emotional disturbance. On the other hand, psychologists and other nonmedical persons trained in psychoanalysis have made many fundamental and valuable contributions toward the elucidation of the basis of behaviour and the understanding of personality development.

2. Great Britain.--In Great Britain the physician may begin his training for the specialty of psychiatry after he has completed his preregistration appointments and his national service. He then serves on the staff of a mental hospital for a minimum of two years, at which time he may be examined for the diploma in psychological medicine (D.P.M.) by the Conjoint board. The D.P.M. does not qualify the recipient as a consultant in the national health service; such senior appointments are approved by a committee of outstanding specialists, who judge the candidate in competition with others applying for the post.

The teaching program of the Institute of Psychiatry of the British Postgraduate Medical federation conducted at the Maudsley and Bethlem Royal hospitals in London is similar to that of the best residency programs in the United States. In terms of formal scholarship. the British institute is more exacting than any of the American institutes. The British institute awards its own D P.M., which has higher standards and requires more extensive training than the certificate of the Conjoint board. While the British institute is the only fully developed British university postgraduate centre in psychiatry, Great Britain has other institutes, hospitals and clinics in which special kinds of psychiatric training can be obtained. The Institute of Psychoanalysis in London provides specialized training much like that of the psychoanalytic institutes and training centres in the United States.

3. Other **Countries.**—In Canada, although each province makes its own arrangements for awarding diplomas in psychiatry, the training of the physician specializing in psychiatry is much like that of the psychiatrist trained in the United States. The training of psychiatrists in Australia and New Zealand is similar to English psychiatric training. South Africa has modeled its training program in psychiatry closely after that of the Netherlands. There, to become registered as a specialist psychiatrist or specialist in mental disorders, the applicant must be qualified as a medical practitioner for at least six years, and must satisfy certain clinical requirements in medicine and surgery as well as in psychiatry. Upon fulfilling these requirements satisfactorily, he obtains a higher degree in his specialty. Several universities in India award a diploma in psychological medicine,

B. Organizations

1. United States.—The American Psychiatric association, oldest national medical association in North America, was founded in 1384, and in the early 1960s had a membership of more than 10,000 psychiatrists, The organization has an information service, and publishes several journals as well as a biographical directory of its members. Its aims are the improvement of treatment of the mentally ill and the furtherance of psychiatric education and research.

The National Institute of Mental Health of the United States public health service is the major federal government agency concerned with the prevention and treatment of psychiatric disorders. Through the provisions of the National Mental Health act of 1946, the institute makes grants-in-aid to support training, research and community services in the United States. The institute also conducts an extensive research program at the National Institutes of Heaith in Bethesda, Md.

2. Great Britain.—In Great Britain the important official bodies concerned with mental illness are the Board of Control (psychiatric division of the ministry of health) and the General Board of Control for Scotland. Under provisions of the New Mental Health act, before parliament in the early 1960s. these boards would be abolished and regional mental health review tribunals established. A standing Mental Health Advisory committee (a statutory body) aids and advises the minister of health on mental health matters. The Medical Research council plays an important role in distributing funds for psychiatric research.

In England, the major professional psychiatric organization is the Royal Medico-Psychological association. Similar professional bodies have been established throughout the British commonwealth. The Canadian Psychiatric association, chartered in 1951 and associated with the Canadian Medical association, has more than 600 members. Since most matters related to the practice of medicine fall within the jurisdiction of the provincial governments in Canada, the Canadian Psychiatric association has been active in developing its relations with these governments.

3. Other Countries.--Psychiatrists of Australia and New Zealand are organized as the Australian Association of Psychiatrists. In India, the psychiatric organization is known as the Indian Psychiatric society. In South Africa the National Group of Neurology, Psychiatry and Neurosurgery represents the aims of the specialty. Each organization supplies information on its aims, its members and the psychiatric facilities of the country. Similar organizations exist in other European and South American countries.

4. International.—International bodies concerned with mental health are discussed in the article MENTAL HEALTH.

(L. C. K.)

PSYCHICAL RESEARCH. Psychical research is the scientific study of various odd happenings which are often reported and believed in but about the reality of which there is considerable doubt. Examples of such alleged occurrences are thought transference, foretelling the future, hauntings involving both appearances of ghosts and movements of objects, messages received through mediums from the spirits of those who have died, etc. All such alleged events may be included in the class of the paranormal, and are such that the general principles of scientific expectations would make them seem impossible. Early subjects of study by psychical research included hypnotism, which is no longer regarded as paranormal and which fits in to the scientific picture of the human organism (see HYPNOSIS). It is the aim of psychical research to achieve a similar scientific understanding of any paranormal phenomena that do not prove to be illusory.

In 1882 the Society for Psychical Research was founded in England. Its first task was to study objectively the evidence for the various paranormal phenomena, in order to discover whether they were real or merely results of fraud or errors of observation. Its second task was the scientific investigation of any paranormal phenomena that were proved to be real, in order that their nature might be more fully understood and that they might take their place with the accepted data of science. In some cases (of which the best-known example is thought transference or telepathy) the first task has been achieved: it is known that they really take place and the present concern is to find out more about their nature. In other cases (such as hauntings) modern investigators possess little more reliable knowledge than the pioneers of the early days of psychical research did; inquiries are still being made regarding how much of what is alleged is description of real events of a paranormal character and how much is the misinterpretation of purely natural events.

The founding of the Society for Psychical Research in London was followed six years later by the founding of a similar society in the United States. Similar societies were founded later in most European countries, and active work is carried on. particularly in the Netherlands, France and Italy. Universities have been slower to recognize psychical research as a serious subject for study. The founding of the parapsychological laboratory at Duke university, Durham, N.C., under J. B. Rhine in 1927 was an important step in this direction. Later a department of psychical research was opened at the University of Utrecht under W. H. C. Tenhaeff.

One of the causes of interest in psychical research in the last half of the 19th century was the rise of the spiritualist movement about the middle of that century; many intelligent persons were uncertain of the reality of the alleged facts on which spiritualism was based, and were uneasy about their uncertainty. Spiritualism grew out of the acceptance of the reality of spirit communication and the use of this as the basis of a new religion. Psychical research grew out of curiosity as to these facts and the determination to submit them to scientific investigation. These were not necessarily divergent interests: some of the early psychical researchers were also spiritualists, as, for example, F. W. H. Myers and Sir Oliver Lodge. Other psychical researchers (such as the physiologist C. Richet) accepted the facts of spiritualism but rejected the spiritualist explanation, while others were not committed to either view.

Existence After Death.—This interest in the problems of spiritualism led to the consideration by psychical research from its earliest days of empirical evidence for human survival of death, evidence derived from mediumistic seances or from any other field of observation. It is with empirical evidence only that psychical research is concerned, not with the validity of any form of reasoning offered in proof or disproof of the continuance of human existence after death. While some progress has been made in this problem, the advance has been by no means spectacular. In some nays, advances in psychical research have made the solution of the problem of providing proof of survival more difficult. The experimental demonstration of the existence of psi cognition (obtaining knowledge by telepathy or clairvoyance) as a paranormal capacity among some persons makes it possible to explain evidence by information apparently coming from spirits, as possibly resulting from the psi cognitive capacities of the medium. For example, some of the early researchers (*e.g.,* Myers and Lodge) left sealed packages with the intention of communicating the contents after their death. In fact, neither experiment was successful, but if they had succeeded their success might have been explained as due to the clairvoyant powers of the medium. A modification of such an experiment is an attempt by a medium to communicate the message during the lifetime of the person depositing it; failure during his lifetime followed by success after his death would provide strong though not coercive evidence that he was communicating after death. No experiment of this type, however, had been completed by the beginning of the 1960s.

Cross-correspondence was a type of evidence which started to develop soon after Myers' death in 1901. Ostensibly this was an experimental demonstration of survival arranged from the other side of the grave, presumably by Myers himself. Essentially it was communication, through different mediums. of fragments of a message which made a coherent whole only when fitted together. Success in such a task cannot easily be explained by reference to the paranormal cognitive powers of the medium. Its results are not easy to evaluate, but many competent judges are of the opinion that the cross-correspondences provide strong evidence of the survival of the deceased persons who were their ostensible originators.

Evidence along different lines was sought by Whately Carrington, who applied psychological tests to communicators in the attempt to discover whether a single communicator coming through different mediums showed constant measurable characteristics that would indicate that he was one and the same person. Critical examination of Carrington's results shows that he obtained no evidence of the identity of his communicators. The research method was ingenious, however, and the problem remained to be taken up by some other research worker.

Telepathy.—Much more striking success has attended the experimental investigation of what is called thought transference or telepathy. The typical form of this experiment is that in which the task is card guessing: an agent turns up and looks at successive cards in a pack of playing cards and a percipient tries to tell him which they are. Promising results were obtained early but critics urged the necessity for further precautions against error before it could be accepted that a thought could pass from one mind to another without use of the ordinary sensory channels of communication. Further experiments with a different type of card mere carried out at Duke university (see PARAPSYCHOLOGY). They were also carried out with full precautions against error and a high rate of success by S. G. Soal and K. M. Goldney in Great Britain.

In the meantime, however, Rhine had thrown doubt on the appropriateness of regarding these as tests of telepathy, since he found that equal success could be obtained when no one looked at the cards. The performance mould then commonly be called clairvoyance. Extrasensory perception (ESP) is a term commonly used now to cover both telepathy and clairvoyance. The more noncommittal term psi has also been suggested to cover all types of paranormal cognition, and is widely used and understood.

There is, from time to time, an arousal of public interest in telepathy through the appearance on the stage of an entertainer who is supposed to demonstrate telepathy. Less frequently the demonstration is of "eyeless sight." The resources of stage telepathy have been enlarged by the development of small wireless receiving sets which can be concealed on the person, although impressive demonstrations were given earlier by the use of codes and other methods. Such trick telepathy has no bearing on the question of whether real extrasensory perception takes place. The experimenter has the task of arranging his conditions so that the experimental subject has no opportunity to trick him. Without such precautions, the experiment is of no value for demonstrating the reality of the phenomenon under investigation.

Supernatural Foresight.—A form of paranormal cognition for which there is a long tradition of anecdotal evidence is the foreseeing of the future by dreams and by various devices such as looking at the flight of birds or at the entrails of sacrificial animals, or listening to the wind blowing through leaves (see DIVINATION). No important contribution to psychical research has been made by studying any of these devices. On the other hand, experiments have been done in which the percipient's task is to guess the future order of a pack of cards after a process of shuffling and cutting. There seems to be a strong indication that some subjects can succeed in such a task of precognition, although the evidence is less overwhelmingly strong than that for experimental extrasensory perception.

Physical **Phenomena.**—Psychical research has also been concerned with paranormal physical phenomena such as levitation, materialization and the moving of heavy objects. Sir William Crookes studied both the phenomena of the medium D. D. Home (*q.v.*) and a materialized figure (Katie King) which developed in the presence of the medium Florence Cook, and satisfied himself as to their genuineness. **A** remarkable physical medium was an uneducated Italian woman, Eusapia Palladino, who exasperated psychical researchers by her crude attempts to cheat if controls were relaxed. **A** critical experimental study of her, however, by three experienced psychical researchers produced striking physical phenomena under conditions which the experimenters considered were such that fraud was impossible.

The most remarkable studies of materializations were made in France by G. Geley and Richet. Wax gloves have been produced which are reported to have been made by spirit hands dipped into molten wax and dematerialized after the wax solidified. There are numerous photographs of the quasi-material substance ectoplasm, which is supposed to be exuded from the medium's body to form the substantial basis for materializations. Many of these photographs show part of the ectoplasmic substance in the shape of human faces or other parts of the human form. These photographs are plainly not in themselves evidence of the reality of ectoplasm, as the wax gloves are not evidence of the reality of materialized hands. In both cases, their weight as evidence depends on the reliability of the persons obtaining them.

Physical phenomena are often lightly dismissed because they can easily be simulated by fraudulent means and are so simulated by dishonest mediums. Their investigation is made difficult by the fact that they are generally produced in darkness or reduced light. At the same time, it should be noticed that those investigators who became convinced of their genuineness were fully alive to the possibilities of fraud and were satisfied that their precautions to exclude fraud were adequate. Such experienced scientific investigators as Crookes, Lodge, Sir W. Barrett and Richet could not have been easily deceived.

Spontaneous Phenomena. — In addition to these various experimental lines of investigation, a large field of spontaneous phenomena has engaged the attention of psychical researchers. This field includes apparitions of the living and of the dead and also hauntings. An early inquiry into apparitions revealed that these had little of the appearance of the ghost of fiction. They were not vague sheeted figures, but of the form and appearance of living persons for which they were often mistaken. It has been argued that there is little reason for regarding them as spirits but rather as hallucinatory perceptual experiences which may originate from a genuinely paranormal process. It was argued that apparitions of persons near the point of death occurred too often for the coincidence between death and the apparition to be entirely a chance coincidence.

Spontaneous reports of hauntings suggest that these are of two main types: that in which an apparition is repeatedly seen in the same place and that in which the main phenomena are noises and displacement of household objects. A good example of the former type is the apparition described by a woman who wrote in the *Proceedings of the Society for Psychical Research* (vol. viii, *1892)* under the pseudonym of Miss Morton. This apparition was constant in form, stereotyped in action, seen only occasionally and never when watched for. It was sometimes seen by more than one person at the same time, but also it might be seen by one person and not by another who was also present; it could apparently be seen by animals. The seeing of it differed, therefore, from the perception of a material object and also from an autogenic hallucination. Various theories have been put forward, but the data on hauntings are neither full enough nor sufficiently systematically collected to make it possible to subject alternative theories to critical tests.

The haunting characterized by noise and displacement of objects is commonly called a poltergeist haunting, and cases have been reported for a long time. Epworth rectory, Lincolnshire, the home of Charles Wesley, was the scene of such phenomena, and W. Barrett had the opportunity of observing and recording similar events at Derrygonnelly farm.

Poltergeist phenomena at different times and different places show a curious parallelism. One feature that nearly all have in common is the presence of a young person, boy or girl, somewhere between the ages of *12* and *20.* This fact led many of the early observers to suppose that all poltergeist phenomena were products of normal mischief. Many cases, however, cannot be explained in this may without much straining of the evidence. There seems to be better ground for supposing that the phenomena (whether normal or paranormal) are products of mental strain in the young person concerned. Various theories have been put forward to account for poltergeist phenomena, many of which have little evidential support. A fuller understanding must await a closer study of such cases with the use of modern recording devices. Sensational newspaper stories of poltergeist phenomena are not to be regarded as a safe basis for any kind of theory. *See* also PARAPSYCHOLOGY; SPIRITUALISM.

PSYCHOANALYSIS. In the years *1880–82* a Viennese physician, Josef Breuer (1842–1925), discovered a new procedure by means of which he relieved a girl, who was suffering from severe hysteria, of her various symptoms. The idea occurred to him that the symptoms were connected with impressions which she had received during a period of excitement while she was nursing her sick father. He therefore induced her, while she was in a state of hypnotic somnambulism, to search for these connections in her memory and to live through the "pathogenic" scenes once again without inhibiting the affects that arose in the process. He found that when she had done this the symptoms in question disappeared for good.

This was at a date before the investigations of J. M. Charcot and Pierre Janet into the origin of hysterical symptoms, and Breuer's discovery was thus entirely uninfluenced by them. But he did not pursue the matter any further at the time, and it was not until some ten years later that he took it up again in collaboration with Sigmund Freud. In *1895* they published a book, *Studien über Hysterie,* in which Breuer's discoveries were described and an attempt was made to explain them by the theory of *catharsis.* According to that hypothesis, hysterical symptoms originate through the energy of a mental process being withheld from conscious influence and being diverted into bodily innervation *(conversion).* A hysterical symptom would thus be a substitute for an omitted mental act and a reminiscence of the occasion which should have given rise to that act. And, on this view, recovery would be a result of the liberation of the affect that had gone astray and of its discharge along a normal path *(abreaction).* Cathartic treatment gave excellent therapeutic results, but it was found that they were not permanent and that they were dependent on the personal relation between the patient and the physician. Freud, who later proceeded with these investigations by himself, made an alteration in their technique, by replacing hypnosis by the method of free association. He invented the term *psychoanalysis,* which in the course of time came to have two meanings: (1) a particular method of treating nervous disorders and *(2)* the science of unconscious mental processes, which has also been appropriately described as "depth psychology."

Subject Matter of Psychoanalysis. — Psychoanalysis finds a constantly increasing amount of support as a therapeutic procedure, because of the fact that it can do more for certain classes of patients than any other method of treatment. The principal field of its application is in the milder neuroses — hysteria, phobias and obsessional states — but in malformations of character and in sexual inhibitions or abnormalities it can also bring about marked improvements or even recoveries. Its influence upon dementia praecox and paranoia is doubtful; on the other hand, in favourable circumstances it can cope with depressive states, even if they are of a severe type. In every instance the treatment makes heavy claims upon both the physician and the patient: the former requires a special training, and must devote a long period of time to exploring the mind of each patient, while the latter must make considerable sacrifices, both material and mental. Nevertheless, all the trouble involved is as a rule rewarded by the results. Psychoanalysis does not act as a convenient panacea (*cito, tute, jucunde,* "I proclaim, be secure, be happy") upon all psychological disorders. On the contrary, its application has been instrumental in making clear for the first time the difficulties and limitations in the treatment of such affections.

The therapeutic results of psychoanalysis depend upon the replacement of unconscious mental acts by conscious ones and are operative in so far as that process has significance in relation to the disorder under treatment. The replacement is effected by overcoming internal resistances in the patient's mind. The future will probably attribute far greater importance to psychoanalysis as the science of the unconscious than as a therapeutic procedure.

Depth Psychology. — Psychoanalysis, in its character of depth psychology, considers mental life from three points of view: the dynamic, the economic and the topographical.

From the first of these standpoints, the dynamic one, psychoanalysis derives all mental processes (apart from the reception of external stimuli) from the interplay of forces, which assist or inhibit one another, combine with one another, enter into compromises with one another, etc. All of these forces are originally in the nature of instincts; that is to say. they have an organic origin. They are characterized by possessing an immense (somatic) persistence and reserve of power (repetition-compulsion), and they are represented mentally as images or ideas with an affective charge (cathexis). In psychoanalysis, no less than in other sciences, the theory of instincts is an obscure subject. An empirical analysis leads to the formation of two groups of instincts: the so-called "ego instincts," which are directed toward self-preservation, and the "object instincts," which are concerned with relations to an external object. The social instincts are not regarded as elementary or irreducible. Theoretical speculation ieads to the suspicion that there are two fundamental instincts which lie concealed behind the manifest ego instincts and object instincts; namely, (a) Eros, the instinct which strives for ever closer union, and (b) the instinct for destruction. which leads toward the dissolution of what is living. In psychoanalysis the manifestation of the force of Eros is given the name *libido.*

Pleasure-Pain Principle. — From the economic standpoint, psychoanalysis supposes that the mental representations of the instincts have a cathexis of definite quantities of energy, and that it is the purpose of the mental apparatus to hinder any damming up of these energies and to keep as low as possible the total amount of the excitations to which it is subject. The course of mental processes is automatically regulated by the pleasure-pain principle, and pain is thus in some way related to an increase of excitation and pleasure to a decrease. In the course of development the original pleasure principle undergoes a modification with reference to the external world, giving place to the *reality principle,* whereby the mental apparatus learns to postpone the pleasure of satisfaction and to tolerate temporarily feelings of pain.

Mental Topography. — Topographically, psychoanalysis regards the mental apparatus as a composite instrument, and endeavours to determine at what points in it the various mental processes take place. According to the most recent psychoanalytic views, the mental apparatus is composed of an id, which is the reservoir of the instinctive impulses; of an ego, which is the most superficial portion of the id and one which is modified by the influence of the external world; and of a superego, which develops out of the id, dominates the ego and represents the inhibitions of instinct characteristic of man. Further, the property of consciousness has a topographical reference; for processes in the id are entirely unconscious, while consciousness is the function of the ego's outermost layer, which is concerned with the perception of the external world.

At this point two observations may be in place. It must not be supposed that these very general ideas are presuppositions upon which the work of psychoanalysis depends. On the contrary, they are its latest conclusions arid are in every respect open to revision. Psychoanalysis is founded securely upon the observation of the facts of mental life, and for that very reason its theoretical superstructure is still incomplete and subject to constant alteration. Second, there is no reason for astonishment that psychoanalysis, which was originally no more than an attempt at explaining pathological mental phenomena, should have developed into a psychology of normal mental life. The justification for this arose with the discovery that the dreams and mistakes (*parapraxes,* such as slips of the tongue, etc.) of normal men have the same mechanism as neurotic symptoms.

Theoretical Basis. — The first task of psychoanalysis was the elucidation of nervous disorders, The analytical theory of the neuroses is based upon three ground pillars: the recognition of (1) repression, (2) the importance of the sexual instincts and (3) transference.

Censorship. — There is a force in the mind which exercises the functions of a censorship, and which excludes from consciousness and from any conscious influence upon action all tendencies which displease it. Such tendencies are described as "repressed." They remain unconscious, and if the physician attempts to bring them into the patient's consciousness he provokes a resistance. These repressed instinctual impulses, however, are not always made powerless by this process. In many cases they succeed in making their influence felt by circuitous paths, and the indirect or substitutive gratification of repressed impulses is what constitutes neurotic symptoms.

Sexual Instincts.- or cultural reasons the most intensive repression falls upon the sexual instincts; but it is precisely in connection with them that repression most easily miscarries, so that neurotic symptoms are found to be substitutive gratifications of repressed sexuality. The belief that in man sexual life begins only at puberty is incorrect. On the contrary, signs of it can be detected from the beginning of extrauterine existence; it reaches a first culminating point at or before the fifth year (early period), after which it is inhibited or interrupted (latency period) until the age of puberty, which is the second climax of its development. This double onset of sexual development seems to be distinctive of the genus Homo. All experiences during the first period of childhood are of the greatest importance to the individual, and, in combination with his inherited sexual constitution, form the dispositions for the subsequent development of character or disease. It is a mistaken belief that sexuality coincides with "genitality." The sexual instincts pass through a complicated course of development. and it is only at the end of it that the "primacy of the genital zone" is attained. Before this there are a number of "pregenital organizations" of the libido— points at which it may become "fixated" and to which, in the event of subsequent repression. it will return (regression). The infantile fixations of the libido are what determine the form of neurosis which sets in later. Thus the neuroses are to be regarded as inhibitions in the development of the libido.

The Oedipus Complex. — There are no specific causes of nervous disorders: the question whether a confiict finds a healthy solution or leads to a neurotic inhibition of function depends upon quantitative considerations; that is, upon the relative strength of the forces concerned. The most important conflict with which a small child is faced is his relation to his parents, the *Oedipus* complex; it is in attempting to grapple with this problem that persons destined to suffer from a neurosis habitually fail. The reactions against the instinctual demands of the Oedipus complex are the source of the most precious and sociaily important achievements of the human mind; and this probably holds true not only in the life of individuals but also in the history of the human species as a whole. The superego, the moral factor which dominates the ego, also has its origin in the process of overcoming the Oedipus complex.

Transference. — By transference is meant a striking peculiarity of neurotics. They develop toward their physician emotional relations. both of an affectionate and hostile character, which are not based upon the actual situation but are derived from their relations toward their parents (the Oedipus complex). Transference is a proof of the fact that adults have not overcome their former childish dependence; it coincides with the force which has been named *suggestion,* and it is only by learning to make use of it that the physician is enabled to induce the patient to overcome his internal resistances and do away with his repressions. Thus psychoanalytic treatment acts as a second education of the adult. as a correction to his education as a child.

Within this narrow compass it has not been possible to mention many matters of the greatest interest, such as the *sublima-*

tion of instincts, the part played by symbolism, the problem of *ambivalence,* etc. Nor has there been space to allude to the applications of psychoanalysis, which originated, as we have seen, in the sphere of medicine, to other departments of knowledge (such as anthropology, the study of religion. literary history and education) where its influence is constantly increasing. It is enough to say that psychoanalysis, in its character of the psychology of the deepest unconscious mental acts, promises to become the link between psychiatry and all of these other fields of study.

The Psychoanalytic Movement. — The beginnings of psychoanalysis may be marked by two dates: 1895, which saw the publication of Breuer and Freud's *Studien uber Hysterie,* and 1900, which saw that of Freud's *Traumdeutung.* At first the new discoveries aroused no interest either in the medical profession or among the general public. In 1907 the Swiss psychiatrists, under the leadership of E. Bleuler and C. G. Jung, began to concern themselves in the subject, and in 1908 there took place at Salzburg a first meeting of adherents from a number of different countries. In 1909 Freud and Jung were invited to the United States by G. Stanley Hall to deliver a series of lectures on psychoanalysis at Clark university, Worcester, Mass. From that time forward interest in Europe grew rapidly; it showed itself, however, in a forcible rejection of the new teachings, characterized by an emotional colouring which sometimes bordered upon the unscientific.

The reasons for this hostility are to be found, from the medical point of view, in the fact that psychoanalysis lays stress upon psychical factors, and, from the philosophical point of view, in its assuming as an underlying postulate the concept of unconscious mental activity; but the strongest reason was undoubtedly the general disinclination of mankind to concede to the factor of sexuality such importance as is assigned to it by psychoanalysis. In spite of this widespread opposition, however, the movement in favour of psychoanalysis was not to be checked. Its adherents formed themselves into an international association which survived World War I, and by 1926 there were psychoanalytic societies in Vienna. Berlin. Budapest, London, Switzerland, the Netherlands, Moscow and Calcutta and two in the United States. There were psychoanalytic polyclinics in Vienna. Berlin and London, and several training institutes were in process of organization. At that time, too, three journals were the official organs of the societies on the continent and in England: the *International Zeitschrift fur Psychoanalyse, Imago* (concerned primarily with applications of psychoanalysis to nonmedical fields) and the *International Journal of Psychoanalysis.* (S. Fr.)

Bibliography.—J Breuer and S. Freud, *Studien uber Hysterie* (1895); Freud, *Traumdeutung* (1900), *Zur Psychopathologie des Alltagslebens* (1904), *Drei Abhandlungen zur Sexualtheorie* (1905), *Vorlesungen zur Einführung in die Psychoanalyse* (1916). Freud's complete works have been published in Spanish (*Obras completas*) (1924) and German *(Gesammelte Schriften)* (1925); the greater part of them has been translated into English and other languages. Short accounts of the subject matter and history of psychoanalysis will be found in: Freud, *Über Psychoanalyse* (the lectures delivered at Worcester, Mass.) (1909), *Zur Geschichte der psychoanalytischen Bewegung* (1914), *Selbstdarstellung* (in Grote's collection *Die Medizin der Gegenwart*) (1925). Particularly accessible to English readers are: A. A. Brill, *Psycho-Analysis* (1922); E. Jones, *Papers on Psycho-Analysis* (1923); S. Ferenczi, *Theory and Technique of Psychoanalysis* (1927).

Controversial Literature,: Karen Horney, *New Ways in Psychoanalysis* (1939) and *Self-Analysis* (1942); Clara Thompson, "Penis Envy in Women," *Psychiatry,* 6:2, p. 123 (1943); Erich Fromm, "Sex and Character," *ibid.,* 6:1, p. 21 (1943), "Selfishness and Self Love," *ibid.,* 2:4, p. 507 (1939) and "Faith as a Character Trait," *ibid.,* 5:3, p. 307 (1942); Franz Alexander and Thomas French, *Psychoanalytic Therapy* (1946); Franz Alexander, "Psychoanalysis Revised," *Psychoanalytic Quarterly,* vol. 9, p. 1 (1940), *Our Age of Unreason* (1942) and "Indications for Psychoanalytic Therapy," *Bulletin of the N.Y. Acad. of Med.,* 20:6, p. 319 (June, 1944).

Discussion of Controversial Viewpoints: Robert Waelder, "The Problem of Genesis of Psychical Conflict in Earliest Infancy," *Internat. Jour. of Psychoanalysis,* vol. 28, p. 406 (1937) and "Present Trends in Psychoanalytic Theory," *Bulletin of the Menninger Clinic,* vol. 8, p. 1 (1943); Fritz Wittels, "Neo-Adlerians," *Am. Jour. of Sociology,* vol. 15, p. 433 (1939); Ludwig Jekels, "Psychoanalysis and Dialectics," *Psychoanalytic Review,* vol. 28, p. 228 (1940); Ernest Jones, "Review of Alexander's 'Our Age of Unreason,'" *Internat. Jour. of Psychoanalysis,* vol. 24, p. 90 (1943); H. Hartmann and E. Kris, "The Genetic Approach in Psychoanalysis," *Psychoanalytic Study of the Child,* vol. 1 (1946). (S. Fr.; X.)

Later Developments. — The above article appeared in 1926. It was written by Freud and translated by Ernest Jones. Except for the omission of certain general topics to which Freud alludes, it represents clearly the status of psychoanalytic theory at that time.

After 1926 there was an uninterrupted expansion of psychoanalytic activities in England and the United States. Before the nazis came into power there had been psychoanalytic societies in the U.S.S.R., Japan, Italy. France, the Netherlands, Switzerland, some of the Scandinavian countries, Czechoslovakia and Hungary, as well as in Germany and Austria. The eruption of World War II and other political upheavals suppressed or disrupted many of these societies. Many members were sent to concentration camps, and all who could escape migrated to other countries. An effort is now under way to rebuild these societies, their training institutes and their clinics.

In the United States there was a steady growth of the societies after World War II and of the institutes which provide psychoanalytic training, either independently or, in a few cases, in connection with universities. As of April 1956, the American Psychoanalytic association had a membership of 619. There were 14 training institutes, and 3 more in the process of formation, with a student body of approximately 1,000. At the same time there were societies and institutes in Argentina, Brazil, Canada, Chile, Belgium, Great Britain, the Netherlands, France, Germany, Italy, Sweden, Switzerland, Austria (Vienna). India, Israel and Japan, and small groups in many other localities, such as Australia, Ireland, Cuba and Ceylon. All of these groups are federated into the International Psychoanalytic association, which after the end of the war resumed its biennial meetings.

During the period of war and upheaval, most of the continental journals were suppressed, but in Great Britain the *International Journal of Psycho-Analysis* and in the U.S. the old *Psychoanalytic Review* and the *Psychoanalytic Quarterly* continued to appear regularly. After the war several additional psychoanalytic journals came into existence. Among these were the American *Imago,* the *Revue française de psychanalyse,* the *Revista de Psicoanálysis* (Argentina) and one in Italy, and such closely related journals as *Psychosomatic Medicine* and *Psychiatry.* Still newer journals and yearbooks are the *Psychoanalytic Study of the Child* (1945–), *Psychoanalysis and the Social Sciences* (1947–) and the *Journal of the American Psychoanalytic Association* (1953–); the *Yearbook of Psychoanalysis* (reprinted articles) from 1944 through 1955. The *Annual Survey of Psychoanalysis* (an extensive digest and review) began in 1953 with a summary of the publications of 1950.

Implicit in Freud's 1926 article are the lines along which both theoretical and technical developments were to occur in the subsequent years. These can be outlined in general terms as follows:

1. The topographical schema of psychological organization, which Freud then emphasized, gradually dropped into a position of relatively less importance. This was largely a result of the influence of Freud's own later writings, in which his attention shifted to more dynamic problems. *(See* Freud, *Hemmung, Symptom, und Angst* [1926; translated into English in 1936, under the title *Problem of Anxiety]*; also Anna Freud, *The Ego and the Mechanisms of Defence* [German, 1936; English, 1937].)

2. The role of anxiety and of the conscious and unconscious defensive measures which the ego utilizes in dealing with instincts and anxiety came to occupy a central position in analytic thinking.

3. These developments were related to a growing interest in the psychoanalytic study and treatment of the child. Starting with the early reports of Freud, Hug-Hellmuth and Jung, child analysis was systematically developed by Anna Freud, Melanie Klein and others, especially in Vienna and London. *(See* Anna Freud, *Einführung zur Kinderanalyse* [1927]; Melanie Klein, *Psycho-Analysis of Children* [1932].)

4. Special problems concerning female sexuality became objects of intensive investigation by Freud, Ernest Jones, Helene Deutsch, Jeanne Lampl-de Groot, Ruth Mack Brunswick, Sandor Rado,

Karen Horney and others.

5. Psychoanalytic theory and technique were applied increasingly to the study of organic physiology and pathology. These studies of the interrelationship between organic and psychic processes are exercising a profound influence on medical education and on the everyday practice of surgery and internal medicine. *(See* Edward Weiss and O. S. English, *Psychosomatic Medicine* [1943]; Flanders Dunbar, *Emotions and Bodily Changes* [1935] and *Psychosomatic Diagnosis* [1943]; F. Deutsch [ed.], *The Psychosomatic Concept in Psychoanalysis* [1953]; E. Wittkower and R. A. Cleghorn [eds.], *Recent Developments in Psychosomatic Medicine* [1954]; "Psychosomatic Medicine Monographs"; and the files of the journals *Psychosomatic Medicine* and the *Psychoanalytic Quarterly.)*

6. Psychoanalytic technique and theory have come into wide use in field work in anthropology and sociology: Geza Roheim, Margaret Mead, B. Malinowski, Abram Kardiner, J. Dollard and others.

A survey of certain of these and of other developments will be found in Freud's *New Introductory Lectures on Psycho-Analysis* (1933) and the *Index of Psychoanalytic Writings,* 5 vol., ed. by Grinstein (New York, 1956).

Areas of Controversy. — It is instructive to look back on the controversies which have revolved around psychoanalytic theory and technique. Early schisms occurred over such issues as the basic role which Freud ascribed to biological instinctual processes in human psychology. Jung moved away from this in a direction which was in essence mystical. Otto Rank reverted to an 18th-century facultative will psychology. Alfred Adler placed an unbalanced emphasis on an artificially isolated power drive. Of necessity these viewpoints entailed a rejection of psychoanalytic technique as well as theory, and the supporters of these psychologies did not designate their theories as psychoanalytic, but used various other names (individual psychology, analytical psychology, etc.) to distinguish them from Freud's psychoanalytic psychology. None of these three early separations resulted in the development of a systematic school of theory. technique, experimentation or instruction. The result was that their adherents were gradually disappearing.

More recent controversies are over details of theory or technique and do not lead to a complete departure from the parent stem. The leaders continue to subscribe to the main body of psychoanalytic thought and to look upon themselves as psychoanalysts.

The more valid among the controversies current at mid-20th century focus on such questions as the definition of instincts, details of libido development and the relative importance of infancy, puberty and adolescence in the genesis of neurosis; and on such technical issues as the duration and continuity of treatment and the handling of transference phenomena. Certain specious issues are often interwoven confusingly with these legitimate issues, however. Some of these are reminiscent of the ancient battles over heredity versus environment, and take the form of polemics over what is called a "genetic" versus a "cultural" origin of neuroses, as though it were possible to isolate the influence of the one from that of the other. Such 'pseudo-controversies are scientific catchpennies, and because they are devoid of meaning quickly disappear.

A more significant area of inquiry is developing around the validity of all quantitative metaphors, as these are used not merely to characterize the interplay of psychological processes but as a basis for explaining variations in human behaviour. This development is related to the rapidly evolving changes in current concepts of the way the human brain works. Through the coming years these developments will lead slowly to important clarifications and simplifications in the conceptual structure of psychoanalysis.

Disagreement is essential to the growth of any science. In the state of psychoanalysis at mid-century one might deplore only a tendency on the part of some critics to broadcast theoretical concepts widely to a lay public before they have been sufficiently tested. This creates a furor of verbal disagreements and makes it difficult to maintain an atmosphere of quiet objective research. It seemed doubtful, however, that any of the issues which were in dispute at that time would lead to the development of new schools or to such schisms as occurred in earlier years.

Influence on Literature and Art. — The two principal figures in the history of psychoanalysis and modern art were Sigmund Freud and Carl G. Jung. Of Freud's work, the most important for literature and the other arts were *The Interpretation of Dreams* (1900), *Three Contributions to the Theory of Sex* (1905), *Beyond the Pleasure Principle* (1920) and a number of the essays and papers in *The Collected Papers of Sigmund Freud* (the English translation published 1924). Conspicuous for their influence on the arts among these last were such essays as "The Dynamics of the Transference" (vol. ii). "Turnings in the Ways of Psychoanalytic Therapy" (vol. ii). "The Moses of Michelangelo" (vol. iv), "The Relation of the Poet to Day-Dreaming" (vol. iv) and "The Unconscious" (vol. iv). The work of Jung best known to modern writers and artists included *Psychology of the Unconscious* (1916), *Psychological Types, or the Psychology of Individuation* (1920), *Modern Man in Search of a Soul* (1931) and several essays which attempted to explain the psychology of art; of these. his "Psychology and Poetry" (which appeared in *Transition,* translated by Eugene Jolas, in 1930) is perhaps best known. A number of other pioneers in the establishment of psychoanalysis in the 20th century contributed to the very large body of work on psychology and the arts. Most of these followed through suggestions made originally by Freud and Jung, but they also investigated more exhaustively subjects that were for the most part only peripheral to the major interests of the two leading spokesmen for the field. Among these psychoanalysts who were interested in the application of their disciplines to the arts and to criticism were Wilhelm Stekel, Otto Rank, Ernest Jones and Charles Baudouin. The most important works of these men were Rank's *The Incest-Motive in Poetry and Legend* (1912), Jones's *Hamlet and Oedipus* (1910 and 1949) and Baudouin's *Psychoanalysis and Aesthetics* (1924). In addition, there were numerous critics whose analysis of the arts was strongly marked by their preoccupation with psychoanalysis and psychiatry: among them the most influential were Herbert Read, Kenneth Burke, Frederick C. Prescott and Maud Bodkin. Psychoanalytic investigations of the lives of writers and artists were responsible for a large body of additional work. Freud himself contributed to this kind of writing in his *Leonardo da Vinci: a Psychosexual Study of an Infantile Reminiscence* (1910) and in his essay "Dostoyevsky and Parricide" (English translation published in *Partzsan Review,* fall, 1945). In both cases, Freud attempted to find in the work of the artists evidence that would help toward an understanding of their "psychic life." Biography, following upon the suggestions contained in these contributions and others, as well as the great body of clinical investigation, developed a special approach toward the arts, in which the work of art was related to and explained in terms of the artist's psychological history. Conspicuous examples of this form of psychobiography were René Laforgue's *The Defeat of Baudelaire: a Psycho-Analytical Study of the Neurosis of Charles Baudelaire* (1931), Saul Rosenzweig's "The Ghost of Henry James" (in *Character and Personality,* Dec. 1943), Edmund Wilson's biographical studies of literature (many of them contained in *The Wound and the Bow,* 1941), Joseph Wood Krutch's *Edgar Allan Poe: a Study in Genius* (1926) and Van Wyck Brooks's biographies of Mark Twain *(The Ordeal of Mark Twain,* 1920) and Henry James *(The Pilgrimage of Henry James,* 1925).

The question of the influence—of the degree of it and of all the peculiarities of its nature—is as complex as the influence itself is varied and widespread. There were writers and artists who professed to have and sometimes had a great knowledge of psychoanalysis and who worked in terms of a direct recognition of its value for their art. These included most of the surrealists, some of whom (like André Breton) had had actual experience as analysts, and other writers who (like Ludwig Lewisohn, Georg Groddeck, H. R. Lenormand) spoke of psychoanalysis with varying degrees of accuracy and conviction. Of Lenormand's plays, beginning with *Le Mangeur de rêves* (1922), those which presented tragedy based chiefly on psychoanalytic knowledge of character included *L'Homme et ses fantômes* (1924), *Asie* (1931) and *Pacifique* (1937); all these works reflect wide and accurate acquaintance with the discipline and the conclusions of psychoanalysis, though Lenormand objected to their being labeled Freudian. Also included in this first group of writers was Thomas Mann, who not only knew and greatly respected the work of Freud, but was also extremely judicious in his application of this knowledge to his fiction. In an essay on "Freud's Position in the History of Modern Thought" (1928; included in *Past Masters, and Other Papers*, 1933), Mann applauded Freud for his intelligent concern with the psychic life as well as his wish to find new sources of cure and therapy. One of Mann's first uses of his wide acquaintance with psychoanalysis was in the novel *The Magic Mountain* (1924), but here the reference to psychoanalysis is mixed with a generous and eclectic use of many other kinds of knowledge and speculation—notably the philosophies of Arthur Schopenhauer and Friedrich Nietzsche. That he remained objective concerning the advantages of analysis for modern society was abundantly indicated in such remarks from the novel as this made by the character Settembrini: "Analysis as an instrument of enlightenment and civilization is good. in so far as it shatters absurd convictions, acts as a solvent upon natural prejudices, and undermines authority. . . . But it is bad, . . . in so far as it stands in the way of action, cannot shape the vital forces, maims life at its roots. . . ." (*The Magic Mountain*, Thomas Mann, p. 283, Mod. Library Ed.; A. A. Knopf, Inc., N.Y., 1927.) In his fictional reconstruction of the biblical story of Joseph, Mann quite deliberately made use of the speculations of both Freud and Jung concerning the value of myth and its symbolic recurrence, through a racial (or "collective") unconscious. Mann's fiction showed the skill of an intellectually disciplined mind whose application of psychoanalysis, as well as of other knowledges, never allowed it to dominate but made it serve the original aesthetic form and subject.

The knowledge of psychoarialysis also led modern novelists to establish the analyst himself as an important fictional personage, sometimes available to satirical observation (as in Waldo Frank's novel *The Bridegroom Cometlz*, 1938), sometimes placed in a crucial role as adviser and "physician of the soul" (as in Lewisohn's *The Island Within*, 1928) and sometimes credited with providing the means of a novel's resolution (as in Arthur Koestler's *Arrival and Departure*, 1943). The substance and content of psychoanalytic disclosures (or their equivalents in the artist's imagination) often dominated the content of works of literature. Reliance upon the revelations of the subconscious mind was conspicuous in such works as the fiction of Anaïs Nin; surrealist poetry, prose and painting; Groddeck's *Der Seelensucher* (1922); F. Scott Fitzgerald's *Tender Is the Night* (1934); Conrad Aiken's *Great Circle* (1933), *King Coffin* (1935) and much of his poetry (particularly *The Coming Forth by Day of Osiris Jones*, 1931); and both the poetry and fiction of Dylan Thomas. Notable for its literary approximation of clinical analysis was the novel by Italo Svevo (Ettore Schmitz) *La Coscienza di Zeno* (1924; translated as *The Confessions of Zeno*, 1930), in which the narrative is presented as a continuous self-analysis by the hero. In musical comedy and the theatre the role of the psychoanalyst was presented in Moss Hart's *Lady in the Dark* (1941) and T. S. Eliot's *The Cocktail Party* (1950).

A second group of writers and artists included those who undeniably showed the influence of psychoanalysis but who resisted the labels Freudian and psychoanalytic. These persons gained prominence in literature and art in one of two ways. either they formulated their own theories of the unconscious and other psychoanalytic concerns in an effort to disprove Freud or to discount his values; or their work followed the lines and treated of the material with which psychoanalysis was largely concerned without having derived from a study of it. An important opponent of psychoanalysis was D. H. Lawrence; his novel *Sons and Lovers* (1913) interested psychoanalysts and critics who found a direct influence in its presentation of familial problems. Lawrence's reply was to repudiate psychoanalysis as too narrowly and harmfully scientific; but in the energy of his protest lay an earnest of the contribution made by psychoanalysis to his thinking. In a great number of letters and essays, Lawrence attacked both Freud and Jung, though he gave a qualified approval of another analyst, Trigant Burrow. His principal long attacks on psychoanalysis were *Psychoanalysis and the Unconscious* (1921) and *Fantasia of the Unconscious* (1922). In these works, Lawrence accused psychoanalysis of putting a false and debilitating emphasis upon scientific probing and examination which not only misunderstood the vital sources of human action but helped to defeat human vitality and tended to reduce the "life forces" to objects of intellectual curiosity. These reflections were associated in a large portion of Lawrence's writings of every kind with a general attack upon modern rational and intellectual life, as well as with his repudiation of the mechanistic, life-defeating impact of modern industry upon human vitality. Other writers offered in their work tempting opportunities for critics who wished directly to attach the label Freudian to them. but in large part rejected it or confessed to an ignorance of the disciplines that had allegedly influenced them. Among these writers were Sherwood Anderson and Eugene O'Neill; particularly in some of the latter's plays (especially *Mourning Becomes Electra*, 1931) there is abundant evidence of his realization of psychoanalytic techniques and discoveries, though O'Neill himself denied any direct line of influence. Franz Kafka was a special case: many of his writings show a line of relationship to his own familial circumstances, revealed especially in "Letter to My Father"; but, while critics did quite successfully exploit that relationship, Kafka's work derived from a complex of other influences which made a too-simple psychoanalytic explanation misleading. (See *The Kafka Problem*, edited by Angel Flores, 1946).

The final kind of influence concerned the role which psychoanalysis played in a number of the major preoccupations of modern writing and art. Psychoanalysis could rightfully claim a share in the motivating influence upon the release (of literature chiefly, but of the other arts as well) from the restraining and inhibiting cultural and traditional limits of taste and decorum which had fairly well held until the end of World War I. In these circumstances, psychoanalysis may be considered a social instrument, providing a rationalization of social change; but this was not to be its enduring purpose, nor had it been its original or exclusive aim. In many ways, the conjunction of psychoanalysis with social revolt was accidental, and the notoriety hindered the serious progress of the science as much as it helped to popularize it. The clinical studies begun by Freud and revealed in *Three Contributions to the Theory of Sex* and other places had a rather important voice, though by no means an exclusive one; the work of other psychologists, of sociologists and anthropologists was equally important, and the general impact of the war served as a primary cause of the release of inhibitions among artists regarding the treatment of these matters. What psychoanalysis did was immensely to extend and partly to provide phraseology for the discussion of sex matters or for their dramatization in works of literature. The attitude toward psychoanalysis on this level of influence was often largely undiscriminating, amateurish and ignorant. The principal terms and the popular notions of psychoanalysis were used over and over again in the popular and semi-popular literature of the 1920s, as the Marxist and pseudo-Marxist ideas found their way into the work of the 1930s. The catalogue of works which reflected this type of influence is very great; the use of psychoanalysis was sometimes very shrewd, sometimes quite mistaken and misleading and often merely the result of a desire to be fashionable. In one way or another the work of the following writers showed the widespread impression made by psychoanalysis upon the modern world: Floyd Dell, Max Eastman, Maxwell Bodenheim, Conrad Aiken, Susan Glaspell, Evelyn Scott, Waldo Frank. F. Scott Fitzgerald, Carl Van Vechten, May Sinclair, J. D. Beresford and Aldous Huxley. In the work of most of these. psychoanalysis was little more than incidentally acknowledged, or was used merely as a form of intellectual small change. By 1940 the relationship of psychoanalysis to social analysis had become much more complex; it was combined with economic determinations of history, with anthropology and with theology.

The actual study of psychoanalytic influence on modern literature and art contains many varied problems. In the first half of the 20th century at least. the influence was often haphazard and incidental, and art borrowed from it a means of confusing its terms and its disciplines. Until the time of World War I, the career of psychoanalysis had been largely handicapped by a considerable rejection of it as a valid psychology. The writer or artist, aware of a significant new contribution to human knowledge, even in the early years, was both distrustful and confused concerning its actual value for him. New terms, discoveries, emphases (or extensions of original terms) served to confuse him further. In addition, the sources of information from which the artist was able to draw were often quite remote in both nature and quality of precision from the original; as psychoanalysis became popular, numerous books, essays, editorials, conversations and amateurish "games" served often to give portions of "information" or vagrant notions of what psychoanalysis was actually doing. This variety of circumstance accounted for the vast majority of errant and erroneous uses of what was, when separated from its accurate source, mostly a fashionable mode of discourse, or a jargon.

For those who considered psychoanalysis seriously and with some accuracy, it made substantial contributions in at least three separate areas of creative work. The first of these was the study of the unconscious itself—often quite aside from the psychoanalytic purpose for making that study. The pioneering influence in this connection was Freud's *The Interpretation of Dreanzs.* His investigation of the "dream work" had a profound and widespread effect upon the arts. especially as it gradually made available to artists certain information concerning the "behaviour" of the unconscious. The dream not only provided an extension of the uses to which the various languages of the arts might be put; it also suggested a range and a new reordering of symbolism which could be applied in varied ways to literature and art. In literature, the techniques practised in stream-of-consciousness writing were greatly extended through adaptations or applications of Freud's original suggestions. A considerable range of literary styles was made possible as a consequence, as well as new departures in the structure of novels, plays and poems. The popularity of this method was largely the result of the great success of James Joyce's *Ulysses* (1922), imitated in a great number of novels which followed its publication. *Ulysses* was followed by *Finnegans Wake* (first published in part as "Work in Progress" in the magazine *Transition,* 1927 to 1929; as a book, 1939), a much more elaborate and exhaustive exploitation of the literary resources of psychoanalysis, in combination with many other disciplines, knowledges and techniques available to the erudition of its author. The techniques initiated or perfected by Joyce were subsequently taken over in other fictions, stylized and combined with more traditional forms of analysis. The most important contribution made by them lay in the revisions seen of the individual dream consciousness and a world view that was at once anthropological, mythical and cultural. Other applications of the information about the unconscious made available to the arts included the so-called "automatic writing" of the surrealists, especially of André Breton, Louis Aragon, Philippe Soupault, René Crevel and Paul Éluard. These artists, and others, did not confine themselves, however, to a mere simulation of mental disorders in their work; it did remain close to what the founders of surrealism thought were their psychoanalytic origins Breton's definition of surrealism, given in the *Manifestes du surrealisme* (1924), established both the nature and the limitation of their work: "Pure psychic automatism by which it is intended to express, verbally, in writing, or by other means, the real process of thought. Thought's dictation, in the absence of all control exercised by the reason and outside all aesthetic and moral preoccupations." (André Breton, *Manifestes du surréalisme,* p. 46; Éditions du Sagittaire, Paris, 1924). In its later development, the sponsors of surrealism acknowledged that such work could easily be confined to a too narrow and repetitious form of creation and proposed (in Breton's essays and in those of Nicholas Calas) to free themselves from the limits of psychoanalytic descriptions of the unconscious. This independence of the limits of clinical psychoanalysis was much less true of surrealist painting (Max Ernst, Yves Tanguy, Salvador Dali and others), which for the most part continued to realize pictorially and without much variation the desires resident in the unconscious.

The second most conspicuous contribution made by psychoanalysis to modern literature and art had chiefly to do with the re-examination and exposition of human behaviour and the motives underlying it. This revision of view, involving as it did much attention to a person's sex life and his relationship to his parents from infancy on, did much to encourage both illuminating and wildly erroneous changes in the explanation of motive. The range of information concerning such mental disorders as were available, to novelists and dramatists especially, increased as the techniques of psychoanalysis expanded and theorists multiplied. Earlier fiction of the 1920s often remained content to speak superficially of "repressions," "neuroses" and "free association" and to narrate visits to psychoanalysts as part of a social fashion. As familiarity with psychoanalysis increased, the use of it became more "professional" in its efforts to achieve clinical exactness. The novels, dramas and motion pictures of the late 1930s and of the 1940s demonstrated much detailed knowledge of psychiatry and a willingness to exploit its opportunities for characterization and melodrama. An early example of such exploitation is Fitzgerald's *Tender Is the Night,* whose major theme depends upon the risk taken by a promising young American psychoanalyst when he marries his patient, and is thus forced to call increasingly upon his reserves of nervous and moral energy until both are completely exhausted. The novel revealed a considerable acquaintance with the terminology, practices and techniques of the clinic and the sanitarium, and some skill in appropriating them to the problems of a novel's form and structure.

The third contribution is largely the work of Jung. The difference between his influence and Freud's can best be explained by reference to their differing explanations of the term "libido." Freud had used this term to designate sexual energy; Jung preferred to expand its definition. Linked with this fundamental difference of interpretation was the much greater emphasis Jung put upon what he called the "collective unconscious," which has been described as "the precipitate of humanity's typical forms of reaction since the earliest beginnings." (J. F. Jacobi, *The Psychology of Jung,* p. 8; Yale University Press, New Haven, Conn., 1943.) The role of the artist became extremely important for Jung; he was considered a form of priest of the "collective unconscious" because he relates the conscious life of his fellows to its archetypes in the unconscious. This view of the unconscious and of its availability to art and literature had no small influence upon 20th-century writers and artists. It was one of several germinal theories which stimulated a great critical interest in myth and mythology. Among the critics whose interpretations of literature showed its influence were Maud Bodkin *(Archetypal Patterns in Poetry,* 1934), Elizabeth Drew *(T. S. Eliot. The Design of His Poefry,* 1949) and P. W. Martin *(Experiment in Depth,* 1955). Jung's influence served in a way to counteract Freud's rather narrow view of the artist and the tendency of his followers to analyze art in terms of the artist's psychic nature. Jung was in a much larger sense concerned with the act of creation and with its significance as a restatement and reshaping of recurrent mythical themes.

At the halfway mark of the 20th century, the usefulness of psychoanalysis for criticism and its influence upon the artist had grown much more complex and varied than at the beginning. New explorations of Freud and Jung continued to appear, as well as a considerable number of studies by psychoanalysts of the arts, by critics of psychoanalysis and psychiatry. In literature especially, the groundwork of psychoanalytic knowledge was accepted as familiar to the majority of both artists and critics. *See* also Index references under "Psychoanalysis" in the Index volume.

PSYCHOGALVANIC REFLEX. The term psychogalvanic reflex (P.G.R.) refers to a change in the electrical properties of the body (probably of the skin) following noxious stimulation, stimulation that produces emotional reaction and, to some extent, stimulation that attracts the subject's attention and leads to an aroused alertness. Galvanic skin response (G.S.R.) and electrodermal response (E.D.R.) are preferable synonyms. Though most of the work on this phenomenon has involved human subjects, it can be demonstrated in other mammals. The P.G.R. can be demonstrated in several ways, but usually with what are essentially modifications and improvements of the method of C. S. Féré (1888). In these, the response appears as an increase in the electrical conductance of the skin (a decrease in resistance) across the palms of the hands or feet. In the experimental arrangements, the subject forms one arm of a balanced Wheatstone bridge electrical circuit *(see* INSTRUMENTS, ELECTRICAL MEASURING: *Indicating Instruments).* When his resistance to the passage of a weak, impressed electrical current decreases, the bridge is thrown out of balance as indicated by the deflection of a galvanometer. The amount of change in his resistance can be calculated from the magnitude of this deflection or from the amount of external resistance that must be introduced elsewhere in the bridge to rebalance it. The response appears with a latency of about two seconds after stimulation with a pin prick, threat of injury, etc.; it rises to a maximum after two to ten seconds and subsides at about the same rate.

The P.G.R. is mediated by the sympathetic division of the autonomic nervous system. It is a part of the general arousal or activation pattern of physiological responses that mobilizes and fits the person for effective reaction in an emergency, as described by Cannon (1932). In addition, parts of the premotor cerebral cortex appear to have a roie in producing the P.G.R., and Darrow (1936) suggested that it is an accessory to the activity of the postural mechanisms, for which it could play a preparatory function. The consensus is that the P.G.R. is associated with activation of the sweat glands by the postganglionic sympathetic fibres, but that the perspiration actually secreted does not produce the characteristic decrease in skin resistance by acting as an electrolytic conductor.

A more sensitive indicator of minimal emotional arousal than other physiological responses, the P.G.R. has figured extensively in studies of emotion and emotional learning. It can help to uncover complexes of emotional sensitivities when used with word association tests or interviews; by observing when the response occurs, the skilled worker can deduce which stimuli evoke emotional disturbance. The P.G.R. is involuntary in the sense that subjects cannot suppress it readily, if at all, though it can be produced by voluntary acts such as deep breathing or moving., As a detector of emotion, the response often has served as one of the indicators in the "lie detector," along with blood pressure, pulse and respiration. If a neutral stimulus such as a light or tone is paired with mild pain, the neutral stimulus acquires the power to evoke the P.G.R. With such conditioning, the response can become a useful indicator for studying human learning as well as for detecting feigned deafness, blindness or anesthesia. *See* also EMOTION.

PSYCHOKINESIS, the influencing of physical events by an organism's psychological state (*i.e.,* by "thinking" or "willing") without the mediation of effector activities or forces known to physics. See PARAPSYCHOLOGY.

PSYCHOLOGICAL TESTS AND MEASUREMENTS. A psychological test may be defined as a scientifically standardized procedure for assessing some clearly defined mental characteristic. It is the scientific standardization—particularly the preliminary checking and calibration by *ad hoc* research—that distinguishes a psychological test from an ordinary interview or an academic examination.

This article is organized as follows:

I. HISTORICAL DEVELOPMENT

1. Earliest Types **of** Test.—The need for precise techniques to assess mental differences between individuals was first explicitly recognized by Sir Francis Galton (*q.v.*) and formed an essential part of his attempt to transform individual psychology into a genuine science. During the latter half of the 19th century. when psychology mas becoming an experimental science, it was found that laboratory measurements displayed marked variations from one person to another. Interest at that time centred chiefly on the general study of the mind as such. and these individual variations were consequently treated as errors of measurement, to be eliminated by some method of averaging. Galton noted that many of the differences seemed to be related to the individual's ability and temperamental characteristics as displayed in everyday life, and resolved to study and standardize the procedures from this new point of view.

Of his earlier "mental tests" (as he called them), many were suggested by the experimental techniques already used in laboratory work. In Great Britain the dominant school of psychology at that date held that all mental processes developed out of the sensory experiences of the individual or the associations formed between them. It seemed to follow that a subject's general efficiency might best be measured by testing his ability to discriminate elementary sensations. Galton therefore began by devising methods for measuring tactile, visual, auditory and muscular discrimination. The discrimination of weights had long been employed by E. H. Weber. G. Fechner (*qq.v.*) and their followers to demonstrate the general Weber-Fechner law (see PSYCHOPHYSICAL METHODS) and one of Galton's earliest and best-known tests consisted of a calibrated series of weights for measuring the accuracy with which each person could discriminate such differences. These sensory tests were later supplemented by tests for speed and strength of movement, quickness of reaction and extent of associative memory. Later Galton came to realize that still more complex processes would yield better estimates of general efficiency and accordingly constructed a number of tests for "higher mental processes." No less valuable were the statistical techniques that he devised for validating and standardizing the new procedures — the percentile and the average deviation as metrical units, the scaling procedures based on the normal frequency distribution and above all the coefficient of correlation.

In the later stages of his work he received active assistance from J. M. Cattell (*q.v.*), a U.S. student who had worked in Wilhelm Wundt's laboratory at Leipzig and acted for a short time as Galton's assistant. In 1890 Galton and Cattell published the program of mental tests which, with various other devices, Galton had regularly used in his anthropometric laboratory for studying the characteristics of individuals. On returning to the United States, Cattell and his co-workers started at Columbia university the systematic application of a similar scheme of tests to college students and thus initiated the long series of researches carried out with the aid of these new techniques. The most important was embodied in a long and influential monograph (1901) by C. Wissler (one of Cattell's research students), which reviewed the results obtained and applied for the first time the Galton-Pearson correlation coefficient to measure the relations of the test results with each other and with independent criteria.

In 1892 James Sully had opened a department of education at University college, London, where a school for boys happened to be available on the premises. There he and Galton (who had transferred his laboratory to the college) joined in applying tests of physical and mental characteristics to school children. Sully held that the measurement of attention would provide the best estimates of a child's intelligence; accordingly he devised tests for the "span of prehension" (the maximum number of letters apprehended in a single glance or of digits recalled after a single hearing) and reported that the differences thus detected varied closely with the child's "general mental capacity."

In 1905 Galton obtained a grant from the British Association for the Advancement of Science for repeating his anthropometric survey of the British Isles, with the inclusion of tests for mental capacities, and a committee was formed to make preliminary inquiries with W. McDougall (head of Sully's laboratory in London) as secretary. It worked in co-operation with a second committee appointed to study mental and physical factors in education. The outcome was a series of investigations, carried out mainly under McDougall's guidance, by W. Brown, C. Burt, C. Spearman and others, with a view to constructing intelligence tests for school children.

2. General and Special Abilities. — Galton, in the course of his investigations, had been led to distinguish between "special aptitudes" (corresponding roughly to the old-fashioned "faculties") and "general ability" — a kind of superfaculty determining mental efficiency in all forms of cognitive activity. In France Alfred Binet (*q.v.*), an admirer of contemporary British psychology and particularly of the views elaborated by Galton, adopted this distinction, but since in French the word "ability" possessed a different meaning he substituted Herbert Spencer's term "intelligence." In 1904 the French ministry of public instruction appointed a commission to study the diagnosis and training of mentally deficient children and, as a member of the commission, Binet set about compiling standardized scales for measuring not only "pedagogical attainments" but also what he termed "general intelligence" and "partial aptitudes." He determined to discard "the instrumental methods popular in German laboratories" and to compile a series of problems, graded in difficulty and requiring for their solution "little else but pencil, paper, pictures, and a few common objects." The success of his novel procedure as a means of diagnosing subnormal pupils attracted widespread attention, and his age scale of intelligence tests was almost immediately translated and adapted by psychologists in Belgium, Britain, Germany and the U.S.

3. Group Tests. — Previously, all such tests had to be applied individually. For the purpose of large-scale examinations of school children, however, it was desirable if possible to develop a type of test which could be applied collectively. Accordingly, in London and elsewhere a number of researches were carried out to investigate the possible use of what were subsequently known as group tests. The result was the type of problem commonly used in the English 11+ examination: "analogies," "opposites," "syllogistic reasoning," "code tests," "completion tests" (a device suggested by H. Ebbinghaus) and the like, usually combined into a booklet of half a dozen subtests. Similar principles were adopted for constructing and standardizing tests for the chief subjects of the school curriculum, and in 1913 the London County council appointed an official psychologist to study and apply mental and scholastic tests, particularly in connection with the examination of cases of subnormal and supernormal ability.

4. Performance Tests. — In the United States, in order to test foreign immigrants, special attention was given to performance tests; *i.e.*, tests not entailing a knowledge of some particular language. H. A. Knox developed "construction" and "imitation" tests, S. D. Porteus a series of graded maze tests, H. H. Goddard and W. F. Dearborn form boards, W. Healy a picture-completion test. Finally. R. Pintner and D. G. Paterson combined a carefully chosen selection to form a "performance scale" which was widely used for those handicapped by deafness, lack of schooling or other disabilities. In the field of education E. L. Thorndike (*q.v.*), who had joined Cattell at Columbia, quickly became the leader of the test movement in the United States and. though at first doubtful about the hypothesis of a general ability, was active in producing scientifically standardized tests of scholastic abilities. By the end of the first decade of the 20th century more than 50 well-tried tests for various capacities — sensory discrimination, perception, memory, attention, learning, imagination and the like — were available in standard form and were described in G. M. Whipple's Manual of Mental and Physical Tests (1910), with tabulated norms of performances and full instructions for use and marking.

5. Vocational Testing. — Just before the outbreak of World War I, Hugo Miinsterberg (*q.v.*) and others in the United States initiated a series of pioneer investigations on adolescents and adults to study the value of psychological tests for purposes of vocational guidance and selection (see PSYCHOLOGY, APPLIED). During the war group tests of intelligence were administered to about 1,750,000 recruits for the U.S. army, and a more limited use was made of aptitude tests for assigning men and women to the most suitable trades in the various fighting services. Similar efforts on a more restricted scale were made in Great Britain. The success of such methods for military purposes resulted after the war in a rapid development of psychological testing for education and industrial purposes. The experience gained during the 20 years of peace in these two fields proved invaluable in World War II, when both countries made full use of mental testing in the various branches of their navies, armies and air forces.

6. Testing Temperamental Characteristics. — The application of test procedures to what were called the affective and conative (as distinct from the cognitive) aspects of the mind developed far more slowly. The emphasis laid by McDougall (*q.v.*) on emotional tendencies as the chief determinants of personality and character led several of his research students to apply test procedures to the assessment of temperamental qualities. At first the procedures used were based chiefly on the ordinary laboratory techniques for investigating the physical effects of emotion — changes in blood pressure, speed of pulse, skin temperature and, most striking of all, the so-called psychogalvanic reflex (a transitory increase in the electrical conductivity of the skin induced by emotional stimulation). As with intellectual testing. it soon appeared that tests based on these more elementary processes and requiring highly elaborate apparatus mere neither the most convenient nor the most effective. Galton had already attempted "psychometric experiments" for the study of associated ideas and had noted how such devices brought to light unconscious interests and motives. particularly early sentiments strongly tinged with emotion, differing widely with different individuals. For stimuli he relied mainly on lists of suitable words. Later investigators tried pictures, ink blots (first used by Binet) or ambiguous drawings (a method described by William James) and so developed what British psychologists called apperception tests and U.S. writers projective tests. The success obtained with these procedures and the growing interest in the affective aspects of behaviour (due largely to the influence of the psychoanalytic school) led to numerous researches with a variety of tests and other devices for assessing these deeper constituents of personality.

7. Recent Research. — From about 1930 onward there were no new developments affecting the basic principles or ideas, most of the work being concerned either with improving research techniques already introduced or with constructing and applying tests for an ever-widening range of abilities, attainments and other characteristics of individual behaviour. On the theoretical side special attention was paid to the refinement of the statistical procedures used in constructing and validating new test batteries, and particularly to such technical questions as scaling, reliability, item analysis, factor analysis, better sampling of test items and test populations and. above all, to improved criteria for validation. On the practical side, the increasing use of tests for educational. commercial and military purposes, especially by public bodies, led to an attempt to assess not merely theoretical value but also the practical value of large-scale testing: test B may have a much lower theoretical validity than test A and yet, because it adds more to information already available and is at the same time far less expensive. it may have a much higher practical value for the purpose intended. Since financial considerations are involved, it is desirable to measure the utility of a test by applying the mathematical procedures used in what the economist terms decision theory.

A classified list of the tests available for various purposes, with a detailed description and critical evaluation of each, is to be found in the *Mental Measurements Yearbook,* published about every five years by Oscar Buros. The *Fifth Mental Measurements Yeavbook* (1959). covering 1952–58, includes nearly 1 000 different tests; the majority are achievement tests, dealing with the chief subjects of the school. college and university curriculums. In particular the adoption of psychological methods in the armed forces during World War II led to a vast multiplication of tests employed for measuring the abilities and attainments of adults.

Most psychological tests are comparatively short lived and are quickly replaced by more adequate versions. A few, however, have proved to be of relatively lasting value. Of these the best known is the original Binet scale; in Britain one of the London revisions and in the U.S. one of the Terman revisions (the Stanford-Binet) are in regular use, particulariy for individual examination of educationally subnormal children. A late version of the latter exists in two parallel forms and contains 62 items grouped into 20 levels of difficulty, 6 (or in one case 8) for each half year (2 to 4 years) or each year (5 to 14 years nith four adult levels) ; *e.g* , for year 5 typical items are defining by classification or description, using two words from a standard list of 45, copying a square, repeating a sentence of five monosyllables from memory; for year 10, reading and summarizing a short paragraph, indicating what is absurd in a picture, repeating six digits. For testing adults the Wechsler-Bellevue intelligence scale gained widespread popularity during the 1950s. particularly with clinicians. This consists of six verbal and five performance tests and, with the aid of a presented table, the measurements are expressed in terms of a conventional intelligence quotient; a simplified version also was devised for use with children. Other tests are available for infants, for the blind, the deaf and those otherwise handicapped.

Group tests of intelligence are even more widely used. Under this title the *Yearbook* describes over *100* U.S. versions, available to the general public. most of them composite batteries based on about half a dozen of the stock types of problem described above. In Britain fresh group tests are prepared every year, but are not published until they are no longer required for official purposes. The name intelligence test is perhaps misleading; most of them are not so much tests of innate general ability as tests for general classification.

Less progress has been made with individual tests for special mental capacities — observation, memory, imagery, quickness and the like—but improved apparatus was devised for testing sensory capacities — form vision, colour vision, hearing, pitch discrimination, etc. So-called multiaptitude batteries became increasingly popular; these commonly cover such aptitudes as verbal, numerical and mechanical abilities and, less frequently, speed, accuracy, memory, judgment, reasoning, etc. One of the earliest and best known is L L. Thurstone's test of primary mental abilities, which largely provided a model for later batteries of this type. There are in addition numerous tests for more complex abilities; *e.g.,* artistic and musical capacity and professional aptitudes for medicine, law, engineering, teaching and the clerical professions.

II. CHARACTERISTICS MEASURED, CONSTRUCTION AND USES

A. Characteristics Measured

As a result of a vast amount of detailed research on the lines of these earlier inquiries, three main types of mental characteristics can be measured by means of psychological tests or similar devices with tolerable accuracy. The majority of the tests in regular use can be accordingly classified under three main heads: (1) tests of attainments (*i.e.,* of acquired knowledge or skill in various fields) ; (2) tests of abilities, either intellectual or practical; and (3) tests of other characteristics of personality; *e.g.,* emotional: temperamental and moral qualities (including interests, attitudes, ideals and motivational tendencies generally).

1. Educational and Vocational Attainments. — The attainments commonly tested may be subdivided into two broad groups, educational and vocational. Of the educational or scholastic tests the most. thoroughly standardized are those designed to measure achievement in the ordinary subjects of the elementary school curriculum — reading, spelling, arithmetic, composition, drawing, handwriting and handwork. With these the norms usually consist of standard (*i.e.,* average) performances for each sex separately at each age of school life, together with some indication of the range of individual variation (generally in the form of standard deviations) and of border lines fur certain types of child or school; *e.g.,* for mentally deficient children or special schools for the educationally subnormal.

Tests also are available for more advanced subjects in the curriculum, to be used with older children at the secondary school stage; *e.g.,* for foreign languages, both ancient and modern, and for the various branches of mathematics and science. However, because of the difficulty of securing fair samples of pupils at these higher stages, the standardization of tests is less reliable. Attempts have also been made, particularly in the United States, to develop tests for academic subjects taken at the university stage — teaching, medicine, dentistry, engineering. accounting and law.

For occupational guidance and selection in commerce and industry. vocational psychologists endeavoured to construct tests for assessing the extent to which a given applicant possesses the kinds of knowledge and skill required for this or that specific type of employment. Norms of performance are commonly given for the occupations to which they relate and border lines below which efficient performance cannot be safely expected. Many large firms maintain their own trade-test departments for compiling, standardizing and administering tests of the proficiency of their own employees (see PSYCHOLOGY, APPLIED: Vocational *Guidance*).

2. General and Special Abilities.—Tests of ability differ from tests of attainment or proficiency in that, while the latter are intended to measure the actual results derived by formal education or occupational training, the former seek to estimate differences in mental capacity, regardless of the effects of instruction, training or experience. Whether such capacities exist and, if so, what is their precise nature, have been the topics of somewhat heated discussion.

Galton's contention that there were two main types of cognitive capacity for which tests could be developed—general ability and special aptitudes—met with a double opposition. Spearman and his followers contended that the assumption of a single general factor only would suffice to account for all innate intellectual differences; the hypothesis of special abilities or aptitudes they repudiated as an obsolete relic of the old-fashioned theory of faculties. On the other hand, most U.S. investigators—Thorndike, Thurstone and their collaborators—early accepted the existence of special or primary abilities but were highly skeptical of anything described as general ability or "intelligence." The numerous researches carried out by educational and industrial psychologists leave little doubt about the existence of special abilities, and in his later years even Spearman acknowledged their influence, at least on a limited scale. Most British psychologists accept the hypothesis of general intelligence as well, and the majority of the former critics—Thorndike, Brown, G. Thomson and Thurstone—retracted or at any rate moderated their earlier objections in varying degrees.

The attempt to identify the precise nature of the various special abilities or aptitudes has formed an important object of later factorial research. Unlike the "faculties" of the older psychologists, the abilities that can most readily be distinguished turn out to be decidedly complex and may themselves be analyzed or subdivided into more elementary types of capacity, almost without limit. In fact, the whole structure of the mind appears to consist in a hierarchy of abilities, the more general being usually the earliest to mature; during the course of the child's development, they become progressively differentiated into the more specialized, while the more elementary tend to combine into the more complex.

The special abilities so far established may be conveniently classified according as they arise from differences in the processes involved or in the mental content. The latter are the easiest to isolate and measure. The more elementary relate to differences in the sensory content: effective tests are available for the visual perception of form and colour, for the discrimination of audible pitch and loudness and for the discrimination of touch, weight and muscular movement. Equally well established are the differences between the chief types of mental imagery, and there are tests and questionnaires intended to discriminate between visualizers, audiles, motiles and (most common) the various mixtures. From the standpoint of educational and vocational guidance, four content factors are of prime importance, namely, the abilities (or groups of abilities) which underlie (1) the understanding and the use of words (so-called verbal ability), (2) the understanding and use of number and numerical relations (so-called arithmetical ability), (3) the visual and kinaesthetic perception of space and (4) the control of co-ordinated movements such as are involved in mental skill and mechanical dexterity. Less clearly distinguishable are the factors entering into the understanding and use of relations, especially logical relations, and into aesthetic appreciation in its various forms.

Of factors defined in terms of the processes involved, the most important are those for speed, mechanical memory, productive association (*i.e.*, imagination in the popular sense of the word) and certain formal processes underlying rational thinking—abstraction, generalization and inductive and deductive inference. Since efficiency in tests for all these different activities depends in some degree on general ability or "intelligence," it is essential, when assessing the primary or specific ability in and for itself, to include some test of intelligence as well in order to eliminate its effects by means of partial regression or some equivalent device. On the whole, however, it must be admitted that tests for special abilities can claim neither the high reliability nor the high validity of tests for general intelligence.

With young children it is desirable, so far as possible, to assess innate potentialities—a problem which cannot be solved by tests alone. With adults it is usually sufficient to assess their actual abilities or aptitudes at the time of testing. Accordingly, the earliest vocational tests were commonly based not so much on abstract psychological theory as on a direct study of the work required, often investigated at first hand by a psychologist who himself undertook employment on the job in question. However, the attempt to compile efficient tests for the complex aptitudes required in all the various branches of commerce or industry is a lengthy and circuitous way of tackling the problem. Hence experts in vocational guidance tended more and more to determine the fundamental abilities required for different occupations on the assumption that the same elementary ability may enter (though in varying degrees) into several different occupations. For this purpose the results of theoretical studies, particularly by factorial techniques, proved of increasing value.

Before turning to the method of assessing temperamental characteristics and what is commonly termed personality, it will be well to consider first of all the various technical devices that were progressively worked out for compiling and calibrating tests of abilities and attainment and then to review the chief uses, both theoretical and practical, to which such tests may be put.

B. CONSTRUCTION AND STANDARDIZATION

1. Sampling **of** Tests and Persons.—Since mental measurements are far more liable to be affected by error than physical measurements, special care has been devoted to ascertaining the most effective methods for constructing and calibrating the procedures used. The first requisite is to define, in precise scientific language and in the light of current psychological theory, the particular characteristic to be measured. Such a definition is needed not merely to select suitable tasks or test material but also to secure an adequate criterion. The abstract definition must be capable of translation into concrete operational terms, so as to indicate what wili be the outward and visible signs of the inner postulated trait. The kind of behaviour chosen for observation may consist of answers to oral or printed questions, manipulations of the parts of some piece of apparatus, or relatively complex reaction to some standard situation.

The main part of the psychologist's task, however, is to test the test, *i.e.*, to determine (1) its reliability and (2) its validity. This involves a twofold process of sampling: it is essential (a) that the items selected for the test include typical specimens of the activities in question and (*b*) that the persons selected for testing form a typical sample of the population for whom the test is designed. Both items and persons therefore must be chosen in accordance with the principles recognized as necessary in order to ensure that the samples are genuinely random or at any rate truly representative. As a rule in the trial experiment the number of persons tested will be far smaller than the number to whom the test eventually is to be applied. On the other hand, the number of items should be much larger than the number to be incorporated in the final version. The items selected must be as numerous and as varied as the conditions of the examination permit. Consequently, unlike the question paper set at an ordinary examination which usually requires one full-length essay or about four to eight questions involving fairly long replies, most psychological tests comprise a large number of short problems—often as many as 50 or more to be answered in half an hour. Each is so framed as to reduce to a minimum all irrelevant forms of skill and knowledge (*e.g.*, reading, writing and cultural information) and to elicit answers that require a minimum of subjective judgment in deciding whether each reply is right or wrong. For example, "Jim is taller than Harry, but shorter than Tom; and Dick is shorter than Harry: which is the tallest of the four—Jim, Tom, Dick or

Harry? (put a line under the right name)." In such a question all the words used can be read by an average child of seven, but the problem in reasoning cannot be solved until a mental age of nearly ten, and at that age every child (with rare exceptions—*e.g.*, invalids absent for long periods) can understand the sentence. For such children, therefore, the ability to find a correct answer depends solely on capacity to reason and their replies can be marked mechanically by a clerk or even a machine.

2. Reliability. — In administering the preliminary version the first thing is to ascertain whether the results are self-consistent or, as it is usually termed, reliable. When any object or quality is measured more than once: the measurements almost invariably differ in some degree, and with psychological traits these variations may be Iarge. Hence earlier investigators made a practice of applying each test at least twice and calculating the correlation between the two sets of results. Later investigators were more often content with a single application and divided the entire series of items into two equivalent subsections. In this case the usual procedure is to carry out an analysis of variance, tantamount to calculating the average correlation for all possible methods of division. The correlation computed by one or the other of these methods is known as the reliability coefficient.

3. Validity. — By the validity of a test is meant the degree to which it succeeds in measuring the trait that it was intended to measure. For this a criterion is needed. The simplest check is to obtain subjective estimates for the trait drawn up by one or more experienced observers who have known the persons tested for a long period. When the test is to be used as a predictor, it is better to follow up the persons tested during subsequent years and secure new and independent measurements based on their after history. Occasionally some well-established test of known reliability and validity is deemed a sufficient criterion. In all these cases the accuracy of the new test is assessed by correlating the test results with those of the criterion, and the index thus obtained is known as the validity coefficient. But, where practicable, by far the safest procedure is to base the criterion not on a single set of assessments derived from direct observation or a single test but on a wide range of tests and assessments, all assumed to measure the same quality; the criterion will then be the general factor underlying the whole series of assessments, each being duly weighted. This method involves calibration by means of factor analysis (see below). With a composite test, it is also desirable to validate not merely the test as a whole but each component item—a procedure known as item analysis—-and those items with low correlations with the criterion are then rejected.

4. Types of Measurement. — When a sufficiently reliable and valid version has at length been constructed, the final step is to reduce the assessments to terms of a quantitative scale and then compile norms for precisely defined groups of the general population; *e.g.*, in the case of children, average performances for either sex at each successive age. To obtain scaled assessments for different kinds of trait, various types of measurement are available; *e.g.*, (1) classificatory, requiring only the determination of the presence or absence of the class attribute, expressed on a binary scale by 0 or 1; (2) ranking, requiring the determination of more or less, expressed by ordinal numbers; (3) differential, requiring the determination of equal differences or intervals; (4) ratio scales, requiring the determination of equality of ratio; (5) multidimensional scales, expressed by the assignment of a matrix of numbers.

In some instances, as in testing for colour blindness, the assessment is essentially qualitative or classificatory. Modern psychology, however, is skeptical of classification into types: border-line cases and mixed types are nearly always found and are often the most numerous. In most cases, therefore, the assessment is quantitative. and the ultimate aim is to obtain a graded measurement. With many tests (*e.g.*, for drawing or handwriting) the quality assessed exhibits varying degrees of excellence! but these have to be judged by subjective impression. In suck a case the nearest approach to a comparable measurement is obtained by simply arranging the individuals' performances in an order of merit. Each examinee is then given a rank, stating his position in the whole group, but, since groups differ in size, the ranks are then converted to percentile form. However. the intervals between successive ranks and percentiles are far from equal, since persons near the general average are usually far more numerous than those toward either extreme. Hence neither ranks nor percentiles are additive. With the majority of tests it is reasonable to assume that, in a representative sample of the population, the underlying measurements will be distributed approximately in accordance with the normal curve. Accordingly, by using tables for the normal distribution. any percentile can be converted into a multiple of the standard deviation (s.d.). Such measurements are said to be in "standard measure" or "standard score" (see below).

Often, however, the trait itself by its very nature implies an appropriate quantitative measure. With tests for elementary processes, such as sensory discrimination or speed of reaction, for instance, there are as a rule obvious objective units; *e.g.*, grams for the discrimination of weight, seconds for the measurement of speed. As ordinarily administered, many of the tests for higher mental processes also turn, directly or indirectly, on the measurement of speed. With group tests a limited time is usually imposed, and the raw measurement consists of the number of correct solutions achieved in the time allowed. With individual tests a limited number of problems may be set, each of the same difficulty as the others and all well within the capacity of the examinees. The measurement then consists of the time taken by the person to complete them all. Speed, however, is not always a satisfactory index of ability, and in general it is better to use a series of items, varying in difficulty and arranged in order of increasing complexity, from one so easy that all can answer it up to one so hard that all will fail; with this modification the actual number correctly solved really depends more on qualitative efficiency than on sheer speed. Tests of the former type are termed uniform tests and tests of the latter type graded tests.

5. Comparable Scales. — Standard *Measure*.—With such varying procedures and different methods of construction the raw measurements, taken as they stand, will seldom be comparable from one test to another. Hence it is usually desirable to convert the measurements as originally obtained to terms of a scale where the zero point and the unit shall always indicate the same amounts. This means a further process of calibration. One device, which is almost always available in a well-planned research. is to treat the average of the entire sample of persons as marking the zero point for the general population; different individuals can then be measured in terms of their deviation about this average, and each deviation can be expressed as a multiple of the average deviation of all the persons in the sample—*i.e.*, the standard deviation of the group. Once again, then, the measurements will be in "standard measure." Yet, even here, it is often wiser to deduce each standardized measurement indirectly from the examinee's rank (as described above) instead of directly from the ra measurements themselves Measurements in terms of the s.d. involve the use of plus and minus signs and of fractions—a type of scaling which has obvious inconveniences in actual practice. Consequently, it is often preferable to substitute an artificial scale in which all the measurements are positive integers (*e.g.*, one with a mean of 50 and an s.d. of 10, or a mean of 100 and an s.d. of 15) ; the latter has the additional merit of yielding scores that are analogous to the familiar intelligence quotients.

Mental Quotients. — As originally computed the intelligence quotient or mental ratio developed out of a method of standardization popularized by Binet. For the fundamental unit he proposed to take the increment of growth from year to year, with the ability of a newborn infant as the zero point. On this basis characteristics which, like intelligence, mature with increasing age or, like school attainments, accumulate from year to year can be assessed in terms of a mental age. Binet therefore standardized the various problems in his scale according to the age at which the average child could correctly answer them, the whole series thus forming an age scale measuring intelligence in terms of mental years.

However, unless the children to be compared are all of the same chronological age. this does not yield a satisfactory indication of their inborn ability. With many graded tests, including Binet's, the standard deviation for successive age groups increases roughly in proportion to the increase in age. This suggests using the ratio of the child's mental age to his chronological age (usually expressed in percentage form) as an index which may be expected to preserve a fair degree of constancy from year to year up to the time of puberty—a device first proposed by Wilhelm Stern in 1911. With a percentage scale the mean is necessarily 100 and, with the versions of the Binet intelligence scale commonly used in the U.S. and Britain, the standard deviation for complete age groups is approximately 15. However, the underlying assumptions on which the method is based are only broadly true, and "mental ages" and "mental ratios" or "quotients" computed in this way are suited only for rough practical purposes, not for scientific research. In the vast majority of cases the most satisfactory scale is one based on standard measures derived from percentile ranks.

Other methods of scaling, based on more complicated statistical techniques. were put forward from time to time. some of them intended to provide an "absolute scale." Since mental characteristics often consist of patterns of traits rather than of simple graded qualities, one or two statistical writers suggested that the ideal measurement in psychology should take the form not of a single figure but of a "matrix" of elementary assessments, such as will describe a complex structure rather than an isolated tendency and can itself be treated as a unitary system. The easiest way to handle such a matrix is to convert it by a canonical transformation into a "factor"—a method developed by British psychologists who adopted Karl Pearson's techniques.

C. Uses of Psychological Tests

1. Theoretical Value.—Psychological tests are widely used both as a research technique for investigating the basic characteristics of the human mind and as a practical tool in studying individuals for purposes of educational or vocational guidance. Their adoption for such purpqses, however, has not escaped criticism. particularly from psychologists of the Cambridge school such as C. S. Myers and O. L. Zangwill. That their warnings need to be borne in mind is shown by the exaggerated claims often made in popular expositions of the subject and by the way in which teachers, school doctors and sometimes education authorities rely on raw measurements obtained from unchecked or inadequately standardized tests, as if they could always be accepted at their face value. Nevertheless, an impartial study of the results achieved fully demonstrates the value of such methods in the hands of those who have been trained in their use and are aware of their inevitable limitations.

Contrary to the common notion, mental tests were first devised for the solution of theoretical rather than practical problems. Galton and most of his immediate followers were interested primarily in problems of mental inheritance. To some extent their early inferences were vitiated by the nai've assumption that innate characteristics are directly observable—a notion accepted by most biologists at that date. So far as human beings are concerned, it is universally acknowledged that any actual measurement is bound to be the composite product of both heredity and environment interacting one uith the other and, without special mathematical techniques, it is difficult to disentangle their relative influence. However. in spite of persistent skepticism as to the possibility of distinguishing the tao components, there has been a fruitful revival of research in psychogenetics, and the substitution of R. A. Fisher's statistical procedures for the cruder methods of Galton and Pearson yielded trustworthy conclusions in regard to the inheritance of inteliigence and other mental characteristics.

The interest of McDougall and those who worked with him centred rather on what they called the structure of the mind. McDougall himself conceived the hypothetical abilities and emotional propensities that enter into various forms of mental activity as analogous to the hypothetical "forces" of physics. This analogy suggested the adoption of a mode of analysis which would resolve the more complex manifestations of behaviour (the "resultants" of such forces) into elementary "components" in accordance with the so-called parallelogram law of dynamics. For this purpose Pearson's mathematical formulas for reducing a matrix of correlation coefficients to a set of orthogonal components seemed to provide the most appropriate working procedure, and, in various simplified forms, it was widely used for determining the "factors of the mind" both on the cognitive (or intellectual) and on the affective and conative (*i.e.,* motivational) aspects. Tests are then constructed for estimating the various "general" and "special" factors (*e.g.,* general intelligence and special or primary abilities on the cognitive). Here again criticism was active, being directed partly against the type of mental structure set up by different investigators and partly against the somewhat crude computing methods used by earlier workers. The introduction of electronic means of calculation have made it practicable to adopt more precise and elaborate techniques, which led to improvements in the test procedures themselves and in the assumptions on which they are based.

2. Practical Value.—From 1910 onward the rapid development of mental testing was due mainly to the recognition of its practical uses. In Britain, particularly in large industrial areas such as London and Liverpool, with their overcrowded slums, the poverty, squalor and truancy, together with the hostility of many parents to the aims of the schools, prevented many pupils from achieving the full educational progress of which they were in fact capable. Surveys carried out during the earlier decades of the 20th century showed that many children were being certified as mentally deficient who were merely dull or backward, while many who had high ability failed to pass the scholarship examination which entitled them to a free place in a secondary school. The introduction of mental tests together with other psychological techniques did much to alleviate these forms of educational injustice.

Where tests are used for selection on an extensive scale, their predictive value is commonly assessed in terms of a correlation coefficient. Thus, to check the efficiency of the so-called 11+ examination carried out annually by most English education authorities (when about 700.000 pupils are examined for admission to a grammar school), representative samples are followed up and reports obtained from the headmasters toward the end of the secondary course. On an average about 20% are selected from the entire age group and out of this 20% roughly one in four are subsequently reported as unsuitable, while about the same number of those rejected appear to have been rejected wrongly. These proportions are equivalent to a correlation of approximately 0.90. It should be noted, however, that the pupils who were wrongly selected or wrongly rejected are nearly always border-line cases, so that the inaccuracy of the assessment is not so serious as is often alleged. Moreover, these apparent errors are due not merely to defects in the examination itself but also to the inevitable fluctuations in each child's subsequent development and to various accidental conditions, such as ill-health or inadequate motivation at the time of testing.

With adults formal testing is, as a rule, less satisfactory. Nevertheless, it is not without its value in occupational guidance and selection. Here the method of estimating the efficiency of the various procedures has to be modified. The commonest method is to adopt the device of matched groups. One batch of candidates is selected in the ordinary manner and the other on the basis of the test results. The after histories of both are then systematically compared. In the main the data obtained fully justify the value of scientific testing as an adjunct to other procedures. When tests are used for diagnosing individuals or for predicting their subsequent progress, it is essential that the marks or measurements not be accepted in isolation from all other information. A single test scale, particularly if obtained during a group examination, may prove a precarious indication of the characteristic the investigator wishes to assess. But when interpreted in the light of other data (past history, family records, environmental conditions, observations of general behaviour, etc.) their value is unquestionable. (Cy. B.)

III. TESTS OF PERSONALITY AND TEMPERAMENT

In personality testing the first major task—shared with all other kinds of psychological testing—is the construction of tests that are sound and reliable and that are addressed to significant traits of individual behaviour. The second major task is the development of interpreters with sufficient diagnostic and interpretive skill to appraise the individual case. Attainment of the first goal requires research procedure and statistical analysis (see Construction and Standardization, above). The possibility of evolving a "psychodynamic portrait" from test scores, however, is more a matter of the intuition and skill of the test interpreter than of the particular tools employed. It is for this reason that so much stress is put upon the professional training of the practitioner in the field of personality testing.

An obvious problem in personality testing is the selection of the proper factors for measurement from among the seemingly endless number of traits, attitudes, values, behavioural tendencies, points of view, qualities of mind and other characteristics a person manifests; the next problem is that of organizing them so as to give rise to an integrated and functional view of this person as a distinct individual. The level of understanding desired rests on proper evaluation of three components: (1) the attributes of personality; (2) the structure or dynamic interplay of these attributes; and (3) the behavioural implications of this system of attributes.

G. W. Allport listed about 50 definitions of the term personality, drawn from philosophical, legal, sociological and theological as well as psychological writings, Many of the definitions stressed the way in which the person is perceived by others. This emphasis, however, seems too restricted, for it neglects the inner. subjective components of mental life and their implications for overt behaviour, An adequate view of personality must be broader. incorporating latent traits as well as those more manifest. It should also emphasize the organized pattern of traits and attributes underlying and determining the behaviour of the individual.

From this standpoint, temperament is seen as a factor or component of personality. Specifically, it refers to typical modes of reaction, states of energy and moods. The descriptive adjective "capable" would refer to personality but not to temperament, the adjective "impulsive" would refer to both. Another broad term often used in speaking of personality is "character." Following the above, character also is to be seen as an aspect of rather than as a synonym for personality. The emphasis in character is on morally sanctioned and approved attitudes and behaviour. (See also PERSONALITY; CHARACTER; TEMPERAMENT.)

The commonest unit of description and measurement of personality is the trait. A trait is an enduring quality showing itself in the typical way a person behaves in many different situations. All trait descriptions imply a basis of comparison with other persons. a dimension of variation. Thus most traits are present to some degree in most persons; the trait becomes salient only if it characterizes a person to a greater or lesser degree than the average. In personality analysis the psychologist looks for these significant departures from the norm; in personality testing one of the tasks is to specify units of variation for a trait and then to locate persons as high, average or low.

A vexing problem in the psychology of traits is their number. Allport and H. S. Odbert assembled a list of 17,953 English adjectives used to describe specific modes of behaviour and thought. Each of these words represents a potential trait for the personality psychologist. Such a list obviously needs to be reduced in length if economy and efficiency of descriptive language are to be attained. One such attempt mas made by Cattell, using the technique of factor analysis, a method developed first by Thurstone on the basis of work by Spearman. Cattell succeeded in defining what he believed to be the 12 "primary" trait dimensions of personality. These dimensions ranged from cyclothymic (voluble, emotionally expressive) *v.* schizothymic (withdrawn, reserved) through surgency (cheerful, buoyant) *v.* desurgency (listless, phlegmatic) to sophistication (cool, detached, aloof) v. simplicity (attentive to people, sentimental).

Another significant attempt to specify the major dimensions of variation in personality was that of H. A. Murray, who defined a set of needs which either singly or in combination could be used to explain the behaviour of any person. Examples from Murray's list are these: need:achievement, to succeed in something difficult, to rival and excel others; need:infavoidance, to avoid humiliation, to refrain from action through fear of failure; need:sentience, to seek and enjoy sensuous impressions.

Several other bases for the choice of terms to describe and analyze warrant citation. The language of diagnostic psychiatry has been a continuously important source of concepts. Personality tests for factors such as hypochondriasis (excessive preoccupation with bodily functions), paranoia (exaggerated and irrational distrust and sensitivity) and hypomania (overexcitability. improvident and unmodulated discharge of energy and impulse) are examples of this tradition. Systematic testing methods also have been based on the theory of value types developed by E. Spranger, on recurrent and self-revelatory modes of perception (H. Rorschach) and on occupational choices and vocational preferences (E. K. Strong).

In the years since Binet's first test of intelligence was issued there has been a great increase in the numbers and kinds of testing instruments. A bibliography for mental testing and rating scales published in 1939 contained 4,279 citations; a supplement published in 1946 contained 3,294. It is obviously impossible to discuss any save the most important or most representative examples in this review. For a more thorough description and appraisal of personality and temperament tests the reader is referred to the series of Mental *Measurements* Yearbooks and to textbooks on psychological testing such as those by Anne Anastasi, L. J. Cronbach and D. E. Super (see Bibliography).

A. EARLY TESTS OF PERSONALITY

1. Free Association. — One of the first methods systematically used as a test of personality was the free association technique introduced by Galton in his studies at the London anthropometric laboratory which he founded in 1884. The free association method was later used by the German psychiatrist Emil Kraepelin, who presented a list of words to psychiatric patients, requiring them to give in response the very first word that came to mind for each stimulus. The Swiss psychiatrist C. G. Jung (1910) developed a special stimulus list of 100 words for use in diagnosis of the "complexes" of unconscious conflict envisaged by his theory; various diagnostic indicators in inner conflict were enumerated, such as delay or acceleration of response, inability to respond, facial grimaces, changes of skin colour, etc. A similar list was prepared by the U.S. investigators Grace Kent and A. J. Rosanoff (1910). Many other lists were later developed, but the two of Jung and Kent-Rosanoff continued to be the most widely used. (See also ASSOCIATION. MENTAL.)

2. Questionnaire. — Galton also can be said to have originated the questionnaire method, although a prominent early practitioner of the technique was G. S. Hall, particularly in his studies of developmental psychology and adolescence (1891, 1904). However. the prototype of the modern personality questionnaire was the Personal Data Sheet developed by R. S. Woodworth (1918) for use as a screening device to detect men psychologically unfit for military service. The Personal Data Sheet included 116 items selected from a much larger number of items on the basis of the correlation between each one and the total score for all the items. This method of inventory construction is called the internal consistency method and was widely followed in the development of other tests. The questions in the data sheet covered ten categories of distress, such as physical symptoms, fears, antisocial moods and compulsions, and included items such as these: "Are you frightened in the middle of the night?" "Do you have continual itching in the face?" and "Does liquor make you quarrelsome?" The score on the test was simply the number of such items answered in the unfavourable or "disturbed" direction. Although at first very widely used, the Personal Data Sheet gradually was displaced by inventories covering a greater number of trait categories and including items less obvious and susceptible of direct dissimulation.

One of the personality inventories widely used in testing of secondary school and university students is the Bell Adjustment Inventory. first published in 1934 by H. M. Bell; the inventory also has a less frequently used adult form. The test contains 140 questions of the "yes," "no," "in" response variety, attempting to assess personal adjustment under four categories (home. health, social and emotional); it also yields a total score. The adult form includes the above plus 20 additional questions covering occupational adjustment. The inventory is useful as a quick diagnostic indicator of the extent and locus of a subject's problems, but is too transparent and easily falsified for use in settings nhere "faking" is likely to occur or where significant deficiencies of self-insight are to be expected.

Another questionnaire that has enjoyed wide usage is the Bernreuter Personality Inventory, first published by R. G. Bernreuter in 1931. In its original version this test contained four scales, each in itself the descendant of an earlier and independent test: neuroticism, self-sufficiency, introversion and dominance. The 125 items in the test were taken from these earlier instruments, and resemble those cited above for the Woodworth Personal Data Sheet. Many of the items contributed to the score on more than one of the factors, giving rise to a doubt concerning their statistical independence. A factor analysis of the test by J. C. Flanagan in 1935 suggested the presence of only two discriminable dimensions: self-confidence and sociability. Nonetheless, most users continued to score the test for the original four scales, occasionally using the two factors of Flanagan as additional scores.

Research analyses of the Bernreuter test showed it to have serious weaknesses in regard to its openness to "faking" and to its failures in the detection of psychiatrically disturbed or maladjusted persons who are unaware of their problems or whose modes of self-defense cause them to minimize or deny their doubts and anxieties when asked to report on their well-being.

3. Ink Blot.—Experimentation with ink blots and interpretive responses given to more or less unstructured materials represents another theme in the development of methods for testing personality. Binet, the originator of the intelligence test, also conducted studies in this domain. A number of U.S. investigators around the turn of the century espoused the method, but tended to be more interested in it as a way of studying imagination and the "higher mental processes" than as a technique for personality analysis. Whipple's testing manual (1910) contained a description of ink-blot methods and instructions for their experimental use. The major impetus to the development of this method, however, came from the Swiss psychiatrist Rorschach, who, on the basis of prolonged experimental tryout of various blots and various methods of administering them to subjects, evolved in 1921 a series of ten blots and a technique of administration and analysis that have remained the unquestioned standards in the field. Rorschach's genius lay in his recognition of the importance of formal and structural elements in response to the blots as well as the content of such responses. Following Rorschach's death shortly after the introduction of his method, the work was carried forward on the continent by his student E. Oberholzer and in the United States largely through the efforts of S. J. Beck and B. Klopfer.

4. Situational-Observational.— In the method of situational testing the subject is asked to carry out some task or to do a certain thing, his behaviour then being observed and rated or calibrated in some specified way. The performance requested may be one from everyday life (*e.g.*, to participate in an impromptu discussion), or it may be quite alien to the subject's usual experience (*e.g.*, interrogation concerning a make-believe crime by a hostile and disparaging investigator). The first extensive application of situational techniques was found in the work of H. Hartshorne, M. A. May and their collaborators (1928–30). Their researches, done primarily with school children, attempted to derive quantitative indices of behaviour such as cheating, lying, stealing, cooperativeness and persistence. Their results were so much opposed to the prevalent belief that conduct is merely the manifest expression of generalized traits (such as honesty, generosity, selfishness, etc.) that for several years other efforts to develop testing methods for these factors were inhibited.

Nonetheless, the situational-observational method began to take root, and a clear statement of its aims and purposes was made in a book published by the United States Office of Strategic Services psychological staff, Assessment of Men: Selection of *Personnel* for the *Office* of Strategic Services (1948). The method, involving the intensive observation and study of the person over a two- or three-day period of time and utilizing a wide variety of techniques and testing aids, gradually came to be called that of personality assessment, and by the mid-1950s this approach had become one of the most significant developments in psychology of the postwar period.

B. Empirically Constructed Tests

The weaknesses of the Woodworth test and other questionnaires of this type are exceedingly difficult to avoid in tests constructed by internal consistency methods. In this approach, the test developer first writes or chooses the items for his test, and also decides how they should be scored so as to indicate "nervousness," "leadership," "occupational dissatisfaction," "poor morale" or whatever the factor is that he intends to appraise. The items are then put into a preliminary test, which is given to a sample of persons and scored. The individual items are next correlated with the total scores, the purpose being to discover any that do not have a significant correlation with the total; such items are eliminated from the test, the justification being that they do not co-vary with the general tendency being measured by the full set of items. The remaining items—those that do correlate well with each other—are retained for the final version of the test.

This psychometric purification results in a scale or test that represents well the view of the psychological trait that the test developer had in mind when he began his work. The method makes no secure provision, however, for correcting the developer's erroneous preconceptions as to which way items should be answered to indicate abnormality (if this is what he is seeking to measure) and for revealing which items are diagnostically useful. "Nervous" people do not always answer an item in the way one would expect from their symptomatology. For example, more often than not they may answer "false" to the item "Thoughts run through my head so that I cannot get to sleep at night," even though they have insomnia, while well-adjusted people may feel rather free to admit that they have this problem on occasion. Following the method of internal consistency, this item might be keyed "true" because it had a high correlation with total score, whereas a comparison of the answers with a nontest criterion of "nervousness" would reveal that denial of this common experience was the diagnostically more important response.

A contrasting mode of test development is the "known-group" or "empirical" method, in which the responses of externally classified groups (*e.g.*, persons in a certain occupation, students nominated as outstanding leaders, diagnosed patients in a psychiatric hospital) are studied to determine empirically (by observation) what if any questionnaire responses differentiate the group from control or base-line groups. Such a method will automatically reduce the effect of preconceptions held by the test maker; furthermore. if his list of test items was large, it will indicate new diagnostic insights for the trait. The former constitutes a distinct gain for test validity, where validity is taken to be the test's correspondence with the external nontest world; the latter constitutes an equally distinct gain in the control of faking, for such newly discovered relationships will be beyond the knowledge of most persons to whom the test is given and they will not know how to distort their answers to produce the desired effect.

1. SVIB.—Perhaps the leading example of the tests that have used known groups in scale construction is the Strong Vocational Interest Blank (SVIB), first published in 1927. The inventory was continuously expanded and revised until by 1958 scores for over 50 different occupations could be obtained. A parallel vocational interest blank for women was brought out by Strong in 1935, this form being scorable for about 25 occupations. The male form of the SVIB contains 400 items, grouped into eight sections. The first five cover the categories of occupations, school subjects, amusements. miscellaneous activities and peculiarities of people. Preferences are indicated for each item by circling the letter "L," "I" or "D" (for "like," "indifferent" or "dislike"). The last three sections of the test call for ranking of certain activities in order of preference, choosing options in pairs of items and the rating of own abilities and other characteristics.

Scoring keys were developed by studying the responses of persons successfully engaged in a specified occupation and then contrasting their item statistics with those obtained from a sample of men in general. Items that revealed clear and significant differences were selected and marked for scoring so as to stress the responses actually given by men in the particular occupation.

The test scores of a person who takes the SVIB are entered on a profile sheet that provides letter-grade equivalents ("A," "B" and "C") for each of his scores. An "A" rating signifies a high score, in the range usually observed among persons actually employed in the field; a "B" rating is in a more indeterminate range; and a "C" rating indicates a score significantly lower than those typically found for persons working in the field. These letter ratings, it should be emphasized, are indications of the correspondence between a person's interests and those of persons in the occupational fields; they do not necessarily indicate anything about his aptitudes for work in those fields. The co-variation of scores for the different occupational keys permitted the grouping of scales on the profile sheet into "job families." For example, scores on the keys for lawyer, advertising man and author-journalist usually vary concurrently and are therefore grouped together into what test interpreters call the verbal-linguistic cluster. These scale clusters on the profile sheet have enabled skilled users of the Strong test to develop complex forms of profile interpretation and even a form of personality analysis that goes far beyond the simple listing of areas of vocational choice and vocational rejection.

The profile sheet also provides for the listing of several scores besides those directly pertaining to a specific occupation. (1) The occupational-level scale reflects differences between interests of unskilled and semiskilled workers on the one hand and those of business and professional men on the other. (2) The interest-maturity scale was based on a contrast between males of age 15 and those of age 25 (the age at nhich Strong iound a fairly stable crystallization of interest patterns). (3) A specialization-level scale reflects interests characteristic of medical specialists and of research workers in other scientific fields. (4) Finally, a masculinity-femininity scale shows the degree of similarity between the person's interests and those characteristic of men or of women, respectively.

2. Kuder Preference Record.—This test. first begun in 1934 by G. F. Kuder. and issued in various forms since then (1939,1942, 1948), also yields scores indicative of occupational interests The vocational form of the test (Form C) includes 168 item triads describing three different activities or interests. The respondent selects in each triad the one he likes most and the one he likes least. On the basis first of logical groupings of the items and later of extensive statistical analysis ten interest scales were developed: outdoor (agricultural, naturalistic), mechanical, computational, scientific, persuasive, artistic, literary, musical, social service and clerical. A verification scale to detect carelessness and failure to observe instructions is also included. A profile sheet for the record provides for an automatic conversion of raw scores to percentiles, and the profile pattern gives a visual picture of the high, average and low rankings over the ten categories.

Both the Strong and the Kuder tests are very popular. The Kuder has the advantage of a smaller and simpler set of categories and lends itself to situations where self-interpretation of scores is a necessity. The Strong test, however, contains a greater fund of information and is also supported by a significantly greater amount of validating research literature.

3. Minnesota Multiphasic.— The Minnesota Multiphasic Personality Inventory of S. R. Hathaway and J. C. McKinley, first published in 1943, contains 550 true-false questions, many borrowed from earlier tests such as the Woodworth Personal Data Sheet and the Bernreuter Personality Inventory. It also includes, however, original items more directly pertinent to the areas typically examined by a thorough diagnostic interview in a psychiatric setting; the questions cover 26 such categories.

Fourteen scores are reported on the standard profile for this test. These scales and the diagnostic aim of each are summarized as follows: (1) Cannot say—to identify records rendered invalid by the exclusion of too many items. (2) Lie—items involving improbable claims to moral virtue and rectitude, the answering of which in the scored direction implies an attempt to falsify or the presence of strong repressive-constrictive trends. (3) "K"—reflects the subject's habitual style of verbal behaviour and self-description, ranging irom restrictive prudence and inhibition at one end to crudity and lack of restraint at the other; scores on certain of the other scales are adjusted up or down according to the person's score on the "K" scale. (4) "F"—includes highly unusual and atypical response choices, serving to identify records with an undue number of answers of an unusual or infrequent kind whether due to carelessness, deliberate falsification or distorted thought processes. (5) Hypochondriasis—reflects somatic complaints and preoccupation with bodily functions. (6) Depression—indicates general morale, feelings of depression and worry. (7) Hysteria—reveals tendencies toward repressive, immature emotional life and psychological expressions of inner conflict. (8) Psychopathic deviate—identifies persons of disruptive, rebellious temperament who find it hard to accept rules, restraints and orderly habits of life. (9) Masculinity-femininity—attempts to detect deviations of interests and outlook toward those characteristic of the opposite sex. (10) Paranoia—indicates attitudes of undue or irrational suspiciousness coupled with exaggerated sensitivity. (11) Psychasthenia—a heterogeneous set of doubts, worries, anxieties and complaints synthesized as a general index of agitation and perplexity. (12) Schizophrenia—reveals trends toward alienation from self and others, loss of self-direction and frankly delusional thought content. (13) Hypomania—a gauge of emotional expansiveness, excitability and accelerated tempo of thought and behaviour. (14) Social introversion—seeks to identify persons of diffident, anxious and retiring disposition.

These 14 scores are plotted on a profile sheet that provides an automatic conversion of the raw score totals to standard scores. A standard score is one that has been statistically adjusted so that its average value is always 50 and its standard deviation 10, to permit direct comparisons among scales. The profile of scale scores for the Minnesota Multiphasic, like that for the SVIB, lends itself very well to complex configural interpretations; psychologists skilled in the use of the inventory are frequently called upon to prepare personality analyses of patients tested in clinics and hospitals. The inventory is principally oriented toward matters of psychopathology and morbidity and has shown its greatest validity when applied to clinical and psychiatric problems; it has shonn less utility when applied to problems of normal behaviour and everyday life.

Personality inventories more directly concerned with the functioning of normal persons have not proved in general to be so popular as tests like the Minnesota Multiphasic, the Bernreuter and the Bell. Among inventories designed for nonpsychiatric testing may be mentioned the Edwards Personal Preference Schedule, published in 1954; the California Psychological Inventory, in 1956; the Maudsley Personality Inventory. 1959; the Study of Values; and the factorial tests described below.

C. Study of Values

The Study of Values was first introduced by Allport and P. E. Vernon in 1931, and then revised in 1951 by Allport, Vernon and G. Lindzey. The test is derived from a theory of Spranger, postulating that in the life of each person a great single unifying theme or value may be discovered. The Study of Values seeks to measure the relative strength of six such values: (1) theoretical—having a dominant interest in the discovery of truth, valuing critical, rational and logical thinking; (2) economic—primarily interested in utility, in the practicality and efficiency of things; (3) aesthetic—places highest value on form and harmony, seeks out and prefers artistic experience; (4) social—directed toward altruism and philanthropy, values the welfare of others and of mankind; (5) political—is power oriented, seeks esteem and renown, control over others; (5) religious—concerned with unity, the mystic nature of existence and of the cosmos.

The test contains 45 questions presenting either two or four propositions that the subject must rate in order of preference. An example is the following: "In your opinion, can a man who works in business all the week best spend Sunday in: (a) trying to educate himself by reading serious books; (b) trying to win at golf, or racing; (c) going to an orchestral concert; (d) hearing a really good sermon." The classification of these options under the value types of theoretical, political, aesthetic and religious obviously is not difficult, and this very ease reflects one of the limitations of the test — its openness to deliberate dissimulation. Another limitation resides more in the theory than in the test itself; that is, in the restricted applicability of the six value types. Even insofar as the unity thema concept in personality is correct, these particular six values contain an aristocratic bias in that they apply more to persons of intellectual, ratiocinative temperament than to the average man or woman.

D. Factor Analysis

The inventories discussed up to this point have dealt with either (1) dimensions of measurement taken directly from the settings in which the test is to be used (*e.g.,* the SVIB) or (2) with dimensions taken from theoretical systems whose goals were to explain and account for human behaviour (*e.g.,* the Study of Values). In inventories developed by the technique of factor analysis a markedly different basis of choice is to be seen. In factor analytic tests the factors to be measured are not necessarily those that seem on the surface most relevant to a particular setting or those that a previous theorist has talked about; on the contrary, the dimensions of choice are those that most economically summarize the variations of response to be found among the components of the testing battery.

The underlying logic of factor analysis is mathematical, and its principie of faith is that mathematically basic test dimensions will also be psychologically basic. Suppose that a number of experimental tests of "personal adjustment" were tried out and then scores on the experimental tests were intercorrelated. Undoubtedly some of the tests would overlap each other, and the full set mould contain an unnecessary amount of duplication. The aim of factor analysis in this example mould be to specify the extent of such redundancy and then to indicate the minimum number of underlying factors that could be used mathematically to account for all the scores found in the experimental battery. Direct measurement of these underlying factors could be said to be a more efficient and more valid way of assessing the domain of personal adjustment.

The technical methods of factor analysis are mathematically complex and difficult, but their purpose is simple: to identify the dimensions that will represent most economically the set of interrelationships given by a battery of test scores or test items. At first discovery, the factors may seem strange or different from the usual ways in which the test elements have been discussed. although this is partly a function of the names the analyst chooses to assign to his factors. A second, more significant, difficulty is that the new mathematical factors may have less accuracy as predictors of nontest behaviour than the mathematically impure tests the factors are designed to replace. In such instances the factor analyst seeks an optimum combination of factor-pure tests from which a valid prediction in a specific practical situation can be made.

Perhaps the leading U.S. exponent of factor analytic methods in personality test development has been J. P. Guilford, whose various inventories are used widely and are among the most important examples of factorially based devices. The Inventory of Factors STDCR (1940) included scales for social introversion, thinking introversion, depression, cycloid disposition and rhathymia (happy-go-lucky, carefree). The Guilford-Martin Inventory of Factors GAMIN (1943) covered the factors of general activity, ascendancy, masculinity. inferiority and nervousness. A third test, the Guilford-Martin Personnel Inventory (1943), included scales for the factors of objectivity, co-operativeness and agreeableness. A later test, the Guilford-Zimmerman Temperament Survey (1949), included 300 questions scaled for ten factors: general activity, restraint, ascendance, sociability, emotional stability, objectivity, friendliness. thoughtfulness, personal relations and masculinity.

Another leading exponent of factorial technique is R. B. Cattell, whose most widely used inventory was the Sixteen Personality Factor Questionnaire (1950). The inventory had two parallel forms, each with 187 items; a third form having 105 items was later added. Several examples from Cattell's designations of the 16 scales can be given: cyclothymia v. schizothymia; general intelligence v. mental defect; emotional stability *v.* general neuroricism; surgency v. desurgency; bohemianism *v.* practical concernedness; sophistication *v.* rough simplicity; and anxious insecurity v. placid self-confidence.

E. Projective Methods

Although projective methods for studying personality were used by Galton, Jung, Kent and Rosanoff and others, as mentioned above, it was not until the appearance of Rorschach's ink-blot technique in 1921 that the approach began its rise to prominence. Even in Rorschach's own work, however, the theoretical implications of the method were little developed. for he saw himself as an empirical scientist engaged in the development of a diagnostic tool having practical objectives. The first significant formulation of the theory and point of view of projective testing was given by L. K. Frank (1939). The fundamental theorem is that when confronted with unstructured stimuli the subject will impose structure on them in such a way as to reflect his own needs and impulses; properly interpreted, the subject's responses therefore can be used as guides to his private world of fantasy, his attitudes, fears, aspirations and the like.

1. Theory of **Projective** Methods. — The word projection in reference to this process and to this category of tests is somewhat equivocal. There has been a tendency to identify the theorem of projective testing with the psychoanalytic (Freudian) concept of projection; *i.e.,* with the mode of ego defense in which unacceptable impulses are externalized and attributed to others or to outside agents (see Defense Mechanisms). However, the projective test protocol is by no means delimited to denied and expulsed ("projected") psychological material of this sort, or even primarily focused upon it.

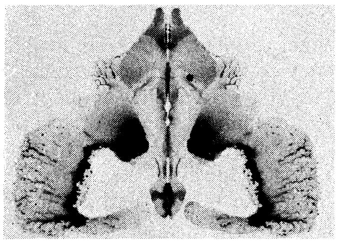
Another meaning of projection is simply that which stands out from its surroundings, that which extends beyond something else. This meaning of the term is somewhat applicable to projective tests insofar as the ambiguity of the stimuli and the freedom of the test situation often do permit the appearance of highly salient mental content, those concerns that are most active and impelling in the mental life of the subject at the time of testing.

However, a third meaning of projective. the geometric or cartographical one, is probably closest to the implications of Frank's thesis. In this meaning the external representation is not considered as merely a general derivative of its originating source. but as a specific point-for-point rendition of it. Thus, a geometric drawing gives an exact representation of the three-dimensional object from which it is made, and a map is intended as a precise guide to a given section of terrain. If to an amorphous ink blot a person replies, "Eyes of bloody fire," and then adds, "but it could be a dear little dancing mouse," the discontinuity is only apparent; each response represents a psychic event. and the path from the first to the second (*i.e.,* the relation between them) is as determined and meaningful in the psychic topography as the interval between points A and B in the geographic counterpart. The theoretical aim of the projective test is therefore no less ambitious than this: to chart in a faithful and interpretable way the full range and depth of the psychic life of a person.

In practice, the classification of tests as projective or nonprojective has followed lines of custom and convenience not always in accord with consistent interpretation of the theory. Freedom for the subject to respond as he wishes would seem to be an essential element of the projective method if crucial features of the subject's mental life are to have full opportunity to manifest themselves. The instructions in the Rorschach test, where the subject is asked merely to report on what he sees, satisfy this requirement very well; on the other hand, an activity check list where the subject simply marks "like" and "dislike" does not. The Rorschach test is therefore properly classified as a projective test, and the activity check list as nonprojective. However, one of the tests classified by custom as projective, the Szondi test, requires the subject to make this same "like" *v.* "dislike" response to a series of photographs of European mental hospital patients; the Szondi test therefore has no more and no less freedom of response than the nonprojective activity check list.

This logical confusion is seen again in the factor of ambiguity of stimulus materials, held to be an essential condition for projective responses. The ink blots of the Rorschach test are for the most part amorphous and lacking in readily perceived meaning. Yet the geometrical figures that the subject copies in the (projective) Bender-Gestalt test are clear and precise, certainly less ambiguous in point of fact than the more difficult items in a (nonprojective) test of spatial visualization. On this particular dimension of stimulus ambiguity, therefore, the nonprojective test of spatial visualization would have to be rated as closer to the projective test ideal than the projective Bender-Gestalt.

2. Rorschach Test.—The Rorschach ink-blot test contains ten stimulus cards, five achromatic ones having only shades of gray and black, and five chromatic blots incorporating various colours. The cards are presented to the subject in a standard sequence with brief instructions on the order of: "I am going to show you a series of ink blots, one at a time. The blots do not necessarily represent specific things; different people see different things in them. Would you please look at this blot and tell me what you see, what it makes you think of?" The examiner keeps a record from this point on of comments, responses, time consumed, how the cards are held and turned, etc. Questions are answered in noncommittal fashion; *e.g.*, "Whatever comes to your mind," "It's entirely up to you."



INK BLOT, SIMILAR TO THOSE USED IN RORSCHACH'S TEST

Analysis of the test covers four principal categories:

1. The first of these is location, the part or parts of the blot utilized in the response. The main elements in this category are the "whole" response, which involves the complete blot, the large detail and the small detail. The usual protocol (record of responses) strikes a balance among these three components; emphasis on one or another affords evidence for significant modes of personality functioning. For example, concentration on large, common details is held to be characteristic of the mundane, practical, fact-centred personality.

2. The second main scoring category concerns the determinants of the response; *i.e.*, whether form, colour, apparent texture of the surface, shadings, etc., in the blot influenced the response. Here again a balance among the elements ordinarily prevails, and deviations from the base line provide hints of salient trends in the personality. An excitable, uninhibited. effervescent person might have many responses in which colour is a vital feature; an aggressive, explosive person might show form elements subordinated to colour in nearly every instance. Where there is doubt about what qualities in the blot have given rise to a certain response, the examiner makes discreet inquiries. For example, to a certain red-coloured portion of blot the subject says, "And there I see a bow tie." The examiner, returning to this response after finishing the ten blots, might ask, "Can you tell me why that part is a bow tie?" If the respondent answers, "Why, because it's shaped like one, that's why," the examiner might go on to ask, "Would it still look like a bow tie if it was entirely black?" The form-dominated perceiver would probably now respond "Of course," the colour-dominated, ('Certainly not."

3. The third category is that of the content of the response. Here again common clusters appear. Most records contain some references to human beings, to animals and to natural phenomena of one sort or another. The absence of any of these or overconcentration on a particular one constitute bases for interpretation.

4. A fourth category, more or less included in the interpretations of the first three but still listed as a separate feature in the scoring, has to do with the popularity or originality of each response. For certain blots certain responses are so typically given that they are labeled "populars." Persons whose perceptual habits and reactions are generally similar to others will give an appreciable number of such "popular" replies during the course of the testing. Psychotic or deranged subjects might give very few or none at all. At the other end of the scale are responses that are seldom encountered or that the examiner hears for the first time. Such responses are called "original." A further classification into good quality (O+), average quality (O) or poor quality (O−) is necessary in order to distinguish between creatively original perceptions and those involving distorted or warped conceptions.

On the basis of these and other ancillary scoring procedures the Rorschach analyst attempts to synthesize a model of the functional psychology of the person, one that depicts the formal properties of his personality (*e.g.*, intellectual ability, introversion-extroversion, inhibitions. constraints, level of affective energy, etc.) as well as his particular concerns and problems. The validity of this final formulation rests in large part on the skill and wisdom of the examining psychologist. Critics of psychological testing methods have too seldom recognized this elementary principle, blaming the tests, when prophecy has failed, rather than the prophets.

3. Thematic Apperception Test.—The second most widely used test of the projective group is the Thematic Apperception Test (TAT). first issued in 1935 by Murray and Christiana D. Morgan. In the TAT, pictures are presented on cards to the subject, who is asked to make up a story having an antecedent. a plot and a resolution. Stress is laid on the concept of "imagination" in instructions, with the offhand comment being made that "imagination is one form of intelligence." There are 31 pictures in all, these being grouped into special subsets of 20 each for younger and older subjects, male or female. The manual calls for two one-hour testing sessions, ten cards being administered at each. The more unusual and dramatic pictures are reserved for the second sitting, along with one entirely blank card. The subject ordinarily tells his stories aloud, the examiner copying them verbatim. However, all these procedural matters vary widely in practice, depending upon the examiner; the variability in this respect is much greater than for other tests of wide usage.

In the analysis of test results there is also much less standardization in the TAT than in other tests. Some examiners have utilized Murray's "need-press" system of concepts or variations of it; some apply psychoanalytic notions of defense, repression, projection, etc.; others merely attempt a subjective-intuitive résumé of the personality of the storyteller. For special purposes the stories can be scrutinized for particular themes or qualities; one such scoring, for example, is based upon the number of manifestations of the need for achievement; another is based on appraisal of the stories for their level of originality. The test method

"SUNLIGHT IN A CAFETERIA" BY EDWARD HOPPER. A PAINTING SIMILAR TO THOSE USED IN THEMATIC APPERCEPTION TESTS (*see* TEXT) also has been applied in anthropological field studies to help shed light, for example, on child-rearing attitudes, on moral codes and sanctions and on philosophical values.

F. Other Methods

There are literally hundreds of additional projective methods for the assessment of personality that could be discussed in a complete review of the topic. A few examples are given below, classified by type of task or method of testing.

1. Constitutive Methods.—In these the subject imposes a form or structure upon an amorphous or plastic substance or upon partially structured or semiorganized fields. Examples are the Rorschach test; Hans Zulliger's three-blot ink-blot test modeled after the Rorschach; the sentence-completion method proposed by A. F. Payne in 1928; and finger painting as introduced by Ruth F. Shaw in 1930.

2. Constructive Methods.—In these the subject is asked to build or construct something, the implication being that some of the organizing principles in his own personality will be manifest in his test constructions. M. Lowenfeld's Mosaic Test, introduced in 1929, is an example. The subject is given a set of 465 small wooden blocks of six colours and five shapes and asked to "make anything you like out of the pieces." The mosaics can then be evaluated on some 23 factors, including such characteristics as concreteness *v.* abstraction. over-all harmony of design, simplicity *v.* complexity and emphasis on form or colour.

3. Interpretive Methods.—In these the subject is asked to tell what a specific stimulus. such as a picture, suggests or means to him. The Thematic Apperception Test provides one example of the type. The Four-Picture Test of the Dutch psychologist D. J. van Lennep, in which the subject is requested to tell a story incorporating the people and backgrounds shown in four pictures, is another.

4. Cathartic Methods.—In these methods the aim is to release pent-up emotions and feelings in such a way as to permit interpretation and personality diagnosis. An example is the "therapeutic doll" of D. M. Levy, which the subject may dismember, cuddle, maltreat. etc.. at will.

5. Refractive Methods.—This category includes the use of any conventionalized mode of communication or expression, verbal or written, as a basis for personality assessment. Handwriting analysis (graphology) is a prominent example.

IV. ATTITUDE MEASUREMENT

An attitude may be defined as the degree of positive or negative feeling associated with some psychologicai object or event (see Attitude). The psychological object may be a job, a racial or ethnic group, a governmental policy or a book title; it may be a person, a thing, an institution or an idea.

A. Approaches

One possible approach to attitude measurement entails asking respondents direct questions demanding "yes" or "no" ansners. This approach often has been used, with varying degrees of success, in the assessment of public opinion to predict, say, voting behaviour. Often it results in a large proportion of "don't know" or "undecided" responses, difficult to evaluate, Not infrequently, particularly on emotionally tinged public issues, respondents either consciously or unconsciously distort their replies, yielding results biased in the direction of the popular or socially approved response. These difficulties have prompted the development of less direct procedures fcr measuring attitudes.

An attitude schedule is a set of carefully constructed statements about a psychological object, together with some device, such as a rating scale, by which the subjects express their feeling toward each statement. Methods of attitude measurement differ, one from another, primarily in the means for constructing and selecting statements to be included on the schedule. The three main approaches to attitude measurement may be distinguished by noting nhether the focus is upon the statements, the subjects or the responses.

1. Methods Focusing on Statements.—These methods utilize judgments from a group of respondents to scale the attitude statements. Subsequently the scale values of the statements may be used to locate any individual on the attitude continuum on the basis of his responses to the schedule.

Procedures for measuring attitudes were pioneered by Thurstone, through a series of articles and monographs beginning in 1927. Thurstone extended the psychophysical methods (*q.v.*) by proposing a model for scaling psychological magnitudes of stimuli independent of any corresponding physical stimulus magnitudes. The class of methods including those proposed by Thurstone, all of which are independent of physical measurement, are known as the psychological scaling methods.

Puired *Comparisons*.—Of the psychological scaling methods, the earliest is the method of paired comparisons. In applying this method to the selection of statements for attitude measurement, statements are presented in pairs, with judges instructed to select that statement of each pair which they view as indicating a more favourable attitude toward the psychological object in question. For example, in selecting items for a schedule designed to measure attitude toward public censorship, the following two items might be paired: (1) "to protect the public it sometimes is necessary that censorship be exercised"; (2) "books and plays should be subject to moral censorship." Each respondent would be asked to select statement (1) or (2) as representing a more favourable attitude toward public censorship.

As presented to a sample of judges, each statement is paired with every other statement. Proportions of responses are generated of the form P,,, the proportion of judgments that statement i is more favourable than statement j; these serve as the basic data for application of the method. Data are treated by Thurstone's law of comparative judgment, a theoretical model transforming the proportions and operating on them so as to provide numerical scale values associated with each attitude statement. (In the simplest application of the model, it is assumed that affective values toward each statement have a normal distribution in the population of respondents and that the population variances and covariances of those distributions all are equal.)

Successive Intervals.—A related method for selecting attitude statements is the method of successive intervals, also suggested by Thurstone. Each separate statement is rated by every member of a group of judges to indicate favourability of attitude implied by the statement, the rating being in the form of a check mark in one of several response categories. Categories are defined to extend from "extremely unfavourable" to "extremely favourable," with intermediate categories suggesting more moderate attitudes. A law of categorical judgment here provides the model by which proportions of category ratings are transformed and yield scale values indicating degrees of attitude associated with the statements. Once again it is assumed that in the population attitudes are normally distributed. The method of successive categories has the advantage of providing quantitative estimates of the degree of ambiguity of attitude for each statement (indicated by the variances of distributions of judgments, measured on the attitude continuum). Such estimates are valuable for selecting statements to be included on an attitude schedule. Because of its theoretical advantages. the method of successive intervals has largely replaced the similzr method of equal appearing intervals for construction of attitude schedules.

Having determined scale values for each attitude statement and selected those to be included on a schedule, the problem remains to estimate the attitude of individual respondents. A simple procedure is to present the schedule to each individual with instructions to check those statements with which he agrees. An average of the scale values for those items checked serves to locate the individual on the attitude continuum.

2. Method Focusing on Subjects. — A method proposed by Rensis Likert treats attitude statements much on the order of objective test items. An attitude schedule is constructed from a group of statements (with unknown scale values) selected to represent either favourable or unfavourable attitudes toward a psychological object or event. For each statement, subjects are instructed to respond by checking one of several possible response categories; *e.g.*, "strongly agree," "agree," "uncertain," "disagree" or "strongly disagree." Likert suggested the arbitrary assignment of weights to these categories: 4, 3, 2, 1, 0, respectively, when statements convey a favourable attitude; 0, 1, 2, 3, 4, respectively, for unfavourable statements. For a given schedule, an attitude score is found for every subject simply by summing the weights associated with the responses of that subject. The approach is aimed at the direct assignment of attitude scores to individual subjects, avoiding the intervening step of assigning scale values to statements.

The Likert method often has been implemented by utilizing techniques of item analysis, borrowed from objective psychological test theory, to select appropriate statements for a refined final form of attitude schedule.

Both the Likert and Thurstone methods have often been successfully employed for measuring attitudes. The several studies comparing results of the two approaches fail to show marked superiority of either approach over the other. Theory underlying the judgment methods of Thurstone is somewhat more completely defined, and in accordance with the theoretical measurement model, application of the Thurstone methods yields scores with wider general interpretations as numbers (as opposed to numerals representing order relations but not distance along an attitude continuum).

3. Methods Focusing on Responses. — In these methods an attempt is made to assign scale values to both subjects and statements from a single administration of the statements to the subjects. The methods demand a set of attitude statements which vary along a single psychological dimension and assume subjects' responses to depend only upon their positions on this same dimension.

Scalogram Analysis. — One prominent response method is scalogram analysis, proposed by Louis Guttman. In applying scalogram analysis, it is assumed that any subject asked to accept or reject a set of attitude statements will accept all those with scale values at or below that point on the attitude continuum at which the subject is located, rejecting those statements with scale values higher than his own location. Consider the following four statements, listed in the order of increasingly favourable attitude toward cold climate.

A. I am able to tolerate occasional cold weather.
B. At times I enjoy cold weather.
C. I would enjoy living where the climate is one of cold winters.
D. I revel in cold weather, and would choose to live only in an area with cold climate.

For this set of sentences, anyone accepting the most extremely favourable statement D also would be expected to accept the statements reflecting a more moderate positive attitude toward cold climate; A, B and C; a person accepting statement C also would be expected to accept A and B; and for someone accepting statement B, acceptance of A also would be anticipated. Conversely, if one rejects statement B, it may be safely predicted that he will reject statements C and D. Under these conditions, the statements are said to be scalable. While there are 16 possible response patterns, patterns of acceptance (+) or rejection (0) among four statements, only 5 of these (in general, $n + 1$, where n is the number of statements) are expected to occur for four scalable statements:

	Statement			
Pattern	A	B	C	D
1	0	0	0	0
2	+	0	0	0
3	+	+	0	0
4	+	+	+	0
5	+	+	+	+

Subjects thus are divided, by responses to the four statements, into five groups classified according to favourability of attitude. Statements also become ordered in terms of the attitude variable by the observed response pattern.

Unfolding Technique. — A second response method for attitude measurement, known as the unfolding technique, was proposed by Clyde H. Coombs. Subjects are asked to rank a set of attitude statements according to the extent of their agreement with each. Analysis of such rankings yields information regarding the attitude of the subject relative to the set of statements.

Let the letters A, B, C and D represent four attitude statements, listed in order from unfavourable to favourable attitude. A given subject, S, might rank the statements in the order C, D, B, A in terms of his agreement with them. By "unfolding" the rank order, the investigator could achieve a conception of the relative locations of statements and subject on the attitude continuum. The following portrayal is consistent with S's ordering of agreement with the four statements. The line segment represents the attitude continuum, progressing from unfavourable, on the left, to favourable, on the right.

S
A B C D

The rank order assigned the statements by a given subject is interpreted as the order of distances between statement and subject on the attitude continuum and thus serves to locate (within a narrow range of values) the affective position of the subject relative to the locations of the statements. Analysis of responses from a group of subjects allows more definite estimates of the locations of statements.

4. Internal Consistency, Reliability and Validity. — Each of the prominent methods for attitude measurement mentioned above includes means for checking the internal consistency of the method. In addition, reliability of measurement may be determined; numerous applications have verified that consistent and reliable measures of attitude may be obtained. A thorny problem, however, is that of determining the validity of attitude measurement. Immediately the investigator is faced with the task of specifying a behavioural criterion against which validity may be assessed. Except for instances in which attitudes are expressed through political action (*e.g.*, voting behaviour), instances of successful specification of such criteria are rare. A few studies indicate that these methods of attitude measurement exhibit at least greater validity than that attending the direct questioning of respondents.

B. Consumer Preference Measurement

Closely related to attitude measurement is the measurement of consumer preference, or acceptance of consumer products. However, the ultimate aim is somewhat distinct from that of attitude measurement: attention is directed toward the degree of acceptance of a product, judged by numerous consumers, rather than toward the placement of a person along a psychological continuum.

Psychological scaling methods that focus upon stimuli (analogous to statements in attitude measurement) are ideally suited to the aim of consumer preference measurement. These methods yield scale values associated with each stimulus rated or judged by a consumer sample. Stimuli might be food items, items of apparel or other consumer products. By the method of paired comparison or the method of successive intervals it becomes possible quantitatively to evaluate the relative preferences displayed for a group of such items. and to estimate degree of acceptance of the items by a population of consumers (when the judging group is a random sample from that population).

An interesting application of models for consumer preference measurement allows prediction of consumer choice of competing products on an open market, or even prediction of relative purchase of each of several competing products when these are offered at different (known) costs to the consumer. For the latter problem. there enters the question of (negative) utility of money, which presumably combines with preference for the commodities to dictate proportions of purchase of each. Exploratory research on these problems suggests that the measurement methods are highly reliable and provide a valid quantitative model for estimation of consumer choice behaviour.

1. Multidimensional **Scaling.**—An extension of the psychological scaling methods not only provides conclusions concerning the distribution of sensory preferences among product samples, but also serves to indicate the (linearly independent) psychological components of the general sensory distinctions. This extension is known as multidimensional scaling, since it yields a solution for the several psychological dimensions responsible for the general differences in preference among stimuli. As an example, consider five distinct samples of coffee, to be evaluated for general flavour characteristics. Preference values could be obtained using the method of paired comparisons, presenting samples in pairs to a group of judges. There are ten pairs of the five samples (in general, $n(n-1)/2$ pairs of n stimuli); for each pair the proportion of judges indicating preferred flavour for each of the two brews of coffee would be determined. Application of the law of comparative judgment would yield solution of general preference scale values for each of the five samples.

Now the coffee samples could be presented again, this time utilizing the method of triads. Samples are presented in groups of three. with judges instructed to determine relative degree of similarity between pairs of samples within the triad. ("Stimulus i is more similar to stimulus j than to stimulus k.") With five stimuli, there are ten triads (in general, $n(n-1)(n-2)/6$ triads for n stimuli), and for each triad, three judgments are required, since each stimulus is compared with the stimuli of every other pair. The result of such an experimental procedure is the generation of n matrices of proportions, one for every stimulus sample, each of order $n \times n$. The elements of the ith matrix take the form ${}_iP_{jk}$, the proportion of times stimulus i is judged more similar to stimulus j than to stimulus k.

The proportion ${}_iP_{jk}$ is postulated to depend upon the difference between distances d_{ij} and d_{ik}, where d_{ij} represents (affective) distance of stimulus i from stimulus j and d_{ik} represents distance between stimuli i and k. Assuming the distribution of differences in distance. $(d_{ij} - d_{ik})$ to be normal in the population, with equal variances and covariances, a solution is provided for every distance of the form d_{ij}. Having solved for all such distances, imposition of a spatial model (*e.g.,* assuming analogy to Euclidean space) will serve to determine the minimum number of dimensions required to account simultaneousiy for all empirically derived distances. Analysis of the configuration of interstimulus distances within the space may provide clues concerning the psychological characteristics of the dimensions.

2. Detection of Sensorv Differences in Consumer Products,—In numerous consumer industries, sensory characteristics of the product assume great importance. For manufacturers of processed foods and beverages, perfumes, colour reproductions, to name only a few, the quality of the product depends largely upon its sensory characteristics. Industrial testing for control of sensory characteristics of products has made considerable use of the psychophysical methods, particularly of the constant method.

A typical problem is that of assuring uniformity of the product. Not always does strict uniformity necessarily result from careful control of ingredients; minor variations in climatic conditions, time of preparation, storage conditions and many other factors as well as quality and quantity of ingredients may affect the product. To assure no major variability in the product as marketed, sensory tests often are conducted. New batches of the product typically are compared aith a standard batch, knonn to be of acceptable quality. In the case of foods and beverages, this constitutes taste testing for flavour characteristics. Samples of the product are judged in pairs, often by expertly trained judges. One member of each pair is the standard, the other is called the variable. The task of the tasters is to judge, for each pair, which is the sweeter, saltier, more pleasant, more bitter or the like. On the basis of numerous ratings, proportions of such judgments are obtained for each variable as compared with the standard. Statistical procedures are available for guiding the decision concerning acceptability of quality. For example, it might be decided that a batch would be unacceptable if as many as 5% of consumers were to detect a deficiency in the product as compared with the usual standards. Application of the constant method and related statistical tests would serve to yield a decision concerning quality of each batch in terms of such a criterion. A rnethod of analysis nearly identical to that of the constant method of psychophysics is the probit method of biometrics, developed in England by Fisher and D. J. Finney, in the United States by C. I. Bliss.

The psychophysical methods have proved useful not only for quality control of a product; they also are frequently applied to the development of improved consumer items. In this application, detection of a difference in a given direction, that the new product has more desirable characteristics than the old, serves as evidence upon which the new product may be marketed, either replacing the old or competing with it with some assurance that the new product will maintain a favourable competitive position.

Guilford, *Psychometric Methods,* 2nd ed. (1954).

(L. V. Jo.)

PSYCHOLOGICAL WARFARE consists of the use of propaganda against an enemy, together with such military, economic or political measures as the propaganda may require. Though often looked upon as a modern invention, it is as old as history. The conquests of Genghis Khan were aided by expertly planted rumours about the large numbers of ferocious Mongol horsemen in the khan's army. False though they were, these rumours frightened the enemy. Centuries later, in the American Revolution, Thomas Paine's *Common* Sense was but one of many examples of pamphlets and leaflets used to strengthen the colonists' will to fight.

In its modern form, consisting of the application of mass communications techniques to strategy and warfare, psychological warfare differs from the military propaganda of the past in two ways: it is proportionately a larger ingredient of the whole process of war; and modern scientific advances in communications, such as high-speed printing and radio, together with important developments in the fields of public-opinion analysis and the prediction of mass behaviour, make psychological warfare more nearly manageable and predictable than techniques used in the past.

Military doctrine of the United States and its allies in the North Atlantic Treaty organization recognizes a specific field of military responsibility for planning and conduct of psychological warfare in time of actual war. In the late 1950s U.S. military experts sought to define the psychological warfare responsibilities of armies in situations short of actual warfare. The suggestion was made that "psychological operations" be used as the descriptive term

DISGUISED TACTICAL PROPAGANDA

Leaflet issued by the colonial command during the battles for Boston, it is an invitation to the British troops to desert for short-of-war measures to be undertaken by armed forces in the international mass-communications field. Psychological warfare and psychological operations are therefore the same function; in both cases they are attached to the military and are separated, except for wartime, from the normal informational, promotional or propaganda activities of the civilian agencies of government.

Within armies, psychological warfare or psychological operations include training and equipping of specialized units in peacetime armed forces, both regular and reserve, and the application of these skills to military situations when action comes. It is most effective when the entire army knows of its availability and effects. The short form of the term, psywar, spread through the U.S. armed forces after the Korean war. The kind of psywar understood by the armed forces is a far narrower and more specialized operation than that to which scholars, journalists and politicians refer when they say "psychological warfare."

In this more general sense of the term; different meanings can be found, no one of which is necessarily related to the others, even though they may frequently become confused.

First, there is psychological warfare as armies practise it. This involves the use of printing presses, radio stations and air-dropped leaflets in pursuing goals of modern warfare.

The term psychological warfare also is used to describe the pseudo-psychiatric twisting of personality by techniques such as "brainwashing" ("thought reconstruction" is the official Chinese Communist term) or the psychopharmaceutical techniques reportedly used in the European Communist countries. In this sense, the United States has not engaged in "psychological warfare." The only U.S. effort in the field has been developing preventives and countermeasures as far as possible.

Finally, psychological warfare is loosely and often improperly used to describe all the forms of power struggle between nations: the "cold war," the "chronic war," "protracted struggle" (in Mao Tse-tung's phrase), "extended strategy" and the like. This is too broad a use for the term to remain meaningful. Marshall plan expenditures, Mutual Security weapons deliveries, technical-aid programs—each of these has a psychological effect on the many audiences which make up the international scene, but unless any technique involves the manipulation of opinion through communications, it embraces more than psychological warfare does under the stricter definition.

During World Wars I and II there appeared a group of new terms for forms of struggle which exceeded the 19th-century concepts of war. The operations in all cases had antecedents; the new element was not in any case the act itself but the labeling of the act and the formal creation of government agencies to carry it out. Four major forms of international struggle were usually described: psychological warfare, political warfare, economic warfare and warfare in the sense of armed combat, sometimes rather redundantly called "military warfare." Political warfare in British usage includes propaganda, diplomacy, intrigue, conspiracy and sabotage. In U.S. usage, political warfare consists of international struggle through the manipulation of persons, organizations or institutions. British usage seems to be yielding to the U.S. in this respect. Economic warfare (*q.v.*) consists of the manipulation of property, prices or other economic factors to the disadvantage of the international antagonist. In view of these definitions, psychological warfare can be restricted to those forms of struggle which depend on mass communication.

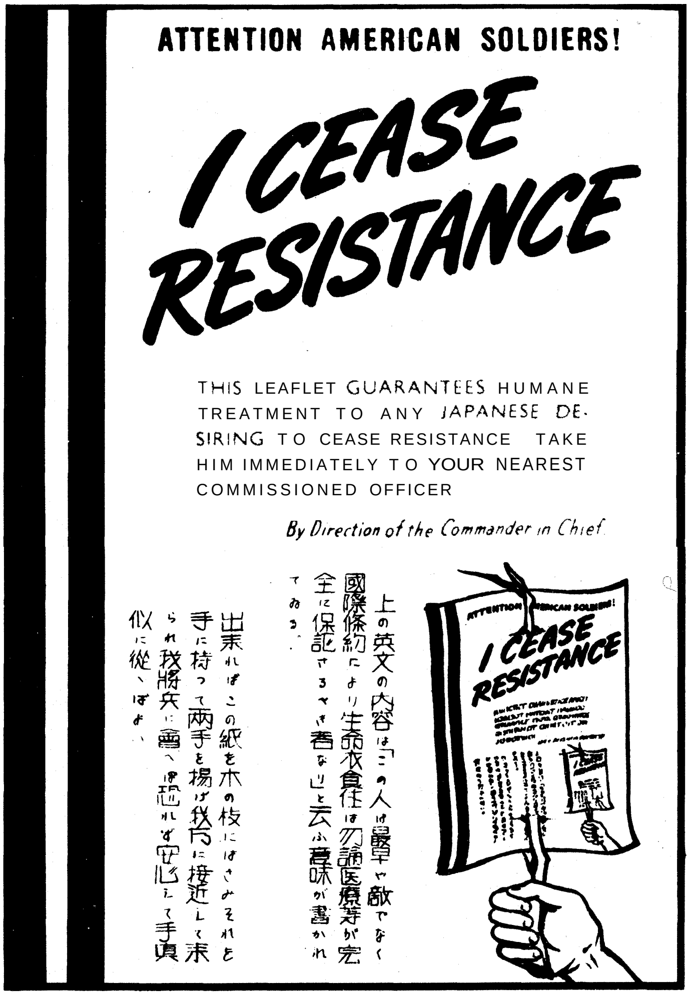
The search for terms has involved both the avoidance of explicitness (when clarity would either assist the enemy or arouse annoyance in the country of the government concerned) and a quest for understandability. These two goals not being reconcilable, a marked degree of governmental indecision has been noted. "Information," "psychological strategy," "co-ordinated operations," "strategic services" and similar euphemisms are often employed.

Modern psychological warfare is neither better nor worse than other forms of struggle. Insofar as it does the least damage to the human body, compared with other weapons, while achieving what may be maximum results in terms of cost. psywar may be regarded as a "better" weapon. A dead enemy is of no use to one's own side or to mankind, and his death may be very costly to achieve, while a live, surrendered enemy is usually useful.

Most psychological warfare material is truthful. Truth is easier to document than falsehood, and it is infinitely superior to lies where consistency is concerned. Lies were used wholesale in World War I; it is a safe guess that they were used less in World War II. Lies continue to be used in military conflict, but they are useful only in exceptional cases. The truth presented in psywar is rarely the whole truth, and the degree of veracity varies with the different countries engaged. During World War II the United States practice of covert psychological warfare, which presumably would be reactivated in the event of future conflict. was the responsibility of the Office of Strategic Services (OSS), while overt psychological warfare was reserved to the army and navy and the Office of War Information (OWI).

Overt or white propaganda is that emanating from a known source, while covert or black propaganda is issued from a falsified source. The British "German" transmitter, Gustav Siegfried Eins, which pretended to be inside the Hitlerian Reich, is a good example of black propaganda. Many Germans thought for a while that it really was German. In contrast, transmissions of the Domei (Japanese) news service in clear newspaper English to the U.S. during 1941–45 were a good example of white propaganda. Though admittedly Japanese, the dispatches filled a lot of U.S. newspaper space and embarrassed the U.S. war effort.

Apart from communications media, psychological warfare is sometimes divided into levels which reflect the frame of space and time in which the military propaganda is expected to operate. Strategic psychological warfare is the term denoting mass com-



TACTICAL PSYWAR

Surrender leaflet distributed to Japanese troops in the Philippines and other Pacific islands during World War II. The first version of the leaflet carried the words "I surrender," which so shocked the Japanese that they would not use it munications directed to a very large audience or over a considerable degree of territory. An appeal to the enemy civilian population to hoard food in order to protect their families against privation would be strategic in character. Tactical psychological warfare usually implies a direct connection with combat operations; the most common form is the surrender demand, although on other occasions tactical psywar may merely ask the enemy to retreat, tell individual soldiers to seek cover, warn city populations of bombing raids or instruct civilians on how to behave if an airborne force suddenly lands among them. Consolidation psywar consists of messages distributed to the rear oi one's own advancing forces for the sake of protecting the line of communicztions, establishing military government and carrying out the governmental tasks of the commanding general.

The same levels of distinction are sometimes made by use of the criterion of "action response." If an armed force or government uses psywar to prepare an audience for an action to be taken at an indefinite later time, the propaganda is called strategic; if a specific action is called for, it is termed tactical. Continuation of the cold war and the threat of "multipolar politics" arising from the admission of a great number of new states to the UN and the community of nations have accented the importance of multinational psychological operations in support. of strategic security.

Two separate but equally important intelligence functions always accompany professionally managed psychological warfare. The first and mosr obvious intelligence function consists of the analysis of one's own and the competing propagandas, together with the general flow of mass communications through the audience which is addressed. Sometimes particularly important decision-making parts of the audience, termed target groups, mill be evaluated in detail. Who is reaching them and through what broadcasts or printed media? What do the audience members prefer? What do they repeat? The amount of communications in an enemy's propaganda to outsiders will often reveal his intentions; an enemy government's home broadcasts almost inevitably show what the enemy leaders think the opinions and problems of their own people are. This is called propaganda analysis; in military form, it is merely an adaptation of civilian methods of public-opinion analysis.

The second form of intelligence is no less important. It consists of audience information for the propagandist. The psywar operator cannot make effective use of persuasion unless he is given concrete details about his audience. In wartime much of this information comes through espionage channels and is therefore difficult to obtain. There is a natural conflict between espionage officials who wish to keep all incoming information secret and psywar officials who wish to use the realistic parts of it to strengthen their messages. Estimates and plans are still subject to wide variations of staff procedure between different modern armies. The U.S. army had a psychological warfare branch, G-2, in 1941–42 and 1943–46 under various names. In 1951 a special staff division, the office, chief of psychological warfare (OCPW), was formed. Later this staff was made the "special warfare" portion of the deputy chief of staff for operations, the army staff division handling all command problems, when psychological warfare and warfare problems were placed under a common jurisdiction.

The communications media most commonly used in psychological warfare are the same as those used in civilian life; radio, newspapers, motion pictures, books and magazines form a large part of the output. Leaflets are more widely used than they are in civilian life. (The World War II leaflet output of the western Allies alone, excluding Russia, was at least 8,000,000,000 sheets.) Loud-speakers are often used in the front lines; both sides used them in the Korean fighting. The slow media are those in which a physical object must be transported to effect the communication: magazines, pamphlets, books, lecturers. Fast media are those which can be transmitted electronically: telegrams, radiobroadcasts, wireless messages. The media used in a mar usually reflect the capacity of the civilian economic system of each of the contestants. Whatever the medium! psywar can be successful only if it is credible, simple and properly timed.

PSYCHOLOGISM, in philosophy, is the view that problems of epistemology (that is, problems relating to the validity of human knowledge) can be solved satisfactorily by the psychological study of the developrnent of mental processes. Locke's Essay on *the Human Understanding* may be regarded as the classic of psychologism in this sense. A more moderate form of psychologism only maintains that psychology should be made the basis of other studies, especially of logic.

PSYCHOLOGY (ARTICLES ON). The subject matter of psychology—the behaviour of man and lower organisms—receives a general overview in PSYCHOLOGY, which surveys the scope and methods of the science, its major schools of thought and fields of specialization.

PSYCHOLOGY, HISTORY OF traces the evolution of psychological theories from the speculations of the ancient Greeks to modern concepts and methods. Prior to the 19th century the content of psychology was predominantly philosophical and introspective. The radical shift to the experimental and behaviouristic emphasis of modern psychology is reflected in the section dealing with the 20th century. BEHAVIOURISM: and PSYCHOANALYSIS are primarily devoted to theory; however, the reader who wishes to obtain a comprehensive view of modern psychological theories should consult, in addition. articles on PSYCHOLOGY, ABNORMAL; ANIMAL BEHAVIOUR; CONDITIONING; EMOTION; INTELLIGENCE; LEARNING; MOTIVATION; PERSONALITY; PSYCHOLOGY, COMPARATIVE; PSYCHOLOGY, EXPERIMENTAL; PSYCHOLOGY, PHYSIOLOGICAL, among others.

The range of psychology extends from the primarily biological (the behaving organism is a biological entity and must be understood as such) to the primarily social (behaviour, particularly in the case of man, can be influenced decisively by social determinacts). Those interested in the biological basis of behaviour should consult the articles on ANIMAL BEHAVIOUR; BRAIN; ENDOCRINE GLANDS; INSTINCT; MEDICINE AND SURGERY (ARTICLES ON); NERVE; NERVOUS SYSTEM: PHYSIOLOGY; PSYCHOLOGY, COMPARATIVE; PSYCHOLOGY, EXPERIMENTAI; PSYCHOLOGY, PHYSIOLOGICAL; and ZOOLOGY. Similarly, ANTHROPOLOGY; ATTITUDE; LANGUAGE; PERSONALITY; and SOCIOLOGY. give a view of the role of social factors in behaviour. Many articles under general psychology headings and elsewhere (*e.g.*, PSYCHOLOGY. ABNORMAL; CHILD PSYCHOLOGY AND DEVELOPMENT; LEARNING; MOTIVATION; PSYCHIATRY) treat behaviour from both points of view, of necessity. because psychology sees behaviour as (1) a function of the total organism. (2) occurring in a context and not in isolation, and (3) a function of both biological and social determinants.

From its beginnings. psychology has had strong interests in methodology and has developed a variety of techniques and apparatus for experimentation and analysis—on its own and by borrowing from other sciences. New devices and methods appear regularly. Most represent elaborations upon or adaptations of general principles and facts well known and widely accepted in psychology. There are many such principles and facts; much, if not most, of the disagreement among workers in psychology is with respect to theory and interpretation rather than with respect to the facts about behaviour. Some of the techniques and devices are primarily for laboratory use (PSYCHOLOGY, EXPERIMENTAL; PSYCHOLOGY, HISTORY OF, PSYCHOLOGY. PHYSIOLOGICAL; and PSYCHOPHYSICAL METHODS). Others have been developed for the school situation, the clinic or hospital, and business and industry (ATTI-

TUDE; PERSONALITY; PSYCHOLOGY, APPLIED; PSYCHOLOGICAL TESTS AND MEASUREMENTS). Applied psychology is an actively growing field; new appiications of basic psychological knowledge emerge continuously as techniques developed for laboratory use migrate to the practical situation where they demonstrate utility for applied purposes. The distinction between applied and pure science is often less clear and categorical in psychology than in some other fields of learning.

PSYCHOLOGY. Psychology studies living behaviour with ultimate reference to human individuals alone and in groups. In so doing it impinges upon several other fields. It is possible to isolate for study living units at the levels of cell, organ, individual, group and society. Physiology and neurophysiology are concerned with the functioning of cells and organs of the body. Sociology studies the structure and function of groups and societies. Anthropology is interested in man as a species which makes multiple cultural adjustments to the world's varied environments. Biology. economics, political science and. in part, history, philosophy and theology all focus upon subject matters in some way related to that of psychology. While there are no clear-cut, universally accepted distinctions among the various sciences, it can be said that the psychologist makes statements about the individual which describe his behaviour in response to a variety of stimuli; turning to physiology and neurophysiology when he wishes to demonstrate "causal mechanisms" by which the effects are produced. Also he studies in the individual "causal mechanisms" that underlie the group and social phenomena which the sociologist takes for his subject matter. In general, the psychologist is interested in the whole individual in relation to his surroundings, his fellow beings and himself.

Since psychology is so inclusive, it encompasses numerous specialties. This diversity sometimes contributes to the impression that there are a number of disunited "psychologies." The appearance of disunity is increased by the lack of a theoretical structure applicable and acceptable to the whole field. Thus there are clinical psychologists, experimental psychologists. physiological psychologists, comparative psychologists, industrial psychologists, social psychologists, occupational psychologists. all of whom, after undergoing somewhat different training, follow separate specialties within psychology. The discipline finds unity, however, in the fact that their common interest is in organisms which are highly organized and integrated. It is thus difficult to discuss sensation without involving perception, perception separate from learning, learning without reasoning, or any of these processes apart from personality, emotion and motivation. And it is difficult to isolate the organism from the influence of the external culture. for the immediate group situation, the interaction with absent but important people and early family experiences are all transparently significant in most branches of the science of behaviour.

Psychology developed as a part of philosophy (*see* PSYCHOLOGY, HISTORY OF), appearing as a separate discipline as recently as the late 19th century and developing into an experimental science with the establishment of laboratories by Wilhelm Wundt at Leipzig, Ger., in 1879 and by G. Stanley Hall, a pupil of both William James and Wundt, at Johns Hopkins university in 1833. Both James and Wundt had had informal laboratories as early as 1875.

The fundamental philosophical questions particularly relevant to psychology are those of epistemology: What is "mind" and how is it related to the body? How does the knower know the world and other minds? What is the relation of experience to reality? These problems were dealt with well before Plato, yet are involved in current discussions of consciousness, the relation of psychological function to structure, phenomenology and the nature of the self. As physics and physiology developed, physicists and physiologists became interested in whether mental activity as well as physical phenomena followed orderly laws. Gustav Fechner (*q.v.*) performed the first experiments in psychophpsics, published about 1851, to show the relations of mind and matter by making "the relative increase of bodily energy the measure of the increase of the corresponding mental intensity.:' (See PSYCHOPHYSICAL METHODS; PSYCHOLOGY, HISTORY OF.) Hermann von Helmholtz, like Fechner a physicist, made contributions in the fields of audition and vision, and did pioneer experimental and theoretical work in perception, holding views similar to those of the English associationists John Locke and James and John Stuart Mill, that perceptions are built from experience and are not native to the mind. Wundt, trained in physiology, who first insisted upon psychology as a separate discipline, held that it is the science of immediate experience, including both subjective feelings and perceptions. and that introspection is its appropriate and primary method. He believed that mind and body are totally different universes, not necessarily parallel, and that events within the mind are subject to laws which can be studied. James, a physician and philosopher who approved of experimentation in psychology, saw mind and consciousness as a "stream." ever changing. whose primary function is knowledge and the selection of relevant data from the mass of sensations confronting the individual. E. B. Titchener, at Cornell university. Ithaca, N.Y., was one of the first psychologists to believe that the epistemological questions could be bypassed, leaving psychology a realm of sensations. .images. feelings and meanings which could be studied scientifically. He agreed with R'undt that introspection is the proper technique for this.

"Pity poor psychology," it has been said. "First it lost its soul, then its mind, then consciousness, and now it's having trouble with behaviour." This summary of its history, though facetious, is not entirely incorrect. since the entities which had served philosophers as explanatory concepts appeared unsatisfactory as data for science. Psychology moved progressively from attempts to prove something about the mind-body question, to consideration of "consciousness." to concern with unconscious processes as well. and then to the insistence that behaviour alone is available for study by public science, and that constructs like "mind" either refer to nonexistents or are irrelevant. In the second and third decades of the 20th century, the behaviourism of J. B. Watson was embraced by many psychologists. especially in the U.S., who believed they found in it a refreshing breeze sweeping out the dust of centuries of speculation and opening the way for true science. They were committed to a view of behaviour based upon the connection of the stimulus with the motor response through a nervous arc, more complex behaviour being built up by the elaborating of connections between the simple nervous elements. Thought was associated not with the brain but with the organs of speech, and experiments showed that while thought was taking place the vocal apparatus was active in a way similar to that during speech, although to a lesser degree. Thought was thus defined as subvocal speech.

The behaviourists were challenged by the Gestalt (German for "configuration") psychologists, a school which was initiated in Germany about 1912, most of whose leaders continued their work in the United States after Adolf Hitler came to power. They experimented mainly with perceptual processes and emphasized the importance of the brain in organizing sensations. They further looked upon behaviour as taking place in a "field" of forces, and they held that organized subjective experience is exactly mirrored by a comparable "isomorphic" physical process with a similar organization in the brain. The relationship of the organism to its surroundings was to Gestalt psychologists much more complex than the behaviourists pictured it. While both stimulus-response and field theories still have their proponents, they usually adhere to modified forms of the older, classical views.

In addition to the questions about mind and matter. philosophers have for centuries concerned themselves with issues of human motivation. the place of emotion in behaviour, the bases of aesthetic choice and the ethical aspects of man's nature. All of these are still live issues for psychology. Sigmund Freud was not the first to point out that many of the most potent factors in human motivation are not ordinarily available to waking consciousness. Plato. for example. in book ix of the Republic, quoted Socrates as explicitly recognizing the same fact. Freud importantly altered psychological thought, however, by developing a complex and sophisticated theory concerning unconscious determinants of behaviour and applying it, in the therapeutic process of psychoanalysis, to the care of the emotionally disturbed and mentally ill. Since the beginning of the 20th century Freud's work has had great impact on the medical and scientific world as well as on art and letters generally. (*See* PSYCHOANALYSIS; UNCONSCIOUS.)

THE METHODS OF PSYCHOLOGY

A few of the techniques which have become classical in psychology can be listed here. These methods are in general similar to those of other sciences, although some are specific, their nature determined by the subject matter. Problems about behaviour frequently involve variables which are not available for direct manipulation and measurement. Almost every act of animals and men is determined by several factors. so they are rarely identical from one to the next or from individual to individual. Psychologists! however, may observe and measure these acts; they use statistics to analyze the findings. Two kinds of statistics are used. The first, descriptive statistics, describes sets of results by various measures of how much similarity they have as well as how. much deviation individual cases display. They constitute a quick means for summarizing meaningfully many single findings on a topic. The other kind, probability statistics, is a mathematics whereby, despite ignorance of some of the related facts, one can estimate the likelihood of a certain future event, or show that a given past event did not occur by chance. If more than a chance number of cases out of a random sample of a class fall in a certain direction on a given dimension, even though all cases in the class are not observed, it is assumed with a calculable risk of error that some factor is acting to influence them in that direction. By such means it is possible to make predictions, as well as to isolate the effective elements in a situation and show how important each is.

Direct observation, in psychology as in other sciences, is the first and simplest way to gather data. Careful noting of everything that takes place in a schoolroom, the keeping of a diary for a year on the behaviour of an infant or the observation and recording of group discussions are all examples of this method.

Controlled experiment arranges the situation, chooses the subjects for certain characteristics such as age or sex or type of pathology, and controls variables that cannot be eliminated. Often this is accomplished by the use of control groups which are matched with the experimental groups in as many ways as possible in order to observe the effect of a specific difference between them, which is the aspect of their behaviour being studied. A specific type of control, the method of co-twin control: is used especially in the study of child behaviour. It is used to distinguish genetic from environmental influences on certain behaviours. such as performance on standard intelligence tests. When accidents of fate separate identical twins so that they are raised apart and given different training, tests before and after can indicate what effects favourable and unfavourable environments have on intelligence quotient (I.Q.). Foster children have also been used to study the problem, by comparing the child's performance on tests with those of his true parents on the one hand and the foster parents with whom he was raised on the other.

In comparative psychology (see PSYCHOLOGY, COMPARATIVE) various apparatuses are employed to study learning. reasoning and other aspects of behaviour, in which animals are taught to make discriminations—say between a black and a white card or a right and a left turn—by reward or punishment. Variations in performance are produced by the systematic introduction of changes in the experimental situation. Various problem boxes and mazes have been devised for such work. Comparable equipment is constructed for studying human verbal and nonverbal activities.

Some of the processes which are associated with emotion can be precisely observed. Facial expressions and gestures can be photographed. The psychogalvanometer (see PSYCHOGALVANIC REFLEX) records changes in electrical resistance of the skin nith increases in microscopic sweating caused by even slight emotion. Breathing rates, blood pressure. pulse rate and other bodily functions alter with emotion and can be measured objectively. Such methods are sometimes used in lie detection in criminology, such measures being made while a suspect is answering questions about his knowledge of a crime.

Subjects' experiences as well as their actions can provide important data. In many experiments only the subject himself can indicate of what he is conscious, and therefore the technique of introspection is used. The subject reports his experience verbally or by depressing a key or performing some other act. Efforts have been made to ensure rigour in this method, such as averaging repeated trials to diminish the effects of incidental fluctuations in awareness, and establishing rules for regarding stimuli in order to minimize subjects' personal involvement with them. Questionnaires of various sorts have been used in the measurement of subjective attitudes toward political changes, family problems and many other situations.

Of course the person being queried may not wish to divulge his true feelings, and therefore may give inaccurate answers. Or he may not be aware of his true feelings, especially if they are shameful or unacceptable to him. And he may have biased memory about many things. His actual behaviour, also, may differ sharply from his indicated attitudes, as is likely to be true in such matters as race relations and family relationships.

Interviews in which the subject is encouraged to talk at length about his attitudes, guided by questions from the interviewer, may lead to more accurate results than simple questionnaires and are increasingly used in surveys of political feeling and public opinion. In both questionnaire and interview techniques sampling is often carried out. The persons to be interviewed are chosen from the population so that all groups whose attitude is relevant will be proportionately represented. The accuracy of the sample is important in generalizing about the results. If significant groups are neglected, predictions will be in error. Such mistakes, for instance, have been made in some forecasts of the outcome of elections.

In clinical, educational and guidance applications of psychology other techniques are used. The clinical interview or psychotherapy is usually designed by the one who conducts it to learn about the patient's personality or to help him express his feelings and understand them. Hypnosis can help the patient remember forgotten material or aid him in overcoming undesirable habits or attitudes. Various drugs: such as sodium amytal, have been used similarly. Controlled and free association may also be employed. In these the patient either says what comes to his mind in response to a question or stimulus word, or is instructed to say everything that comes to mind during a period. When the latter is continued over a number of sessions, it facilitates recovery of memories of past feelings and events and is conducive to the expression of repressed or suppressed attitudes. It is a characteristic method of psychoanalysis.

Psychometric tests measure various sorts of performance as compared with previously established norms (see PSYCHOLOGICAL MEASUREMENT). These may be objective tests, designed to measure specific traits, skills or achievements; or projective tests, consisting of pictures, ink blots, lists of words, sentences or other stimuli, designed primarily to reveal unconscious emotions or attitudes. These techniques are employed widely in the diagnosis of mental and emotional illness and as aids in guidance. Factor analysis, a statistical method developed by C. E. Spearman and Sir Cyril Burt in England, L. L. Thurstone in the United States and others, has been increasingly used to derive the dimensions of behaviour and personality measured by psychometric tests.

Stress interviews and other situation tests are recent developments used in selecting personnel for special military duties or industrial assignments. These techniques are designed to create circumstances in which emotional factors are sufficiently strong or events develop with sufficient realism so that the reactions of the person being tested can be assumed to be like those he would manifest in critical situations on his assignment.

Play therapy with children too young for adult methods of psychodiagnostics and therapy ordinarily involves the use of play materials either as a sort of projective device (for instance, to see how the child treats dolls representing faniily membersj or to facilitate expression of feeling and allow the child to "act out" his conflicts in play with his therapist. Various forms of therapy through role playing have also been developed. The patient may play himself or another character, and additional actors, therapists or patients act other roles. Usually the plot is not specified and action proceeds extemporaneously. This technique often serves as an opportunity to express feelings and also to practise meeting the problems of real life.

THE CONTENT OF PSYCHOLOGY

The individual is an organized system maintaining equilibrium among the inputs and outputs of each of its constituent subsystems and over-all stability in a constant flux of inputs from and outputs to the environment. In common with others, the individual is a subsystem of larger systems like families and other groups. countries and societies. The present state of any of these behaving units is the result of its genetic constitution and the past inputs to it. In this general framework it is possible to see the interrelationships among the various areas of psychology. Sensation is the name of the area concerned with the inputs of stimuli to the sense organs of the individual. The patterning or organization of these inputs is the subject matter of the field of perception, and apperception deals with processes whereby perceptions become meaningful by being associated with memories of related past experiences.

Among the internal processes which regulate the organism, learning and memory (and its converse, forgetting) deal with the storage of experience for periods of time. Attention or set are functions which result in certain sorts of input having more influence on the organism than others. Various "higher mental processes." though demonstrable in other complex animals. are particularly characteristic of man with his intricate central nervous system—reasoning, decision making. problem solving and concept formation. Emotion and temperament concern processes related to feelings and closely associated with the autonomic nervous system and endocrine system (see ENDOCRINOLOGY). Motivation is the area which deals with the internal needs or drives which provide the impetus that makes the person act. And the complex notion of personality, which is similar to but not identical with self and ego, is used to represent the organization of all the characteristics that make the individual unique, dependable in his responses and consequently recognizable to others over long periods.

Psychology is also concerned with the outputs to the environment or larger systems of which the individual is a member These include such responses as his reflexes and his complex physical acts. Included also are his patterns of work, and the effects of fatigue, distraction motivation and social interactions on them, as well as his gestures and his speech.

The study of the development of human behaviour from infancy through the "seven ages of man" is a part of psychology. So, too, is the systematic comparison of the actions of different species and the relating of this to known facts of comparative anatomy (*see* PSYCHOLOGY, COMPARATIVE). Psychopathology, the study of abnormal states. is also part of the science. Deviation from norms produced by genetic or experimental influences and abnormal states produced by toxins. drugs. hypnosis. injury, illness and unknown factors are studied both as phenomena in their own right for the light they shed on healthy function and in the hope of learning how to cure or improve afflicted individuals (see PSYCHIATRY; PSYCHOLOGICAL MEASUREMENT).

Finally the field embraces social psychology, which is concerned with the behaviour of systems larger than individual and deals with interpersonal and group relationships, the influence of societal and cultural factors, the place of the individual in society and problems of communication among individuals.

A relatively new development is the growth of psychology as a profession distinct from the science. This development mas inevitable with the rapidly increasing number of applications of psychoiogical knowledge in business, military and political life, and since psychologists developed tools useful in the clinic in studying and treating patients, both psychiatric and medical. (See APPLIED PSYCHOLOGY.)

SPECIFIC TOPICS IN PSYCHOLOGY

Some of the most important theoretical formulations and empirical findings of psychology are summarized below under the main topics suggested in the preceding statement input, central and output processes; developmental history; pathology; and interpersonal relations.

Input Processes.—The world impinges upon us through our senses of vision, hearing, smell, taste, touch, vibration, hot and cold. The state of our body is reported to us by pain, muscle and joint sense and the vestibular balance sense. Of these the earliest to be studied scientifically and the most thoroughly understood today are vision and hearing. Impulses reaching the appropriate sense receptors are transmitted by peripheral nerves to the central nervous system. The nature of the receptors and of the neural transmission dictates which sort of energies mill be sensed and which will riot, as was recognized by Sir Charles Bell and Johannes Müller early in the 19th century. The receptors are sensitive to certain wave lengths and not to others, and these must be of sufficient intensity to cross the limen or threshold of the particular sensory subsystem involved. The eyes are stimulated by light sources whose wave lengths fall between ultra-violet and infra-red, both limits being invisible. In this limited range of all light frequencies, species differ as to which frequencies they see best. Dogs and some other species can hear high-pitched sounds which human beings cannot hear. A single nerve cell (neuron) .either reacts to the full or does not respond at all. Therefore increase in intensity of sensation is brought about in a stepwise manner by the involvement of more and more neurons in a nerve trunk, or by other means. The "just noticeable difference" is a unit of psychophysical measurement representing how much more intense a stimulus must become to produce a report of awareness of change by the subject. Donald Hebb and his associates and John Lilly reported evidence that for normal function, the nervous system needs a constant minimal input through the senses; otherwise hallucinations and abnormal behaviours may be produced.

Central Processes.—The Central *Nervous* System.—(See BRAIN; NERVE; NERVOUS SYSTEM; PSYCHOLOGY, COMPARATIVE.) More complex animals in general have larger brains in proportion to their body sizes and show encephalization, which is a tendency for the higher nervous centres to integrate functions controlled by lower centres in less complex species. In man this tendency has resulted in even those vegetative functions which are mediated by the spinal cord and older portions of the brain having representation in the cortex. The histology and neuroanatomy of the nervous system have been studied in detail and the activity of many areas is well understood. The brain is known to be incessantly alert and active chemically and electrically throughout life. even in sleep. Knowledge is incomplete, however, concerning the function of much of the brain, including the frontal lobes. Studies on animals which have undergone operation and on brain-injured and surgically treated human patients have located areas whose damage permanently impairs or destroys certain such processes as sight or speech. The neural bases for learning, memory: reasoning and perception are not clear?and the meaning of such factors as attention, will, decision making and personality organization in terms of brain activity is uncertain. There are, however, theories which account for many of the observable facts. Electronic computers and "behaviour simulators" have been viewed as models of brain mechanisms and have furthered understanding of them.

The two classical theories of brain function are those based upon the stimulus-response model and field model. respectively. In the first, the elements of sensory nerve, central process and motor nerve are assumed to be elaborated with many interconnections strengthened by repeated use, so that more complicated behaviours are built up from the same elements as the spinal reflex arc. The second, field theory, regards behaviour as related to energic changes in the whole cortex or brain rather than through the connection of elements. There is no common agreement as to which is a better way to conceptualize central processes like perception, learning and memory.

Perception is the organizing of the raw material of sensation into a constant "world of experience" in which sight, hearing and other senses are co-ordinated with each other and recognizable objects are located in space. Study of the different images on the retinas of the two eyes indicates that the images change shape and size if the object causing them moves in the visual field. Their colours change with light and shadow as backgrounds alter. The observer, however, knows that the steadily enlarging image of a car means that it is approaching; that the yellow of a lemon remains the same in sunlight or shadow; that the square has four right angles even, though its image on his curved retina has none. He is able to recognize familiar songs in any key. All this being true, it is not surprising that the question has arisen both in philosophy and in science of the extent to which the observer is responsible for the characteristics of the world which he inhabits. What is "really there" outside? Our whole experience of the world comes to us in the form of such percepts, and these cannot be observed by anyone but the perceiver himself.

The point of view known as "phenomenology," a position particularly popular among existentialist theorists on psychological issues in Europe, stresses both the privacy of experience and the activity of the perceiver in giving form to reality. The classical modern view of perception was based upon the associationist philosophy of Locke, David Hume and John Stuart Mill in the 18th and 19th centuries, according to which ideas are bonded together to form a total idea of an object. Titchener, who developed a late form of such theory. believed that a number of sensations are incorporated into a connected whole and supplemented by images from past experience in such a way that they become part of the percept. They have meaning according to the context or total situation in which they arise.

The perceptual theory of the Gestalt school developed in the tradition of Kant, who held that the mind imposes categories upon experience. The Gestalt movement began about the time Max Wertheimer published experiments in 1912. These demonstrated that "apparent movement" of a single object from one place to another is perceived when two adjacent lights are lighted sequentially at a time interval longer than those which make them appear simultaneous but shorter than those which make them appear successive. Wolfgang Kohler, Kurt Koffka and others published further research and additions to the theory. They were. as noted above, committed to a field theory of brain function and believed that innately the brain is able to perceive certain simple forms such as a square or circle. Their experiments showed that there is a perceptual tendency to "closure" in which partial figures are seen as wholes, patterns are organized from amorphous materials and unfamiliar constellations are seen as familiar. It was emphasized that in perception the whole is greater than the sum of its parts. Gestalt theory opposed the associationist theories with cogent arguments.

Hebb, in 1949, challenged the Gestalt view at least in part. He held that there is indeed some innate organization of perception but contended that a given perception depends upon the excitation of particular neural cells. He cited experimental evidence to show that congenitally blind persons who, after ophthalmic operations, are able to see, can readily perceive figures as standing out against background, but must learn to recognize and name them. Even after a training period they must sometimes count the corners to tell a triangle from a square. Objects are often not recognized against altered backgrounds until a learning period has passed. Neurologically the Hebb theory assumes that cell assemblies form which, through growth of neurons, come to be so connected as to discharge in a co-ordinated way. They are also integrated into more complicated organizations. These make possible the perception of wholes as "greater than the sum of their parts." Hebb's theories concern other psychological processes besides perception, sometimes in detailed fashion but often only sketching in general outline.

Even early theories of perception recognized that other functions are related to perception. One of these is attention and another the set or direction of activity already in process in the individual at the moment of perception. Though attention can alternate rapidly when two or more stimuli demand notice simultaneously, we cannot pay attention to every stimulus which assails our sense organs. What is chosen to be attended to is therefore partly determined by the characteristics of the stimulus—suddenness, frequency of repetition, intensity. unusual characteristics such as strange colour or unexpected motion are among these—and partly by factors within the perceiver. If he is hungry, he will pay more attention to the restaurants he passes than if this drive is satisfied. An artist will observe the play of light and shadow over a cornfield while a farmer will notice the vigour and probable yield of the crop.

Set influences perception by leading the perceiver to expect a continuation of the sort of situation which has been in progress. A picture of a red sphere will commonly be called "apple" if shown in the midst of a series of pictures representing various foods or fruits. The same sphere is a "ball" if the series is of toys or sports equipment. It is "sphere" if in company with abstract geometrical designs. Words identical in sound gain their meaning from the context in which they appear. We do not look for "flower" in a cake recipe, or "flour" in the gardener's account of his successes.

Within relatively recent years new sorts of determiners of perception have been emphasized. Not only is the present drive state of the perceiver recognized as important, but his past history, his emotional characteristics, his personality structure and his motivation can all be demonstrated to affect perception. A fearful soldier or a recruit will perceive a threatening situation in battle differently from a brave or experienced man. Emotions and past experiences determine to a great extent what things will be singled out as important. The way we perceive another person may be affected by attitudes we have had about similar persons in the past. A man whose father was overly strict. for instance, may perceive all older men as threatening. forbidding and likely to cause trouble. This, of course, is an extension of the classical sense of "perceive."

Social factors in perception are important in the theories of Jerome Bruner, Leo Postman and others, published in the 1950s. Muzafer Sherif and others have shown that social pressure can strengthen a weak conviction about what one is perceiving, or throw doubt upon a relatively strong one.

Phenomenology, as contrasted with objective theories of perception. has its greatest number of adherents among psychologists in Europe where the philosophical implications of the theory are believed to be in keeping with current thinking in literature and other fields. Albert Michotte, a leading exponent of such theory, conducted a considerable body of research relevant to his ideas. He studied the effect upon perception of stimuli which are in some way discordant—for example, when two senses, like vision and touch, seem to give conflicting information about an object. His results indicate that some subjects behave as if the object lacked unity, yet seem untroubled by the difficulty; others make a compromise of some sort. He also studied the perception of volume, finding that a plane figure with metal wires arranged in certain ways will be perceived as having volume. Perception of causality, he found, can be gained by moving objects in such a way that they appear to affect each other without doing so. For instance, a motion picture of circles going toward and away from each other in certain patterns and at certain rates is perceived by the viewers as showing billiard balls bouncing against other balls and causing them to roll. Michotte found that in perceiving distance and size, situations in which people are used to being deceived by appearances, they readily admit that an illusion is operating. However, in novel circumstances involving no previous experience of deception, adult subjects behave as Jean Piaget found children to behave; that is, they find it difficult to convince themselves that they are perceiving incorrectly. Carl Rogers in the United States championed a point of view related to phenomenology, applying it in nondirective or client-centred psychotherapy; this involves the acceptance by the therapist of the client's subjective frame of reference, including his perception or conception of himself.

Learning is a central process which has been a major concern of psychologists since the earliest days of the science. By the mid-1950s there existed a formidable bulk of experimentally demonstrated fact upon which to build theory and to base further research. It continued to grow as rapidly as scientific journals could print papers on the problem. Hermann Ebbinghaus' well-known experiments on memorizing nonsense syllables. published in 1885, were among the earliest of these studies. He demonstrated that such material, without meaning or emotional connotation, is acquired in an orderly way that, when plotted graphically, results in regular curves. Learning of meaningful material can produce such curves under certain conditions, but the process is more complex, being affected by the difficulty of the task, familiarity with its content, attitudes toward its meaning and other factors, Motor habits such as operating a typewriter are learned in similar regular fashion.

Increasingly it has been possible to specify precisely what conditions facilitate or inhibit learning. Active participation of a subject in an experiment, for instance: produces rnore rapid learning than when he merely listens passively as the material is read to him repeatedly. Motivational factors. such as expectation of reward or fear of punishment, also operate to influence the rate of acquisition of new information. The law of efiect of experimental psychology, as first stated by Edward Lee Thorndike and as modified by Clark Hull and others in terms of "reward" and "reinforcement," and the pleasure-pain principle of Freud's psychoanalytic theory agree (in spite of many differences on other points) that information and action patterns which produce pleasure or prevent pain are learned and retained while those which produce pain or prevent pleasure are forgotten or repressed. Research has also indicated that, up to a point, increasing distraction operates to speed the rate of learning, but beyond that point the process is hampered. The set or attitude of the learner, his emotional reactions to the material, his motivations, social factors such as the presence and reactions of other learners, all affect the process.

The work of I. P. Pavlov on conditioning in animals, which first appeared early in the 20th century, was classical physiological research with important implications for the psychology of learning. In this work an animal was presented with an "unconditioned stimulus," *e.g.*, an electric shock, a short time after he heard a bell ring—the "conditioned stimulus." The animal would withdraw the paw which received the shock from its position, thus ending the painful stimulus. After a number of trials of this sort the animal would begin to remove the paw upon hearing the bell ring, so avoiding the shock. This action was called the "conditioned response." It could be established by the use of reward as well as punishment. A bell ringing shortly before meat was offered to a hungry dog would set up conditioning whereby the sound of the bell would cause the dog to salivate in a way that had formerly been elicited by food alone. It was found that this response would slowly disappear unless it was "reinforced" with a meat reward from time to time, and that it could be made to disappear more rapidly if the ringing of the bell were followed by punishment instead. The investigations of Pavlov deeply affected the behaviourism of Watson, who maintained that any personality traits desired could be built up in children by proper conditioning.

We do not know exactly what goes on in the nervous system when even a simple motor habit. much less a complex idea, is acquired. But it is assumed that in some way neural connections are strengthened or organizations developed by repeated passing of impulses in given patterns. It is considered significant that for almost all learning more than one experience of a given sort is necessary. "One trial learning" is possible where the situation is dramatic or extreme—one touch of the hot stove is usually enough to make a child avoid it. In some lower species a process like learning, known as imprinting, takes place; in which the first experiences have an immediate and lasting effect. Konrad Lorenz has shown that a gosling will follow a human being who quacks at him during the first few minutes after hatching if the mother goose does not get there first. Thereafter the gosling will follow the human being in preference to the goose. According to Lorenz this effect is permanent, although this has been questioned by others. Learning differs from imprinting in involving the more gradual development of some sort of connections or restructuring over time.

The determinants of learning have been specified in great detaii for the white rat, but less fully for humans and other species. Animal learning is studied with mazes and other types of apparatus. as for instance those which permit animals to jump or press levers or make sorne other specific response to differently patterned cards or lights. (See PSYCHOLOGY, COMPARATIVE.) Human learning is investigated using finger mazes, memory drums that automatically expose cards with pictures or words, discrimination situations and other procedures.

As in other fields of psychology, there are both associationist learning theories and field learning theories. In the first class learning is regarded as proceeding from the formation of many reinforced connections between sensory events, central processes and motor events. In the second it is viewed as the organization of a field. Stimulus-response theory, in the first class, conceptualizes learning as a continuous function, proceeding as connections are strengthened in an orderly way. Field theory conceives it as discontinuous; the field is structured first according to one set of cues and then restructured to another.

Hull hypothesized that "bonds" are formed between stimulus and response, and that these are reinforced when drive reduction occurs through a reward such as food or escape from a punishing situation. He did not, however, insist that there are definite sensory-motor pathways in the nervous system, conceiving instead of "habit family hierarchies," interrelated patterns of action which can be elicited repeatedly by a specific sort of stimulus.

Edward Tolman, a field theorist, placed more emphasis upon "cognitive" factors. That is. he assumed a more active role for thinking and reasoning and less for reinforcement by the situation. He assumed that an animal learns a maze by forming a series of hypotheses as to the correct direction to take at each choice point, checking them and continuing those that are rewarded by success, so developing ultimately a "cognitive map" of the total configuration of the maze.

4 third important learning theorist was B. F. Skinner. Instead of guessing at what might be going on "inside" the animal, he tried to specify exactly and in units of detailed acts the conditions under which learning takes place. Skinner preferred as a measure the rate of response in animals as related to the degree of drive—measured by the amount of weight lost through hunger or the number of hours of fasting or thirsting. He pointed out that if a rat is trained to depress a lever in order to receive a measured amount of food, the number of times the lever is depressed during a feeding period can be considered a measure of the rat's drive.

Memory of learned material was regarded classically as the maintenance of associations established in the learning process. Sir Frederic Bartlett studied memory experimentally and his findings indicated that more is involved in memory than the storage of information or the maintenance of established bonds. He showed that as time passes the memory "trace" is modified. He asked subjects to make successive drawings from memory of an outline picture of an owl. Typically such drawings progressively dropped out details?finally losing the characteristics of an owl and ending as the more familiar outline drawing of a cat. His theory assumed that organization of memory is subject to change as ii is affected by prior experience and by later events. Ebbinghaus had found earlier that forgetting of nonsense syllables, like learning, followed a smooth curve—in this case a decay curve.

Much research relevant to memory actually deals with its opposite, forgetting. As learning mas held to be the setting up of connections! and meinory their maintenance; forgetting, to classical association theorists, involved wearing them away. Pavlov found that to keep a conditioned response lively it must be reinforced from time to time, He also found that extinction can be hastened by presenting the conditioned stimulus without the reward or punishment which established it.

Events occurring after learning or conditioning can interfere with retention. This is "retroactive inhibition." J. G. Jenkins and Karl M. Dalienbach showed that memory is better after sleep than after a comparable waking period, presumably because in sleep there are no interpolated tasks to inhibit memory retroactively. "Proactive inhibition" also occurs, whereby later learning is prevented or altered by earlier events.

Freud challenged classical views of forgetting. By hypnosis or free association he could retrieve from patients verifiable memories of long-forgotten events. Frequently these mere confused with "cover" or "screen" memories which the patient preferred to recall, but the original impressions were available under special conditions. He therefore concluded that memories of shameful or disturbing events could be repressed into an unconscious aspect of the personality. This repression mas somewhat similar to Pierre Janet's "suppression," which in extreme cases even embraced the "forgetting" of whole parts of the personality or functions of the body. Both Freud and Janet found that memories outside of awareness continue for long periods to exert an effect upon behaviour. This discovery led to the view that little is ever forgotten but that in some way the brain retains most impressions made upon it, mhich under favourable circumstances can be recalled. Evidence is accumulating that brain processes are continuously suppressing and repressing selectively various stored memories.

Problem solving has been studied in men and in animals. *(See* PSYCHOLOGY, COMPARATIVE.) Though thinking and reasoning are often held to be "higher mental processes" particularly characteristic of man, the body of experimental material on them is relatively small and theory is primitive. About the turn of the 20th century the chief argument in this field centred around the question of whether a thought was characterized by a temporal chain of conscious images, as a group at Leipzig contended, or could be carried on without such an association of images, as their Wdrzburg antagonists believed.

Later, as has been mentioned, controversy raged around the behaviourist insistence that thought is subvocal speech, minimal activity of the laryngeal muscles. Thorndike and other associationists held that the solution of problems proceeds by random trial and error, the scope of trials becoming more delimited gradually as partial solutions are achieved. Problem solving by animals has been studied in various kinds of problem boxes in which the animal receives a reward for completing the task. Multiple-choice apparatus has also been used to observe human problem solving.

The Gestalt school made new assertions about problem solving, stressing the instantaneousness of arrival at a solution as the conceptual field is restructured. They pointed to the surprise with which subjects suddenly see the answer, calling this the "aha experience." Karl Duncker published research on such cognitive reorganization in 1926 and 1935. He made use of difficult problems whose answers were not immediately apparent from past experience. He found that solutions were not reached in a single step, but proceeded by one or more restructurings of the problem so that it was viewed differently, and this process led to the final correct ansaer.

Norman Maier also gave difficult tasks to human subjects and analyzed the solution process. He believed that it occurs by the formulation of a theory as to what should lead to solution, testing of it and eventual confirmation or rejection with the consequent statement of another hypothesis. This is neither the trial-and-error process of Thorndike nor the insight of the Gestalt group. Maier held that only problems that were easy for the subject were solved by insight, but he recognized that when they could be grasped at once and structured readily the solutions were "seen" with the "aha experience."

In ways somewhat similar to the problem-solving process, the central process of *decision making* has been increasingly investigated. In some region of the nervous system, many inputs from the environment, from other parts of the body and from the memory must be resolved in order to give rise to a single output, or a limited number of them. In neurophysiological terms, a "final common path" must be selected. Psychologically and psychoanalytically this is classed as a "self-" or "ego-function." Many influences, both external and internal, impinge on us—sensations and perceptions of the outer environment; social factors; motivational conditions and somatic needs involving physiological states of the "internal environment" within our bodies; feelings, emotional states and aesthetic preferences; memories, both conscious and unconscious; the resultants of learning, thinking and reasoning; ethical values and religious beliefs. All these must be reduced to a common denominator before one behaviour occurs in a given situation rather than another. This is decision making, and it is being increasingly investigated by psychologists, sometimes with the assistance of a new branch of mathematics known as "theory of games," which was introduced by John von Neumann and Oskar Morgenstern.

Emotions such as fear, rage, sorrow and love are central reactions which involve visceral and emergency mechanisms of the body *(see* EMOTION). The autonomic nervous system, which controls functions like respiration, digestion, circulation and glandular secretion, mediates through its sympathetic branch various states of excitement and preparedness for action which characterize emotion. Digestion may stop, heart and respiration rates increase, adrenaline be excreted into the blood stream and the blood sugar content be increased. Measures of blood pressure, breathing rate, blood sugar and the psychogalvanic skin response *(see* PSYCHOGALVANIC REFLEX), among others, have been used in experiments as indicators of emotional states.

Psychologists have asked what are the relations between the physiological conditions of emotion and the concomitant introspectively reported feelings. James in 1884 and Carl Lange in 1885 independently proposed that emotions are the conscious awarenesses of the bodily changes which occur as direct responses to emotion-provoking situations. Thus, "we feel sorry because we cry." A revision of this theory, by Walter Cannon and Philip Bard, held that the hypothalamus, a midbrain centre, is the seat of emotional response, sending impulses both to the cerebral cortex, where awareness of them probably arises, and to various internal effector subsystems of the body, producing visceral, glandular, muscular and other responses.

Charles Darwin, in 1872, wrote about the distinctive gestures and facial expressions which characterize the different emotions, and suggested that at least some of these behaviours are inherited from lower species. The human sneer, for instance, may be related to the carnivore's baring of its canine teeth in rage or in preparation for attack.

Continued emotional stress, conscious or unconscious, is recognized to have a role in causing many "psychosomatic" diseases, although the mechanisms by which these effects are produced are poorly understood. The relief of the underlying tensions may alleviate symptoms when other sorts of therapy have been ineffective. Mental diseases such as schizophrenia have a profound effect not only on cognitive processes but also on the emotional state of the patient, characteristically producing an apathy or "flatness" of affect. Manic-depressive psychosis results in either excited or depressed emotional states or cyclical alternations between the two.

(See ABNORMAL PSYCHOLOGY.)

Also there are *feelings,* somewhat but not exactly like emotions and consequently often classed separately. Among these are anxiety, which has been given many diverse definitions and explanations by experimentalists and clinicians, but which is most commonly considered a subjective state of discomfort signalling an unresolved internal tension or apprehension about a potentially harmful input from the environment. Anxiety neuroses are moderately severe emotional disturbances characterized by such feelings, which are often overuhelmingly powerful and which frequently swell into acute "anxiety attacks" associated with sweating, trembling. palpitation and other autonomic responses *(see* ABNORMAL PSYCHOLOGY).

Pleasantness and unpleasantness are also feelings, rarely occurring together, which characterize the "hedonic tone" or degree of satisfyingness of subjective experience. They are studied experimentally as determinants of preference among various objects or events in the environment. Since satisfaction of drives is usually pleasant and frustration of them unpleasant, they also are related to motivation.

An associated problem was mentioned in the section on learning, in discussing the lam of effect.

Personality is the characteristic organization of the individual's traits which makes him unique and which to a large extent remains constant throughout his life. If it is to claim completeness, any theory of personality must deal in some way with such questions as the following: What is the self? What drives the individual? What relative importance have various influences upon the development of adult personality? How can one account for the temperament, or characteristic emotional climate, of a person? What are the bases for individual differences in capacity, perception and reaction? What are the causes and nature of extreme deviations in these? And what is the effect upon personality of interpersonal relations and cultural influences?

There are a number of current theories of personality. Some of the theories dealt with above—particularly under perception and learning (*e.g.*, those of Hebb, Bruner, Hull and Tolman)—have been extended into the realm of personality. Other theories were derived chiefly from clinical observations. A moderate amount of experimental work in this field has been carried out, but in general it is characterized by a wealth of words amid poverty of reliable evidence.

Foremost among the clinical theories of personality, the psychoanalytic system of Freud (see ABNORMAL PSYCHOLOGY; FREUD! SIGMUND; PSYCHOANALYSIS) presents a coherent body of concepts which has had deep influence on personality theory as well as other fields of psychology. The results of efforts to test experimentally the psychoanalytic formulations based on observations with patients have been difficult to interpret and, taken altogether, still are inconclusive.

To Freud the ego is the conscious, socialized, directing part of the personality and is distinguished from the unconscious, antisocial, libidinal or id forces which exert their influence through evasion of the repressive mechanisms of the censoring superego. The energy for psychic functions comes from instinctual drives, mainly sexual and aggressive. The ego employs such mechanisms of defense (see DEFENSE MECHANISMS) as rationalization, sublimation, projection and repression in making adjustment to the changing environment on the one hand and the libidinal drives on the other.

The explanation of individual temperamental differences lies in the importance of divergent infantile experiences and the differential enforcement of societal demands for repression of instinctual behaviour by the parents or others who care for the child. The way in which feeding and nursing care are given, the amount of frustration the child experiences through having its cries ignored, the ability of the mother to express love for her child, the sternness or gentleness of the father, the presence or absence of competing brothers and sisters, the effect of others who map be in contact with the child—all combine with genetic influences to mould him into the unique individual that he becomes. Freud's use of characters and situations of the classical Greek stage—Oedipus, Electra—to symbolize the "family drama" in which the developing child is enmeshed have become an integral part of western culture. Relationships between father and son, mother and son, and so forth, which are basically similar in most families regardless of individual differences, are seen as expressions of repressed instinctual drives.

Throughout life we tend unconsciously to react toward unrelated people as if they were playing roles of members of our family. Thus a child of a stern father might in adulthood unconsciously expect similar behaviour from his employer even though actually he was not that sort of person. Extremely deviant early relationships and experiences lead to psychopathology later.

Freud's theories have been criticized and extended since his death. An important trend is the introduction into modern psychoanalytic thought of cultural relativism. It is pointed out that Freud was familiar only with western culture and that the psychosexual development of children in other cultures is clearly different. So typical personalities will also differ.

Alfred Adler and Carl Jung (*qq.v.*) were associated with Freud early in their careers, but later deviated importantly from him. Adler emphasized the drive for power and control over others as well as the "inferiority complex." Jung stressed the importance of the racial heritage historically represented in myth, art and symbol. He recognized relatively less significance in unconscious sexual drives than in the will to wholeness of the individual. He also originated the concept of the complex and the distinction between introverted and extraverted personality traits.

Other personological theories centre around the dynamic interplay of needs or drives. Examples of these are the systems of William McDougall and H. A. Murray. They included both the fundamental physiologic needs of living organisms and many socially derived needs such as gregariousness or need for affiliation with others. Murray recognized repetitive themas of fantasy and behaviour which characterized specific persons. He had a major role in devising the widely used Thematic Apperception test which identifies and measures the strength of these themas. (See PSYCHOLOGICAL MEASUREMENT.)

Theories dealing specifically with temperament include the ancient description of personality in terms of the four humours, a preponderance of one of which gave the person his characteristics. Thus individuals were sanguine (for blood), phlegmatic (for phlegm), choleric (for yellow bile) or melancholy (for black bile). Ernst Kretschmer in 1921 held that the shape of the body influences personality characteristics and determines what sorts of mental illness a person may develop. He measured large numbers of mental patients and found significant relationships between body type and the important mental diseases. This theory was extended to normal people by linking types of normal personality with the most nearly similar mental disturbances; thus the introverted person with a thin, flat-chested, long-limbed body he called "schizothymic." somewhat like "schizophrenic." William Sheldon later attempted to correlate personality characteristics and body build, using a complex measurement system chiefly on normal individuals. He found three basic components of physique and could rate any subject's body on how much of each component was present. His equating of these components with personality types is based more upon impressions than upon experimental demonstration, although some objective data have been gathered.

An important extension of Gestalt theory into the realm of personality m s made by Kurt Lewin, a mernher of the original Gestalt group whose early work concerned problems more typical of that school. Later he employed notions from the mathematics of topology, which deals with nonmetric spaces, in conceptualizing the personality as divided into "regions"! or "systems" separated by more or less permeable "boundaries," within which dynamic exchanges of energy are going on in the general direction of equilibrium or reduction of tensions.

Objects and people in the individual's psychological field or environment are assumed to have positive or negative "valences," power to cause him to approach them or withdraw from them. Conflicts occur when valences of almost equal strength are in opposition or when "barriers" exist to stop progress in the direction of strong forces. A toy may have a strong positive valence to a child, but his approach to it may be stopped by a barrier; *e.g.*, a store window or a stronger child who holds it. Many such forces act upon the person, and his behaviour is the resultant of them.

Personalities differ in the degree to which the boundaries of the component subsystems influence one another. as well as in other aspects. An infant has a relatively unstructured personality in which the self is not well differentiated from the world and other people. With maturation distinctions become firmer, but may shift from time to time as the personality is reorganized, as by education or psychotherapy. Lewin's theory provided confirmable hypotheses for experimental testing and there is some empirical literature in this tradition, particularly in the fields of child behaviour.

Output Processes.—The output of the organism, aside from secretions and excretions resulting from physiological processes! is produced through the "effector system," the subsystems of motor nerves and muscles which control bodily actions. All responses, from the reflex knee jerk to the most complex verbal communication, are included, and of course preceding sections of this article have mentioned reactions and responses as necessary in describing input and central processes. For example, the learning of motor skills and habits has been discussed.

Work is another sort of output which has been investigated experimentally. Time and motion studies, studies of conditions favouring and interfering with working efficiency, studies of optimum length of work periods have become usual in industrial psychology. All concern aspects of motor output.

The finger ergograph, a device which records the performance of the finger muscles in pulling a weight, has been used to do research on fatigue. Other devices, such as treadmills, have been employed to study larger muscle action. The resulting work curves show a characteristic rise in output as the muscles first "warm up" and then a decline with fatigue. The effects of rest pauses, interpolated activity, various drugs and different motivations have been studied by these means. Fatigue in industrial settings, however, depends upon more complex factors than the ability of muscles to do work. Boredom, the feeling of tiredness which may precede real fatigue, variations in motivation, changes in morale—all alter output. Change of task, even though the same muscles are still used, for instance, may result in improved output. The effects of distraction upon work are complicated. Some distracting sound seems to improve performance, but too intense or too prolonged or too unpleasant distraction, noise or confusion reduces output significantly.

Speech is another sort of output. The neural and muscular mechanisms of speech, its efficiency and its pathology in such conditions as stuttering and aphasia are being increasingly investigated. Information theory, derived from physics, is providing new concepts and measuring units for research on the linguistic and communication behaviour of man. Throughout the history of psychology there has been a tendency to minimize the output activity of the organism, putting primary emphasis on input and central processes, although the output is the overt evidence that the other processes have occurred. Much of the work in output processes is recent.

Developmental History. — The study of the development of animals (see PSYCHOLOGY, COMPARATIVE) and human beings from the embryo state to old age is called the longitudinal approach. Studies of embryonic and infant motor development indicate that the earliest movements are unco-ordinated, involving the whole body. Reflexes such as the sucking response and the Babinski sign (fanning upward of the toes when the sole of the foot is scratched) are present in human infants at birth. Controlled voluntary actions begin to develop within the first weeks of life, as the nervous system matures, proceeding in general from the head downward.

The progression of development of muscular activity is from larger movements involving a whole limb to fine motor adjustments and complex co-ordinations, as between the eye and the hand. Mary Shirley published detailed reports on motor development in infants. Arnold Gesell observed and tested a large number of children from birth to adolescence and provided norms for each age. His studies include not only the appearance of physical skills and characteristics, but of speech and of typical psychological adjustments, interests, fears and preoccupations. He has described characteristic behaviour at each age level, reporting changes from week to week in infants and over longer periods in older children.

Alfred Binet and Théodore Simon in 1905 published the first intelligence scale for children. A need for this had been felt in the crowded schools of Paris as there had been no precise procedure for distinguishing those children who could profit most from school. Such intelligence tests were adapted for English-speaking children by Frederick Kuhlmann and Lewis Terman, among others, and construction of tests measuring other aptitudes and abilities followed (see PSYCHOLOGICAL MEASUREMENT).

A number of long-term developmental studies have followed children from infancy through the school years, measuring physical growth, mental development and, in some, emotional progress. In addition many researchers investigated these factors at various stages of life.

Piaget, for example, made extensive observations of the reasoning processes, thought and language of young children. In them he demonstrated a growth in the use of conceptual material that was related to age. He found that certain sorts of explanations of natural and physical phenomena characterize certain ages and are not found in normal children of more advanced age—for example, younger children make more use of animistic and magical explanations than do older ones. His method was to ask children questions such as "What makes the wind blow?" or to perform a simple experiment which illustrates natural lams and ask the child to try to explain it. He has also studied the child's growth in understanding of social concepts.

With the increase in life expectancy there has been an increase in interest in the physical, psychological and social effects of aging.

Psychopathology. — (For a full discussion, see ABNORMAL PSYCHOLOGY; PSYCHIATRY; and PSYCHOANALYSIS.) The most important problems in this field relate to understanding the cause, mechanisms and possible treatment of deviations from behaviour considered pormal and acceptable by the culture in which the patient lives. The relation of neurosis to psychosis is still in the realm of theory. It is not entirely clear whether they are, respectively, mild and severe manifestations of the same essential processes, as some theorists have believed, or are qualitatively different.

There is probably a genetic causal factor in schizophrenic and manic-depressive psychoses, and there is increasing evidence that there are changes in body chemistry in them. On the other hand, pathological interpersonal relations with members of the family and others are commonly found in the early developmental and later histories of mental patients, which indicate that environmental stresses are also important in mental disease.

Psychotherapy is commonly considered most likely to be effective in mild or fairly recent illnesses. Some severely disturbed patients have been helped by such procedures alone. Among the most popular schools of psychotherapy are those following the techniques advocated by Freud, Jung, Adler, Karen Homey, Harry Stack Sullivan and Rogers. Experiments with the tranquillizing drugs, psychosurgery (or prefrontal lobotomy) and insulin, metrazol or electric shock treatments indicate that these can affect the course of even severe mental disease.

Interpersonal Relations. — The interactions among individuals in such larger behaving systems as groups and societies are studied by several disciplines including psychiatry, psychology, sociology and anthropology. The study of small group dynamics, initiated by Lewin and significantly advanced by the prolific research of his followers and others, became important in both psychology and sociology. This basic research has been applied to group psychotherapy, found to be of value in treating mental illness; group interactions in the fields of labour relations, race relations and politics; committee functioning; and behaviour of clubs and small civic organizations.

There have also been social psychological studies of whole communities, such as those done by Lloyd Warner, Robert Havighurst, Roger Barker and others, in which the complexities of intergroup and interpersonal relationships are analyzed by interviews, analyses of statistical and economic reports on the community and observation. Warner found that there is an important element of class structure in U.S. society and investigated the factors that place a person in a given class in his own eyes and those of the community, as well as the mobility of Americans in moving from one class to another in various rural and urban locales.

There are also important recent theories of social interaction, that of Talcott Parsons and Edward Shils for instance. They view the interpersonal and social processes as the interaction of "action systems" in which an individual participates through the "roles" in which he is cast by circumstance and the people around him.

He may be, for instance, a father, a Protestant, a plumber, a member of the middle class, a Republican and so forth. He participates in different ways in the social structure depending on these various roles. The groups to which he belongs interact with other groups according to the decisions of their members or other social forces. Communication and information theory are increasingly important to the study of interpersonal relationships. Many fundamental disturbances in focal, national and international social processes have been shown to arise from distortions of communication or psychological and political barriers to the free flow of information.

PSYCHOLOGY, ABNORMAL. Psychology is the study of behaviour, and abnormal psychology is the study of deviations from normal behaviour. Under the term behaviour is included not only attitude and action but also such functions as motivation, perception (*qq.v.*), imagination, thought and memory (*q.v.*). Abnormal behaviour is classified today under the psychoneuroses, psychoses and psychosomatic disorders, the personality and sociopathic disorders, and the disturbances occurring in intoxications, brain damage and brain disease.

Certain basic phenomena, not in themselves pathological, are dealt with more extensively in abnormal than in normal psychology because of the central role they play in human psychopathology. Among these are anxiety and the defense mechanisms used to control it; unconscious motivation and the drives; the differentiation in early childhood of ego, id and superego; the significance of conscious, preconscious and unconscious processes; and the part played by frustration, conflict and regression in precipitating and maintaining abnormal behaviour. In addition, it is customary to include the study of normal dreaming and hypnosis, as well as such obviously pathological phenomena as hallucinations and delusions. Much attention has been focused upon the effects of extreme deprivation, found among concentration camp victims and hospitalized infants, and, under experimental conditions, among volunteer subjects isolated from normal sensory stimulation.

This article is organized as follows:

I. NORMAL AND ABNORMAL

A distinction between normal and abnormal behaviour is of considerable practical importance not only in psychology and medicine but in all studies of social interaction among individuals, groups, social classes, communities and nations. Problems of communication, for example, are fundamental to all social interaction. These problems cannot be met effectively without knowledge of the distortions of perception, interpretation and decision which personal factors introduce, many of them lying close to or within the borders of the psychopathological. In another area, the legal profession is beginning to deal with the stupendous task of revising some of its fundamental orientations in the area of crime, responsibility and punishment, so as to bring these into closer relationship with modern knowledge of normal and abnormal motivation.

Unfortunately, it is extremely difficult to work out a definition of normal behaviour that is generally acceptable — far more difficult than to define normal business conditions or normal weather. Human beings are infinitely complex and they live in a complex social environment that is continually changing. The average naive person tends to consider himself the standard of normality and to regard as signs of abnormality any actions, attitudes or experiences of other people that differ markedly from his own. Such a criterion, however reasonable it may seem to the person employing it, is obviously useless. For one thing, it begins by assuming that each person is the sole competent judge of his own conduct, an assumption that no one else will accept in practice. For another, it implies that every person's behaviour is at all times normal, which is also absurd. Millions of neurotic and psychotic persons consider themselves normal, and everyone at some time or other acts or thinks a bit strangely.

An alternative to the naive individualistic approach is clearly one of judging each person's behaviour in relation to that of others in his culture who are of the same sex, belong to the same age group and live under similar socioeconomic conditions. To make such judgments exact and incontrovertible, a system of well-defined, established norms is needed with which any given sample of behaviour may be compared and its degree of conformity or deviation determined. There are, however, formidable obstacles to the construction and use of rigidly specified behaviour norms. The most serious of these are. (1) the heterogeneous composition of contemporary industrial society; (2) the increasing social mobility of individuals and groups, which inevitably increases the incidence and complexity of cultural conflict; (3) the rapid changes in accepted standards of behaviour within recent generations; and (4) the enormous accumulation of 20th-century knowledge concerning human motivation, which has not yet been assimilated into our major social institutions.

Because of these difficulties, and the existing limitations in available techniques, a strict differentiation between normal and abnormal is still out of the question. We must be satisfied for the present to work with rough approximations. Bearing this in mind, we can take as the most useful criterion of normality the relative adequacy of a person's behaviour, including his actions, attitudes, perception imagination, thought and memory, as compared with the behaviour expected of other persons who share his status in his society. Such a criterion begins not with the fiction of the perfect or ideal personality but with the fact of a relatively wide range of culturally acceptable behaviour It allows us to include as normal the many variations and fluctuations that can be found in the everyday experience of ordinary persons.

It is important to recognize that, in this context, adequacy of behaviour is not necessarily the same as work efficiency or social conformity. Efficient work sometimes involves the compulsive exploitation of oneself or of others, and may stem from a deviant need to display personal power, to punish oneself or to eliminate irresistible temptation by eliminating one's leisure. Likewise, social conformity is not always a sign of health. Sometimes it expresses extreme social timidity or fear of one's own antisocial impulses, in which case it can lead to severe personality impoverishment. In short, behavioural adequacy as a mark of relative normality must be viewed not only from the point of view of an outside observer but from the inside of the personality system as well.

With this dual orientation. behaviour may be called abnormal under the folloning conditions: (1) if a person, otherwise in good health. shows himself incapable of establishing and maintaining mutually satisfying interpersonal relationships; (2) if his behaviour, including perception and thoughr, is or becomes strikingly inappropriate in terms of prevailing social norms; (3) if, in order to carry on ordinary activities, a person is obliged to expend disproportionate effort, in comparison with others of his own age, physique, intelligence and training; (4) if he is unable to obtain satisfaction from his activities, his memories and his prospects; (5) if he experiences chronic lack of feeling, sense of isolation or emotional instability; (6) if he suffers from high levels of tension, anxiety or conflict for prolonged periods, or must defend against such suffering through pathological symptom formation.

II. RISE OF MODERN PSYCHOPATHOLOGY

Mankind has shown profound concern over abnormal behaviour from ancient times. Attempts to account for the phenomena of abnormal psychology have varied all the way from ascribing them to demoniac possession and loss of the mind or soui to blaming them upon hereditary taint and organic disease, chiefly of the brain but by no means exclusively so. Galen, for example, ascribed hysteria to malfunction of the ovaries; the medieval philosophers related melancholia to an excess of black bile, which the word actually means.

Treatment over the ages has fluctuated irregularly over a correspondingly wide range, especially with respect to insanity. At one extreme are found drastic medical and surgical interventions; purging and bleeding were extensively used and the ancients as well as many moderns relied upon "mind drugs" and cranial operations. At the other extreme are found the use of incantation and exhortation, of flogging and cold-water shock, and for centuries the use of capital punishment, as in the world-wide witch prosecutions.

The emotional origins of abnormal behaviour and the crucial part often played by interpersonal relationships have been implicitly or explicitly recognized for millenniums. But it remained for Franz Anton Mesmer (*q.v.*) to demonstrate, consistently and on a large scale, that emotional crises and pathological symptoms can be deliberately induced and cleared up through the influence of one person upon another. He thus ushered in the modern era of psychopathology.

Mesmer rose to fame and fell to disgrace in Paris during the latter part of the 18th century. His theory that the influence of one person upon another was due to "animal magnetism" sounds strange to modern ears and his therapeutic methods were highly theatrical and even orgiastic. Nevertheless, there is no reason to doubt his sincerity, the genuineness of what he demonstrated and his tremendous influence. Because of the tempest of controversy he raised, his methods were shunned by reputable persons. and for a long time his positive contributions were overlooked. A gradual revival of mesmerism, renamed hypnotism, developed during the middle third of the 19th century and led to a second public controversy. This time it was betneen J. M. Charcot (*q.v.*), the great neurologist in Paris, and H. Bernheim, professor of medicine in Nancy. Charcot maintained that only the potentially hysterical could be successfully hypnotized. while Bernheim insisted that anyone could be. Each was partly right; it is known today that most adults can be hypnotized. and that many hysterical symptoms can be hypnotically induced in apparently normal people. By far the most important outcome of this celebrated quarrel. however. was a greatly increased interest in the origins and characteristics of psychopathology. *(See* also HYPNOSIS; PSYCHIATRY: *History: Hypnosis and Hysteria.)*

Two of the men who came directly under Charcot's influence during the last quarter of the 19th century became themselves internationally famous psychopathologists. Pierre Janet (*q.v.*), who ultimately succeeded Charcot, began a long series of contributions to abnormal psychology in 1889, devoting his attention first to obsessions and then to hysteria. His early writings have some of the germs of modern psychodynamics and his later clinical descriptions were brilliantly clear. Nevertheless, his influence upon the field has steadily declined, both because of the limited scope of his descriptive studies and his lack of theoretical originality and fruitfulness.

Sigmund Freud (q v.) spent the year 1885 in Charcot's clinic while Janet nas there, but he also looked into the other side of the controversy by visiting Bernheim in Nancy for a few months in 1889. He translated the writings of both Charcot and Bernheim into German soon after his visits. Unlike Mesmer, Freud shunned public controversy, worked with the utmost self-critical care, for many years almost in isolation, and met the condemnation of others largely by piling up further incontrovertible clinical evidence. Unlike Janet, he ranged over the whole field of psychopathology and invaded normal psychology as well, and his theoretical contributions were daring, revolutionary and of such fruitfulness that their importance seems still to be growing. In his *History of Experimental Psychology* (1950), *E. G.* Boring lists Freud as one of the "four very great men in psychology's history." Certainly no one else has influenced the development of abnormal psychology so profoundly and extensively as Freud. (For an evaluation of the related but divergent views of Alfred Adler, Erich Fromm, Karen Horney. Carl Jung, Otto Rank and H S. Sullivan. *see* R. L. Munroe. *Schools of Psychoanalytic Thought*, 1955.)

Largely as the direct result of Freud's brilliant contributions, the major emphases of modern abnormal psychology are placed upon the following factors: (1) the overnhelming importance of early childhood in laying the foundations for normal and abnormal behaviour in later life; (2) the differentiation of functional subsystems nithin the personality organization, called ego, id and superego; (3) the prevalence of unconscious motivation, especially in relation to sexual and aggressive drives; (4) the development and operation of unconscious defenses in relation to anxiety; (5) the basic role of frustration, regression and conflict in precipitating and maintaining abnormal behaviour.

III. ORIGINS OF PSYCHOPATHOLOGY

A. Early Childhood

At birth the infant is separated physiologically from his mother, but for years he remains dependent upon her, or upon her substitute. for his very existence from day to day. His interrelationship nith the mother figure is the most important factor in his earliest cycles of need and satisfaction, in his earliest experiences of security and anxiety, in the comforting and disturbing aspects of bodily care, in his development of love and hate, in what he learns to expect from the world around him and how he learns to handle it.

1. Symbiosis. — Even the child's differentiation of his own body from his surroundings, and of himself from other people, depends upon a healthy maturing of the mother-child relationship. At first the relationship is normally symbiotic, that is, one in which mother and child form an interdependent unit, each individual being of great importance to the other. There is much clinical and observational evidence to suggest that the infant in a symbiotic relationship does not distinguish between his mother, or her substitute. and himself. He makes such a distinction slowly, over a long period, by means of the normal maturing and use of his equipment for independent action. Under ordinary conditions this process of growing independence and differentiation goes on progressivcly and at an accelerating rate, especially with the development of walking and talking.

Whatever interferes with the gradual evolution from a symbiotic relationship to one of eventual independence may lay the groundwork for abnormal behaviour later on. An obvious source of difficulty is a mother's inability to give up her child's dependence because of the personal satisfactions she derives from it or because of the anxiety aroused in her by the child's attempts at independent activity.

Such a mother is often called overprotective. Her protection may take the form of overindulgence, which tends to leave a child always infantile in what he expects and demands. even after he grows to adulthood; or it may take the form of domination. which prevents him from developing initiative and enterprise. In either case, he is likely to remain a dependent person, even in adulthood. either expecting privileged treatment without earning it, or looking continually for guidance and approval from everyone. Needless to say, the presence of a strong father and of siblings in the home can offset to a considerable degree the stunting effects of maternal overprotection.

A less obvious but no less fruitful source of difficulty lies in an unsatisfactory symbiotic relationship, particularly one which fails to foster infant trust. This may be the result of maternal coldness or resentment toward the child. It may come from mothering which is carried on with unusual tension and anxiety, or from mothering that is grossly inconsistent and unpredictable. It may also develop because the child has behavioural characteristics. whatever their cause. which make him an unwelcome or uneasy partner for his mother. Apparently if an infant for any reason cannot enjoy a satisfactory symbiotic relationship when he is helpless he cannot later develop into a satisfactorily independent person, for if he does not experience a high degree of infant trust he will not be equipped later to experience the basic trust in others which is the foundation of normal emotional relationships. He is likely to grow into a lonely, emotionally withdrawn or suspicious adult

2. Identification. — One of the most important means whereby a growing child develops psychologically is called the process of identification. Unlike the simpler forms of learning and problem solving, this process involves taking over the behaviour of other people on a large scale and becoming in some important respects like them. Early in life identification seems to be relatively massive. rapid and indiscriminate, but also relatively unstable. It occurs in relation to members of the family mith whom the child is in close contact. As time goes on identification grows less complete. slower and more discriminating, as well as more stable. The child takes over certain aspects of the people around him and ignores or rejects other aspects (partial identifications). Eventually the process of identification leads to a recognizable patterning of child personality, and this patterning influences not only what the child is like but also the direction of his further identifications and therefore of his ultimate character structure.

It is a peculiarity of personality organization that the effects of early processes seem never to be wholly lost. The earliest wholesale identifications may be profoundly modified by later experience; and many shifts in the general direction of identifications may occur during maturation. But in a crisis some of the apparently lost infantile patterns may reappear and create serious disturbances of function. This is especially true of the deep and massive regressions seen among psychoses, but it is also responsible for many psychoneuroti'c symptoms in which regression is more limited in scope and less deep. Failure to establish adequate stable identifications, because of defective parental relationships or the absence of basic security, is especially obvious in sociopathic personality disturbances.

3. Rivalry. — Rivalry is an inescapable element in family living. Living together means sharing; and sharing means giving something up as well as getting something. The birth of a sibling is an unfailing source of rivalry for a first child, and a common source for any child. Not only may it provoke anger and a sense of being unloved in the older one, but it also may lead to retaliative aggressions against the younger one which disturb his development. Such retaliations at first may be quite open and direct, but in the face of parental disapproval they become disguised and indirect, although still effective. Most children survive the common experiences of rivalry without noticeable harm. The lives of many adults, however, are overshadowed by excessive competition, envy and jealousy, or by reactive inability to compete and to be envious, which turn out to have their roots in unmastered sibling rivalry.

A small child's rivalry with one parent for the love of the other is potentially the most serious interpersonal conflict in early life. The mere intensity of his own feelings, and the tremendous size and power of his adversary, can conjure up a situation of unreal but frightening danger. And this oedipal conflict is further complicated by the fact that, as a rule, the child also loves his rival parent and needs his rival's love. The eventual resolution of this problem is at best slow and painful. Out of it comes the mature form of the normal superego and a new-found freedom for the child to turn with self-confidence to active mastery of the world of people outside the home. Failure to resolve the oedipal conflict optimally can be found in a majority of persons showing abnormal behaviour.

4. Maturational Sequence. — A final point of importance is the factor of maturational sequences. Success in any phase of childhood development is in part dependent upon success in preceding phases. A boy, for example, who remains too long in a symbiotic relationship with his mother may lose early opportunities for handling rivalry with his siblings and for resolving rivalry with his father. He begins late. and with less than optimal freedom, to develop initiative in adapting to external reality and mastering its problems. The child with good early identifications is better equipped to make good ones later on than a child whose early identifications are distorted and confused.

Moreover, a child who is insufficiently emancipated from close infantile ties with a parent is not free to take advantage of close friendships and group ties as these become available outside the home when he is six or seven. These relationships are critical for his development into a socially adequate person who is capable of mature emotional experience. A child who does not enjoy these maturing relationships will be poorly equipped to enter the turbulent period of adolescence and work out his self-identity in early adulthood. It must be said, however. that a good start does not guarantee freedom from serious difficulty in later emotional maturation; and, on the other hand, it is not impossible to overcome the handicaps of a bad start if a later phase of development provides unusually favourable conditions.

B. Development of Ego, Id and Superego

On the basis of extensive clinical and genetic studies. it may be assumed that during early childhood certain groupings of psychological functions are differentiated into permanent, organized systems called ego, id and superego. If these systems are incompletely differentiated from one another, the result may be a personality with an abnormal defensive organization, with serious difficulties in controlling impulses and with inadequate reality relationships. All of these appear, for example. in the symptomatology of schizophrenia. On the other hand, exceptional strength in the operation of one or another system also may result in serious distortions, such as those seen in depressions. where a dangerously powerful superego may drive a person toward self-destruction.

1. Ego. — The earliest differentiation is that into id and ego. This differentiation begins with the infant's earliest explorations, through which he learns to distinguish between his own body and his surroundings. Through his experiences of tactile, visual and kinesthetic stimulation, as well as his internal organ sensations, the child develops a body image. The body image is the nucleus around which subsequent ego development crystallizes. As the child's experiences expand and multiply, and as processes of mental representation and symbolizing develop, his ego organization grows in complexity. It develops both adaptive functions and defensive functions.

The ego adaptive functions, which come to include the maturing perceptual, motor and glandular co-ordinations, lead to more and more effective performance in relation to the realities of the environment. The adaptive ego becomes organized, during this process, in such a way as to make possible the complex kinds of interpersonal feeling, action, imagination, remembering and thinking nhich characterize human beings. Most ego adaptations function automatically and unconsciously in the mature adult. Processes of childhood identification, mentioned above, make indispensable contributions to ego organization. They lay the groundwork for the eventual internalization of culture and for the evolution of social attitudes, value orientations, role taking and self-identity.

Ego defensive functions are also as a rule automatic and unconscious. It is through these defensive functions that the ego maintains its integrity as a system in the face of potential intrusions from three directions: (1) the ego sets up functional barriers against being overwhelmed by stimulation from the environment and from internal activities of the body; (2) the ego maintains other functional barriers against being disorganized by id activities and primitive fantasies, such as those normally experienced only in dreams; (3) as superego functions begin to differentiate from ego functions, the ego defensive organization is modified in such a way as to protect ego processes from being disrupted by superego pressures also. (The ego is discussed more fully in the separate article EGO.)

2. Id.—The id consists of the most primitive, loosely organized and potentially disruptive psychological activities. Its impulses push forward constantly for immediate discharge or gratification, without regard for the demands of external reality. It is completely unconscious in the adult. Its existence and its modes of operation are inferred from certain peculiarities appearing in preconscious and conscious activities, such as the puzzling characteristics of manifest. dreams, of slips of the tongue and of wit. the nature of symptom formation in neuroses and of delusion and hallucination in psychoses. Whereas the conscious and preconscious ego operate in accordance with the secondary process, which corresponds more or less to the logic of ordinary conversation, the id operates in a manner called primary process.

Some of the more important characteristics of the primary process follow directly from the nature of id activity. The id is perpetually seeking immediate discharge or gratification, even during sleep. How the discharge is achieved is not important so long as it takes. place. Thus, in the id's primary process, energy from blocked impulses can be displaced to other impulses which have access to discharge, no matter how illogical or inconsistent the relationship between them may be. Several different impulses may be condensed to form a single symbol or a single symptom. The primary process is also timeless and devoid of negatives. Contradictions operate side by side without mutual interference or compromise. It is more fluid than the strangest, most unstable manifest dream. Certain acute psychoses give fleeting glimpses of the mode of operation of the primary process.

3. Superego.—The superego reaches the climax of its differentiation from the ego during the third to fifth year of life. Its familiar conscious form is called conscience. This we experience as a part of us that at times criticizes, reproaches or condemns the rest of us, and at other times seems to approve, justify or praise the rest. In the first case we feel guilty, bad, inferior or worthless; in the second case we feel worthy, good or superior. This conscious split into two functional systems is based upon a permanent split at unconscious levels into an evaluating system, which praises or blames, comforts or threatens (superego), and an evaluated system which receives the praise, blame, comfort or threat (ego).

The superego is largely unconscious. In normal adults it is less responsive to current reality factors than is the ego. A great deal of its activity is primitive and irrational. This is because it crystallized during the first three to five years, in relation to powerful infantile emotional conflicts and long before logic or realistic thinking had evolved. Evidence of prirnitive superego magic is seen in obsessive-compulsive symptoms. The clearest evidence for irrational, infantile superego function, however, appears in depression and in mania, the one expressing consciously the most cruel and hateful attitudes toward the self and the other expressing extravagantly unrealistic self-adulation and self-will.

The general effect of superego development is to increase psychological stability. In organizing a superego the child acquires his own internal system of moral control. He can regulate his own behaviour without having to watch his parents continually to see if he is right. He builds up his own standards and ideals which he can carry with him wherever he goes. The superego is also a potent source of conflict. Since it is inside a person, it can condemn not only his acts but his thoughts, impulses and intentions. Even unconscious fantasies can stimulate the superego to arouse unconscious guilt. This is seen in the gnawing sense of inferiority that troubles many neurotics and in the projected unconscious fantasies which make up delusions and hallucinations.

4. Interdependence.—These three psychological systems are interdependent, interacting parts of an integrated whole. No one system makes any sense without the other two. Impulses and fantasies derived from the id are modified and channeled by ego defensive and adaptive functions into realistic thought and action, into daydreams, make-believe and recreation. Interaction with superego functioning provides value orientations and moral qualities for action, thought. daydream and play. The fact that most of the interaction among these systems is unconscious and preconscious means that much human activity cannot be accounted for on the basis of strict conscious rationality, that it has richer meanings and goes much deeper than is realized at the time.

C. CONSCIOUS, PRECONSCIOUS AND UNCONSCIOUS

In modern abnormal psychology three levels of mental activity are distinguished: conscious, preconscious and unconscious. The conscious level is familiar to everyone and need not be discussed here. It includes whatever a person is aware of at a given moment and constitutes only a small fraction of mental activity.

1. Unconscious.—The unconscious includes all id activity, most of the ego defensive organization and the greater part of superego functioning. Its purest form is in id activity. which, as stated above, operates wholly in terms of the primary process. The clearest evidence of unconscious id, ego and superego functioning comes from the study of manifest dreams, with their related feelings. fantasies and thoughts, which find expression during free association (see ASSOCIATION, MENTAL). Usually the person who is free associating does not recognize the evidence of unconscious processes in what he is saying, but a person trained in observation often can do so. Other normal expressions of unconscious activity appear in poetry, painting and sculpture. In the abnormal field psychotic symptoms are sometimes found reflecting unconscious thinking and feeling more or less unchanged. Neurotic symptoms, on the other hand, are as a rule more realistically adaptive. so that their unconscious origins may be, and remain, obscure for a long time, even during intensive therapy.

2. Preconscious.—The term preconscious has two meanings, one quite simple, the other complex. (1) The simple form of preconscious consists of all mental activity which is not conscious at a given moment but can easily become conscious by a shift of attention. Its organization is presumably the same while it' remains out of conscious awareness as when it becomes conscious. (2) In addition to this, there are other preconscious processes whose organization seems in many respects different from that of conscious awareness and that can become conscious only with considerable effort. These include relatively well-organized daydreams which are realistically organized but whose material contradicts present reality and manifest dreams which. although they reflect unconscious processes, can be experienced consciously after waking and can be described in words to someone else. Obviously it is impossible to make sharp distinctions among conscious, preconscious and unconscious.

I). NEED, DRIVE AND MOTIVATION

It is generally agreed that unsatisfied or frustrated need is of prime importance in shaping behaviour from the moment of birth. The newborn is at once made dependent upon satisfying his need through his own efforts, as in breathing and suckling, and upon the good offices of his mother, who is now a separate person who can gratify his needs at will. It is through his prolonged dependence upon older persons that the human infant and child becomes progressively socialized. His parents and parent substitutes at first can control virtually all of a child's need satisfactions. By means of this control they gradually assimilate him into the family unit and lead him in the direction of ultimate independence. During the early phases of this process the broad foundations are laid for personality development, normal as well as pathological.

While it is generally agreed that need is a basic factor in determining behaviour, there is still confusion over the use of the term. Some experts, for example, speak of need and drive as though the two were synonymous, but most show a strong preference for one term and slight or neglect the other. There is actually a difference in emphasis involved. Need stresses what is wanted (*e.g*, need for food, for love, for mother), whereas drive stresses an internal force or push which seeks an outlet. There is also some lack of agreement as to the number of basic needs or drives, which varies in psychological literature from one to a dozen.

The prevailing psychodynamic trend in abnormal psychology shows a preference for the concept of drive (also called instinct) as the most fundamental. This view may be summarized as follows: Empirical evidence indicates two basic drives, sexual and aggressive, whose derivatives impinge upon the unconscious ego through activities of the id. In controlling, channeling and discharging these drive derivatives, the ego develops its complex system of defense mechanisms which modify the drive derivatives before these reach the preconscious or emerge in consciousness. The ego at the same time develops adaptive organizations in relation to external reality and, later on, in relation to superego functions also. This ego organization of drives in relation to reality and the superego leads eventually to the formation of complex systems of motivation which have their own hierarchies: *e.g.*, a man's love of country may take precedence over love for his children, whereas a woman's love of her children may reign supreme over everything else.

The factor of unconscious motivation is of prime importance in abnormal psychology, and the empirical evidence for it is overwhelming. Of course. as long as life goes reasonably well, it need not be of great significance that a person does not really know why he does many things or has certain fixed attitudes, that he sometimes feels pushed to do unreasonable things and avoid doing reasonable ones. or that his troubles seem always to follow the same genera! pattern no matter where he is. If, however, life goes badly, if a person's actions grow unmanageable or his satisfactions are overshadowed by anxiety, doubts or gloom, the unconscious origins of his behaviour can become of major importance. It should be said, however, that contrary to a widely held public opinion, therapy does not necessarily mean rendering unconscious motivation conscious to the patient. Often it is best kept unconscious. The question of what procedure is best to follow must be left in skilled, experienced hands. (See also INSTINCT; MOTIVATION.)

E. EGO DEFENSE AND ANXIETY

Most ego defenses are directly related to the control of anxiety, which an adult may experience in two major forms. The more primitive form, called traumatic anxiety. is that of feeling in danger of imminent destruction. The less primitive, called signal anxiety, is in effect an anticipation of such danger, experienced in a much attenuated degree.

1. Traumatic Anxiety. — Traumatic anxiety is what an adult may experience when he is overwhelmed by a sudden catastrophe for which he is wholly unprepared. His response may be panic and headlong flight, a violent reckless assault or a sudden trance state in which he nanders aimlessly about or becomes paralyzed and mute. Dramatic examples of such responses were reported from the battlefields of World War IT; and in civilian life similarly violent and often maladaptive behaviour may be seen. for example, in theatre or school fires. Traumatic anxiety is especially common when flight and attack are both impossible, as when a soldier is isolated and pinned down in extreme danger by enemy fire.

Traumatic anxiety also is experienced when id derivatives break through ego defenses and threaten to disorganize ego function. This occurs in normal and neurotic persons during sleep if for any reason id derivatives threaten a breakthrough and produce a night terror from which the frightened sleeper is glad to awake. It also occurs in psychoses when a defective ego organization proves incapable of coping aith direct id derivatives. Acute psychotic episodes sometimes include panic reactions like those seen on the battlefield and in fires.

2. Signal Anxiety. — Signal anxiety is a relatively mild experience of impending danger. If it is conscious. and its source seems outside, the anxious person becomes vigilant, cautious and defensive. If there seems to be no source, he feels uneasy, tense and anxious aithout being able to understand why. In most neurotic and psychotic disturbances there is at least some conscious anxiety. Much more commonly, however, the experience remains chiefly unconscious, and the threat comes from inner processes. The immediate automatic result is to increase ego defensive action, which also takes place at unconscious levels.

Increases and shifts in ego defense as a result of signal anxiety. are assumed to occur automatically throughout the 24 hours of every normal person's daily life. What defensive pattern prevails at any moment, and what the commonest changes in ego defense shall be. depend upon the internal economy of the person, upon his personality structure and upon the nature of the experienced threat. (See DEFENSE MECHANISMS.)

F. FRUSTRATION, REGRESSION AND SYMPTOM FORMATION

1. Frustration. — Disturbances of behaviour are usually precipitated by a series of frustrations. Frustration is experience of strong need acconipanied by a sense of being prevented from satisfying it, What prevents satisfaction may be (1) an external obstacle—physical, social or personal; (2) an internal conflict, conscious or unconscious; or (3) the absence of facilities for satisfaction, in the environment or in oneself. These factors of course can be understood only in relation to each individual person. Though some obstacles, conflicts and lack of facilities affect everyone. even these affect diiferent persons to different degrees. What seems an insuperable and intolerable obstacle to one person does not seem insuperable to another, or else does not seem especially important to him. Conflict and lack of facilities likewise are tolerated differently.

Additional variables are the strength of the drive and the character of the need involved. A frustrated powerful drive, especially one that is not successfully warded off by unconscious defenses, is more likely to precipitate a disturbance than a frustrated weak or well-defended one. Also, a need that involves too much physical, social or psychological danger is almost sure to be frustrating, because each attempt to satisfy it will arouse intolerable anxiety. The closer one comes to its satisfaction the more intense the anxiety grows, and the less possible it becomes actually to achieve satisfaction.

Two of the commonest normal responses to frustration are aggression and withdrawal; *i.e.*, fight and flight. The aggression may be directed against the frustrating obstacle or it may be directed against a substitute, as when a person shouts at his child after he has been humiliated by his employer, whom he fears. The withdrawal may be in the form of physical retreat or merely of passive withdrawal of interest. This last is the most important in abnormal psychology, because it is the most likely to result in regressive fantasy and symptom formation.

2. Regression. — Passive withdrawal of interest is not in itself pathological. When a normal person is bored. or when he is in a relaxed state before going to sleep; he automatically loses interest and turns to daydreams and fantasies. These imaginings are usually less realistic than are his thoughts about what he plans to do or remembers doing when he is more alert. It is not difficult to demonstrate that unconscious processes play a large part in such normal daydreaming and fantasying. Anyone who examines his thoughts immediately after he has been deeply preoccupied or dozing will find some elements that certainly do not belong to his ordinary logical thinking.

This lowering of the level of functioning. from more to less realistic, is called regression. It is a movement away from logically ordered thought toward more primitive forms. An effective contact with reality and processes of logical thinking tend to prevent the appearance of such primitive functions, although these latter seem always to be potentially present. We see what happens when we withdraw as much as possible from the environment and go to sleep. Dreams eventually appear which are obviously regressive. They seem unintelligible when we wake up because their logic is not realistic logic but a reflection of regressive unconscious logic. Wishes. fears and conflicts that are expressed in dreams often surprise or shock the dreamer mhen he awakens and make him feel that he has been wandering in strange places with a different kind of reality and different moral codes. Nevertheless, it is usual for manifest dreams to exhibit some degree of superego function and ego defense. as well as to reflect raw id impulses and their fantasy derivatives.

3. Symptom Formation.— Symptom formation in neuroses is the result of processes much like those resulting in a manifest dream, but the neurotic person withdraws a part of his interest in objective reality to escape frustration while he is awake. and not merely to enable him to go to sleep. In neuroses this withdrawal is never total as it is in sleeping and in some psychoses. A more or less effectual contact with external reality is always maintained Likewise, regression is neither so sweeping nor so profound as that in normal dreaming and in psychoses. Usually a neurosis is precipitated not by one frustrating experience but by a long series of them. each leading to some withdrawal and partial regression. Eventually the succession of withdrawals and regressions leads to the reactivation of a primitive conflict whose origin lies in early childhood. This reactivated conflict now tends toward becoming conscious.

As in dreaming, so in neurotic symptom formation the superego and the unconscious ego defenses are hard at work. The id impulses and derived fantasies, which help make up the reactivated conflict, do not erupt in their naked, primitive forms. They are subjected to defensive transformations more radical than most of those suffered by manifest dreams and. since the adaptive ego is wide awake and most of it attuned to external reality, the erupting impulses are subjected to further transformation until they harmonize more or less with reality. Thus a phobia based on an irrational childhood fear of one's father becomes transmuted into an adult fear of dogs which the adult finds easy to rationalize and accept. It is only when, during therapy, a frightening father figure appears in a dream or free association reveals a stil! more direct relationship, that the substitution may become apparent and the road cleared toward working through the basic conflict. (*See* also NEUROSES.)

Symptom formation in psychoses is similar to the process in neuroses. A major difference is that ego organization is fundamentally unstable. Defects in ego adaptation stem largely from defective early identifications and from early interference nith the development of reality testing and initiative. Defects in ego defense consist mainly in the overuse of such primitive defenses as denial, projection and introjection in situations which normal persons would handle through repression. A succession of frustrations, or sometimes a single severe frustration, leads to massive withdrawal from reality and sweeping regression.

The functioning that emerges in psychosis is typically that of an adult who is trying to deal nith the world around him by means of delusion and sometimes hallucination. These delusions and hallucinations are constructive attempts to rebuild external reality. The reconstructed reality must be made to correspond to primitive id, ego and superego activities nhich have become conscious with relatively little defensive and adaptive transformation.

In this may be seen one respect in nhich a psychotic solution may be the opposite of a neurotic one. Whereas the neurotic transforms his emerging conflicts adaptively, to make them conform as much as possible to external reality. the psychotic tries to transform reality. by delusion and hallucination, to make it conform to his emerging conflicts. The relative ineffectuality of ego defense and ego adaptation in psychoses renders it impossible to make an extensive transformation of unconscious material before it erupts into consciousness.

G. Individual Susceptibility to Psychopathology

Sex differences. physiological age and relative biological competence, especially of the brain, may all enter into the determination of psychopathology. When it comes to individual differences in susceptibility. however, the major factors seem to be differences in frustration tolerance. in ego adaptive and defensive development, in superego maturation and in the adequacy of object relations and self-representation.

Wide variations in tolerating frustration are to be found not only in comparisons of one individual with others, but also in comparisons of the same person's tolerance level at different times and under varying conditions of stress. Moreover, one person may exhibit low general frustration tolerance (i e., he reacts maladaptively to almost any frustration) while another may exhibit low specific frustration tolerance (*i.e.*, he reacts maladaptively to some particular kind of precipitating factor but not to others). 'This multiple variability in frustration tolerance helps account for the great range found in both intensity and variety of precipitating factors in abnormal psychology.

Ego adaptive and ego defensive development are directly related to a person's ease of regression under stress, to the completeness of his regression and to the depth to nhich his regression goes. In general, the more realistically a person has adapted to his social environment and the richer his psychological resources, the less likely he is to lose his grip on reality mhen frustration forces him into a withdrawal. The stronger and more mature his ego defensive organization and the less it is dominated by denial, projection and introjection. the less likely is regression to bring the sudden eruption of primitive processes. Thus, mildly defective repression and the ready use of projection may result in a neurotic phobia that is not at all disabling, whereas severely defective repression and the ready use of projection may lead to a paranoid psychosis.

Defective superego maturation goes hand in hand with defective ego development. but its effects are sometimes more striking. Thus, susceptibility to severe inferiority feelings an unfailing indicator of superego pathology. often appears in persons who adapt well to reality in most important respects, even though with greater than average effort. Likewise. susceptibility to psychotic depressions often appears in adults nho have managed to handle their lives responsibly and well. It is only when frustration becomes acutely intolerable and such a person grows seriously depressed that one realizes how powerful a fixation in primitive superego functioning he has been hiding most of his life.

Object relations and self-representation have their origins in the symbiotic mother-child relationship and its resolution. As the infant learns to differentiate himself from his mother and from other objects, he develops relationships with these objects and becomes able to represent them to himself and to distinguish a self that is more or less distinct from them. These basic differentiations, relationships and representations will determine the effectiveness of his conception of reality, his emotional interaction with other persons and his recognition of himself as an entity. There are infinite possibilities of defect in object relations and self-representation, and many of these are implicit in the various forms of psychopathology described below (*See* also PSYCHIATRY: *Diagnosis: Predisposing and Precipitating Factors*)

IV. ABNORMALITIES OF BEHAVIOUR

Abnormalities of behaviour are divided into a number of groups having similar characteristics. The task of classifying in the field of abnormal psychology has always been difficult because, no matter how the groupings are formed, each actual case will exhibit some symptoms belonging to a different group. A compulsive person may have a sudden phobia, or a phobic person may show minor compulsive trends A schizophrenic may be subject to depressions and a depressed person may have brief periods of temporary disorganization. The most useful procedure in classification is to determine what seem to be the dominant pathological characteristics, name the disorder accordingly and bear in mind constantly that such naming is a convenience and not a final judgment.

The current official classificat on is oriented primarily toward mental hospital diagnosis and statistical recording. Consequently, it stresses heavily the illnesses characteristic of a mental hospital population rather than those most commonly seen in office consultation and therapy. Brain disorders and psychoses, for example, make up 50% of its listed illnesses. whereas the psychoneuroses make up less than 10%. In what follows, a few of the most typical varieties of abnormal behaviour encountered in the community outside mental hospitals will be described using, insofar as possible, the terminology of the official classification.

A. Neurotic Reactions

Four of the chief pathological reactions seen in neurosis are discussed fully in the article on neuroses, and hence will not be dealt with here. For anxiety reactions, phobic reactions, conversion reactions and obsessive-compulsive reactions, see Neuroses: Types of *Psychoneurotic* Disorders.

A fifth reaction seen in neurotics is that of psychosomatic disorders, called also organ neuroses or somatization reactions. What all these names refer to is a variety of disorders in the functions of internal organs, blood vessels and glands. The disorders are either the direct product of continued emotional disturbance or at least an intensification of symptoms by emotional disturbance.

Recognition that internal organs, blood vessels and glands are affected by strong emotion is by no means new, but the systematic study of their emotional disturbances, the field of psychosomatics, is relatively recent. So is the realization that many chronic organic disorders may have primarily an emotional origin and that structural changes may result from prolonged emotional stress. Among the disorders that have been most emphasized are stomach ulcer, colitis. vascular hypertension, aching in postural muscle systems and joints, allergies. asthma and skin rashes.

As so often happens when a new field opens up, there was at first a great wave of enthusiasm and speculation regarding psychosomatic disorders, and for a time the nonemotional origins of dysfunction in these areas were in danger of being overlooked For example. there is direct evidence that the stomach lining is sometimes much more easily injured by abrasion during emotional disturbance than during emotional calm, and that such injury can lead to ulcer formation. But there is no justification in assuming. as many enthusiasts did, that all stomach ulcers are produced in some such manner. In another direction there have been concerted attempts to tie up definite personality types with definite psychosomatic disorders; but most of the conclusions drawn in this relationship have still to be confirmed.

To understand psychosomatic disorders it is necessary to bear in mind three things: (1) that emotional expression normally involves widespread changes in internal organs (*e.g.*, diarrhea or loss of appetite during fear). in blood vessels (*e.g.*, flushed face during anger or love) and in glands (*e.g.*, sweating and urinary hypersecretion in anxiety); (2) that intense emotional expression can continue for long periods of time with little relief; and (3) perhaps most important of all, that a person may be unaware most of the time that he is emotionally disturbed. He is most likely to concentrate on his somatic symptoms and to seek help on this basis; he may resent any nonorganic interpretation of them as an insult. Although dramatic and lasting improvement sometimes rewards psychotherapy in psychosomatic disorders, the results may not be so gratifying if the disorder is of long standing. It should be added that sometimes a psychosomatic disorder is a person's best defense against neurosis or psychosis (*e.g.*, a stomach ulcer may substitute for a serious depression), and it is sometimes in the patient's best interest to avoid intensive psychotherapy.

There is still some controversy as to whether or not psychosomatic disorders can be clearly differentiated from anxiety reactions and conversion reactions. A distinction between psychosomatic disorders and anxiety reactions is attempted on the grounds that the former focuses on one organ or one system in any given person, while in the latter most or all visceral systems are involved. As for conversion reactions, they stress perception and voluntary motor functions rather than internal organs, blood vessels and glands. Moreover, conversion reactions seem to free a person from anxiety, and they tend not to result in structural lesions. The position of psychosomatic disorders in relation to the psychoneuroses has been the subject of controversy for many years, and must still be regarded as unsettled.

B. Psychoneuroses and Psychoses

Turning to a discussion of the psychoses, the question of their relationship to the neuroses or psychoneuroses arises. In the past this relationship was conceived in two different ways. According to one view. psychoses are fundamentally different from psychoneuroses in origin and in dynamics. They are basically manifestations of brain defect or disease, or of disturbances in physiology or biochemistry, whereas psychoneuroses are products of personal stress. According to the other view. psychoses are only graver manifestations of the same fundamental psychodynamic processes as those underlying psychoneuroses.

The first view was much more generally accepted by experts during the 19th century than it came to be in the 20th. All psychoses were assumed to be expressions of some constitutional defect. in the form of a hereditary taint or a brain disease. During the 1890s and early in the present century it became fashionable to ascribe psychoses to the presence of toxic substances in the blood, to changes in blood chemistry. to endocrine imbalance or to faulty metabolism. Even today the press shows an eagerness to report research in these general areas as if it were new and revolutionary and as though for the first time a hopeless illness had become treatable. Such reports, however earnest, succeed in misleading the public. Actually the approach by way of physiology and biochemistry is old and conservative. and the many promising leads it turned up after the turn of the century had not, by the 1960s, fulfilled their promise.

A major source of confusion comes from the fact that such symptoms as delusion, hallucination, stupor and excitement are common in known states of intoxication. They also occur in fevers. infections, starvation. anoxia and other forms of physiological disturbance. The superficial resemblance between these states and schizophrenic, paranoid and affective reactions is so impressive that it has taken thousands of years to recognize that symptomatic resemblance does not mean identity. Today even an undergraduate medical student can learn to make the distinction reliably. Further, a patient's active behaviour during a known intoxication is likely to be a function more of his own personality organization than of the chemical properties of whatever toxic substance is used. Additional light on the problem was shed by studies of sensory deprivation. Normal adults who are as completely isolated as possible from normal sensory stimulation develop striking hallucinatory experiences without being exposed to any form of intoxication or other artificial physiological disturbance. Mere isolation from the normal environment allows primitive processes to dominate mental activity.

When it comes to heredity the evidence can neither be fully accepted nor simply dismissed. Originally. of course, a belief in the prime significance of hereditary taint for psychoneuroses was also widespread, but the field has come to be restricted to controversy over the psychoses. There is statistical evidence of a significantly higher incidence of schizophrenia and affective disorders in certain families than in the general population. Among identical twins the incidence of schizophrenia in both members, if one member is schizophrenic, is higher than for fraternal twins; and the incidence is higher among near than among distant relatives. On the other hand, the more closely psychotic persons are studied in psychotherapy, and the better their family structure is understood, the more important the home setting becomes as a source of psychosis. Further, the fact that both schizophrenia and affective disorders develop in families with no record of previous psychotic members is unquestionable.

The trend among experts is strongly in the direction of accepting psychoses in accordance with the view that they are manifestations of the same fundamental dynamic processes as those which underlie psychoneuroses. This does not exclude the possibility that physiological or biochemical malfunction may be demonstrated some day in some psychoses. It means only that as more experience is gained in studying psychotic persons, intensively and individually, there is steadily mounting evidence that the predisposing and precipitating factors in their illnesses do not differ basically from those in the psychoneuroses. With this increased understanding has come an important change in general attitude on the part of therapists. Whereas in the 1930s intensive psychotherapy with psychotic patients was unusual, by the 1960s it had become commonplace.

The traditional belief that adults who develop a psychosis suffer from some basic personality defect seems to be justified, but not on the assumption of brain disorder or hereditary taint Evidence points to personality defects whose origins are to be found in the early mother-child relationships. These defects leave a person vulnerable to deep and extensive regression when he is severely frustrated, and it is the type of regression he suffers that leads to the psychotic symptoms. Like neurotic persons, the psychotic lives by means of ego defenses and ego adaptations which represent compromises with respect to reality. id impulse and superego pressure. Unlike neurotic persons. he is liable to lose these defenses and adaptations, sometimes suddenly, and to fall back upon primitive unrealistic ways of handling his situation, such as hallucination and delusion.

C. Psychotic Reactions

1. Paranoid Reaction. — This illness is characterized by persistent delusions, usually persecutory but sometimes grandiose, without the presence of hallucinations. General behaviour and emotional response are consistent with the patient's ideas, and there is little or no impairment of intelligence aside from the delusions Paranoia is a rare form of paranoid reaction in which there develops, slowly and progressively, a complex, intricate and logically elaborated delusional system. The commoner paranoid state is not so highly systematized and elaborate, is sometimes of brief duration and often ends in symptomatic recovery.

Paranoid states are most likely to arise in tense, insecure persons who are basically mistrustful of others and of themselves and nho are ill at ease in interpersonal relationships. The paranoid illness is precipitated by a person's regressing in the face of serious frustration.

In the common persecutory variety, the patient begins to see signs of aggression and evil intent in the actions of people around him His vigilance grows in such a way that he becomes increasingly alert to further evidence that he is in personal danger. Regression has reduced the effectiveness of his reality testing to a point where he can accept only evidence that confirms his delusional suspicions. His need for an explanation leads him to believe that the signs of hostility he sees are part of a plot of which he is the focus. The more fixed this belief becomes the more difficult the patient is to treat.

The paranoid reaction illustrates clearly tivo defense niechanisms, denial and projection. When the patient regresses, his already defective repressive defenses become still more ineffectual, and he experiences a breakthrough of id derivatives, especially aggressive ones. To escape ego disintegration he denies and projects the impulses he can no longer repress, and he misperceives in other people (real ones and imagined ones) the aggressive intentions which are actually his own. His persecutory delusion is thus a reconstruction of his human environment in such a way thnt what actually threatens to destroy him from within seems to threaten him frorn without. It goes without saying that this achievement neither gets rid of the threat nor leads toward a happy solution, (*See* also Paranoid Reactions.)

2. Schizophrenic Reactions. — Schizophrenia, or dementia praecox, seems to include a nurnber of psychotic disorders which have in common certain basic disturbances in reality relationships. thought processes and emotional response. Delusions are commonly less well organized and more fantastic than in paranoid reactions, and hallucinations are usually present. Schizophrenic patients show a marked tendency to nithdraw frorn contact aith other people, to regress deeply and disorganize.

It is convenient to distinguish four general types of schizophrenia on the basis of symptomatology. (1) If delusions predominate, the condition is called paranoid schizophrenia. The delusions, characteristically vague and fantastic may be of persecution, grandeur, magical influence or body change. (2) If, instead, the patient's most prominent symptoms involve motility, the condition is termed catatonic schizophrenia The catatonic patient postures, gestures, shows great excitement, or grows mute, motionless and sometimes stuporous. (3j If the patient behaves in a silly, giggling way, with peculiar mannerisms and evidence of hallucination, the disorder is called hebephrenic schizophrenia. (4) If there is an insidious, progressive withdrawal and personality impoverishment, a general deterioration without dramatic symptomatology, the term used is simple schizophrenia. It must be emphasized, however, that patients seldom correspond exclusively to one of these general types. There is much overlapping, and a patient may shift from one type of symptomatology to another.

Controversies over the origin and nature of schizophrenic reactions were touched upon above. There is an additional point of interest. Earlier in the 20th century, experiments with mescaline demonstrated that florid hallucinations and weird distortions of the body image could be produced in normal adults mhich resembled those reported by schizophrenics. Later the use of lysergic acid and other toxic substances resulted further in the production of schizophreniclike symptomatology. The majority expert opinion, however, including that of some of those who have carried out such experimentation, does not accept the intoxication or its symptomatology as representing a form of schizophrenia.

In the most advanced therapeutic centres; psychotherapy is the preferred form of treatment for schizophrenics, and is considered the most successful. Close study of individual schizophrenic patients reveals as good evidence that their illnesses are precipitated by stress and frustrations as in the case of psychoneuroses. The high incidence of recovery under competent therapy weighs heavily against purely physiological and biochemical theories. In a university community, for example, 50% of those students who developed schizophrenic reactions serious enough to demand hospitalization were able to return to college, continue their work and graduate without further mishap. (See also Schizophrenia.)

3. Affective Reactions. — This group is characterized primarily by a severe mood disorder, either depressive or elated, with disturbances in thought and general behaviour in keeping with the mood. Psychotic depressions are either agitated, in which case sustained tension, overactivity, despzir and apprehensive delusions predominate, or retarded, in which case the patient is slowed up, his activity is reduced, he is sad and dejected and he suffers from self-depreciatory and self-condemnatory delusions. Suicidal attempts are common and often successful. Manic excitement is a circumscribed psychotic episode of elation or self-assertive aggression, usually with grandiose delusions.

Although most patients who suffer a depression do not ever develop a frank manic attack, and few with mania ever become frankly depressed, there is a close relationship between the two illnesses. While recovering from a depression, many patients go through a brief period of overoptimism and mild euphoria; and manic patients sometimes have transient episodes of gloom and self-depreciation. A minority of patients actually do pass from a depression into an elation, or vice versa, and some of these go through whole cycles of mania and depression. This close relationship has been recognized ever since the ancient Greeks wrote about it. Even the current. term, manic-depressive psychosis, is derived from *folie maniaco-mélancolique,* introduced in the 17th century.

Statistical studies are often cited in support of hereditary predisposition to affective disorders. but they are more inconclusive than for schizophrenia. It is tempting to postulate a large-scale metabolic disturbance to account for the dramatic contrast between a slowed-up! retarded. depressed patient and an excited manic; this is what Emil Kraepelin did. One is quickly disillusioned, however, when comparing the commoner agitated depression with a manic, for between these two there are no differentiating metabolic measures. The differences boil down to differences in level of activity and not in basic mood.

Significant environmental precipitating factors can be demonstrated in a great many affective reactions? but not in all. The official classification provides for a major class of reactive psychotic depressions. It is believed that a predisposition to affective psychoses lies in abnormal fixations at an oral, dependent level of development. This is thought to leave a person especially vulnerable to deep regression in adulthood, but not to the disorganization characteristic of schizophrenia. The controversy over the origins of affective reactions is far from settled. Its literature is much more sparse than that on schizophrenia.

4. Brain Disorders.—The official classification includes under this head what used to be called toxic and organic psychoses. About 20 different varieties are distinguished. The commonest changes in mental function found in brain disorders are (1) impairment of intellectual abilities, memory, judgment and orientation; (2) shallowness or instability of emotional response; and (3) alteration in general personality or character.

Brain injury, brain disease and brain intoxication can result in such changes, either gradually or acutely. So also can general systemic disorders if they interfere with the supply of nourishment and oxygen to the brain or interfere with the removal of waste products. Only one type of brain disorder will be discussed here, that occurring in old age. In old age the brain gradually shrinks in size, certain types of cells disappear and the blood vessels harden. If the blood vessels suffer serious damage, the brain changes may be extensive and may come on suddenly.

Among persons with aging brains will be found all the basic characteristics of brain disorder. The aged person grows forgetful, and he unintentionally distorts what he does recall. He becomes unable to continue at his usual level of work, especially if it involves meeting new situations and making new judgments. He may grow confused about his surroundings, particularly at night and in strange places. He tends to become tearful easily, but he can often be cheered up quickly and even made to laugh through his tears. He is easily annoyed and he may have temper tantrums. Sometimes striking changes in general character develop. Usually these are only exaggerations of previous personality traits. but occasionally they appear as something new. A kindly, considerate person grows selfish, harsh and vindictive; a morally strict person becomes involved in taboo or even antisocial activities; an honest, reliable person steals, equivocates or embezzles.

It is disconcerting to find that even in brain disorders, where organic damage is easy to demonstrate, the causation of behaviour disturbances is still far from simple. The brains of senile persons have been microscopically studied, and attempts made to correlate the anatomical findings nith the clinical pictures. A surprising lack of close relationship has been found betneen the extent of cerebral degeneration and the degree of behavioural disturbance. Some patients with widespread cellular destruction show relatively little behavioural deterioration or character change during life. Others with only moderate cellular destruction show considerable behaviour pathology.

In general, old people who live in a peaceful environment. where they experience reasonable satisfaction of their emotional needs, seem to suffer much less deterioration than those whose lives are frustrating, empty or in turmoil. The patterns of functional change which develop with senility seem usually to correspond more to the patient's previous personality, and to the structure of his social environment. than to his pattern of senile brain decay. Eventually. of course, if the brain grows sufficiently incompetent as an organ. its owner mill decline to a vegetative existence no matter nhat his present situation or his personality structure. But the point is that this can occur without psychotic episodes or emotional storms. It is probable that, as we grow better able to understand the ordinary emotional needs of the aged, we shall find the incidence of psychopathology lower than at present and the task of providing for their last years less onerous. (*See* also DEMENTIA.)

PSYCHOLOGY, ANIMAL: *see* ANIMAL BEHAVIOUR; PSYCHOLOGY. COMPARATIVE.

PSYCHOLOGY, APPLIED, represents the use of the findings and methods of scientific psychology in solving practical problems of human behaviour. A more precise definition is impossible because the activities of applied psychology range from laboratory experimentation through field studies of specific utility to direct services to troubled persons. Its practice is not fully controlled by professional or legal methods; there is a zone in which charlatans operate for personal gain. The intelligent layman's major protection against fraudulent practitioners lies in his general knowledge of psychology and in investigating the qualifications of the psychologist whose heip he seeks.

This article, which attempts to make reference to all the major areas of applied psychology, is organized as follows:

I. THE FIELD

Psychology deals with the origin, development and modification of behaviour. These concerns define the specialized knowledge of the field: the genetic and physiological bases of behaviour; the social and cultural setting in which behaviour occurs; learning theory and the modification of behaviour via learning: personality theory and the motivational forces producing normal and abnormal behaviour; measurement theory and methods for the quantification of behaviour; experimental and statistical methods for the assessment and prediction of behaviour under defined conditions. The applied psychologist is trained first in these areas of knowledge; to them is added a period of specialized research or apprenticeship in the area of his particular interest.

A. History

The same intellectual streams whose confluence produced psychology as an independent science of behaviour in the latter part of the 19th century led to the later development of an applied psychology. Philosophy, physiology, evolutionary theory, naturalism and measurement concepts borrowed from the natural sciences contributed to the new discipline. Self-analysis, as a basis for speculation about behaviour, gave way to controlled observation and study. In Germany, England and France these ideas took shape in laboratories, technical journals and books. *(See* Psychology, History of.)

1. Early History.—Francis Galton's publication in 1883 of *Inquiries Into Human Faculty* foreshadowed the entire field of measurement of individual differences. In 1896 Lightner Witmer established at the University of Pennsylvania, Philadelphia, a clinic that was the forerunner of the broad field of clinical psychology. Intelligence testing began with the work of Alfred Binet and Théodore Simon in the Paris schools; the publication of their classic scale for intelligence in 1905 was followed in 1908 by H. H. Goddard's translation of the French mental age scales and in 1916 by the U.S. standardization of the Stanford-Binet scale by Lewis M. Terman and his associates. On *the Witness Stand* (1908) and *Psychology* and *Industrial Efficiency* (1913) by Hugo Münsterberg extended the new science into two additional areas of application. Sigmund Freud's writings gave major new insights into the motivations of behaviour *(see* Psychoanalysis). In 1913–14 E. L. Thorndike published his *Educational Psychology.* At the Carnegie Institute of Technology a division of applied psychology was established as a teaching and research department in 1915 by Walter V. Bingham. The *Journal of Applied Psychology* appeared in 1917 along with the first applied psychology text, by H. L. Hollingsworth and A. T. Poffenberger.

Broad application of psychology occurred during World War I, particularly in the U.S. army. Over 2,000,000 men were tested and classified for military service, and the Army Alpha test became the forerunner of a group-testing movement that spread through education and industry in the next two decades. In the period 1919 through 1921 four applied psychology organizations independent of universities were established: the Scott company (U.S.). founded by Walter Dill Scott; the Psychological corporation (U.S.), founded by J. McKeen Cattell; the National Institute of Industrial Psychology (Great Britain), headed by C. S. Myers; and the Personnel Research federation (U.S.), directed by Bingham.

Between World Wars I and II the basic findings of general psychology and the special techniques of practitioners came to be applied in courts, clinics and hospitals, classrooms, libraries and museums, factories and offices, social service agencies and government bureaus. Even the great depression of the 1930s was a period of expanding activities; vocational counseling was extended to the unemployed, buying habits of the public were analyzed and opinion polling became an aid to government policy formulation.

2. World War II Period.—Many problems related to the war involved the understanding, prediction and management of human behaviour. To select and assign persons for military duty, psychologists devised or adapted tests that resulted in efficient and rapid classification. Since learning time was short, psychologists worked on problems of efficient and rapid learning at all levels of military training. With manpower in short supply, persons judged to be illiterate or undereducated had to be brought to a minimum level of literacy; psychologists worked with such groups. At the point of induction, those whose personalities would probably break under the strain of military service had to be screened out; psychologists worked with medical specialists in devising more effective screening methods.

Polling methods mere developed for evaluating the morale and attitudes of military personnel; psychologists were members of research teams working on studies of physiological and psychological stress, as in flight, submarine, espionage and combat operations. to determine which persons might best be assigned to these functions and what stress conditions would create dangerous decrements in human functioning. As new machines of war were developed, psychologists studied the man-machine relations in order to increase speed of training, increase equipment effectiveness and simplify and improve the design of military equipment.

As the number of physical and psychological casualties of war increased, rehabilitation and reassignment to limited duty became problems to which psychologists—as clinicians, as rehabilitation specialists and as co-workers with specialists concerned with restoration of lost bodily function—turned their attention. Leadership, group effectiveness and survival under stress were major concerns and psychologists conducted field studies of leadership, morale and combat operations. In cases of military discipline and delinquency, the methods of clinical psychology, counseling and rehabilitation of offenders were employed in corrective programs.

In civilian life, psychologists concerned themselves with the most effective methods for war bond sales; assisted in developing child-care and day-care centres for families temporarily disrupted by civilian employment or military service; and concerned themselves with spread of rumour, use of propaganda and psychological warfare and collecting intelligence data. With the end of the war, civilian readjustment and veterans' benefit programs required great increases in clinical and counseling services, and government training programs for specialists in these fields of applied psychology were established. The political climate of the postwar years required continuation of applied psychological research and services and accounted in part for the rapid growth of all fields of psychology. In the United States, for example, each of the military services maintained specialist groups of psychologists, and each supported both contract and in-service research programs on a wide range of military problems related to human behaviour.

3. Period After World War 11.—Many of the trends in applied psychology were accentuated by the demands of the "space age." Educational psychology is applied to the task of early identification and discovery of talented persons as it has become recognized that trained intelligence is an important national resource. Such activities are linked with the work of counseling psychologists, who seek to help persons clarify and attain educational, vocational and personal goals. Counseling services sponsored by government agencies, social service organizations, schools and colleges and offered by private practitioners are widely available; referral to competent service may be obtained from most college or university departments of psychology. Concern for the optimum utilization of human resources also has increased the importance of industrial psycholcgy in business and industrial organizations. The aviation industry and the various space agencies and organizations have been important factors in the rapid development of the field of engineering psychology; as machines and engineering systems have grown in complexity it has been necessary to study man-machine relationships. In response to society's concern for treatment of the mentally ill and for preventive measures against mental illness, clinical psychology has shown the greatest absolute growth rate within psychology; it also has produced some of applied psychology's major professional problems, involving as it does relations with older medical specialties.

B. Applied Psychology as a Profession

Until about 1940 the majority of psychologists held academic appointments, but after World War II there was a great increase in the number of psychologists engaged in work outside institutions of higher education. Support for such activities, including research, came from the military services, government agencies and business and industry.

In the United States, where this development was most marked, the American Psychological association was active in developing a code of ethics for practitioners, examining relationships with other professions and supporting through consultation the licensing or certification of psychologists in many states. In 1947 the American Board of Examiners in Professional Psychology was independently incorporated to grant diplornas representing special competence to experienced psychologists in the clinical, counseling and industrial fields; by the latter part of the 1950s the cumber of diplomates was about 1.500. Great Britain, with an early emphasis on educational and industrial psychology. was a leader in engineering psychology and in applied social psychology in industry. Australia and New Zealand were particularly active in industrial psychology, as were the Scandinavian countries. Counseling received much attention in India and Japan as well as in France, which was particularly important in the historical development of clinical psychology. Industrial and educational applications were characteristic of German psychology. (A. H. Br.)

II. PSYCHOLOGY IN TREATMENT

A. Clinical Psychology

Clinical psychology is concerned with the assessment and alleviation of the problems of persons who are mentally distressed or disturbed. It can be understood properly in any one of three ways: as a type of personal service performed by psychologists; as a professional subgroup of psychologists having commonly recognized and self-imposed standards of training and practice together with sanctions designed to ensure compliance with those standards; or as a special area of scholarship within the main body of psychological knowledge.

1. History. — Clinical psychology emerged at the beginning of the 20th century mith the establishment of individualized treatment programs for disturbed or handicapped children. At first the emphasis was upon sensory handicaps and basic defects in muscular skills. The clinic established by Witmer in 1896 had such an emphasis and, moreover, it dealt with children whose problems arose primarily in school.

The practice of clinical psychology in hospitals and in collaboration mith physicians dates also from the turn of the century. A psychological "laboratory" was established by Shepherd Ivory Franz at the McLean hospital in Waverley, Mass., in 1904 and was continued under Frederic Lyman Wells. In 1909 William Healy. a physician, founded the Juvenile Psychopathic institute — later the Institute for Juvenile Research — in Chicago. At the beginning Healy, a psychiatrist who also had had psychological training under William James at Harvard, and Grace M. Fernald, a psychologist, constituted the entire professional staff. Clinical psychology as practised in the tradition established by these two ventures has been characterized both by its mutually supportive collaboration with advanced medical practice and by its attention to the so-called dynamic or motivational factors in the human personality.

Another current in the stream of clinical psychology started with the publication of the first successful intelligence scale by Binet and its subsequent adaptations by Goddard and Terman. Through these events the practice of clinical psychology came to be characterized by use of precise and objective measures of psychological traits and capacities with, nonetheless, continued emphasis on dealing with troubled persons one at a time and taking into account those personal factors still requiring, in large measure, the psychologist's judgment.

At the beginning of World War II there were between 400 and 600 trained clinical psychalogists in the United States. In other countries, except for the fact that the numbers are disproportionately smaller, the figure is difficult to estimate, primarily because in other countries the clinical psychologist is more difficult to identify. By 1943 the armed services of the United States were employing 1,500 persons as psychologists, a third of them in assignments that might be called clinical; a large proportion of these persons, however, had had inadequate training. At the end of the war the U.S. Veterans administration adopted a policy of employing clinical psychologists in all its hospitals and clinics; the U.S. public health service and the various state mental health authorities moved in a similar direction; and child guidance clinics, as well as public and private schools, created new positions. By 1958 clinical psychologists in the United States numbered more than 7,000.

In addition to the types of positions mentioned above, there are also places for clinical psychologists in industry, where some specialize in services to emotionally disturbed employees and others in services for managerial officials who need psychological consultation to help them cope with work stresses and interpersonal problems. Other clinical psychologists serve the courts in assessing psychological factors that bear upon judicial decisions; others serve prisons; some are employed by the armed services; and some teach. Many, in all types of positions, are engaged in research. A small proportion are in private practice.

2. Activities. — Clinical psychologists generally classify their essential activities under three headings: psychodiagnosis, psychotherapy and research. In psychodiagnosis emphasis is placed on skill in the administration and interpretation of psychological tests, particularly those administered to one person at a time. Such tests are described in the article Psychological Tests and Measurements. Less formal diagnostic procedures also are employed. including the psychodiagnostic interview. In psychotherapy a variety of methods is used (see Psychotherapy). Research generally is considered to be a further obligation for the clinical psychologist, but it is often crowded out of his schedule; in some cases, where research is undertaken as a primary service to the client, it continues to be, because of the skills employed, a clinical service.

A considerable number of clinical psychologists perform their services in hospitals and clinics. The patterns of collaboration between clinical psychologists and their colleagues in medicine and social work vary greatly among such institutions. The variations are most marked with respect to psychotherapy; some institutions assign most psychotherapeutic duties to clinical psychologists, others to psychiatrists only. Institutional collaboration with pediatricians follows a more regular pattern. the clinical psychologist being more likely to be held responsible for services requiring his clinical skills.

3. Professional Aspects. — Clinical psychology gradually is assuming organized responsibility for its own-standards of training and practice. This development was considerably delayed because of the conviction, widespread among psychologists, that the sanctions and restraints of a profession are antitheticai to liberal scholarship and that they would impede the advancement of psychology as a science. Because of the threat of restrictions imposed from organized psychiatry, however, clinical psychologists were reluctantly joined by their colleagues in an effort to establish standards of training and practice and to provide legal refuge for the continuing development of psychology as a whole. Thus U.S. psychology, and especially clinical psychology, sought to achieve what no profession previously had achieved, a body that was at once both science and profession.

British clinical psychology, in contrast, assumed a more ancillary role, the certification of clinical psychologists being at the discretion of physicians.

4. Training. — The pattern of training for clinical psychologists in the United States was established by a committee headed by David Shakow during the 1930s. A broad training in psychology as a science and in related disciplines, as well as demonstration of research competence, was recommended for the doctor of philosophy degree, to which were to be added practicum courses and a fourth year of graduate training to allow time for internship in an interdisciplinary setting.

The American Psychoiogical association, through its Education and Training board, annually identifies the universities and internship agencies that meet its standards. The American Board of Examiners in Professional Psychology, established in 1947, certifies selected advanced specialists in psychological practice, including clinical psychologists, after examination. As a general guide to the practice of professional psychology the association developed a code of ethical standards, which was accepted by its membership and is used as a basis for disciplinary action against those who fail to conform. (G. A. Ke.)

In Great Britain the training of clinical psychologists is divided between the departments of psychology in universities, which assume responsibility for the purely academic aspects of psychological training and for the awarding of degrees, and medical institutions, directors of which individually certify the clinical competence of psychologists who have worked under their supervision.

B. Counseling

In psychological counseling a psychologist participates in interviews with a client for the purpose of increasing the client's level of self-unification or personal integration. This definition emphasizes (1) that treatment proceeds through communication; (2) that the motives and personality structure of the client are the focus of interest; and (3) that the help offered is nonspecific. This latter means essentially that total personality organization is dealt with. Such issues as marital, sexual, job and educational problems and symptoms are not the main concern of the counselor, although they may be resolved as part of the counseling process. Influence rather than guidance is the aim; adjustment of the client, in the sense of fitting in or of conforming to the environment, is not a goal of the counselor.

1. History and Philosophy. — Before 1940 the emphasis in counseling mas the reverse of that described above. The goal of the counselor would have been to help his client to find some educational or occupational environment conceived to be optimal for the client. The main function of the counselor was to assess personal and environmental possibilities so that the client might make reasonably realistic educational and vocational decisions.

Counseling psychology has its roots in two distinct traditions, both established at the turn of the century. The first is that of mental testing, the second that of vocational guidance *(see* below), as influenced by Frank Parsons and others, with emphasis on matching person and environment. Originally interests, aptitudes and abilities were given great weight in the counselor assessment of the client. Later, after successful use of intelligence tests and personality inventories had been demonstrated in World War I, the assessment came increasingly to be based upon the results of mental tests and psychometric methods. Since psychometric methods required considerable sophistication in the psychology of individual differences and statistics. the "professionalization" of counseling began under the influence of the mental test movement.

During the period between World Wars I and II great emphasis was placed upon scientific quantitative assessment of the person and also of his educational and occupational environment, and considerable progress in the study of individual differences and of occupational psychology occurred as a result. The main goal of the counselor'remained constant, however; the person was to be matched to the environment and helped to decide upon one of a set of educational or occupational environments. The textbooks of the period, abounding in discussions of tests, individual differences, etc., discuss personality structure and dynamics, if at all, only in terms of their relation to environments; personality was considered relevant to possible milieus but not to vocational or educational counseling. If the client was too maladjusted to discuss and make decisions rationally, he was referred to a psychotherapist; the counselor's client was required to be sufficiently integrated to have vocational and educational problems only through misinformation or lack of information.

World War II brought to the attention of counselors the importance of personality structure and dynamics. In 1942 Carl R. Rogers published *Counseling and Psychotherapy,* in which he stressed the counseling process rather than diagnosis and assessment; he presented a radical new approach to counseling and psychotherapy; and, most important for counseling psychology, he brought together two traditions with different origins but in many ways similar purposes: the traditions of counseling and guidance and of psychotherapy.

2. Activities. — While Rogers' recommendations with regard to treatment have deeply influenced professional practice in many ways, his emphasis upon personality development and psychological growth processes has been even more influential. The great difference in emphasis can be seen by comparing a textbook such as E. G. Williamson and J. G. Darley's *Student Personnel Work* (1937) with E. S. Bordin's *Psychological Counseling* (1955) or with J. Hadley's *Clinical and Counseling Psychology* (1958). In the first text "psychotherapy" does not appear in the index; in the latter two counseling and psychotherapy are used as virtual synonyms, the distinction being one of degree only. The tendency to identify counseling and psychotherapy, however, is not so significant as the tendency to think of counseling and psychotherapeutic processes in terms of the general psychology of behaviour. Whereas formerly counseling and psychotherapy were discussed in, for example, the specialized terms of individual differences, mental test theory and psychoanalysis, there has come to be a distinct tendency to relate them to the general psychology of learning, behaviour and perception.

The shift in interest from specific vocational and educational problems toward personality integration and unification, with educational, vocational and other problems remaining as important but derivative, has still broader implications. The client usually has immediate and specific problems he wishes to solve; from the counselor's point of view the solution of these problems often must await the resolution of personal deficits that brought them into being. Initially, therefore. the goals of the counselor and the client are different: the client wishes to make a satisfactory adjustment, the counselor wants to modify the personal organization that created the problems. Because of this initial difference in goals the establishment of a suitable counseling relationship becomes a matter of prime interest.

3. Counseling and Psychotherapy. — In focusing on the modification of personality, the psychological counselor approaches the field of the psychotherapist. Are there useful differentiations to be made between counseling and psychotherapy? With regard to the psychological processes involved the answer is probably no; they are identical. Counseling and psychotherapy are indistinguishable with respect to their primary goal, modification of personal organization in the direction of increased personality integration. Psychological counselors usually, however, assume more of a distributive function. Assessment of aptitudes, abilities and interests in relation to educational and vocational goals occurs much more often in the counseling than in the psychotherapeutic situation.

A useful distinction between counseling and psychotherapy can be made in institutional terms. Psychotherapy has been confined largely to medical settings, hence psychotherapists have developed points of view on personality derived from medical experience; the language of health, disease, pathology and hygiene is used in their approach to treatment and to the understanding of personality. In the approach of psychological counselors, on the other hand, deriving as they do from the academic and scientific discipline of psychology, concepts of theory of perception, behaviour theory, learning theory, theory of individual differences and of mental testing and research methods dominate.

Besides the difference in approach, psychotherapists and counselors serve a somewhat different clientele, although there is a very large overlap. Psychiatrists and psychotherapists, by custom and often by law, tend to serve persons whose lack of personal integration is severe enough to be incapacitating or to render them dangerous to themselves or others. Counseling psychologists seldom work with persons so severely ill; when they do so, they conventionally place themselves under medical supervision. In sum, the distinction between counseling and psychotherapy is essentially one of degree, not of kind.

4. Professional Aspects. — In the United States the trends discussed have resulted in an increase in professionalization, and with this has come an increased demand that psychological counselors have the Ph.D. degree and increased emphasis within graduate training programs on the psychotherapeutic aspects of the counseling process and upon mastery of projective psychology and projective tests. In other countries, such as Great Britain, the emphasis continues to be upon the distributive aspects of counseling. However, it is becoming clear that the trends on the American side of the Atlantic are having some effect on the European

side. In Japan a deep interest in psychoanalysis, Rogerian psychotherapy and counseling has developed. The Japanese seem not to make the intellectually arbitrary distinctions forced upon Americans by their history; consequently interaction and mutual influence between counselors. clinical psychologists and psychotherapists is possible and evident to a degree not realized in the United States and Europe. See also PSYCHOTHERAPY.

(J. M. Bu.)

III. VOCATIONAL GUIDANCE

Vocational guidance is based upon theories and methods derived from the social sciences, mainly psychology. economics and sociology. It assists the person (1) to obtain accurate information about his abilities, aptitudes. vocational interests, skills and personality characteristics; (2) to learn about the world of work, kinds of jobs available, training required and duties. responsibilities and rewards of jobs; (3) to integrate this iniormation about himself and about available alternatives so that he can arrive at a realistic and reasonable vocational decision; (4) to make sensible educational and vocational plans that eventually mill lead to his vocational objective; (5) to acquire the skills and attitudes requisite for success in his chosen occupation; (6) to obtain a job that provides adequate opportunities for him to express and use the skills he has acquired; and (7) to develop further skills that will lead to advancement and promotion once he has started his career.

1. History and Scope.—Systematic vocational guidance in the United States had its origins in Boston about 1905, in Parsons' book *Choosing a Vocation.* It began under the sponsorship of community agencies. and such organizations have maintained their interest in it. The schools however, soon began to express interest. and gradually vocational guidance became largely a school function. Most vocational guidance in the United States is provided by school and college counselors trained in adolescent and developmental psychology, psychological testing and measurement. occupational information and guidance and counseling methods. In addition, vocational counselors in many state employment offices use the comprehensive system of vocational aptitude tests, the General Aptitude Test Battery developed by the United States employment service. The U.S. Veterans administration expanded its vocational rehabilitation program started for disabled veternns of World War I and, in its advisement and guidance program, provided vocational guidance to millions of World War II and Korean war veterans through counseling centres located throughout the country. Most states, in conjunction with the U.S. office of vocational rehabilitation, provide vocational guidance to physically disabled persons.

In Great Britain vocational guidance is provided to school-age youth primarily through government employment agencies. In Australia and Canada schools have assumed major responsibility for vocational guidance. Vocational guidance in France was officially made a responsibility of the ministry of education in 1522. and since 1928 the national counseling service has been known as the Institut National d'Étude du Travail et d'Orientation Professionnelle; in 1953. 500 counselors were employed in 209 guidance centres in France. The first Belgian vocational guidance centre was established in 1912, and in 1937 a national system of vocational guidance was established under the jurisdiction of the minister of education; in the early 1950s between 50,000 and 60,000 persons were provided with vocational guidance yearly in more than 80 local counseling centres. The first vocational guidance bureau in Japan was opened in 1920, and in that country the program has been sponsored by the ministry of education, ministry of welfare, ministry of labour and the Japanese Vocational Guidance association.

2. Methods and Functions.— The methods used in vocational guidance include those of both teacher and counselor. In order to help the person better understand his own potentialities. many methods for appraising personality are utilized. Psychological tests provide information useful in predicting success and satisfaction in various occupations. Tests of general intelligence frequently are used. Following World War II increasing use was made of batteries of ability tests, such as the Differential Aptitude Tests and the General Aptitude Test Battery. which provide measures of general intellectual ability and such special aptitudes as clerical speed and accuracy, mechanical comprehension and form perception ability. Other tests of special abilities. such as the Minnesota Clerical Aptitude test and the Bennett. Mechanical Comprehension test, frequently are used. Tests of skill and achievement, particularly academic achievement, include the Cooperative Achievement test and the Iowa Tests of Educational Development. Vocational interest blanks, such as the Strong Vocational Interest Blank or Kuder Preference Record. identify occupations that have the greatest probability of providing satisfaction. At times other tests of personality. temperament or character are used for purposes of vocational guidance, such as the Minnesota Multiphasic Personality Inventory or the California Psychological Inventory. *(See* also PSYCHOLOGICAL TESTS AND MEASUREMENTS.) The results of these psychological tests are supplemented in interviews by additional information about the person's previous experience and achievement.

Use of psychological tests in vocational guidance requires skill and training. and in most states vocational counselors employed in schools must have completed a minimum of a year's work in a graduate school of a university, specializing in guidance, counseling and psychological measurement.

As important in vocational guidance as test information is occupational information, obtained from a variety of sources including government departments. colleges. universities, professional associations and commercial firms. Gertrude Forrester's *Occupational Literature*, an annotated bibliography published in 1954, listed approximately 3.200 selected references to occupational literature.

In vocational guidance. relevant occupational information is provided in individual interviews and group meetings. Courses in occupations are taught at the secondary school level, and frequently units in other courses. particularly in the social studies, are devoted to the study of occupations.

Helping persons obtain jobs, or placement, is another important function of vocational guidance. Persons are taught how to locate jobs. write letters of application, behave during employment interviews and evaluate job alternatives. In a few organizations. counselors and personnel workers are available to assist employed persons in meeting problems encountered on the job. Personnel workers also discuss with employees on-the-job training programs leading to advancement and promotion. relationships with other employees and supervisors and other matters affecting the worker's vocational adjustment. Thus, vocational guidance is a continuous process. (R. F. BE.)

IV. ENGINEERING PSYCHOLOGY

Engineering psychology—also called human factors engineering or ergonomics—seeks to ensure that the tools and machines man uses and the work he performs in a technological society. are congruent nith his own characteristics. capabilities and preferences. Such aims are as old as the field of engineering. However. past efforts to achieve them rested chiefly on the ingenuity of inventors and on the application of practical experience rather than on scientific knowledge of human performance and other characteristics. The accelerated pace of modern technology, the increasing complexity of modern machines and the trend toward automation have led to increasing emphasis on a scientific approach to the design of efficient man-machine systems and to the adaptation of machines to fit man's characteristics and preferences. This emphasis resulted in the rapid growth of engineering psychology.

Work in engineering psychology was greatly accelerated in response to demands arising during World War II. particularly in the field of aviation. Questions concerning the design of aircraft instruments for ease of interpretation, the design of flight controls for accurate manipulation and the matching of man's dynamic response characteristics to the dynamic characteristics of aircraft were among the many critical human-factor problems encountered in military aviation Similar problems arose in designing other types of military equipment. It was found that some of these problems could be solved by the application of data already available from research in experimental psychology, and that existing experimental methods could be used to solve still others.

One of the oldest problems of engineering psychology is the design of signs and symbols—*e.g.*, alphabetic symbols, the signs used on highnays, the codes used in telegraphy and the symbols used in printing for the blind—so as to increase speed and accuracy of information transmission. As new display media, such as radar and television, were developed, new problems of visibility, legibility and ease of interpretation arose, and research on display problems continues to be an important topic.

Another class of problems of historical importance involves the design of tools and various types of controls so that they are adapted to man's capabilities in respect to strength, dexterity, speed and accuracy of movement. As new types of machine controls are designed, new questions of this sort also arise.

The scope of engineering psychology has broadened to include consideration of the proper functions to be performed by men in large man-machine systems. Such questions as "How far is it advisable to go in eliminating people and making manufacturing processes completely automatic?" fall in this area. Answers to such system-design questions obviously should be based on quantitative analysis of the relative capabilities of complex machines, such as electronic computers, versus the capabilities of human beings in performing comparable tasks. Thus the role of people in future man-machine systems. as well as more specific questions regarding the design of displays and controls, can best be settled on the basis of knowledge of human behaviour characteristics.

Engineering psychology applications thus depend heavily on knoaledge of human performance characteristics and on theory that predicts the levels of performance and ranges of human variability and reliability that can be expected in various types of tasks. especially the effects of variables that engineers can manipulate in designing new machines. Engineering psychology also seeks scientific knowledge of individual differences, learning and human motivation, with a view to understanding how such variables affect performance in man-machine systems.

In summary, engineering psychology is concerned with improving efficiency, with increasing reliability and safety. with simplifying jobs and the learning of new tasks and with increasing motivation, job satisfaction and user acceptance, especially insofar as these objectives can be achieved through the design of machines and human tasks. **(P. M. Fi.)**

V. INDUSTRIAL PSYCHOLOGY

Industrial psychology is concerned nith the utilization and conservation of industry's human resources. This is accomplished by the study of people at work and by the development and application of principles designed (1) to increase production; (2) to promote individual satisfaction and adjustment; and (3) to establish a basis for harmonious relations between management and workers.

Emphasis on human welfare is to be found in the first detailed program of industrial psychology as formulated in 1913 by Münsterberg (*q.v.*), then serving as director of the Psychological laboratory at Harvard university. In Great Britain the Health of Munition Workers committee, organized in 1915, and later the National Institute of Industrial Psychology also based research and practice on the view that it is necessary to give the worker greater ease at work—both mental and physical—as well as to raise output.

A. Personnel Selection, Placement and Training

1. Selection and Placement.—Application of scientific procedures for matching jobs and workers involves (1) an analysis of the requirements of each job in terms of aptitudes, interests, personality, etc.; and (2) the development of techniques for measuring the capacity of applicants for employment or transfer to meet these requirements. In the main, such measuring devices take the form of psychological tests.

Many industries have reported striking results from the use of psychological tests, as have the military services. During World War II failures in the U.S. air force pilot training program were reduced from 65% to approximately 35% following the introduction of tests for the classification of candidates for pilot training. A remarkable development in the air force program was the use of a single battery of tests for the differential classification of candidates as pilots, navigators and bombardiers, respectively. Increasing use of such differential aptitude test batteries in placing applicants for employment, and also in the vocational guidance of young people, represents one of the most significant developments in psychological testing in the third quarter of the 20th century. This approach contributes to the most effective utilization of the capacities of each person at the highest occupational level he is capable of achieving.

Another significant trend is the application of psychological techniques for appraisal and development of supervisory and executive personnel. Not only psychological tests but also rating scales, patterned interviews and biographical inventories show promise in this area. In fact, such traditional methods, refined and validated, have proved to be more effective in selection for some types of jobs, such as insurance salesmen, than have psychological tests. (See also Psychological Tests and Measurements.)

2. Training.—The person who is fully qualified for the job may become inefficient and even maladjusted in the absence of proper training. Principles derived from research on the learning process (see Learning) are applied to increase returns from training in the way of improved quantity and quality of output; to reduce training time; to enhance ease; to increase safety at work. Such research has focused attention on the need for supplementing repetition or routine practice by positive reinforcement. In industry this can be provided most easily and cheaply by giving the trainee immediate and frequent knowledge of results. As an example. in one case a revised program for training radio code operators, in which the correct symbol was given immediately after the trainee had written down each signal as he understood it, reduced by about 25% the time taken by trainees to reach a speed of five groups per minute. The effectiveness of training also can be improved by telling the worker why a job is done in a particular way, as well as how to do it. Principles mentioned above and others have been introduced into programs for teaching supervisors to give better instruction on the job. Notable among these is one known as Job Instruction Training (JIT), developed by the U.S. War Manpower commission, which has been advantageously used throughout the world.

A highly crucial problem in industry is that of reducing the frequency and severity of accidents. Although some progress has been made, it generally has been found that little can be done in this direction through the use of tests for measuring accident proneness. On the other hand, training programs in which supervisors make sure that each worker uses only correct methods of work can contribute much to the reduction of accidents.

B. Hours of Work and Physical Environment

1. Fatigue.—One of the significant psychological and physiological costs of work is fatigue, which is discussed at length in the separate article **Fatigue.** The term fatigue has been used to characterize three interrelated phenomena: (1) a decreased capacity for work, known as work decrement; (2) modifications of the physiological state; and (3) tiredness and related feelings.

Work decrement is reflected in a reduction in output toward the end of a work spell. The quality of performance also suffers as the worker becomes fatigued. Physiological changes occurring during work provide clues to the amount of energy expenditure. commonly known as effort, required to do the work. Measurement of oxygen consumption and carbon dioxide discharge, pulse rate, frequency of blinking, muscle tension, urinary excretions and many other functions have been used to assess the expenditure of physiological energy. Feelings of tiredness, weariness, etc., which appear with prolonged work are another expression of fatigue. A feeling of fatigue plays a protective role in preventing exhaustion, but it does not provide an index of either the physiological state of the body or of the capacity for continuing work. Nevertheless, the subjective constituents are significant characteristics of fatigue. In fact, investigators view these not merely as symptoms but as basic expressions of an aversion to continued activity. which is in itself fatigue.

Though it is not possible to avoid fatigue altogether, it is possible to eliminate unnecessary fatigue by adjusting the work situation. However, increase in output cannot properly be used as the sole criterion for measuring the effects of changes in the work situation. It cannot be said that fatigue has been reduced when increased output is achieved only at the cost of an increase in effort or energy expenditure, or of adverse effects on feelings of fatigue and adjustment. Involved here is a psychological concept of efficiency differing markedly from the narrower economic concept, which overlooks the risk of physiological and psychological impairment to man.

2. Hours of Work.—During the 19th century a work schedule including a minimum of ten hours per day and six days per meek was predominant. Opposition to reducing hours of work has been overcome by the discovery that production is not adversely affected, indeed is frequently increased, by shortening the working day and the length of the working week. Output does not fall off with a shortening of the work week because of a tendency for the human being to adapt his rate of mork to the length of the work spell and to the total amount of work to be done.

There is no single best pattern of work hours uniformly applicable to all kinds of jobs. British investigators have shown, for example, that a sortie of four to six hours in a piston-engined plane produces no appreciable fatigue effect, although deterioration in pilot performance occurs after about eight to ten hours of flight. By contrast, two or three one-hour flights in a jet-engined airplane appear to produce as much fatigue as ten or more hours in a conventional plane.

While there is no "optimum work schedule" suitable for all of industry, there is considerable evidence that, on the whole, a five-day week and an eight-hour day are more efficient than a work schedule with longer hours, especially where the worker. rather than the machine, sets the pace. Further shortening of the work schedule may be economically feasible and of psychological advantage in some instances, but built-in human limitations in the way of rate of work and also the time required to "warm up" at the beginning of each work shift may make it impracticable to shorten the work periods radically without adverse effects on total output.

3. Scheduled Rest Pauses.—It is advantageous to break up a spell of work by scheduled rest pauses. Rest pauses are desirable because they may heighten motivation and combat boredom as well as reduce fatigue. Furthermore, they may involve no actual loss of time, since workers will take equivalent time off, sometimes surreptitiously, and unauthorized "breathers'! do not provide the equivalent of scheduled rest pauses in the way of relaxation and release from tension. Support for well-controlled coffee breaks; tea breaks or "elevenses" is found in studies showing that the intake of food during a rest pause contributes to its beneficial effect.

4. Illumination.—Unsuitable lighting accelerates the onset of fatigue, chiefly by increasing the muscular activity involved in seeing. A major requirement of good lighting is adequate brightness, associated with intensity of illumination. Low intensity continues to present a problem in many factories and offices, where the level of illumination is lower than 5 foot-candles, as contrasted with the 1,000 to 1,500 foot-candles characteristic of the outdoors even on a cloudy day. Difficulties in measuring the physiolcgical cost of work under varying levels of illumination and other factors have led to disagreements as to applicable minimum standards for different jobs. Nevertheless, those listed by organizations such as the Illuminating Engineering society, illustrated below, represent widely accepted guides to the establishment of lighting specifications.

Type of work	Foot-candles (30 in. above floor)
Assembly (rough)	10
Bookbinding (cutting, punching, stitching)	20
Clothes pressing (hand)	50
Electrotyping (blocking, tinning)	30

Proper diffusion and distribution of illumination. designed to eliminate glare and undesirable shadow effects. are also necessary for clear vision and easy seeing. Brightness contrast (*i.e.*, the ratio between the brightness of the object and that of the background) must be considered in determining the quantity and quality of illumination. Colour may play a part; it has been shown that ease of seeing is increased through the use of contrasting colours on machine tools and that this serves to emphasize danger points on the machine as well as to increase efficiency. (*See* also LIGHTING.)

5. Atmospheric Conditions.—According to a study conducted by the American Society of Heating and Ventilating Engineers, 50% of people engaged in light work in the United States find air temperatures of 63° to 71° F. comfortable in winter, and temperatures of 66° to 75° F. suitable in summer. The same percentage select 30% to 70% as the desirable level of relative humidity. However. people vary widely in their reactions to these atmospheric conditions and also to the rate of air movement, which is another important factor in maintaining efficiency and comfort at work. Much depends also upon the nature of the task.

For the exact study of human reactions to atmospheric conditions. use is made of an index, known as Effective Temperature (ET), which shows the combined effect of air temperature and humidity on the sensation of warmth or cold for a specified rate of air movement. In general, studies indicate that human performance is impaired to a serious degree with effective temperatures in the middle 90s or above, and that incentives do not offset the effects of high temperatures. At temperatures below 50° F. the precision of hand and finger movements is reduced. There are no materially adverse effects on mental activities even at temperatures below 0° F.. although impairment occurs in the performance of manual tasks. Furthermore, both physical and mental processes suffer and feelings of fatigue are increased under conditions of anoxia, or oxygen deficiency, such as occur moderately at an altitude of 10,000 ft. or less and critically around 20,000 ft. and above (*see* HYPOXIA).

Careful selection of personnel, provision of protective clothing and oxygen equipment, adjustment of the work spell. etc., can help to ameliorate the effects of atmospheric conditions characteristic of extreme climates and also of work around blast furnaces, in mines and submarines, in flying, etc. However, atmospheric conditions create negligible human problems in modern, well-ventilated, properly heated, air-conditioned plants. (See also HEATING AND VENTILATION.)

6. Noise.—Adaptation takes place in the case of regular exposure to expected and continuous noises of high intensity in the work situation; especially in the presence of high incentives. Prolonged exposure, however. to high noise levels and certain types of noises—as, for example. those experienced by boilermakers and airplane pilots—contributes to hearing loss. On the question of direct fatigue effects there is considerable disagreement among research workers. Thus K. D. Kryter states that there is little evidence of damage to health, either psychologically or physiologically, from intense noise: even though it may be annoying. Other investigators maintain that available evidence tends generally to show that noise detracts from efficiency and well-being. Underlying this controversy are deficiencies in experimental methods and also limitations in methods for measuring the physiological cost of work. It is not safe to disregard the possibilitv that. excessive noise acts on the human organism as excessive friction acts on the machine; that it wastes energy.

C. WORK METHODS AND MACHINE DESIGN

1. Efficient Methods of Work.—Waste in the use of human resources in industry can be curtailed by the elimination of awkward and unnecessary movements in doing the job. A comprehensive program for doing this, including time-and-motion study procedures. mas first developed at the beginning of the 20th century 'This and a variety of subsequent programs undertake basically to eliminate unnecessary movements and to combine selected "best" motions into a standard method frequently designated as the one best way of mork. The concept of the one best way of work has been a matter of concern to psychologists. Involved, in part, is a question as to whether any single rigid pattern of work is uniformly applicable to an entire group of workers, since these differ from one another in physical and mental make-up. There is need to make allowances for the personal equation of the individual, so long as departures do not result in a reduction of output or in increasing work hazards.

Modern programs designed to improve work methods, generally known as methods engineering or work simplification. reflect these newer outlooks. There is an increasing tendency to make use of general rules of motion economy—dealing with such factors as symmetry, continuity, smoothness and rhythm of movement—as a substitute for rigid patterning of so-called basic motions. Furthermore, many supervisors and also workers are being taught how to apply these rules. Such an approach embodies a concern for individual differences. Participation of this kind also contributes to a psychological climate conducive to harmonious industrial relations.

2. Posture and Distribution of Load.—Fatigue is increased when a static posture must be maintained. Furthermore, the energy cost of work is increased by departures from normal, erect positions in carrying loads. In general, it appears that a load should not be in excess of 40% of the body weight in continuous work of this kind. In such activities as pushing wheelbarrows, a normal, brisk walking pace without stopping appears to be most efficient in terms of energy expenditure. While of decreasing importance in highly industrialized countries, excessive fatigue induced by improper posture and excessive burdens can represent a major human problem where the task of carrying loads is still primarily a human rather than a machine job.

3. Alleviation of Boredom.—Highly specialized. repetitive work, widespread in modern industry, leads to a feeling of boredom; as indicated by both U.S. and British studies, considerable boredom is experienced by approximately 25% of factory workers. Boredom produces a change in the shape of the daily production curve which, contrary to the situation when fatigue is experienced, tends to fall in the middle and to rise at the end of the work spell. Furthermore, employees who experience boredom are responsible for a considerable number of complaints and frequently exhibit low morale.

Efforts to develop tests of susceptibility to boredom and assign to repetitive work only those who are not highly prone to it have not been successful. As a result, attention has been turned increasingly toward modifying aspects of the work environment that contribute to the arousal of boredom. Research conducted from this point of view has shown that appropriately spaced rest pauses, freedom to engage in conversation, music and the social environment of the plant, especially as reflected in the formation of closely knit small work groups, contribute to the alleviation of boredom.

A high degree of specialization in work has been favoured in the belief that this tends to increase over-all production. However, it has been shown that redesigning jobs so that the worker can perform a variety of tasks reduces the incidence of boredom and improves general attitudes without adversely affecting production. Thus job rotation and also job enlargement are being used increasingly as ways of alleviating boredom and its attendant effects in the way of unrest, low morale and possibly impaired social adaptation.

4. Machine and Instrument Design and Man-Machine Systems.—With the growth of mechanization in industry. it has become increasingly necessary to view man and his machine as an integrated functional unit. There is continuing need to approach the design of machines with full consideration of basic patterns of human perception, communication and motor response, and also of built-in limitations in the speed, accuracy and co-ordination of these and other human functions. Failure to consider the human element in the design of machines has led to the construction of mechanical monstrosities, such as a mine hoist that requires the operator to read a dial tilted 30° upward and sideward while standing spread-eagled with his weight resting on one foot. Many machines and tools tax the capabilities and energy of human operators.

Since approximately 1940 there has been growing acceptance of the principle that machines should be made for men rather than men forcibly adapted to machines. This view finds expression in specialized research and practice most frequently described as engineering psychology (see Engineering Psychology, above).

Visual Indicators.—The widespread use of instruments such as pressure gauges, tachometers, voltage meters, etc., has led to extensive studies of visual indicators. An example of poor design is found in a control panel 17½ ft. in width where all major gauges were 2 to 3 ft. above eye level. Operator complaints of eyestrain and fatigue led to the redesign of the control panel to a width of six feet with better positioning of instruments for seeing.

Poorly designed instruments can cause accidents as well as produce unnecessary fatigue. Thus a survey of 270 "pilot errors" showed that 13% of aircraft accidents investigated resulted from a misreading of the altimeter by 1,000 ft. There is evidence that the substitution of a numerical counter for the conventional type of altimeter reduces the percentage of errors in reading from 11.7 to 0.4 in the case of experienced pilots. Studies of many kinds of visual indicators have led to the formulation of principles designed to improve both the ease and accuracy of instrument readings, covering such characteristics as intervals between scale markings, size and style of figures, shapes of pointers, conditions of illumination. etc.

Controls.—The placement, shape and direction of movement of controls represent important factors in the design of mechanical elements of the system. Wide separation of controls leads to reduction of output and to increase of effort in the operation of machines; by contrast, too close proximity of major controls may produce accidents. The latter has been demonstrated in the case of aircraft. where the nearness of the flap control to that used in operating the landing gear has contributed to accidents because of accidental operation of the wrong control.

Coding.—Strain can be reduced and safety increased by coding or associating differently shaped controls with distinctive operating functions. Certain basic principles with respect to direction of movement have been developed, including the rule that for adjusting a lever or control knob the movement should be in the same direction as the perceived adjustment. Thus toggle switches should move upward for "on," "go" or "increase" and downward for "off," "stop" and "decrease."

D. Psychological Climate

In many instances, hours of work and physical conditions play a less important role than the psychological climate of a plant or office in determining the output. satisfaction and attitudes of the working force. Psychological climate is determined by the personnel policies and practices of the company, the attitudes and behaviour of supervisors and executives and the multitude of interpersonal and social relationships in which people are involved at work.

1. Social Situation.—Studies conducted in the Hawthorne, Ill., plant of the Western Electric company between 1927 and 1932 attracted attention to the significance of such aspects of the work situation. These studies included extensive observations of the effects of changes in number and distribution of hours of work, illumination, rest pauses, wage-payment plans, etc. Such changes were accompanied by increased production, but the upward trend did not disappear when the favourable physical conditions were eliminated. It was concluded that the production increase was the result of a change in the social situation. The conditions of the experiment created a friendly and closely knit working team and a relationship of confidence between the employees and their supervisors which did not exist in the ordinary work situation in the plant. Employees did their best not primarily because of wage incentives, reduced fatigue or similar factors but because the psychological climate was conducive to maximum co-operation by the work group.

Subsequent research by different investigators in many plants has clearly confirmed the view that the way the person acts, the way he feels about his job, the level of his morale — in the sense of willingness to strive for the goals of the company — are very much affected by the sentiments and attitudes of his co-workers. Of particular significance is the influence of the small work group or team to which he is assigned by management. and of the small informal organization which develops spontaneously as a function of the work situation. The influence of the social situation is intensified because the employee is simultaneously a member of many groups. and because some of these, *e.g.*, the company and the union may be competing for his interest and his loyalty.

2. Incentives. — This emphasis on the influence of the social situation does not mean that workers' behaviour and attitudes are determined only by "social motives" or drives derived from group membership. Other and even more fundamental motives, associated with basic drives for the satisfaction of needs for food, shelter, job security, self-expression, etc., play a tremendous role.

Research has thrown considerable light on the sources of motivation (*q.v.*)—on the variety and strength of needs and desires that must be gratified in the work situation. There also exists a wealth of information concerning factors in the industrial situation that operate as incentives to production and in promoting high levels of employee satisfaction and morale.

There is evidence that executives, and also union leaders, err in their judgments of workers' perceptions of their needs and the potency of financial incentives. In a survey conducted in 1947, 75% of executives and of labour leaders and less than 30% of employees included compensation among five factors rated as most important to workers. In a later study workers listed "full appreciation of work done" as first and "good wages" as fifth on a list of morale factors. By contrast. supervisors predicted that "good wages:' would turn out to be the most important item looked for on the job by the workers. and that "full appreciation of work done" would rate in eighth place.

Desire for money is only one of many factors in motivation and morale. This does not mean that the pay envelope is unimportant in satisfying workers' needs; a low nage scale is a significant source of dissatisfaction and lack of co-operation. Nevertheless, voluntary restriction of output in plants using wage incentive systems and strikes in plants with high wage scales show that wage schedules and nage incentive systems have limited power as incentives. A nage incentive may have no efiect if the work operation is disliked, if elements of the psychological climate produce frustration or are perceived as barriers to the satisfaction of basic needs. Furthermore, as wages rise above the subsistence level, other needs and wants. satisfied by plant conditions other than pay, become more influential. In addition to material rewards. workers seek such mental and spiritual returns as the opportunity of doing something worthwhile; the feeling of being recognized as somebody; a sense of belonging; a chance to get somewhere; approval of work done; a safe future; guidance by a strong and understanding leader in establishing goals and learning how to achieve them; the opportunity of contributing from their knowledge in dealing nith their own problems.

The question has arisen as to whether union or management carries the prime responsibility for satisfying such needs. There is evidence that the worker has strong attachments to the union and sees it as a powerful agency for the increasing satisfaction of material nants through higher wages and job security. It is not so clear that he views the union as the primary medium for the satisfaction of other wants. On the contrary, many studies show that employees at all levels look to management for the establishment of policies and practices conducive to the satisfaction of these needs.

3. Work Groups. — A study conducted in two British automobile factories showed that higher production and greater satisfaction occur in smaller than in larger nork teams. Observation of four gangs engaged in repairing railroad passenger cars in Great Britain shoned that, under a group wage incentive, productivity increased at a higher rate in gangs of small size and with a particular pattern of stability than in larger work gangs. These and other studies also yielded evidence of higher levels of satisfaction and morale in smaller work groups.

The explanation of such findings is to be found in the social structure of the groups. Smaller working groups tend to be more cohesive than larger groups do. Under appropriate conditions, especially in the presence of a high quality of leadership, such cohesiveness leads to higher work standards, to acceptance of technological change and to better achievement of other goals important to management.

A conscious effort to combine in a work team members who like and are friendly toward each other is conducive to the development of such positive attitudes and behaviour. The advantages of using such sociometrically organized work groups are illustrated in an experiment conducted in the construction industry; total production costs were reduced by 5% when carpenters and bricklayers were permitted to select their own workmates instead of being required to work with arbitrarily assigned teammates.

4. Democratic Leadership. — A number of studies covering many occupations and many countries — ranging from telephone operators in the state of Michigan to textile workers in India— have demonstrated that an atmosphere of democratic leadership, which provides opportunities for employee participation in setting goals and in other aspects of decision making. results in higher production, greater job satisfaction and improved morale. Evidence of such returns was first demonstrated clearly in a study conducted in a garment-manufacturing plant, where there was considerable resistance of production workers to necessary changes in jobs and work methods. Providing opportunities to the workers to participate in planning the details of the change and in setting production goals led to higher output, decreased turnover and a more harmonious relationship between workers and supervisors. Such benefits appear not only nhen small job changes are involved but (as was shown in later developments in a garment-manufacturing plant and in the Indian studies) also where a widespread program of modernization or reorganization of the plant as a whole is required.

Experience of companies introducing electronic office equipment and other forms of automation shows further that industry can profit from permitting workers to participate in decision making, without any abdication of the responsibility of management for the operation and growth of the business. In fact, the extent to which the worker is involved in participation may determine his reaction to management when demands are made for loyalty to tno overlapping membership groups: the company and the union. A study conducted in an automobile-manufacturing plant showed that, uniformly, where the foreman is active in involving men and the union steward is not, the workers are more likely to be high on an index of management affiliation and low on an index of union affiliation, and vice versa.

5. Supervision. — Many studies, including that cited above, have demonstrated that the quality of supervision exercises a tremendous influence upon employee motivation and morale. Studies of nork groups, including insurance office workers, labourers in railroad gangs, linemen, etc., conducted by the Survey Research centre of the University of Michigan, showed that employees who perceive their supervisors as "employee centred" have better production records than do groups working under "production centred" supervisors. There is evidence that absence rate is inversely related to quality of supervision.

Analyses of finding:, from studies conducted in the 1940s and 1950s show that the quality of supervision is good (1) when workers feel free to discuss their problems with their supervisor; 12) when norkers know what he thinks of their work; (3) when workers feel that the supervisor supports them nhen they have a complaint; (4) when the supervisor uses general rather than close supervision; (5) when the supervisor frequently conducts group meetings where work matters are discussed.

Recognition of the central role of good supervision has led to the formulation of programs to select for supervisory jobs those persons nho are most capable of meeting such requirements. More important and more widespread are numerous and extended training programs designed to help the supervisor develop proper perception of workers' needs, feeiings and attitudes, and skill in dealing nith employees on the job.

6. Communication.— Evident in much of the discussion above is the important role played by communication in determining the quality of interpersonal relations. Small groups become cohesive, in part, because in them information can be passed along quickly. Employees look to supervisors for opportunities to discuss what is of importance to them. Adverse attitudes toward company pension plans and other benefits change for the better when facts concerning them are properly communicated to employees.

The need for adequate communication exists at all levels. Supervisory personnel often complain of the failure of higher management to keep them informed about matters that are of interest to them and their employees. Formal channels of communication following the lines of the organization chart may not be sufficient for full dissemination of information.

7. Management Atmosphere.— Basic principles of good supervision cannot or will not be put into practice unless the climate is such as to stimulate supervisors at all levels to perceive themselves and to act as members of the management team. Along with keeping the supervisor informed, it is necessary to define the scope of his responsibility and to delegate to him the authority to use it. A study made in 1954 showed that 79% of foremen with high morale and only 37% of foremen with low morale had a clear understanding of their duties. Similarly. 79% of the former and only 30% of the latter claimed that they had adequate authority to deal with employee and other problems. In addition, the supervisor is at a disadvantage on the job unless his status is made clear by the wage scale and by such physical symbols as desk, office space. etc., and unless he is permitted to play a role appropriate to his rank in policy administration and even in policy making. *See* also INDUSTRIAL RELATIONS. (M. S. VI.)

VI. MOTIVATIONAL RESEARCH

Motivational research is the branch of applied psychology that is concerned with the deep-lying and often hidden motivations of human beings, and with the influencing of their behaviour through understanding of these motivations. It finds its chief uses in business. solving, by studies of mass behaviour, problems of sales, advertising and merchandising. Motivational research resembles —and some of the basic fact-gathering methods it uses are similar to those of—public-opinion polling (*see* PUBLIC OPINION; STATISTICS). Public-opinion polls, however, are concerned mainly with how people behave. Xfotivational research attempts to find out why people behave as they do and, further, it acts on the assumption that many human motives are unconscious or not readily admitted because they do not always represent desirable aspects of behaviour.

The methods employed to uncover underlying motives for human behaviour are borrowed from the general fields of psychiatry, psychoanalysis and depth psychology (*see* PSYCHIATRY; PSYCHOANALYSIS). They include such devices as the depth (nondirective or open-end) interview, projective tests, laboratory experiments and psychodrama. The depth interview is one in which the subject rarely is asked a direct question; for example, the researcher will not ask him why he bought a particular make of car, but will attempt to discover this from his answers to indirect questions. In using projective tests, pictures illustrating specific situations are shown to subjects who are then asked to project themselves into these situations; this often reveals their true motivations (*see* also PSYCHOLOGICAL TESTS AND MEASUREMENTS: *Projective Methods*). Laboratory experiments seek to measure the relationship between people and objects—including products, services and mass media. In psychodrama, people are asked to act out on a stage a purchase. interpersonal relations or emotional problems; in doing so. they often discover insights into their own behaviour, and the researcher gains understanding of their motivations.

Motivational research, since it attempts to change such activities as voting. buying and national and international attitudes toward various issues, has exposed itself to a question regarding the ethics of using social sciences to influence people, often against their will. Motivational researchers answer that people always have tried to influence each other and that the real issue is one of determination of goals. (E. D.)

VII. FORENSIC PSYCHOLOGY

Part of the scientific research on human behaviour carried out by psychologists and other social scientists is pertinent to a wide range of legal problems. At one time or another, psychologists have studied detection of guilt and deception, distortions of perception and memory in relation to testimony, the behaviour of juries, problems related to the determination of competence and sanity, personality and motivational factors related to crime, factors influencing success and failure on parole, the sociopsychological organization of prisons, the psychology of drug addiction and the like.

In addition, a number have served as clinical psychologists or guidance counselors affiliated with juvenile and criminal courts, prisons and other legal agencies. Further, psychologists sometimes serve as expert witnesses in cases involving determination of mental deficiency or "insanity" or other problems in which technical psychological knowledge may be of use.

In the main, however, the application of psychology in relation to the law has not emerged as a clearly delineated, professional field. Few psycliologists have obtained sufficient legal training to make them familiar with court procedure and to enable them to adapt their findings to the general rules of evidence. Most of the practical application of psychoiogy to legal problems is carried out by specially trained police officers and attorneys. (H. F. HT,)

PSYCHOLOGY, COMPARATIVE, concerns the study of similarities and ditierences in capacities for environmental adjustment and for behavioural organization among the important types of living beings, from plants and unicellular organisms to the primates including man. A view of the subject held earlier by W. Wundt and others included human comparisons now generally studied under the titles of genetic or child psychology, abnormal psychology and ethnology or folk psychology. The present article is concerned with an examination of the psychological nature and capacities of lower animals and man in comparison with one another.

Comparative psychology is studied because the behaviour of animals is in itself interesting, because of important applications in fields such as medicine and animal training, and also because of significant bearings on human psychology. With the rise of an experimental comparative psychology in the latter half of the 19th century and its rapid growth during the 20th century, the scientific study of lower animals has cast increasing light on questions in human psychology, such as the development of individual behaviour, motivation, the nature and methods of learning and many others. Psychologists often employ lower animals as subjects in their experiments because these are easier to obtain in numbers and can be much better known as to background and better controlled under experimental conditions than human subjects. and because of relationships in behaviour. Much can be learned about man by studying lower animals; moreover, the discovery of differences illuminates the similarities.

In primitive times man had to learn about animals because of his constant struggle with them for existence. Animals became familiar members of human households, and many cultures used animals as totems or worshiped them as magical beings. The common-sense tendency to endow lower animals with human capacities always has been strong. People often talk to animals, appealing for action or for sympathy as though dealing with human beings. An extreme development of this tendency is the doctrine of metempsychosis (*q.v.*), or transmigration of souls, which holds that after death the human soul may reside either in another person or in a lower animal.

In recorded history two different views have developed concerning man's relation to the lower animals. One, termed for convenience the man-brute view, stresses differences often to the point of denying similarities altogether; the other, the evolutionary view, stresses both similarities and differences. Aristotle formalized the man-brute view, attributing a rational faculty to man alone, lesser faculties to the animals. On the other hand, from the 19th century Darwinism led scientists to look for relationships between man, considered a highly evolved animal, and the other animals. This has come to be the modern view in science. Scientific evidence indicates that continuity in the evolution of organisms provides a basis for essential psychological similarities which exist, together with differences, between lower and higher animals.

This article is organized as follows:

I. METHODS

1. Gathering Evidence. — The evolutionary position, which has been substantiated in its main contentions concerning mental relationships among animals, has its basis in experimental evidence. Fact gathering, whether by observation or by experiment, requires, beyond a keen interest in animals, special training in the scientific methods of investigation for which personal feelings are no substitute. An animal story, even when reported by a person of repute and veracity, carries no automatic guarantee of its soundness. All reports. whether from laboratory experiments or from studies of animals in their natural habitats, must be evaluated for reliability according to what investigative conditions prevailed and what precautions were taken against error in gathering the facts.

In comparative psychology, as in science generally, the soundest method of study at hand is used. An observer of nesting behaviour in birds constructs a hide-out or blind to minimize disturbances resulting from his presence. Binoculars, a camera and special mechanical means for recording the bird's reactions may further increase the reliability of his investigation.

Experiments in the laboratory are designed to obtain the maximal control over conditions. There it is possible to regulate general factors such as age and physiological condition of the subjects, to exclude disturbances, to change environmental conditions or keep them constant, according to the experimental plan, and to introduce apparatus designed to ensure accuracy both in the test itself and in recording results. Thus animal psychology has employed the maze method as one means of testing learning, special problem boxes to test intelligent behaviour and a variety of other techniques planned to increase the significance of the evidence obtained.

2. Interpreting Evidence. — No theory can be sounder than the validity of its evidence or the logic of its construction. To illustrate the necessity of checking evidence at the source and logically examining theory, a famous case in which humanlike abilities were claimed for a performing animal may be cited. Late in the 19th century, several horses owned by a Herr von Osten of Berlin, particularly one named Hans, became renowned for purported mathematical capacities. When a problem was written on a blackboard before him, Hans, by tapping first with right forefoot and then with left, indicated the answer in digits and tens respectively, with such success as seemingly to support the owner's claim for mental calculations by the horse. Although skepticism was expressed by many, and some alleged trickery, others asserted that the owner must be honest and his claims therefore valid. Scientific surveys of the case, particularly by the psychologist O. Pfungst, supported the following analysis. The horse performed well whether the owner was present or not, apparently ruling out trickery due to the owner's presence. But Hans failed unless the trainer or someone else was present who knew the answers; hence success depended somehow on human influence. The fact that the horse failed when blindfolded excluded telepathy while indicating some other effect from persons present. Observing the audience carefully, the psychologists found that when a problem was written down, someone who knew the answer would bend forward very slowly, whereupon the horse would begin tapping. After the correct number of taps the person mould relax, usually nith a iittie movement, as of the head. and the horse would stop. Slight movements of this kind were known to psychologists as inadvertent activities accompanying acts of close attention. From these facts, Pfungst concluded that, without the owner's knowing it, the horse had learned to start and stop his taps according to appropriate sensory cues. This interpretation was favoured by still other facts. The horse was equally successful nhether the problem was in simple arithmetic or in calculus; also. his responses to easy and to difficult problems alike often were incorrect by only one or two digits, suggesting a direct control of the tapping that could operate now early, now late. rather than mental operations. Supporting this conclusion was the fact that Hans typically began tapping mechanically nhen all was ready. without even looking at the figures.

This case brings out some important principles of interpretation in comparative psychology. The investigator selects a likely hypothesis, but considers it tentative until it is supported by experiments in which all factors of possibie importance are controlled. (In the Clever Hans case, the roles of sensitivity and habit in the horse, the factors of audience knowledge and of subtle motor aspects of attention. and still others were tested.) After his experiments, the scientist sifts and organizes the available evidence logically, using mathematical techniques when possible, to find what theory best fits the facts. These safeguards are elementary, whatever the nature of the behaviour problem.

3. Anthropomorphism. — There is an irresistible human tendency to ascribe human attributes, emotions and capacities to other beings. Thus it is said that moths and other insects fly to the light out of curiosity; the rattlesnake sounds its rattle in order to warn intruders; pets and domestic animals are noble or sly and deceitful according to conditions; and so on. The practice of interpreting behaviour on the basis of selected stories is called anecdotalism. Thus Plutarch in ancient Rome, La Fontaine in 17th-century France and countless other writers have busied themselves in narrating stories about mental feats in lower animals.

Although valuable literary works may be created by authors attributing human traits to animals, anthropomorphic literature risks two fundamental flans which make it an undependable source of evidence. First, it typically involves the implicit assumption that any person is well acquainted with his own behaviour and thoughts and even understands their causes. About this belief modern psychology is seriously doubtful, advising caution to writers about behaviour and particularly those unskilled in observation or interpretation. Another difficulty is that a scientifically untrained person, however well intentioned, may rest content with a single outstanding occurrence in the life of an animal as a basis for his interpretation, especially one nith dramatic features making its telling and retelling a gratifying act. But a single observation has low reliability, as have any number, when perception is influenced by prejudices and preconceived notions. Furthermore. with each narration, new features are usually introduced and old ones changed so that the report becomes increasingly unreliable.

4. Adaptive Behaviour or Purpose. — Unnecessary complexities often arise in interpretation because of the interpreter's point of view. Under natural conditions. for example. animal behaviour generally conforms to what a human observer might call "appropriate" or "best" in the given situation. Thus the Venus's-flytrap closes its hinged leaf when a fly alights upon it. but not when stirred by a breeze; the scallop closes the valves of its shell as its common enemy, the starfish, approaches; the octopus frequently remains secluded until its common prey, the crab, is nearby; the chimpanzee, attracted by food out of reach, may attain it by piling hoxes. Acts that seem well adapted to the given animal's welfare under particular conditions are often described as purposive. For those interested in obtaining valid explanations, this generalization of purposiveness in behaviour raises difficulties.

The above cases are typical—what can be said about them? First. these acts occur as described: the reports are reliable. Also, the acts have in common one characteristic: each of them furthers the life processes of the animal and fits it to its surroundings. In this respect they are all adaptive, and indeed, animal behaviour tends to be adaptive. Although many theorists mean only this when they use the term purposive to describe behaviour, a distinction seems desirable between what is adaptive and what is purposive in behaviour.

The names of H. Driesch and W. McDougall are associated with a view in the nature of teleology (*q.v.*), through which all animal behaviour of the type termed above adaptive is endowed with directive forces comparable with human volition. When a man behaves purposively, with the assistance of thought processes he strives for an end which he anticipates or expects. If all animals actually performed their adaptive behaviour on the basis of such a process, the theoretical problems of comparative psychology would be relatively simple! for the same type of solution would apply to all cases. But the danger exists that the teleological type of explanation may arise from the theorist's preconceived notions rather than from reliable supporting evidence.

5. Morgan's Canon. — A useful rule in scientific interpretation is the principle of parsimony, which may be stated as follows: of alternative expianations for a given phenomenon, choose the simplest, that requiring the fewest assumptions, provided it meets the facts adequately. This principle was stated for comparative psychology by C. L. Morgan *(An Introduction to Comparative Psychology, 1894)* as follows: "In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale."

The purposive type of explanation for the above examples would be that the Venus's-flytrap needs food, hence closes when touched by insects but not by inedible objects; the scallop recognizes the starfish as an enemy and closes its valves to avoid destruction; the octopus hides so that its enemies cannot see it and its prey may come close; the chimpanzee stacks boxes in order to obtain suspended food. Although at first sight these purported explanations all may appear simple. actually they are all complex and no one of them should be adopted until alternatives have been considered in the light of Morgan's canon. Each hypothesis assumes that the animal anticipates the consequences of one action or its alternative (*e.g.,* the scallop anticipates death if it does not close) and can weigh the possibilities somewhat as a reasoning man might. Humanlike capacities, such as understanding meanings, anticipating results and choosing between alternatives, are thereby implied by these purposive explanations. The evidence, however, favours a purposive explanation in only one of the described instances, the case of the box-stacking chimpanzee. W. Kohler and others have shown that this animal can anticipate success when jumping from the ground to suspended food, can understand the significance of a box as a means of reaching food and can solve problems by reasoning. Conversely, to account for the flytrap's reaction, only a simple reflexlike reaction to stimulation need be assumed, for the leaf closes when its delicate filaments are touched by a foreign object. As for the scallop, experiments show that it closes in response to any sufficient chemical effect, as to starfish broth released in the water nearby, but not to a starfish presented behind glass (visual control). In the case of the octopus, an intent to hide is excluded by J. A. Bierens de Haan's finding that the animal slips between plates of glass, where it remains in full sight, as readily as between pieces of slate. The simpler explanation consistent with the facts is that the octopus comes to rest when its body touches between surfaces, not because it understands hiding.

These cases illustrate the value of investigation in comparative psychology to test assumptions and reach an adequate explanation. Too frequently a purposive account rnerely names the gains of an activity (*e.g.,* protection, food) without clarifying the process involved. But a name alone is no explanation, and may in fact suggest an incorrect interpretation. Adaptive acts must be explained through evidence from investigation rather than by analogies between lower animals and man, for activities which lead to similar adaptive results (*e.g.,* both the leaf closing of the flytrap and the box stacking of the chimpanzee are "food-getting behaviour") may be very different psychologically.

6. Objective Attitude. — Early in the 20th century the view gained ground that careful experimentation on behaviour under controlled conditions should produce evidence improving psychological theories of animal capacities. A chief contribution of this movement to comparative psychology was its emphasis on objective techniques as against subjective procedures for evaluating and comparing the psychological resources of different animals. To appraise any animal activity, the psychologist must consider its nature and adaptive value, the situation and what factors in the species' organic make-up and in individual experience may have contributed to it.

The first task in comwarative studv is to discover the characteristic capacities and resources of behaviour in each animal type; the next is evaluation. It is not sufficient to assign positions in a series, classifying some animals as inferior and others as superior; the presumed inferiority or superiority must be clarified through comparisons. Neither the stability nor the adaptive efficiency of behaviour are as indicative of superior psychological status as are modifications of behaviour to fit new conditions. The principal weakness of a topical study is the implication that capacities such as "memory" are much the same wherever found. But any given capacity, such as learning, overlaps others and may also differ greatly according to the animal type involved. Higher animals do not necessarily repeat the make-up of lower animals with the addition of certain new abilities. Rather than a recapitulation of the characteristics of lower animals in the higher, research discloses similar properties and others which assume new psychological significance. These matters may be illustrated by passing in review some outstanding differences observed among various types of animals.

II. PSYCHOLOGICAL STANDING

1. Psychological Levels. — The earliest formal statement of psychological levels was the scheme of Aristotle, endowing plants with a nutritive faculty alone, the lowest animals with sensory faculties also, higher animals with an appetitive faculty also and man alone with a rational faculty. Descartes's ideas embodied a simpler scheme: a lower level of animals, viewed as automata, and man as the sole rational being, on a higher level. In 1905 R. M. Yerkes differentiated levels on the basis of functional criteria and experimental evidence: (1) discrimination, a general form of reaction, shown by lower invertebrates; (2) docility, or modifiable reactions, shown by rodents; and (3) initiative, or variability in reaction, shown by primates.

One objection to such systems is that they are speculative and may restrict the experimenter's viewpoint. Another is that they tend to oversimplify animal nature. even in the lowest animal forms, and encourage categorical interpretations of animal capacities. Distinctions of psychological levels are rejected by those who believe that capacities such as perception and learning exist in all animals. Experience, however, favours the concept of psychological levels to usefully represent transitions from lower to higher psychological stages and validly summarize knowledge of animal relationships, so long as complete discontinuities from level to level are not assumed.

2. Consciousness. — Attributing consciousness to any lower animal and speculating as to how it must feel to be that animal is a popular tendency which has its formal counterparts in speculative philosophy. When we see another individual behaving more or less as we do under comparable conditions. that being, whether man or lower animal, is assumed to have an experience similar to our own. Thus Montaigne, from occurrences such as the starting and barking of dogs in their sleep, thought that brutes must possess the power of imagination. Late in the 19th century when experimental comparative psychology began to develop, the prominence of introspective methods in general psychology encouraged a strong tendency to analogize consciousness. This tendency weakened in time, mainly through objective tendencies succeeding the failure of attempts to use consciousness as a criterion of animal mentality. The chief objections mere, first. that introspection. a method considered low in validity for human psychology, could not be valid for studying lower animals, which lack speech; and, second, that if inferences concerning the subjective aspects of even the simplest mental states in man are held doubtful, little justification exists for applying the method of anthropomorphic analogy to lower animals. In the words of M. F. Washburn (from *The Animal Mind*, 3rd ed., 1926, Macmillan Co.):

> We speak, for example, of an "angry" wasp. Anger, in our own experience, is largely composed of sensations of quickened heart beat, of altered breathing, of muscular tension, of increased blood pressure in the head and face. The circulation of a wasp is fundamentally different from that of any vertebrate. The wasp does not breathe through lungs, it wears its skeleton on the outside, and it has the muscles attached to the inside of the skeleton. What is anger like in the wasp's consciousness? We can form no adequate idea of it.

Comparative psychologists have thus come to favour objective procedures for understanding lower animals, and to mistrust analogies from human states when these stand alone.

A. Critical Points of Change in the Animal Series

1. Protozoans **and** the Concept of **"Simplicity."**—Protozoans frequently are termed the simplest animals. This cannot mean that their activities are few, for H. S. Jennings and F. Alverdes found that the reactions of the ciliate *Paramecium*, for one, are many and varied.

This organism is propelled forward, rotating about its long axis, by the beating of minute, hairlike cilia covering its ovoid body. When stimulated, it pauses momentarily, rotating narrowly or widely before continuing in a new direction, or backs away at an angle varying from acute to obtuse. Specific properties of the stimulus, particularly its intensity. may be critical; for example, weak contact typically elicits slight interruptions of forward movement, strong contact a pronounced backing reaction, and physicochemical properties of stimulation directly influence the extent and the duration of modifications in forward swimming. Although the protoplasmic changes underlying the many variations of ciliary stroke in these different reactions doubtless are biochemically complex, this behaviour is simple in the sense that it can be understood in terms of psychologically simple concepts. for a dictation of response by the physical properties of stimulation is the lowest order of psychological process.

Protozoan behaviour, nevertheless, is adaptive. When Jennings dropped a stream of carmine particles upon the disc of the attached trumpet-shaped ciliate *Stentor*, there occurred a series of reactions from a slight contraction of the oral disc to increasing general contractions which at length broke the animal free from the substratum. Jennings characterized these variable reactions to conditions of repeated stimulation as a series of "trials." More objectively considered, such behaviour is the product of protoplasmic changes forced by repetitive stimulation. At first only the funnel end reacts; then as internal excitation spreads, the stalk contracts progressively toward its attached base. Behaviour thus changes successively through a progression of physiological summations producing new results as they reach more remote localities. Although the notion of .'trials" emphasizes the adaptive aspects of these processes, it misrepresents the acts. which are forced by stimulation rather than arising as attempts to attain expected results.

This case illustrates how, in the simple psychological system of the protozoan, variable reactions widen an animal's adaptation to surrounding conditions. Jennings demonstrated that paramecia collect around a drop of acid in their medium not through direct approaches to the acid but because they first swim readily into the area. then recoil from the acid-deficient border zone on each encounter. Since, in the ciliates, stimulus changes typically interrupt forward swimming differently according to their intensity and other physicochemical properties, the organisms thereby can avoid injurious and approach beneficial agents in their environment. The adaptability of such reactions in unicellular organisms, through the gaining of optimal conditions thereby, stems from the persistence of variable swimming until conditions favour normal locomotion.

The status of behaviour changes in protozoans has been much discussed. As examples, amoebae, repeatedly exposed to bright light, put forth fever pseudopodia before each further reversal of direction; *Paramecium*, introduced successively into a capillary tube from uhich it can escape only by doubling around, reverses with increasing promptness. Some nriters consider such changes equivalent to the "learning" of higher organisms, pointing to graphic records of reduced time or movement in these cases. Others. conversely, stress the limited duration of such changes in protozoans, also that many of them have been duplicated (as by chemical treatment) without putting the organism through "trials." Thus. although F. Bramstedt reported that repeatedly cbmbining light (generally ineffective) with heat (generally avoided) caused *Paramecium* to avoid light in tests, J. B. Best found that light avoidance came about in *Paramecium* through experimental exposures to high temperature alone. Best therefore interpreted Bramstedt's results not as "conditioned responses" but as hysteresis, or a general sensitizing of the protoplasm to the action of one physical agent through the effect of another. Perhaps the most relevant point favouring the latter, simpler interpretation is that, the described changes soon disappear without evidencing any lasting alteration of the species behaviour pattern.

2. Psychological Limitations of Lower Invertebrates.—Significant for determining the psychological level of an animal is its behavioural organization. Perhaps least endowed in these respects are lon multicellular animals such as adult sponges. The sponge is a bottom-attached organism of the colonial type that feeds by filtering organic substances from water drawn through chambers in the body wall. The reactions of sponges are simple, local and sluggish. As G. H. Parker *(The Elementary Nervous System,* 1919) found. sponges lack integration among their parts except that resulting from structural unity and a crude transmission of mechanical impulses through certain primitive cells around the opening to the body cavity, combining sensory and motor properties. Such limitations may have characterized the early ancestors of multicellular animals prior to the appearance of neural tissue.

In the coelenterates, behavioural organization has improved so that a measure of integration exists in activities such as feeding, locomotion and withdrawal from intense stimulation. These gains were found by G. J. Romanes and by Parker to be attributable to a generalized conduction system. with a nerve net. a continuous conduction network permeating the body wall and transmitting impulses from specialized sensory cells to specialized muscle tissue. Activities here, although far better integrated than in sponges, are still relatively sluggish and considerably below the level of cephalopods, for example. One limitation is in the low-grade centralization of the conduction system, which distinctly handicaps behavioural organization.

Activities are better integrated in echinoderms such as starfish and sea urchins. In normal behaviour, local activities are so effectively combined that J. von Uexküll, who investigated the neurophysiology, was led to characterize the echinoderm in action as a "community of reflexes." In a reflex, stimulated sensory cells transmit impulses to association cells in the neural system. which arouse muscular contractions. Thus, the tube feet. small fingerlike muscular structures capable of adhering to the substratum by their terminal sucking discs, when stimulated lightly, bend toward the affected side through one muscular action; when stimulated intensely, they bend away through another action. An appreciable local autonomy is indicated by the fact that the characteristic echinoderm structures, tube feet, pedecillariae (nippers) and spines, when cut from the animal and appropriately mounted. react to stimulation much as before. To be sure, throughout the animal series, reflexlike actions enter into the normal functioning of internal organs (*e.g.,* the vertebrate heartbeat), controlled reflexly in a more or less automatic manner. Even in mammals, reflexes may intervene in general behaviour, as in scratching or sneezing, but with a very different significance than in loner invertebrates. For the latter. the community-of-rcflexes concept has some validity for a behaviour in which somewhat autonomous local activities are combined differently according to the conditions of arousal.

Yet the behaviour of lower invertebrates such as coelenterates and echinoderms is more than a chain-reflex combination of functions, as sense organs and motor structures are linked functionally together by the nerve net. Thus, soon after pedecillariae have caught prey, the tube feet extend, attach and "walk" the object toward the centrally located mouth. which meanwhile everts and folds around the victim. The simplest nerve nets (as in the coelenterate *Hydra)* have a minimal polarization related to the growth gradient. and conduct according to the strength and localization of external stimulation without strict directionality. Such nerve nets exemplify the function of primitive conduction systems, joining local operations without specifying the behaviour pattern. Although in mammals nerve-net functions are visceral and local (as in co-ordinating intestinal activities in digestion), in the lower invertebrates nerve-net correlation is the main agency unifying behaviour.

Echinoderms advance materially in behavioural organization as compared with coelenterates. A more versatile integration of local function exists in the righting response. aroused when the animal is turned on its back. In the inverted starfish, with previous stimulation and handling equalized, two or three rays twist about, and when the ventral surfaces of these rays touch the ground, tube feet progressively closer to the central disc attach. These rays thereby swing the body of the starfish, overbalance and right it. For this reaction to occur. it is necessary that the rays of one side become dominant.

A. R. Moore demonstrated that this organization normally depends on impulses through the nerve ring interconnecting the radial nerves of the five arms. When this nerve ring is sectioned, all rays attach, behaviour is unco-ordinated and righting occurs slowly and abnormally. Through nervous impulses, therefore. the normal unitary behaviour of echinoderms involves the temporary subordination of certain local activities to others dominating general action. The studies of J. E. Smith on the starfish nervous system reveal new complexities, including ganglion-cell mechanisms involved with the nerve net, advancing behavioural organization beyond that of the coelenterates.

An improved organization of behaviour thus enters with the subordination of local, reflexlike functions to wider patterns, as when scratching is inhibited as a dog sees food. The local activities themselves are then not only more elaborate and diversified. as in the reflex-cleaning activities of insects, but also better related to other behaviour. Echinoderm behaviour is more than a community of reflexes; sponge behaviour is far less.

Although echinoderm adaptive activities are impressive, they are sluggishly performed and their level of organization should not be overestimated. Jennings endowed the starfish with the capacity to learn, on the basis of tests in which individuals shortened the time required to right themselves. One pair of rays was prevented from attaching by a glass rod used to disengage the tube feet from the substratum, and after 180 trials these arms attached less readily than before the trials. Although Jennings interpreted this as "habit formation," Moore produced similar results merely by rubbing the tube-foot surfaces of particular rays with a glass rod or treating them nith weak acid. He therefore attributed Jennings' results not to "learning." or changes in central organization through experience, but to injury of restrained arms through continuous friction with the rod which altered sensory and motor function in further trials. These results are therefore equivalent to the impairment of action through motor fatigue. or its reduction through sensory adaptation or injury, not ordinarily classed as learning in higher animals.

B. Cephalization and Centralized Control

1. Functions of a Simple Brain.—Improvements in both organization and capacities of behaviour appear in norms, mollusks and particularly insects. Basic advances are illustrated in a simple form in the earthworm Whereas echinoderms are radially structured, and any of the body sections can lead in locomotion or other activities according to circumstances. worms have an anterior specialized end, which is not only the most sensitive and mobile of all body sections but also the dominant one by virtue of a superior ganglionic centre or brain. Cephalization, or head dominance, improves organization basically, nidens the range of environment and action. and carries behavioural organization beyond the conditions prevailing in protozoans. coelenterates and echinoderms. The significance of specialized head receptors and a brain for efficient behaviour in a marine norm is indicated. after the brain has been destroyed, by irregular crawling about, by turning much more clumsily on contact and burroning less readily than a normal worm.

The animal after operation cannot extend from its burrow (on chemical stimulation) and seize prey as does the normal individual. Removal of the worm's brain, although not preventing normal reactions altogether, materially reduces their directness and precision. This is therefore a primitive type of brain, a collector and a transmitter of impulses from the most sensitive parts of the organism, presumably also an amplifier, but not a major organizing centre. The brain of insects, in contrast, is an indispensable organizing centre. Although a bee or ant with its brain destroyed may stagger about for a time before dying, with a degree of locomotor coordination, only scattered reflex acts such as stinging occur and the complex normal repertory (*e.g.,* foraging, building) is gone.

2. Advances in Orientation. — Regulation of locomotion and way finding under changing external stimulation improves in worms, mollusks and arthropods over its status in lower invertebrates. J. Loeb emphasized that the evolution of a specialized anterior and bilateral symmetry opens the way for new patterns of orientation in space. These improvements admit more appropriate changes in adjustment to external stimulation, as when an octopus turns toward the side on which a crab is seen but does not pursue if the object moves too swiftly. At this stage the crude energic properties of stimulation are dominant, as when a worm or snail approaches the source of a weak chemical but withdraws from the source of an intense stimulus, with variable behaviour at intermediate concentrations. The directive effect of stimuli of different intensity acting on receptors of the opposite sides of the body is shown by experiments in which a fly with its right eye covered turns toward the right under strong light but toward the left under weak light.

Progress in the organization and variability of orientation is indicated from the Norms to insects, depending on the complexity and specialization not only of receptors but also of the central nervous system. The octopus, for example, has eyes much better fitted than those of marine worms for general vision, with accommodation to distance, and can inhibit its dash at a crab until within range. Social insects such as ants and bees have compound eyes, admitting versatile reactions to visual movements as well as movement with reference to changing visual stimuli. Although the evolution of orientation in space involves receptor specializations, advances in this capacity are especially correlated with the nervous system. Operative longitudinal sectioning of the brain introduces progressive impairments in the orientation of animals from worms to insects. Z. Y. Young demonstrated that the octopus, through experience, can master conditioned responses to a crab, or to visual forms experienced with food. In such functions the octopus, far superior to worms, loses correspondingly much more through brain operations. Although in the lower'invertebrates quantitative aspects of stimulation such as intensity, size and rate of change basically control the timing and precision of orientation, in the cephalopods and insects, as compared with the worms, the patterns not only become more complex but also more changeable according to experience.

3. Simple Learned Modifications. — Clear evidence for learning appears first in the worms, in which conditioned responses have been demonstrated. H. B. Hovey found that, although light ordinarily keeps the marine flatworm *Leptoplana* active, presenting a light together with head contact (which stops movement) trained the worm within 20 five-minute periods to stop moving in light. Comparably, M. Copeland conditioned the marine worm *Nereis* to emerge from a tube in response to iight or to dark, whichever condition had been paired with meat juice in training. A more complex habit was acquired by earthworms in Yerkes' experiment, in which turning to the left at a T junction led to electric shock, to the right into a dark box. Within 160 trials some of the worms regularly turned right on reaching the junction. This habit does not depend on specific sensory or muscular changes; when L. Heck reversed the electrodes and dark box after the habit was learned, worms which required more than 120 trials to acquire the right turn now reversed it within 75 trials. Such modifications indicate a basis in central nervous organization rather than in peripheral function. No learning comparable to this adjustment in worms has been demonstrated in coelenterates or echinoderms.

The organization of behaviour is greatly enhanced by a capacity for learning. Worms, through simple learned changes, can alter their normal activities, though not as much as higher invertebrates. In learning, illustrated by the conditioned response. through experience a specific reaction is given to a stimulus previously incapable of eliciting such behaviour. In Copeland's experiment, light (the conditioned stimulus) initially did not bring the worm from its tube. Meat juice (the unconditioned stimulus) mas effective, however, and pairing these two stimuli brought for light a new control over reactions. In the worm's T-maze behaviour, through comparable changes, stimuli near the junction control the right-turning reaction, rendering contact with the electrodes unnecessary. An adequate basis for such changes is afforded by a central nervous system with ganglionic centres and interconnections admitting appropriate new sensory-motor organizations. The mere presence of ganglion cells is not enough, for the starfish despite such equipment seems incapable of true learning. In arthropods, neural evolution admits further advances in the learning capacity. See also NEUROLOGY, COMPARATIVE.

III. EVOLUTION OF BEHAVIOUR

1. Behaviour and the Processes of Evolution. — Modern science interprets behavioural differences in animals, from protozoans to man. as the outcome of long and complex evolutionary processes. The role of behaviour in evolution is by no means obvious, however, as inferences from fossils must be validated by evidence on the relationships of structure and behaviour in existing organisms and these, rather than forming a linear series, represent different branches of a complex related system of which many sections have vanished. Also, the relations of structure and behaviour not only resist unraveling, but seem to have very different properties in the principal types of existing animals. Despite these and other obstacles, behaviour has clearly evolved.

There is little question that behaviour has played a critical and major role in organic evolution. Efficiency in widely different activities, from foraging to defense and shelter getting, has much bearing on the success of reproductive processes and hence on species survival. In many ways, behaviour must have influenced intimately the selective processes underlying evolution.

The initiatory mechanism for evolutionary change, biologists conclude, involved mutations in the chromosomes, effected through the action of radiation on the organism through chemical, mechanical or other extrinsic agencies. Mutations (see EVOLUTION. ORGANIC) may have involved any aspect of structure in the organism, thereby altering behaviour in diverse ways from the specific to the general. Widespread effects of structural mutations on behaviour probably were commoner in higher animals such as mammals, with more complex interrelationships between structures and functional systems, than in phyletically primitive organisms such as echinoderms. As further mutations affected existing structures, modifying function from its previous basis, behaviour may have changed in different directions from the patterns of the principal ancestral types.

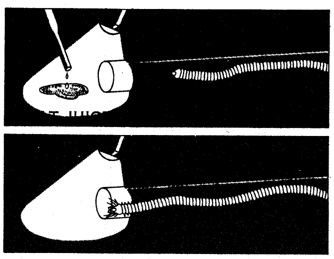

FIG. 1.—COPELAND'S STUDY OF CONDITIONING IN THE MARINE WORM NEREIS

At first, light is ineffective, but after having been combined several times with meat juice, light alone brings the worm from the tube

According to conditions, success in behaviour affecting reproduction must depend on what responses are made both in everyday existence and in critical or marginal situations. Because behaviour results from the interactions of functional systems (sensory, neural, secretory, motor and others), a mutation affecting structure locally can often influence functions in the organism a a whole. For example, a more sensitive eyespot may improve directed responses to light so that orientation and foraging become more efficient, and adding a lens to the system widens the range and efficiency of adaptation still more.

Structural changes through mutations therefore admit behavioura! specializations giving surviving species distinctive habitats or "niches." Within any period, the relative success of behaviour affecting reproduction determines which strains and species can adapt to appropriate niches and survive and which types perish through mutations leading to detrimental or inefficient behaviour. As accumulating mutations favour diversity, successful animal types tend to expand into lineages differing increasingly in their adaptive patterns. The survival of a species then depends on its possessing a set of genes contributing under appropriate conditions to the development of a behaviour pattern adequate to maintain the reproducing population in its species niche.

2. Evolution, Structure and **Behaviour.**—Structure, physiology and behaviour are intimately related in all animals, and the principles of evolution therefore apply to all three. The course of evolution does not reinstate earlier conditions, but transforms and adds to them in new phyletic settings. The fate of species and species relationships in evolution depends primarily on the relative efficacy of structures rather than on purposive considerations, which involve a basic misconception of species-typical acts and their dependence on structures. Thus a dragonfly which ordinarily lays her eggs on water may lay them on a freshly tarred roof, not by mistake, but because she responds to the sensory characteristics of any shimmering surface.

At early stages in evolution, structure bears rather directly on behaviour, favouring stereotyped patterns. Invertebrate activities thus are dominated by the functional characteristics of specific sensory, motor or other equipment or of particular physiological conditions. These relationships can be misunderstood, particularly when they are complex. Thus J. H Fabre believed in an "inflexibility of instincts" in insects. attributed to inherited nervous patterns, arguing from cases in which performance presumably could occur only once, as he reported the callow mason bee able to escape only once from the paper cell of pupation. But L. Verlaine found that in this case the critical matter was strength of the jaws, for when the cell wall was not too tough, the bee could escape more than once even on the first day. Dependence of behaviour on particular organic conditions is ilicstrated by the fact that spiders can repair their torn nebs or not according to the supply of secretion in their different silk glands. As we shall see. structure is much less directly related to behaviour in mammals.

Throughout evolution, and particularly at times of crisis and other turning points, there evidently was a premium on mutations increasing the complexity and functional relationships of structures favouring nider and more versatile environmental adjustments. Significant sequences thus are indicated, as when local specialization of the skin of early vertebrates added a lens to the primitive eye, increasing the efficiency of space perception, which increased still further when specializations in retina, eye muscles and brain admitted binocular vision and an augmented depth effect.

New adaptive levels were achieved in evolution not just through added complexity of existing structures affecting function but through qualitative changes as well. In a succession of adaptive radiations from the acellular to the multicellular, and from the primitive vertebrate ancestor to the reptilelike mammalian ancestor. basic changes occurred in the conduction system with important consequences for behavioural organization and for new behaviour. The result presumably was not so much that mechanisms of lower levels were repeated on higher levels as that they were modified in relation to the new context. Accordingly, it is probable that in vertebrate evolution from fish to man the "old brain" was not merely retained in a more complex form, but was progressively repatterned correlatively with increasing cortex In mammals, as compared with invertebrates, not only are structural mechanisms much more versatile in their functional relationships but limitations of action by specific structures relax increasingly, widening the breadth and plasticity of behaviour in its bearing on species adaptation.

3. Ancestry and Behavioural Resemblance. — In the animal series, behaviou: patterns tend to exhibit similarities in proportion to the degree of phylogenetic relationship and dissimilarities in inverse proportion. All animals are similar in the general sense that behaviour is adaptive and that each type, in characteristic ways, behaves so as generally to attain beneficial and avoid injurious conditions. This similarity depends on the fact that all species have mechanisms favouring approach to stimuli of weak intensity, withdrawal from stimuli of strong intensity. In phyla from bacteria to man, however, these reactions differ in their structural bases and in their ontogeny.

In principle, existing animals represent parts not so much of a linear series as of a multibranched system, hence discontinuities as well as continuities prevail among them. Body form exerts a basic influence on general type of behaviour, as in the head-first progression and bilaterality in orientation of all bilaterally symmetrical animals. Superimposed on such general patterns are disparities among groups from phyla to species, roughly proportional to ancestral affinities.

Striking differences among the specific adaptive patterns of surviving phyla show that the principle of continuity in evolution must be qualified in view of different branch lines in ancestry. For example, arguments, on grounds of evolutionary continuity, that a learning capacity exists in protozoans analogous to that of mammals oppose the fact that since unicellular and multicellular animals diverged in remote geologic times they have differed progressively, and the advent of mechanisms basic to the learning capacities of multicellular organisms may well have postdated the common ancestry.

Because structure may influence function very differently on different animal levels, both in the relative directness and in the nature of its effect, the principle of structural homology (*i.e.,* basis in common ancestry) cannot be generalized directly to behaviour. A different reservation concerns resemblances through convergence, or adaptations evolving independently, whereby similar niches are occupied or similar activities arise. Owls and bats, for example, have analogous adaptations for flight and the nocturnal capture of prey; termites and ants have similar patterns in nesting and other social activities.

0. Heinroth, particularly. and later K. Lorenz stressed behavioural characteristics as an additional clue to evolutionary relationships. Thus similar activities in closely related species often exhibit gradations evidently corresponding to the relative recency of the species. For example, in the mating patterns of empid flies prior to coupling, in one species the male presents to the female a freshly killed insect, in another species he presents the booty within a cocoon he has spun and in still another he presents only an empty cocoon. The last pattern is presumably the most recent.

Striking similarities, not convergences, are often found between related species living in widely separated habitats, as, for example. both English and South American thrushes line their nests with mud Comparisons are complicated, however, in the similar patterns of related species which are sympatric (*i.e.,* live in the same habitat) by the rise of specialized differences through competitive processes influencing natural selection. Thus two closely related species of army ants in the genus Eciton, sharing the same tropical forest habitat. differ strikingly in the patterns of their predatory raids. with colonies of one species pillaging in large swarms, colonies of the other in complex systems of columns. These species also differ in the booty they capture, with the first taking mainly hard-bodied arthropods, the second soft-bodied brood of various insects, and significant differences are also found in the properties of their cyclic nomadic acrivities.

4. Phylogeny, Ontogeny and "Instinct." — The traditional view that ontogeny recapitulates phylogeny, questioned for structure by G. R. de Beer and others, is even more doubtful for behaviour. What individuals in each species inherit are their chromosomes, influencing ontogeny in species-characteristic ways provided development occurs under species-typical conditions Under other extrinsic conditions, different phenotypes (developmental forms) appear, diverging from the species-typical pattern not only structurally but often also behaviourally. Species-characteristic behaviour patterns, considered in relation to species genetics, constitute the problem of "instinctive behaviour."

A useful way of stating this problem is to say that although heredity influences all behaviour in all animals, its influence is more direct in some animals (evidently the more primitive) than in others and may be very different on different phyletic levels. This interpretation contradicts the traditional view that the "instinctive" and the "learned" may be clearly distinguished in animal behaviour, with the latter increasingly prominent in higher animals. It is more likely that behaviour evolves through new and increasingly complex reorientations, with the old rebuilt and extended in terms of the new, than through the replacement of the "innate" by the "learned."

On each phyletic level, striking differences appear in the relationships between genes, species-typical structures and physiology, situational conditions at successive developmental stages, and the predominance of species-typical behaviour as against genotypical patterns. In the sense that the activities of invertebrate animals are more directly dominated by structure than are those of mammals, invertebrate behaviour is more instinctive. Accordingly, agencies mediating among genes, organic mechanisms and behaviour are fewer, with less numerous and less involved interrelationships, in protozoans and sponges than in insects, with insects in turn below rodents and rodents below mammals. In this succession, the role of heredity in behavioural development is not decreased, but rather becomes increasingly indirect and plastic as further and more diverse intervening variables are added. Consequently, contrasting behaviour patterns arise which are not only increasingly complex but also qualitatively progressive. For understanding these differences, the classical nature-nurture dichotomy is not only too simple but also misleading. Psychological superiority must have emerged in higher animals not through less nature and more nurture but through increasingly complex and qualitatively new properties of nature and nurture, inextricably interrelated in development in ways characteristic of the level.

As an example, function varies strikingly with age both in invertebrates and in mammals. In honeybees, G. Rosch attributed such differences to growth-conditioned organic changes. Young workers emerging from pupation tend to specialize in feeding larvae, but when the salivary glands atrophy at about the 15th day the main function becomes comb construction. The wax glands seem influential in the latter work, as building drops off sharply when these glands end their active phase at about the 25th day. Foraging outside the hive then typically begins. In mammals, however, ontogenetic changes in function usually cannot be correlated readily with specific structural changes.

It is therefore probable that the relationship of behaviour to survival, always important in evolution, is very different on various phyletic levels. As it is realized that assumptions of innateness in apposition to the acquired can explain no activity, increasing emphasis is placed upon the need for analytical investigation.

Although geneticists often state that the genes impose species-characteristic limitations on development, even after the mid-20th century this generalization lacked proof for behaviour. Actually, the influences of the genes are not direct or exclusive in determining behaviour in any animal but are exerted through diverse interrelationships between organism and developmental medium. The gaps between genes and somatic characters are great; those between genes and behaviour, which are far greater, can be bridged only through investigations directed at disclosing the intervening variables and their interrelationships.

In all phyla, the functioning of organic factors underlying the rise of instinctive activities requires a developmental situation typical of the species. Frequently, certain conditions of stimulation (*i.e.,* experiences) can be detected as critical for the development of the species-typical pattern. Thus J. E. Harker found that the normal day-night activity rhythm of the adult May fly does not appear when developing individuals have been subjected to continuous light or darkness, but only when eggs or larvae have been exposed to at least one daily light-dark cycle. Comparably, species patterns such as the spinning of characteristic cocoons by caterpillars result from a close relationship between structural growth and features of the developmental situation. G. van der Kloot and C. Williams found that if a Cecropia larva cannot attain an upright posture against a support such as a twig, no cocoon is spun. Instead, the thread is arranged, as, for example, a cone around a peg or a sheet lining a balloon, according to prevalent physical conditions. In the parasitic ichneumon fly *Nemeritis,* responses to the host upon which eggs are laid are influenced by larval experience, as such responses can be modified by changing the type of insect on which the individual feeds as a larva. indicating the possibility that conditioning influences insect development, although in a secondary and obscure role, is evidence that the act of following odour trails arises in many ants on the basis of individual habituation to nest chemicals beginning as early as the period of larval feeding.

In lower vertebrates, species-typical behaviour such as mating and nesting have the characteristic of stereotypy, as in insects, but with a different aspect relevant to the level. The claim of Lorenz and others that certain critical acts called "instinctive movements" arise through innate neural patterns determined isomorphically by the genes lacks effective support. Rather, Z. Y. Kuo, from his significant studies on pecking in chicks, concluded that intimate relationships exist between factors in growth and in the extrinsic situation. Comparably, D. Lehrman found that adult ringdoves experimentally injected with the hormone prolactin did not feed their young. Instead they underwent organic changes such as the production of "pigeon's milk" by the crop and an increased thoracic sensitivity, contributive to action although not specific action. The characteristic pattern of feeding the young did not occur unless the adult had experienced a sequence of reciprocal stimulative exchanges with nestlings. Therefore, although such patterns are species typical and involve genetic influences, they are not predetermined neurally, but result from a development in which organic processes interact intimately with situational factors. In vertebrates, the development of behaviour involves more diverse and plastic relationships between organic and extrinsic factors than in any of the invertebrates.

5. Ontogeny of Vertebrate **Behaviour.**—Vertebrate behaviour patterns characteristically exhibit essential differences from those of invertebrates, evidently due not only to organic differences basic to perception and motivation but also to the potentialities of a nervous system with a fundamentally different central pattern. Although certain functions, such as locomotion and equilibrium, are well developed even in fishes, in mammals these too may vary according to the conditions of individual development.

6. "Maturation."—The concept of maturation, emphasizing the role in behavioural development of organic changes through growth and differentiation, has been focused by many upon the nervous system. In the study of G. E. Coghill on the salamander *Ambystoma,* successive stages in action were observed with correlated histological changes in the nervous system. In this tailed amphibian, an early nonmotile stage was identified when, with sensory surfaces still unconnected nervously with muscles, the only action was an anterior bending to the side of direct muscular stimulation. At about 30 hours of age, the head bent away from the stimulated side, paralleling the appearance of crossed nerve connections from the skin of the head to muscles on the opposite side. Then S movements of the body and, later, rapid swimming movements were correlated with further growth changes in the nerve tube. Coghill concluded that in the development of swimming in this vertebrate, the status of neural growth is critical. This conclusion found support in the research of L. Carmichael, who immobilized salamander embryos with Chloretone during the period in which swimming normally appears, yet found that when later released from the drug, these animals apparently swam as well as undrugged normal specimens. The conclusion that organic neural growth alone is sufficient for development of normal swimming in this amphibian is tentative, however, in view of evidence obtained by A. Fromme. His results indicate that opportunities for action and stimulation at certain stages in development also contribute to the swimming pattern, since embryos immobilized then, when later released from the drug, swam less well than normals.

Maturation, as defined; seems basic to the behavioural development of lower vertebrates from fishes to birds. The concept needs revision, however, in view of evidence cited below, bearing on the interaction of processes within the developing organism and between organism and external situation, characteristic of growth stage but extending beyond the specific bounds of growth and differentiation.

Although the development of behaviour patterns is often held to depend on an innate central neural control, this question is still controversial. Certainly. neural growth limits behaviour at any stage (*e.g.*, the salamander cannot bend its head until crossed neural connections have grown). Other factors also are involved. The characteristic head lunge of lower vertebrates probably requires sensory maturation as well as neural maturation. Several such mechanisms evidently contribute to the adult lunging response, which, as in many fishes. amphibians and birds. occurs on weak stimulation. Thus the characteristic lunge is elicited by objects below a certain size if these are in motion at not too rapid a rate. Presumably, in lower vertebrates, tissue growth promotes adult patterns such as feeding and mating in distrete mays as through sensory-threshold factors in visual-movement responses. To understand the ontogeny of behaviour, however, the study must be broadened. Although, for example, gonadal hormones are basic to the appearance of mating behaviour in all vertebrates, evidence suggests that they may function in diverse ways beyond their possible neural effects, as by increasing local sensitivity.

7. Factors in Organization. — Against the traditional predeterministic view that instinctive behaviour is organized neurally on a native basis, the alternative epigenetic view holds that such behaviour develops through co-ordinations of many organic resources in the organism interacting with the developmental medium. Experience, definable as the effect of stimulation on the organism, participates in all development, and in diverse forms, including learning.

From the same genotype (see HEREDITY), variations in the conditions of development may result in phenotypes differing behaviourally as well as organically. Under different temperature conditions in development, M. H. Harnly obtained fruit flies which were flightless, limited and eccentric, or species typical in flight; and K. Moore in a comparable experiment obtained rats differing in both body form and learning ability.

For the organization of instinctive behaviour, evidence for invertebrates and for vertebrates shows that species-typical factors both of maturation and of experience in the standard developmental situation are essential. Certain poecilid fishes, raised apart from species mates in neutral surroundings in which, for example, they never saw their own reflections from the water film or other surfaces, scored much lower than normals in mating tests at maturity. That the role of experience may involve learning in amphibian larvae is suggested by the fact that N. L. Munn found the early swimming stages of certain amphibians capable both of being conditioned and of learning a simple T-maze habit.

Although the roles of maturation and of experience are fused in all behavioural development and resist experimental separation, certain generalizations are possible. Thus organic factors seem relatively more determinative of behavioural development in lower vertebrates than in mammals. In the former, accordingly, naive responses to stimulation are less readily modified through experience than in the latter. The lizard Lacerte, studied by H. Ehrenhardt, gave its forward (feeding) lunge most readily to the movement of figures such as circles with even outlines, least readily to figures such as crosses with irregular outlines. When a circle was presented with a quinine-treated meal worm, a cross with an untreated meal worm, initial responses were virtually unmodified aithin 850 trials. In comparison, mammals such as rats normally change their initial responses readily according to the conditions of training. In lower vertebrates, discrete properties of the stimulus such as movement. size and brightness characteristically dominate behaviour, evidently as a result particularly of correlated factors in sense organs and nervous system. N. Tinbergen and others use the term "releasers" for stimuli which typically elicit certain types of response; however, this concept has been criticized as too simple and as obscuring ontogenetic processes. For example, the gaping (mouth-opening) response of nestlings in passerine species such as thrushes is first aroused by mechanical stimulation, as by vibrations of the nest, later by the movement of any object (*e.g.*, a black disk) of sufficient size presented above the nest edge. The facts suggest that, through conditioning, naïve responses (*e.g.*, to nest vibration) become attached to specific features of the external situation, such as first the parent bird's bulk at the nest edge, then the parent's head. The organization of such responses in birds is a complex matter in which experience may figure in various ways.

In this sense, birds have a far more extensive and complex repertory of instinctive, organically determined activities than have mammals. In the organization of activities such as migration, the role of maturation seems predominant. that of experience secondary. The investigations of W. Rowan and others show that the northward spring migration of birds such as juncos is set off through the excitatory effect of internal changes (*e.g.*, pituitary and gonadal secretions) caused by a progressive increase in daily illumination. How these factors relate to those influencing the direction and the course of migration (*e.g.*, temperature gradient; angle of the sun) requires further investigation.

For activities such as homing, in contrast, the influence of organic factors, although undoubted, is difficult to discern; the role of experience, clearer. Whereas the studies of E. Schiiz and others show that some species on release in strange territory may be oriented as in migration, homing in birds such as the pigeon is known to be strongly dependent on experience with landmarks and topography.

The organization of species-typical activities such as pecking in fowl is known to have a complex individual history, starting in the egg. Kuo showed that, with maturation in sensory, nervous and muscular tissue, the embryo's head lunge to touch modifies under the influence of self-stimulation through its own actions. Crude conditioning processes are evident before hatching. Shortly after hatching, the significant activities of the head lunge, bill opening and closing and swallowing are crude and essentially separate. Head lunging occurs, however, on the appearance of small. moving objects and (limited by maturational properties such as muscular strength) within a few days an organized and discriminative pecking at edible objects comes about. Thus it appears that whereas maturation dominates the development of individual components of pecking such as the head lunge, experience factors are required even for the early appearance of these components and are heavily involved in organizing the eventual efficient act. The influence of maturation is emphasized by the fact that, when chicks are kept in the dark and hand-fed for varying times after hatching, the process of improvement leads sooner to efficient pecking than in normal chicks; *i.e.*, experience is more advantageous when strength and other organic factors have advanced. The influence of experience is emphasized by the fact that chicks fed artificially for longer than two weeks after hatching learn only with great difficulty to peck at food, since they have learned to feed otherwise than through pecking. The greater predominance of stereotypy in lower vertebrates than in birds seems attributable to the greater influence of experience in the behavioural development of the latter.

8. Nervous Systems and **Behaviour.**—An important approach to understanding psychological differences between lower animals and mammals is through the role of the nervous system. Although in worms the appearance of a dominant brain permits definite advances over the radial pattern of the starfish, this centre is of a low order, mainly a transmitter rather than an organizer. Insects, much advanced in organization, still reflect a strong influence of sensory and other local components in behaviour.

As comparative neurologists have shown, the anterior nervous system of lower vertebrates is not only more sparsely supplied with interconnections than is that of mammals, but the brain exerts only a rudimentary control over lower centres and is not equipped to influence general behaviour in terms of numerous changing sensory factors in a situation. The olfactory system, dominating the forebrain, and the visual system, in the midbrain, are best equipped for integrations within the status of reflexes. Such characteristics go far toward accounting for the characteristic stereotypy of behaviour in these animals and for their shortcomings in modifying naïve responses based on specific stimulus aspects such as intensity.

With the appearance of cerebral cortex, correlation among the principal centres of the vertebrate brain improves greatly. Cortex, although restricted in reptiles to a small area in the upper forebrain and obscure in birds, covers the entire forebrain in mammals. Cortex interconnects the principal centres of the nervous system both directly and indirectly, admitting new types of organization which override specific sensory effects and local activities according to the animal's experience. The evolution of cortex, particularly. admits for mammals their psychological superiority.

IV. PSYCHOLOGICAL SUPERIORITY OF MAMMALS

In mammals, from marsupials to man, the psychological limitations of lower animals are overcome progressively. Through more versatile capacities and better organization of behaviour, the world of the individual increases in content and in variety. The general superiority of mammals shows itself particularly in their resources for developing new behaviour. For example, reptiles, although they can be tamed so that they become docile, do not form attachments or take the initiative in play with the person who satisfies their needs, as do mammals.

A. Development of Behaviour in Mammals

1. Maturation. — Correlated with the longer developmental period typical in mammals, their resources admit a greater weight for experience and a greater variety of behaviour appropriate to changing circumstances than in inframammalian animals. In general, higher mammals require a longer time than lower to develop. Accordingly, whole-body adaptive behaviour appears earlier in lower mammals, which often fend for themselves sooner after birth than the young of higher mammals. For example, the young opossum, just 12–15 days after development begins, crawls from the mother's cloaca over her abdomen to the pouch, moving along by a reflex hair-clutching and forelimb progression. At 60 days it leaves its nipple in the pouch on occasional excursions to the outside, where it runs and climbs about. The young of ungulates, such as the goat, are capable of upright progression shortly after birth; the human infant, in contrast, is incapable of self-progression until it crawls at about eight months of age.

Most mammals are relatively more immature at birth than the young of lower vertebrates, and hence cope less effectively with their environments. Young marine turtles, on emerging from the egg, crawl toward the moonlit sea (in response to reflected light). Newborn kittens and puppies, however, accomplish only a highly variable, nonvisual locomotion to the mother, and in specific activities have little more than crude sucking and righting responses. These mammals improve very slowly from birth in orientation and locomotion. At one week (before vision enters) the kitten returns slowly and inefficiently to the nest when set down nearby, mainly requiring tactual guidance. Although in the appearance of crawling in kittens and walking in human infants maturation is basic, limiting the rate of development somewhat as in lower vertebrates, in mammals the factors of experience have increasing weight.

Man's adult behaviour pattern appears later than that of any other animal and is the least specifically influenced by maturation. When a chimpanzee and a human infant were raised from birth in the same household, with similar treatment, the advantages of more rapid maturation were at first all in the chimpanzee's favour. At five months it exceeded the average one-year performance level of human infants in climbing, manipulating objects and responding to companions. Although the chimpanzee's motor superiority continued, soon the human infant excelled in other respects. At one year, in acquiring word sounds, object meanings and social meanings, the human infant far surpassed the chimpanzee. Man's psychological superiority over other animals rests on his greater capacity for profiting from experience and not simply on his longer infancy and childhood.

2. Genetics of Behadour. — Although genetic factors underlie ail animal activities, heredity seems to influence behaviour more directly in the lower mammals than in the higher. Sexual patterns, for example, are less stereotyped in chimpanzees than in rats, as a result of evolutionary advances in the primate cortex which admit new relationships between structure and behaviour and make experience and learning more influential.

The study of correlations between genetics and behaviour, in psychogenetics, offers techniques for comparison. For example, the trait "wildness" appears to be dominant in the offspring when the gray Norway rat is crossed with the docile albino rat, and the behaviour of future generations as well as that of backcrosses of the hybrids indicates the opposed influence of different gene combinations (see Genetics). With this knowledge the organic basis of such behavioural differences can be studied in different strains. The increasing difficulty, as maturity approaches, of taming the young of genetically "wild" strains of rats, much greater than in domesticated strains, indicates that glandular secretions contribute to strain differences of this type. Supporting evidence is found in the fact that the adrenal glands of wild strains are larger than those of domesticated strains.

3. Influence of Experience. — Traditionally, species-typical activities appearing soon after birth, in isolated animals, have been considered inborn. But experience is not excluded thereby, as conditioned-response learning is demonstrated prior to hatching in certain birds and before birth in certain mammals, including man. Furthermore, under equivalent developmental conditions, experience may influence different individuals similarly and its role therefore may be overlooked. For example, Kuo found that the appearance of mouse-hunting behaviour in kittens depends upon a situation in which organic equipment is utilized. The kitten's first pounce is not "hunting," but darting toward a moving object. This response resembles the forward lunge of certain lower vertebrates, except that in the kitten the new stimuli that enter and the patterns that eventuate are largely matters of experience. In the typical feline environment, pouncing soon leads to tasting blood, since the kitten inherits sharp claws capable of piercing the mouse's skin; tasting blood stimulates biting, and with experience the kitten becomes a mouser. Kuo obtained different results by varying developmental conditions. By always shocking kittens with mice present, he displaced pouncing with a fear reaction; by raising kittens with mice, pouncing was inhibited and social companionship developed. Thus, although certain species-typical equipment favours pouncing, drawing blood and other events essential for mousing, mouse killing as a pattern requires certain interactions of organism and developmental field most likely to occur in the normal species environment.

4. Drive and Motivation. — Certain classes of behaviour once called instincts are related by modern psychology to drives. Drive is a term for physiological processes energizing individual behaviour. Examples are the thirst, sex and hunger drives. Each of these patterns has its basis in physiological processes; for example, the sex drive emanates irom complex conditions centring around glandular secretions, the hunger drive from both gastric processes and changes in blood chemistry. The influencing of changes in general behaviour by internal drive fluctuations has been established experimentally for many different animals. A classical example is G. H. Wang's demonstration of relationship between the ovarian (egg-maturation) cycle and periodic fluctuations of general activity in the iemale rat. Organic examinations showed that oestrous or heat periods recurred at four- to five-day intervals, and at corresponding times striking increases occurred in the daily amount of activity. Wang concluded that the activity rhythm depended on glandular changes incident to oestrus, as it disappeared in mature females after spaying and during pregnancy and was absent in immature females.

Some broad differences exist in the responses of different types of animals to drives. On maturing sexually, invertebrates and lower vertebrates tend to behave in more stereotyped ways than do higher vertebrates. A female solitary wasp of certain species, fertilized and with mature eggs, stirs about and excitedly stings a spider or other characteristic prey when it is encountered; an egg-laden jewel fish is particularly attracted by objects having certain general properties of movement, coloration and size. The effective stimuli are species typical. In contrast, the incentives or stimuli governing the drive-impelled responses of mammals, increasingly broadened and individually more variable than in lower vertebrates. seem related to superior capacities for learning through experience.

A related difference exists between lower and higher mammals in the ability to satisiy or change a drive tension through conditions related only indirectly to the original incentive. Thus a pat on the head stimulates a properly trained dog to intensive efforts but affects a rat much less. Chimpanzees can learn to work for poker chips which are then inserted into a food-delivery slot, whereby an inedible object acquires a measure of drive satisfaction for the animal. A comparable mammalian superiority in motivated behaviour is seen in the individual's ability to initiate the secondary stimulus, as when a dog "ready for a walk" brings out his leash. Such behaviour has not been established reliably in reptiles or other lower vertebrates. (See also INSTINCT; MOTIVATION; PSYCHOLOGY, PHYSIOLOGICAL).

5. Sensitivity and **Perception.**—Von Uexkull and others have undertaken to describe the world of lower animals in terms of what is known about sensitivity. Thus one might speculate that for the honeybee in flight a flower patch is a flickering mosaic of colour with a glimmer of ultraviolet here and there; for the bird skimming low the patch has a distinct colour geometry without ultraviolet effects; for the house cat the scene has a washed out, colourless appearance. Such descriptions, from subjective inferences, are in the class of rudimentary speculation.

Only the first step toward understanding an animal's effective environment is accomplished by exploring its sensitivity. The chief problems are: what types of physical effects the animal is equipped to sense, what upper and lower limits (thresholds) hold for the various aspects (*e.g.,* intensity) in vision and other modalities, and nhat the acuity is in each field. In the sensory properties of animals, striking differences are found. Among the insects, the housefly, honeybee and others. although blind to the long nave lengths of light seen by man as red. are visually sensitive to very short rays (the ultraviolet band) not seen by most vertebrates including man. Carnivores such as dogs, cats and rats are insensitive to wave-length differences in light which man sees as colours; whereas bees, many fishes and most diurnal birds and primates have a distinct wave-length sensitivity. Although these animals may not see hues as does man, they have colour vision, since under experimental conditions they can discriminate between wave lengths and between wave lengths and grays of corresponding brightness.

Important differences also are found in the ranges of corresponding types of sensitivity. Most fishes can discriminate among intensities and pitches of sound; many crickets and other insects possess receptors known as chordotonal organs, sensitive to high frequencies of sound; many lower animals react to auditory frequencies above the human limits. The hunter's dog responds to the tone of a whistle near 30.000 cycles per second. soundless to the hunter, whose upper threshold lies below 18.000 cycles.

Striking sensory adaptations, important for orientation, are common. In bats, insect-feeding species and certain others have remarkable aptitudes for flying in the dark, long attributed to tactual sensitivity but found to depend on a keen perception of the bat's own ultrasonic utterances reflected from objects. When D. R. Griffin releasec! bats in a dark room they flew skillfully among wires strung close together, but when hearing mas eliminated by plugging the ears, or when the sounds mere stopped by fastening shut the mouth, the skill disappeared. The work of K. von Frisch shows that honeybees and other arthropods can orient with reference to the plane of polarization of light, a visual capacity still undemonstrated for any vertebrate animal. In primitive vertebrates, such as sharks, olfaction tends to be a highly developed and dominant sensory field; in higher vertebrates, and especially in primates, the dominant field is vision. In most birds, taste is acute but smell is poor; in honeybees and many other insects, olfaction through antenna1 reception is exquisitely acute but taste seems poorer than in man.

An animal's sensory equipment fundamentally influences its way of life. Bats and oilbirds can live in dark cares because of their delicate ultrasonic auditory sensitivity; mammals with keen olfaction can track prey by scent and tend to become night foragers, particularly (as in the cats) when dark adaptation processes favour dim-light vision. In contrast, animals with superior bright-light vision and inferior smell, as the diurnal monkeys, settle into a routine of daytime activity and nighttime sleep. Interesting relationships are often found between the fields of sensitivity and differences in habitat. There are species such as cave fishes living in complete darkness that have poor vision or are blind with tactual and chemical sensitivity highly developed. Comparable inverse relationships between vision and olfaction prevail in many insects. Most diurnal birds have excellent vision but are low in olfaction. Sensory equipment basically defines the limits and the nature of an animal's world.

6. Sensing v. Perceiving.— Sensory data, although indispensable for behaviour, are not the best indicators of an animal's psychological standing. Many birds, for example, approximate man and are far superior to most lower mammals in visual acuity. Yet. in the critical matter of using sensitivity to master object meanings and their relationships, in which sensory factors are secondary, birds are inferior.

An animal's capacity for perception, definable as sensing in terms of meanings, is best judged according to how it deals with objects under varying conditions. The relatively stereotyped responses governing food-getting activities in cold-blooded vertebrates seem best interpreted in terms of "taxis" types of relatively direct stimulus-response relationships (see ANIMAL BEHAVIOUR). For these vertebrates, object-organism relationships evidently depend mainly on specific characteristics, such as intensity and rate of movement, and not object meanings, and feeding depends essentially on what stimuli are adequate in their physical properties to elicit a reflexlike combination of forward lunge and mouth opening. These animals seem to behave far more in terms of seeing than of perceiving.

7. Simplest Perceptual Relationships.— The organic basis of capacities for response to sensory change and for perceiving is evidenced in the lowest vertebrates. Minnows trained by P. Schiller to snap at the movement of a small bar of light presented with food then reacted to the light when it was presented twice within $\frac{1}{20}$ sec. in closely adjacent positions. The fish evidently perceived a movement, somewhat as would a human subject under comparable conditions. Experiencing "apparent movement" thus may be present throughout the vertebrate series. Many psychologists, and especially Gestaltists, consider this class of phenomenon an index of capacity for relationships, basic to perception.

It is probable that such capacities are essential to a meaningful sensing of objects. G. Révész presented chickens with successive pairs of circles, triangles and arcs differing in size, the smaller one of each pair bearing food, thereby training the bird to peck only at the smaller figure in grain-free test pairs. Then two identical arcs were presented, one directly above the other, both with grain. The trained chickens pecked mainly at the upper figure, apparently seeing it as smaller than the lower arc, thus evidencing an illusion of size similar to that of human subjects under comparable conditions. Correspondingly, chickens trained by Kohler to peck at the brighter member of a training pair pecked mainly at the brighter card in new test pairs of different brightnesses. Similar results were obtained in equivalent tests of a chimpanzee and a human child, except that the training was more quickly accomplished.

Thus widely different vertebrates have a capacity for reacting to successive visual situations as unities in which the members are bound together reciprocally. An organization of this type may be termed a relationship, although in the simplest cases the unity seems due to processes on a physiological level rather than to qualitatively superior functions involving intelligence.

8. Contrasts in Perceptual Capacity.— Social insects normally accept members of their own colony but attack nestmates bearing the odour of another colony. That the perceptual capacities of lower vertebrates are comparably low is indicated in tests with species mates. Male Siamese fighting fish. for example, respond similarly to femsles and to artificial objects such as clay plugs, unless size is too great or movement too rapid, whereupon

the artifact is attacked as are other males. Hence the male's responses to species mates evidently depend on physical characteristics but not meanings such as "mate" or "enemy." In pigeons, kittiwakes and numerous other birds, a parent which feeds young regularly on the nest will neglect them when they are off the nest even if close by. Evidently the young have a very simple meaning for the mother bird, rigidly dependent on the nest locus (at least in the early stages of incubation) and much below the level of maternal perception in monkeys, in which mothers feed and protect their young under a variety of conditions.

Sensory Discrimination.—Critical for evaluating perceptual levels is the extent to which experience brings more versatile adjustments to objects under changing conditions. The first step is sensory discrimination, a learning to distinguish sensory differences and respond appropriately. As far as sensitivity permits, stimulative discriminations in every sensory field can be learned with appropriate responses by insects and other higher invertebrates, and by vertebrates from fish to man. The learning is relatively simple for a mammal, which characteristically requires fewer trials than lower vertebrates; the critical matter is nhether the animal is sensitive and reactive to stimulative differences under the conditions. Thus dogs discriminate tones more readily than do rats because of better reception as well as superior sound localization and learning capacities. A hunting dog must first discriminate among types of animal scents (*e.g.,* raccoons and rabbits), then he must learn to set himself for the one aspect of scent emphasized by his master.

Complex *Discriminations.*—The next degree is mastering complex discriminations, forming schemata in which successful response under experimental conditions depends on two or more characteristics of the positive pattern (*e.g.,* brightness and size), two or more characteristics of the negative pattern, or on relationships between the positive and negative patterns. Correspondingly, the tracking dog at this stage distinguishes the "correct" scent from similar "false" scents depending on different combinations of characteristics.

Conditional Discrimination.—A qualitative advancement is that of conditional discrimination, which demands intelligence well beyond that required for simple discriminations and schemata. This step is not indicated for reptiles and birds, and may exceed the capacities of rodents. Problems requiring conditional discrimination arise when similar schemata are encountered in many situations with important differences in their relevance. For example, not all pet dogs can learn that unless the master also wears his hat he does not necessarily intend to go walking when he holds the leash. When an animal can give the critical response to the essentials of related schemata without mistakes due to conflicting details. he has mastered a set of contingent relationships termed an abstraction. For example, white rats after long training can jump to a triangle, however it stands, rather than to a circle; whereas chickens, having learned to differentiate these two figures in set positions, are lost if the triangle is tilted.

For success in conditional discrimination, aspects such as complexity in the combination of critical details from experience to experience are crucial. Discerning patterns in varying circumstances, in which confusing differences may obscure key details, is an accomplishment in the discrimination of relationships excluded to all but higher mammals. In contrast to the rat, whose limits for abstraction are soon reached, chimpanzees progress well in matching-from-sample tests, as N. Kohts found, and can single out a schema such as a triangle even when it is presented with others matching it in details such as colour and size. Monkeys, although less apt pupils than chimpanzees, as H Harlow has shonn can advance from simple discriminations of objects to very complex discriminations involving a number of characteristics.

Very different attitudes have been taken in animal psychology toward the subject of perception. Some would use this term for any reaction to sensory effects, others would reserve it (as above) for grasping meaningful patterns through sensitivity. The former practice seems to have its basis in implicit analogies between any animal sensitivity and human "consciousness of environment." On this view, the simplest sensory processes indicate perception. Such analogies, however, are vague. Modern experimenters prefer objective methods in mhich judgments of perceptual capacities depend on data from systematic object-discrimination tests under controlled conditions. The critical matter is not sensitivity alone, but how the animal organizes sensory data in adapting to new conditions. For this, resources for learning are critical.

B. Learning Capacity

The rich endowment of lower animals in species-typical adaptations related to structural specializations is well balanced in mammals by superior capacities for modifying behaviour. Writers such as E. Hering believe, however, that all organisms have "memory," in that the action of a stimulus on protoplasm always leaves traces which influence further responses. In this very general sense, the term learning would be extended to the simplest types of behaviour changes through stimulation, as in plants and protozoans. An alternative view is that such changes should be classed as equivalent to the general kinds of trace effect termed hysteresis (*q.v.*) in physical systems rather than to learning as in higher organisms. For comparative psychology, the primary fact is not just the production of some trace effect through stimulation, but nhat class of trace is involved and what its relevance to the organization of behaviour may be.

1. Varieties **of** Learning.—Adaptation and *Fatigue* Phenomena.—The simplest types of trace phenomena are based on processes akin to sensory adaptation or muscular fatigue. A dog or a man kept in the dark for even a few minutes undergoes chemical changes in the retinas of the eyes increasing the sensitivity of the rod cells so that dark vision is good, but on release to bright light, vision is poor and orientation inefficient. A worm, after circling counterclockwise inside a dish, is likely to turn left when transferred into a T maze; a dog after running all day scratches himself weakly, because chemical products of action and associated phenomena (fatigue) have temporarily changed muscular contraction. Similar instances based on changes in receptors or muscles are common throughout the animal series. They are not classed with learning because they centre around peripheral changes and not directly around central-nervous traces altering individual behaviour in persistent ways.

Sensory Integration; Habituation.—Certain classes of experience may arouse neural trace effects influencing behaviour without altering it specifically. For example, the larvae of many ants and other social insects, through feeding on substances characteristic of the species (chemical stimulus I) in the nest situation of the colony (chemical stimulus 11), may accomplish a sensory integration with neural traces influencing adult behaviour in varied ways as in trail following and in foraging. In a comparable phenomenon in mammals, termed "sensory preadaptation," after different stimuli such as a light and a buzzer are experienced together repeatedly without any specific action being involved, a response then conditioned to one of these stimuli also is elicited by the other without further training. In a similar phenomenon, generally termed hzbituation, commonly experienced disturbing stimuli lose their initial effect, and may even facilitate ongoing behaviour. Thus snails in an aquarium, bumped and otherwise disturbed for weeks by fish, then carry out their activities without the initial stoppages; a clerk becomes able to work in a noisy office. In such cases, through common experiences, nervous traces are set up which influence behaviour in general ways. These phenomena seem related to conditioning because new integrations are formed; they are, however, distinguishable from other types of learning in that specific behavioural changes are not primarily essential.

Conditioned Responses.—In conditioned-response learning, the gain is a new stimulus-response connection, the nature of mhich depends on what specific stimuli are experienced together. To take an example from the lowest animal in which learning has been demonstrated, a flatworm moves about in response to stimulus A (light). hut halts at stimulus B (head contact); stopping occurs to A, however, after the stimuli have been combined many times. Conditioning, therefore, depends on what stimuli are combined under appropriate conditions, through everyday experience or the plans of an experimenter or animal trainer. With each repetition, an "unconditioned stimulus" (B) which arouses the critical resonse (B_R) at the outset is experienced by the animal together with a conditioned stimulus (A) which initially does not arouse this response. Through experiencing the combination, the animal forms both an A-B integration and neural traces permitting A to control the critical response B_r. In the pioneering experiment of I. Pavlov with dogs, A was a bell sound; B, meat powder in the mouth, was a stimulus arousing B_R, a reflex salivation. Through repeated combinations of bell and meat powder, at length A-B_R was accomplished and the bell controlled salivation.

In vertebrates, and in the invertebrates including worms, probably most reflexes and other local reactions may be conditioned if stimuli are appropriately paired. Although at first young dogs scratch only in response to local skin irritation (*e.g.,* flea bites), appropriately pairing this unconditioned stimulus with the smell of flea powder, hearing "scratch!" or seeing his collar normally conditions the dog to form the corresponding A-B, pattern. The potentialities of the conditioning principle for practical animal training depend mainly on ingenuity and patience, as is illustrated by a popular Russian film of the 1950s portraying an animal enterprise in which dogs run trains, rabbits behave excitedly on missing them, cats punch tickets and theatrical doings are also represented convincingly, although evidently without understanding, by the actors.

In the mammals, particularly, aspects of the situation other than the focal stimuli can control behaviour through conditioning, thus serving as secondary conditioned stimuli. In Pavlov's work, stimuli incidentally seen and heard in the test room (*e.g.,* hearing experimenter's movements) at length elicited the critical response in the absence of the experimental stimuli. This enlargement of the habit was indicated also by a reduced responsiveness when the animal was tested in another room or without his harness. In such ways, in laboratory experiments or with pets at home, stimuli considered incidental or even overlooked come to control a habit, as in the Clever Hans case.

Conditioning is not the same in all animals capable of it but varies considerably in its internal pattern and relations to other behaviour. For this fact, differences in neural resources are critical. In invertebrates capable of it, and in lower vertebrates! conditioning is largely restricted to combining simple stimuli with reflex or stereotyped responses, and naïve responses to potent stimuli are reversed only with difficulty if at all. Examples are the difficulty of conditioning an inhibition of the snail's foot retraction to intense contact or the lizard's snapping at figures of complex but not smooth outlines. Mammals can form. systems of conditioned. responses in which a wider range of responses may be controlled by the same stimuli, the responses themselves varying more than in lower animals. The traditional milkman's horse, starting and stopping skillfully according to combinations of footstep-and-bottle sounds, is an everyday example. The significance of such learning is illustrated by the great variety and flexibility of combinations possible through systematic training in almost any mammal, compared with the limitations of turtles, toads and fish, increasing in that order.

From the lowest to the highest mammals the ability expands to modify conditioned responses according to prevailing conditions. It is difficult to condition a fish to move one fin alone to a light combined with shock, but with a dog, in time a light paired with shock to one leg controls not only the flection of that leg, without the shock, but other changes also. Reduced forms of the conditioned stimulus and subtle secondary stimulus effects enter, and the response is curtailed and modified until at length the paw alone moves just enough to avoid the shock. Cases of learning in this class, in which both stimulus and response undergo precise modifications according to motivation and the consequences of action (*e.g.,* obtaining food or evading shock), evidently represent the merging of the conditioning type with the selective type of learning (see below). The inferiority of lower vertebrates to mammals in such learning doubtless corresponds to differences in neural equipment. Thus, although normal dogs can be conditioned to withdraw a specific paw skillfully on signal, dogs deprived surgically of cerebral cortex advance little beyond the stage of general excitement and variable responses to the conditioned stimulus. The limitations of dogs without cortex remind the experimenter somewhat of lower vertebrates with their inferior neural equipment. (See also CONDITIONING.)

Operant Learning. — Variations of conditioning are possible depending on the animal and technique used. A method known as operant learning approximates conditioning by routinizing stimuli and other conditions, but differs from it in that initiating the response depends specifically on the animal. In the classical experiment of B. F. Skinner, a rat learns to approach and press a bar for a food reward. If the reward is given only in the presence of a signal, say a light, the rat will tend to press the bar during presentation of the light and not in the dark. If his hunger is reduced, he stops pressing, and so on. This method is very useful for research on the properties of sensory discrimination, reaction and drive; however, it may not be suited to the comparative study of learning. In the operant method, the experimenter plans the situation for the animal so that the successful response is sure to occur, thereby greatly reducing the time and variable behaviour for solution (if indeed the "solution" otherwise could be learned at all). Despite the specific utilities of this method, the fact remains that by selecting nhat action is to be "correct," and by maneuvering the animal's behaviour so that this action occurs, the experimenter substitutes his own role for unexamined selective processes otherwise dependent upon the animal. By this method, therefore, similarities are obtained for pigeons, rats and men which may be very misleading as to how far the basic processes of learning may actually be similar or different through the animal series. (See LEARNING.)

Trial-and-Error or Selective *Learning.*—This complex form of learning, not clear below arthropods, reaches its peak in the mammals. It is illustrated by the behaviour of a hungry dog outside a food box that can be opened only by pulling a cord. The first responses of dogs to such problems are highly varied, and include nearly all activities possible under the conditions, from pawing and sniffing at the box and at the floor nearby to running about at intervals and also, finally, sitting and howling. At length the dog, in the course of biting and pawing at objects, happens to pull the cord and enters the door to food. The first trial, particularly, is likely to be very long, but, as E. L. Thorndike found in his pioneering work with cats. random activities decrease and the cord is pulled more and more promptly in further trials. From these characteristics. such learning is called trial and error. Because the animal improves by working more frequently in the correct locus and adapts more efficiently through organizing appropriate responses from initial variable behaviour, the process may be termed selective learning. When D. K. Adams prehabituated animals to the general situation, thereby reducing initial disturbance and emotional excitement, random behaviour decreased and the correct solution was more promptly and efficiently acquired than in naïve animals.

Many kinds of problem situations have been used in studying selective learning, including types in which escaping shock or getting food depends on pressing a pedal or pulling a string, combinations of these and other devices. Higher mammals such as the chimpanzee can solve problems involving latch combinations which are difficult for the monkey and insoluble for rats and lower mammals, not merely because the chimpanzee excels in manipulative ability but because of his superior capacity for organization in learning. Birds, in contrast to mammals, are limited to easier problems. which they learn more slowly. Sparrows are slow, pigeons much slower, in learning to press a string admitting them to a food box, then do not relate the string response to the act of entering the door. The bird's inferior organization of the habit is shown by the fact that, nith the habit learned, if the string is moved he tends to work in the habitual place instead of directing his efforts at the shifted string, as most dogs would. The inferiority of lower vertebrates to mammals in problem solving, as W. Fischel has shown, lies especially in their shortcomings for interrelating the critical act (*e.g.,* string pulling), the object acted upon (*e.g.,* the string) and the goal (food).

A method much employed in studying selective learning involves the maze, in which establishing a correct route despite blind alleys makes possible investigating both the elimination of errors and the organization of a complex orientation habit. Animals from earthworm and crab to chimpanzee and man have been tested, and striking differences are found. To learn a T maze with only one blind alley the crab *Cambarus* needed more than 60 trials, chimpanzees only a few. In about half the trials needed by the crab for its simple learning, Formica ants master mazes containing six blind alleys. Rats, on the other hand, given this pattern used for the ant in an appropriate scale, need only 12 runs or less.

As T. C. Schneirla found, submammalian animals require more trials to learn comparable problems, commit far more errors than mammals and accomplish an inferior habit in a different and more limited way. The ant, to learn the six-blind maze mentioned, first became habituated, next mastered local difficulties, finally a general organization of the habit, all very gradually. The rat, in contrast, exhibited no distinct stages but mastered local difficulties and organized the general route simultaneously. The superiority of the rat's habit is shown by its facile modification when maze changes shift the correct route through a former blind alley. The rat reverses maze habits readily when required to start at the former exit, whereas for the ant this is a very difficult problem. The ability to reorganize behaviour in new situations is a particular mark of the mammal's superior capacity for selective learning.

Tests requiring modifications in learned habits reveal even more clearly than do studies of initial learning how strikingly different the capacities of ants and rats are for organizing solutions of comparable tasks. To compare fish and rat in this respect, M. E. Bitterman and J. Wodinsky used a technique requiring successive reversals to the stimuli of a discrimination habit. Although in these experiments the rats improved steadily from day to day in shifting between two similar alternative habits, the fish usually failed to improve except within given days, and in successive reversals their habits seemed to interfere with each other. Differences thus are indicated between ant and rat and between fish and rat, with the rat excelling not only in its method of acquiring habits but also in changing mastered habits.

When learning is reviewed comparatively (as in the foregoing discussion) the possibility arises that the chief difference between invertebrates and lower vertebrates, on the one hand, and mammals on the other may not so much involve the formation of neural traces, emphasized by S-R learning theory, as in capacities for organizing traces, emphasized by other theories. Thus. using food or shock in training techniques may be important in inframammalian forms mainly for the rate of forming the neural traces themselves, although in mammals its influence on the course and organization of selective learning can be much greater.

For good results in training mammals, although conditioned-response procedures may be held basic, the use of punishment or reward to control what is learned must be tempered by a broader conception of the role of incentives and motivation than would be necessary for lower animals. Accordingly, for mammals, punishment is advisedly used only in mild forms (as intense stimuli emphasize avoidance reactions to trainer and situation) and reward, similarly, to encourage desirable responses and their efficient organization.

2. Experience and Capacities in Learning. — Mammals surpass invertebrates and lower vertebrates not only in learning new problems but also in reorganizing habits adaptively. Adapting to this comparison the neurophysiological theory of D. O. Hebb for the ontogeny of perception, one would say that rodents and higher mammals, with further related experiences, advance much more readily than lower forms from trace effects to linkages to complex neural patterns. Mammalian learning is typically more efficient in familiar situations, not only because the animal is less excited and behaves less erratically than under strange conditions, but also because mammals can extend habits progressively to better effect than can lower animals.

Virtually any type of problem is mastered more readily by mammals, not only because of their superior organic equipment for original learning. but because experience is brought more effectively to bear on further problems. Harlow investigated these matters at length with monkeys given long series of discrimination tests with problems of increasingly difficult natures. Results showed that monkeys master more complex discrimination problems of the same general type with progressive facility. Harlow applied the term "learning sets" to the successive stages of the monkey's progress in "learning to learn." He was inclined to emphasize the similarity of learning at successive stages and to doubt that qualitatively new processes enter at the advanced stages. But, as N. R. F. Maier and Schneirla suggested, the discrimination method may not be adequate to reveal qualitative differences in learning. This problem seems to require other methods more appropriate for the investigation of similarities and differences in learning and intelligence at different animal levels.

C. Intelligent Behaviour

1. Criteria. — Intelligence (*q.v.*) is definable as the capacity to utilize experience in adapting to new situations. Intelligence is not efficiency in adaptive behaviour, a quality shared by all surviving animals. Furthermore, although intelligence depends to some extent on the organism's aptitude for conditioning, and more so on its capacities for selective learning, the crucial matter is how readily the gains of past experience are adapted to new problems.

It is difficult to diagnose any solution correctly without adequate knowledge of the animal's background. Morgan described a case in which, after he had observed a dog in repeated erratic attempts to pull a crooked stick through a paling fence, the animal finally yanked the stick through when the crooked part accidentally broke off. A passer-by, who saw only the last and successful part of the series, remarked, "Clever dog that, sir, he knows where the hitch do lie." Whether success results through accident, a gradual process of selective learning or an efficient reorganization of experienc'es appropriate to the problem may depend on (1) species capacities, (2) the capacities and experience of the individual and (3) the conditions under which the difficulty is encountered.

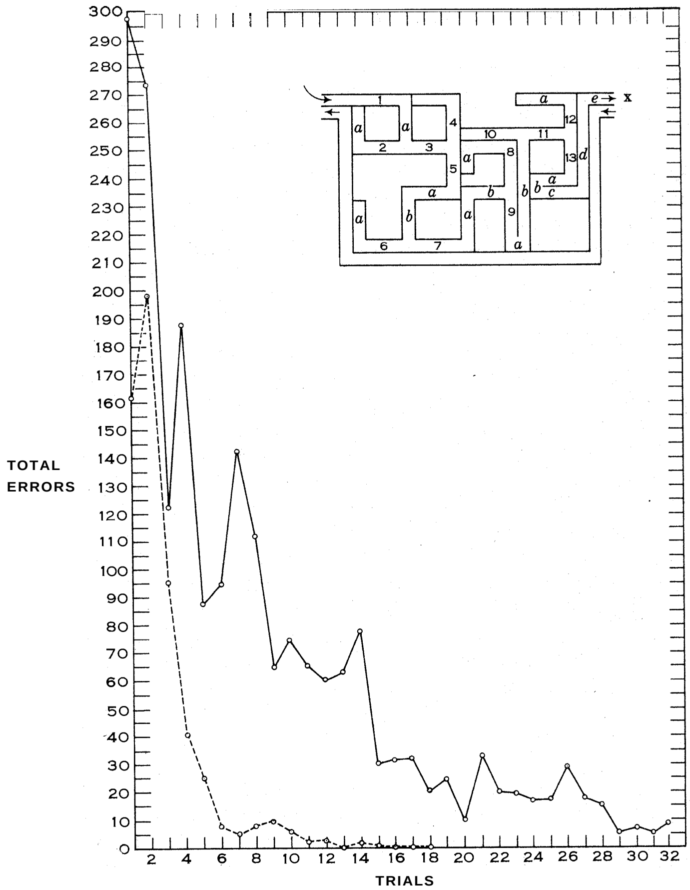
FIG. 2.— COMBINATION PROBLEM BOX USED IN TESTING MONKEYS. TO ENTER THE BOX AND OBTAIN FOOD. THE ANIMAL MUST DEAL WITH THE ITEMS IN THE SEQUENCE INDICATED BY THE NUMBERS

2. Insight. — Commonly accepted as an index of intelligent behaviour are short-cut solutions known as insight, in which the animal appears suddenly to "see the point." Calling such solutions insightful does not of course explain them but may only analogize success with a hypothetical process of seeing into something. The mere rate of accomplishment does not indicate insightful solution, for insects in certain problems occasionally achieve rapid but noninsightful improvements. Insight involves a kind of organizing ability not demonstrated in insects or lower vertebrates, superior to both conditioning and selective learning for overcorning new difficulties.

Pioneer studies by M. Haggerty and others shortly after 1900 revealed that problem solutions by monkeys are often better than would be expected through trial-and-error processes alone. For example, a monkey, after having watched another, in four successive trials, climb the side of a cage and reach into a chute to obtain fruit, when given the problem himself soon solved it by working directly around the chute until he reached the fruit. Later, in the research of Kohler and Yerkes particularly, similar abilities were demonstrated for chimpanzees, superior to those of monkeys.

In these experiments, chimpanzees were presented with problems such as food overhead or behind a fence, unobtainable by direct responses such as reaching or jumping but obtainable only by indirect procedures. Although there were failures and some animals never did well, some of the chimpanzees reached distant food by means such as stacking boxes or raking it in with a stick.



FROM T. C. SCHNEIRLA IN "INSECT PHYSIOLOGY"; REPRODUCED BY PERMISSION OF JOHN WILEY & SONS, INC.

FIG. 3.— SIX-BLIND MAZE PROBLEM USED FOR TESTING BOTH ANTS AND RATS. SOLID LINE INDICATES TOTAL-ERROR SCORES OF EIGHT ANTS. BROKEN LINE. THE TOTAL-ERROR SCORES OF EIGHT RATS

One of Kohler's chimpanzees, which had previously used only single sticks as rakes, was shown food beyond reach, requiring a stick longer than any available. First there were actions such as merely reaching out with the arm, or using one bamboo piece alone or to push out another, for getting at the incentive. Even though inappropriately! the animal in such behaviour was using foreign objects as a means to an end—in other words, as crude tools. After an hour, the goal was unattained and the animal sat facing away from the food, idly handling two bamboo sticks. Then a change appeared, as follows:

> Sultan . . . picks up the two sticks, sits down again on the box, and plays carelessly with them. While doing this, it happens that he finds himself holding one rod in either hand in such a way that they lie in a straight iine; he pushes the thinner one a little may into the opening of the thicker, jumps up and is already on the run toward the railings, to which he has up to now half turned his back, and begins to draw a banana towards him with the double stick. (W. Kohler, The *Mentality* of Apes, Eng. trans., 1925, Harcourt Brace.)

That the sticks were perceived as a useful tool and not combined by accident mas indicated by the fact that when the pieces happened to separate, the animal straightway recombined-them in a manner impossible without some understanding of their function together.

3. Relative Capacity for Indirect Solution.— Solutions of such types resemble the pattern recognizable in mammals as "perception of relations." Much evidence indicates that lower mammals are inferior to primates in this respect. Cats and dogs can learn to manipulate levers, but neither can assemble a tool or use it as chimpanzees can in solving problems.

Kohler emphasized the superiority of primates over lower vertebrates in correcting their initial direct responses to the incentive! when necessary, with indirect ones. A hen separated from food by a wire fence persists in zigzag running against the fence, opposite the food, whereas dogs in time abandon direct responses for a detour to the food. and monkeys do so sooner than dogs. Fischel demonstrated that although dogs can respond to one of two incentives with the direct or indirect action that is appropriate, thus solving a task failed by turtles and by birds, they master the critical relationships less effectively than primates do. Chimpanzees clearly surpass monkeys at solving the type of problem requiring the subject to push food away from him around a barrier before raking it in, indicating a superior mastery of the relationship of the subject's position, the barrier and the goal.

4. Reasoning as Reorganized Learning.— Indirect or insightful solutions are frequently differentiated from patterns acquired directly through selective learning in that the former type of solution often appears suddenly, after a period of apparently fruitless trial and error. Sudden improvements in progress toward or in attaining a n e type of solution are notable in the problem-solving behaviour of higher primates such as chimpanzees, less prominent in monkeys, still less in dogs, cats and rats in that order. This fact does not mean that insightful solutions occur independently of previous learning.

Insightful solutions have not been clearly demonstrated in any inframammalian animal, and various anecdotal claims for such processes, as in insects! seem attributable rather to uncontrolled possibilities for direct responses. What is unique about insightful solutions is that they are attained by reorganizing two or more patterns of response available from experience in similar situations, although previously independent of each other. Thus, perceptual adjustments such as jumping to food and handling a box may exist separately in the animal's repertory until he combines them in solving a new problem. In one of the experiments of Maier. who studied simpler forms of this type of solution in the rat, the subject was first habituated to the elevated pathway shown in fig. 4, passing between each two tables frequently, without receiving food. In the test, the rat was first given food on one of the tables, *e.g.,* no. 3, then was transferred to no. 1, for example. On the basis of his specific habits, the rat in this case would have turned with equal readiness to tables no. 2 and no. 3; the results, however, showed that adult rats were able to return with better than 80% success to the one food table correct in the particular test. Achieving correct solutions when a direct recall of learned responses would have led to chance scores indicates a capacity for combining learned items which had been separate in previous experience.

Maier emphasizes the qualitative similarity of such solutions to reasoning in man. As an example of a solution by reasoning, not demonstrated in mammals below primates, the joining of short sticks when a longer one is needed has been mentioned. As H. Birch found, however, chimpanzees cannot solve this stick-combination problem by reasoning unless they have previously handled sticks as in play and appropriate unitary perceptual adjustments are thereby made available. The feat then is to combine these elements insightfully in an intelligent adaptation to new difficulties.

5. Relative Independence of **Stereotypy.**—*Nonsoluble Tests.*—Mammals differ greatly in their freedom from stereotyped behaviour in problem situations, as G. V. Hamilton found. In his nonsoluble test, the subject was presented with four doors, one door unlatched on each trial, but never that unlatched on the preceding trial. This fact was discovered by the human subjects, but not by any lower animal. Sext in complexity of response were monkeys, the other primate tested, which often tried all four doors successively and distributed their efforts without trying any one door repeatedly on any one trial. Stereotypy of response. or repeating particular reactions frequently: occurred often in dogs and cats and very often in horses. Significantly. the tendency for stereotypy and persistent repetition of errors is marked in the

maze learning of rats in which 20% or more of the cerebral cortex has been destroyed. Maier found partially decerebrate rats very inferior to normal subjects on reasoning problems, much as lower mammals are distinctly inferior to primates on such problems. Superior cortical endowment thus inhibits stereotypy in mammals so that new adaptations become possible.

Multiple-Choice Test.—The Hamilton situation was adapted by Yerkes in further studies of plastic behaviour in his multiple-choice test. Here the subject faced nine doors in an arc, with a sequence of five doors unlatched on each trial, but (to eliminate simple position habits) always a different set. Food was to be found behind just one door each time, and the problem was to discover how the correct door was systematically related to the others. Sample problems were: (1) always first at the right; (2) always second from the left; (3) always the middle door. The aim here was to compare the levels of intelligence in different animals. In the above problems (1), presumably the simplest, was solved both by the crow and the rat, which both failed (2). Problem (3) was solved by the monkey but not by the pig. Chimpanzees solved problems more difficult than (3), in which success may have depended on capacity to abstract a significant pattern from among complex settings, or on what Yerkes called "ideational processes." To the claim that the multiple-choice method is valid for testing animal intelligence comparatively, critics object that the method affords no basis for clearly appraising such processes; also that this situation handicaps some animals unduly by admitting irrelevant features such as emotional reactions, which may have caused gorillas to fail problems solved by chimpanzees.

6. Representation as a Secondary Factor in Reasoning.—Attaining solutions by combining previously independent experiences, demonstrated in lower mammals including rodents, represents the reasoning process in simpler outline than in man. Animal psychologists have studied "mental processes" in lower mammals, in comparison with man, to find what other factors are contributive. One interesting method is that of delayed response, an outcome of earlier attempts to test capacities for "ideas." In the form developed by W. S. Hunter: this method involved first training the animal to go through the one of three doors marked by a light; then, in tests, the lamp over one of the doors was first lit briefly and after a given delay the animal had to respond without the light. In modifications of this test by others, the animal was first shown food under one of several cups or saw iood buried. and after a delay had to locate it.

The general result of such experiments, although specific results differ according to procedure and situation, is that lower mammals require more preparatory training for success and in general rely more on specific bodily orientation during certain types of tests than primates do. In food-concealment tests, monkeys and chimpanzees can delay successfully over intervals of 24 hours or longer. The general interpretation is that success depends on a capacity to represent the absent object or the appropriate adjustment to this object as a cue for recalling its location after the delay. Ability to delay the correct act over an interval is often interpreted as centring around an abbreviated form of the actual adjustment; lifting a box, for example, might be represented by a slight tensing of the arm muscles as in raising the box. In comparison with man's great advantage of symbolizing experiences verbally, lower mammals are handicapped by having to represent their adjustments in much less versatile ways.

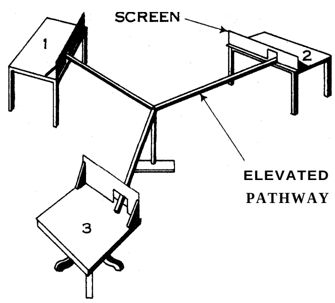
A related capacity indicated in lower primates and certain other mammals is the anticipation of particular absent objects. In one delayed-response experiment with monkeys, in which banana was used in some of the trials and lettuce (less preferred) in others, the subject became disturbed and refused a piece of lettuce surreptitiously substituted for the banana he had seen concealed before the delay. Evidently the animal then specifically anticipated banana, for lettuce was accepted readily in delayed trials preceded by the showing of lettuce.

The ability to represent absent objects and situations may be considered a contributory factor in reasoning. This type of process is suggested by trials in which a chimpanzee, aiter having worked at suspended food for some time without success, suddenly rushes around the corner for a box previously seen there, then promptly uses this box in a solution. The ability to represent absent objects, although it aids solutions by reasoning, cannot alone account for such solutions, for merely representing an experience without change or recombination would constitute a direct recal! rather than a new solution. In the primates. the newness of solutions achieved through reasoning is far more striking than in other mammals.

V. MAN COMPARED WITH THE LOWER ANIMALS

Although man is not structurally the most highly evolved animal. he is psychologically the highest. His superiority is not absolute, however, for most of his advantages are also possessed, though to lesser extents, by mammalian relatives.

1. Time, Reasoning and Foresight.—Although reasoning is found in mammals down to rodents, in the lower orders it is simpler and evidently plays a far smaller part in adaptive behaviour than it does in man.



ADAPTED FROM N. R. F. MAIER AND T. C. SCHNEIRLA, PRINCIPLES OF ANIMAL PSYCHOLOGY. REPRODUCED BY PERMISSION OF MCGRAW HILL BOOK CO.

FIG. 4.—MAIER THREE-WAY APPARATUS FOR TESTING REASONING IN THE RAT (see TEXT)

One of man's psychological advantages is foresight, or reasoning with reference to problems in the more distant future. Time, for lower primates, is largely restricted to the present and is much less extensive and meaningful for the past than it is for man, who lives in the future as well as in the past and present. The anticipations of lower animals can be conditioned within limits to coming phases of recurrent events, through internal or external stimuli characteristic of given times of day. In rodents, discrimination of short intervals of time in terms of action has been demonstrated; however, their anticipations are held to shorter times and simpler processes than they are in primates. Even in apes, anticipation is far shorter than it is in man, and largely involves more familiar occurrences. The capacity to think far forward in time requires a wider reorganization of the traces of experience than is found in any lower animal.

Man's intelligence is capable of systematic sequential reasoning. or planning, organizing into systems the traces of very different experiences nith reference to future goals. Foresight in the chimpanzee is typified by his food expectancies, anticipative of specific episodes only a day or two off. If lower primates are capable of utilizing reasoning to obtain goals or forestall hazards expected in the more distant future, these abilities remain undemonstrated.

Planning for future needs requires not only foresight but also reflective thought, or reasoning about one's own condition in relation to the past, present or future. Differentiating and identifying the self in thinking, marked typically by the first significant use of personal pronouns such as "me" around two years of age, is a major event in human mental development. This symbolic accomplishment is far superior to reacting emotionally about one's own behaviour or appearance, as might a monkey observing himself in a mirror or a growling dog preparing to fight.

Foresight involves taking note of one's own status or condition, in reference to that of other individuals, objects and situations, to achieve appropriate measures. This type of self-reactive reasoning expresses man's superiority over the lower primates better perhaps than any other aspect of development. The comparison is weakened neither by subnormal human intelligence nor by the fact that any man at times uses his mental capacities poorly. The best human foresight infinitely surpasses the best in subhuman primates.

2. Verbal Language and Communication.—Although language and communication are often confused, the former constitutes a special case of the latter. In communication the behaviour

(or related processes; *e.g.,* odours) of one animal influences the behaviour of others; in language, a special system of symbolic processes is used with the expectation of influencing others in given ways. Odours produced reflexly from an excited bee's scent gland or vibrations produced in a termite colony through the head rapping of excited individuals on gallery walls are communicative events but not language. Processes such as the flashing of fireflies, the chirping of crickets and the colour changes, movements and sounds of mating animals are by-products of excited behaviour rather than language symbols initiated in view of expected effects on other individuals.

Communication approaches closer to language when social responses advance through conditioning, as in groups of birds or mammals when the excited cries of one individual throw others into flight. Another advance is made mhen a general activity is modified through experience into a special device used to influence the behaviour of others, as when barking and biting in a dog change into baring fangs and growling as means of intimidation. When merely beginning the act often causes flight, the abbreviated form is learned as a special social device. Instances of simple, discrete communicative processes of this sort are not uncommon in the everyday life of mammals, as in the "begging" of hungry dogs and the mewing of cats before closed doors. When 'used with even a limited anticipation of their social effects, such acts approach the stage of language.

Infrahuman primates seem not to develop systems of symbols in the class of language. Yerkes, however, from his extensive experience, indicated in the chimpanzee a variety of sounds and movements which influence other individuals, keeping them in touch with and informed about the presence and attitude of one another as well as about significant features of their environment. To be sure, these sounds and movements of lower primates more often appear as incidental features of the first animal's excitement (*e.g.,* the "hunger cry") than as intentional means of informing others of something. Although proof is lacking that chimpanzees use sounds symbolically, S. Crawford and H. Nissen demonstrated experimentally that these animals can use gestures as language symbols, as in tapping the shoulder of a lagging companion when food can be obtained only with his co-operation.

Man alone has the capacity for systematic codes of language symbols. Nonmimetic, conventional types of symbols, particularly, qualitatively distinct from the acts or objects they represent, account for the great efficiency of human language. In contrast. the communicative activities of lower mammals are essentially mimetic in that the sign or signal is a specific part of a series of experiences which represent the whole. Even the chimpanzee, which has a facility for vocal utterances and an intelligence that makes it perhaps the best candidate for language next to man, falls short of achieving verbal language symbols. Attempts to teach chimpanzees true words attain only the stage of stereotyped responses given under set stimulus conditions. Parrots can learn to repeat frequently heard sound patterns, which, however, constitute skilled acts largely devoid of any meaningful association uith the objects or situations eliciting them and are not manipulated with anticipation of the results; hence, not language.

3. Conceptualization and Intelligence. — The psychological deficiencies of chimpanzee as compared with man, and of monkey as compared with chimpanzee, relate significantly to the elaboration of cerebral cortex. In the mammalian series rat-dog-monkey-chimpanzee-man, there is not only a progressive increase in the proportion of cerebral cortex to body weight but also an increase in the number of cortical cells and the complexity of their interconnections. Such increases parallel improvements in capacities for complex functions centring around learning and its reorganization in perceptual, conceptual and language processes. This is validated by findings such as K. Lashley's of a high positive correlation in rats between amount of intact cerebral cortex and performance in learning problems, and Maier's that losses exceeding 20% of cortex abruptly reduce to a minimum the scores of rats in reasoning tests. Limitation of symbolic behaviour by the amount and pattern of cerebral cortex is emphasized for man by the deficiencies of imbeciles and by the degeneration of symbolic functions in step with progressive cortical loss as in tumours. In the final stages of such disorders, the patient may see once familiar objects without being able to name them or recall their meanings.

Mastery of verbal language symbols evidently requires a foundation in object meanings beyond the resources of subhuman intelligence. To be sure, a chimpanzee can be taught human activities such as using utensils, yet the circumstances of training and of use indicate a limited perceptual and conceptual command over the adjustments and a performance more rigidly bound to specific sensory properties and motor routines than in man. The chimpanzee thus can learn to ride vehicles without forming the abstraction "ride" and using it verbally to initiate the act as does the human child through mastering the common properties of vehicles. Although human infants in their first symbois are bound to particular situations and concrete uses, later they progress steadily with verbal symbols whereas chimpanzees remain in the nonverbal stage.

Chimpanzees are not sufficiently intelligent to attain the level of perceptual development essential for human conceptual processes. Their concepts do not reach the stage of conventional symbols such as words, and are too simple and rigid to be combined in symbol sentences. Correspondingly, their adult problem-solutions are simple and discrete and, like their tool concepts, cannot be interrelated into systems to form progressive principles. From the lower primate's episodes of reasoning, discontinuous as compared with man's, the gains therefore are not consolidated as communicable knowledge or social heritage.

4. Emotion. — In higher and lower animals alike, a relationship may hold between outer causes and the individual's initial excited, emotionalized responses. Although in the higher mammals these processes progressively involve perceptual states of variable stability and psychological complexity characterized as pleasant or unpleasant, they are grounded in visceral conditions. Primitively. strong stimuli elicit withdrawal and an interruptive visceral condition, neak stimuli approach and a vegetative visceral condition. What may be called the strong emotions, characterized by interruptive visceral changes such as hampered digestion, quickened heartbeat, secretion of adrenin and impulsive responses such as flight or fighting, are aroused by intense stimulation. W. Cannon identified equivalent interruptive physiological reactions of these types as accompaniments of strong emotional excitement in both lower mammals and man, "putting the organism on a war footing." Conversely, weak stimulation promotes vegetative changes such as facilitated digestion, and the related overt response is an approach toward the stimulus source, naïvely in mammals a general relaxation and reflex extension of limbs. The interruptive condition seems inherently episodic, the vegetative condition relatively continuous and potentially basic to social life. In mammals, however, nith their capacities for psychological plasticity, which of these becomes dominant in personality and society seems increasingly dependent on the prevalent development conditions. Lower mammals and very young children readily tend to perceive objects and situations in terms of their general emotional associations, as conditioned-response learning prevails first. Under severe environmental conditions, with punishment and strong stimulation frequent, interruptive emotional tendencies may become dominant, as in the trembling, cringing, uhining behaviour of a frequently punished dog when the whip, his master or a stranger is encountered. In contrast, an emphasis on approach tendencies and selective learning in development brings intelligence to the fore and contributes to social rather than asocial behaviour.

In man, visceral processes play a far more indirect and delicate role in emotional reactions which are much more influenced by the perceptual significance of the situation than they are in lower mammals. Because man's emotional development is dominated by his perceptual and conceptual processes. according to circumstances, it is unsafe to infer experiences of "fear" in the human sense in the excited flight of insect or fish from a suddenly moved object or "maternal love" in the queen ant licking her first brood. That the difference depends particularly on the intimate involvement of cerebral function in man's emotional development is indicated by lapses in emotional specialization and social restraint with cortex-inhibiting agents such as alcohol or more lasting deficits when brain tumours or injuries reduce cortical function. Comparably, in cats and other lomer mammals, when the cortex and brain stem are disconnected surgically there are marked increases in activities such as snarling, biting, panting and other signs of interruptive visceral disturbances normally episodic and associated with high emotional excitement. Man's cortical equipment admits an emotional specialization comparable with his intelligence and involved with it in an intimacy well beyond the range of lower mammals in general.

The temperamental resemblance of lower primates to man appears much closer than their intellectual resemblance to him. Although %ell-domesticated dogs are frequently very sensitive to subtle differences in human behaviour, acting almost as members of the family, domesticated chimpanzees seem far more delicately and complexly attuned both to man and to chimpanzee companions. Hebb, by simulating the approach of a "timid man" and of a "bold man" in successive tests, obtained significant chimpanzee responses, with one animal friendly in the former situation but aggressive in the latter, tno others interested but aggressive and unafraid in both. The first animal may have been hoodwinked by the act, the other two not, as the experimenter was known to them.

Experienced observers report patterns meriting terms such as confidence and discouragement. bluff, suspicion and others, appearing under comparable conditions in the ape and the human child. These responses involve rough similarities in external signs of emotionality, including facial expressions and general tensional changes, reliably interpreted as indicating emotional attitudes. A common difference is that, in excited emotional responses, overt processes tend to emerge more readily in adult lower primates, with the whole body involved as in stamping and shrieking when rejecting something. and in this sense they are much more "dominated emotionally" than adult man.

5. Aesthetic Perceiving. — The capacity for perceiving objects or situations in emotional terms such as distress or reassurance appears first in mammals. Although in lower vertebrates and some invertebrates stimuli such as body colours or characteristic sounds may be excitatory or calming, repellent or attractive, evidence suggests that specific effects such as intensity (controlling physiological changes), and not their perceptual significance, dominate such responses. Neither simple conditioned responses nor naive responses to stimuli are truly aesthetic, in that emotional effects accompanying attraction or repulsion reach the level of appreciating object significance, object qualities and emotional effects as related.

Simple aesthetic perceiving, so defined, is indicated in the subhuman primates. Kohler observed chimpanzees hanging material such as plants or fruit skins about their necks or shoulders or applying clay or other substances to their bodies or to surrounding objects. Other behaviour was seen which Kohler considered rudimentary dancing, as when animals pranced around a circular path in single file or stood in pairs, one stamping the feet alternately as the other rotated with outstretched arms. Such actions are accepted as primitive types of aesthetic perceiving both because individuals evidently derive an emotional gratification from manipulating object qualities with reference to themselves and because these actions exert an emotional effect on others. D. Morris, from studies of finger painting by chimpanzees in the London zoo. suggested that free-choice and project methods often reveal indications of aesthetic appreciation in selecting and combining colours, somewhat comparable to the tendencies of human infants. B. Rensch thought that the preferences of *Cebus* monkeys for certain combinations of colours and grays, and certain geometrical patterns, express processes resembling some of the simpler aesthetic tendencies in man.

The capacities of lower primates for aesthetic perceiving are slight in comparison with the potentialities of man, uho alone seems able to create systematically visual patterns such as thematic paintings, auditory patterns such as symphonies or dances worthy of choreography with the expectation of exciting appreciative emotional responses in himself and others. Not only are the chimpanzee patterns vague and lacking in subtlety, but their significance apparently involves only a momentary emotional appreciation, as capacities are lacking for the intellectual synthesis of emotional effects and patterning of material essential for a wider orientation in time. The human artist, with an appreciation of his own relationship to the theme and resources for planning his work to play upon the emotional susceptibilities of others, can treasure and recreate aesthetic experiences. Through his foresight, experiences remote in time and space and with disparate meanings are continued creatively to enrich the environment for himself and others.

6. Personality and Abnormal **Behaviour.**—Normal behaviour is definable as the developmental pattern characteristic of the given animal group. The major animal forms have been compared here in terms of their normal or typical patterns. Although this is justified, it is also true that every species presents individual differences in all characteristics of behaviour. Individual differences in organic characteristics and in adaptive behaviour constitute an important fact in evolution. Generally such variations are predictable, in that correspondingly fewer individuals deviate from the species norm in more radical ways. Some ants or bees are superior and others inferior to most of their colony mates in orientation, foraging and nest activities; chimpanzees differ widely in capacities from reaction time to reasoning, and so on for every psychological property of every animal species.

Individual differences that are matters of degree in sensory acuity or in the efficiency of learning may be considered regular or ordinary. Radical psychological deviations from typical species behaviour are uncommon in the lomer animals, although special departures may result from extraordinary conditions as in development. Pathological and disease conditions affecting the nervous system can produce behavioural eccentricities. Thus the signs of rabies in dogs and other mammals are extreme emotional excitability with indiscriminate running and biting; brain tumours produce sleepiness, reduced sensitivity, irritability or depression and other extraordinary signs according to their locus and extent. In these disorders, however, psychological disturbances are secondary results rather than causes. Man seems to be the one animal frequently plagued by psychological complications arising through disrupted organization of personality and behaviour rather than primarily through organic defects.

Under special stress, lomer vertebrates may exhibit emotional disorders resembling those of man. Gun-shy dogs tend to be extremely fearful in specific situations, and perhaps generally, because of emotional conditioning. Disturbances resembling neuroses have been produced in mammals and also birds with Pavlovian conflict technique, in which an animal, trained, for example, to respond to a circle but inhibit response to an ellipse, is then forced to respond to a figure intermediate between these two. As the animal cannot both respond and inhibit response simultaneously, a conflict condition results, with tension, excitement and even violent movements, and usually great difficulty in repeating either habit (*see* NEUROSES, EXPERIMENTAL). Under marked frustration in problem situations, with strong hunger but with no response adequate to get food, chimpanzees and other mammals become emotionally disturbed, negativistic and neurotic. Frequent experiences of this sort cause lower primates and human children alike to exhibit symptoms such as temper tantrums or chronic sulkiness with evasion of or dependence on others rather than attempts at direct solutions. By frustrating chimpanzees from infancy, with frequent stress and blocking of strong motivation (as many human parents treat their children). one may obtain abnormal personality trends resembling human neuroses.

One important reason why types of personality disorganization common in man are less prominent in his animal relatives centres around their deficiencies for redirected motivation. perception and reasoning and their consequent freedom from morbid anxieties about unobtainable goals. When a chimpanzee is away from the scene of its frustrations, its limited capacities for symbolism hold down related emotional stress in other situations. The effects of frustration are thereby reduced for the animal and it is freer to recuperate than is a man, who can recreate the situation with its tensions and even enlarge on these.

Lower animals are protected from mental illnesses in still other ways, also related to their psychological inferiorities. Not so dominated as man by remote goals or dangers or by attitudes of personal prestige, they can leave the frustrating situation outright when this is possible, or hit on some irrelevant response as an escape. Even so, similar personality defects frequently arise, with some resemblance to human reactions in frustrating work situations, as in caged mammals persistently circling their enclosures. Stereotyped habits arising under these conditions tend to reduce emotional tensions from conflicts between escape motivation and the necessity to remain. Although such behavioural fixations, as a rule, neither satisfy the dominant motivation nor resolve persistent emotional difficulties, they help the animal to survive frustration without excessive emotional tensions; hence they are adaptive. Similarly, in man, characteristic delusions and other fixations in behaviour and thinking may save the individual from more serious personality disorganization and thus permit survival in society.

7. Contrasting Social Patterns.—Aggregations are fairly common among all animals. Cells of sponges and other colonial organisms are unified organically, members of general associations remain together temporarily through common responses to the same extraneous stimuli. Social groups as in insects, birds and men are unified and organized on the basis of interdependence among the individual members and their responses one to another.

Natural selection has placed a premium on mechanisms making for interattraction and grouping of species members. As W. C. Allee demonstrated. even the biochemical products of death facilitate survival of others in various invertebrate associations. In insects and mammals, secretions and other processes have evolved which attract members of the species one to another, facilitating unity in local groups while repelling strangers. In various animals, and particularly birds, specialized visual and auditory mechanisms have a comparable function. Variously, the conditions of development favour the effectiveness of such processes and in many ways grouping contributes to species survival.

Striking similarities in social patterning, as between insects and man, encourage analogies as in A. E. Emerson's stress on the social group as supraorganism and his argument that natural selection affects different animal groups in the same ways. Such views can usefully attract attention to comparable organic factors ensuring social life in very different animals, but they also may obscure major differences. In social insects, cuticular secretions, tactual and other factors promote reciprocal stimulation among workers, queen and brood, unifying the colony; in mammals, including man, the organic products of parturition assure the female's attention to and licking of young; suckling and approach to the female by neonates strongly promote the development of a parent-young bond basic to individual socialization. Yet Schneirla has emphasized the significance of differences in the socialization process itself on different animal levels, terming the insect patterns biosocial, the mammalian patterns psychosocial.

Analysis shows that. on different levels, comparable biological factors promoting specialization can differ greatly in their developmental consequences, according to phyletic psychological differences such as those discussed in this article The abiding characteristic of the biosocial level, as exemplified differently by insects and birds, is that organic processes exert their effects rather directly on group behaviour; that of the psychosocial level is plasticity and diversity of outcome according to conditions in development and in the social situation. Whereas the many types of insect social pattern over the world had reached substantially their present forms by Tertiary times. more than 60,000,000 years ago, man has passed from the Stone Age to the space age, producing complex cultural systems, civilizations, science and recorded knowledge, within the past 50,000 years. Insect social evolution was achieved through organic evolution, whereas man has developed socially within a period when his organic make-up, particularly his cerebral cortex, seems not to have changed in any important respect. Insects have fixed communication patterns, men have plastic symbolic languages; insects have structurally canalized caste functions, men only those fixed circumstantially, through social heritage or through differences in intelligence; insects have organically stereotyped forms of co-operation but men are capable of intentional forms of concerted goal striving or of competition, according to upbringing and prevalent conditions.

It is valid to speak of a "worm nature," an "ant nature" or even a "bird nature" but not of a "human nature," for man can have whatever nature the conditions of his rearing and social situation permit. He may be tolerant or intolerant, with narrow prejudices and violent hatreds or broad interests and congenial attitudes dominant, depending on developmental, social and cultural background. The resources of his maturation may be directed either to avariciousness and cruelty or to charity and kindness, but none of these patterns is inherent in him. If one tendency seems more convenient for man than another, it is to discover or create a habitat in which interruptive, excited emotional disturbances are minimized most of the time. He shares this tendency with most of the other animals, but as a psychosocial being he has his own conventional, sophisticated ways of achieving it. Man stands on the psychological pinnacle not only intellectually but also emotionally, and the struggle for social conditions of peace and quiet has predominated in his history despite frequent disturbed, noisy exceptions.

It is not only through his intellectual but also through his emotional capacities that man has succeeded in merging small groups into widespread integrated societies as against the local groups to which all lower animals are held. He has achieved not only vast unitary social organizations, but true *internationales* in art, literature, music and science. Perhaps the most important task of comparative psychology is to show in what respects these achievements are unique and in what respects they are equivalent to the various ways in which lower animals adapt to their worlds.

PSYCHOLOGY, DIFFERENTIAL: *see* Differential Psychology.

PSYCHOLOGY, EXPERIMENTAL, is a method of studying psychological problems, but the term has come generally to be used to connote all those areas of psychology which use the experimental method to obtain their data. The experimental method as it applies to psychology is a systematic attempt to discover the conditions which determine human and subhuman behaviour by manipulating, one at a time, the variables that enter into the situations which give rise to the behaviour under study; it may also investigate the behavioural effects of modifying the organism. rather than manipulating the conditions external to the organism. Like other sciences, it is thus primarily concerned with discovering causal laws.

The areas of study in psychology which embrace the experimental method exclusively. or almost exclusively, include those of sensation and perception, learning and memory, motivation and physiological psychology. Other areas utilize the experimental method in some of their branches or subareas, and thus there are experimental child psychology, experimental clinical psychology, experimental educational psychology and experimental social psychology. Usually the experimental psychologist deals with the behaviour of the normal, intact organism, but in the area of physiological psychology, studies are conducted with organisms modified by brain or other nervous system surgery, radiation, drug treatment, induced convulsions or long-standing deprivations of various kinds. The experimental psychologist often finds that his problems overlap with those of physiologists, neurophysiologists, radiologists, biochemists, zoologists, pharmacists, physicists and geneticists. The main line of demarcation between experimental psychology and the closely related fields is the psychologist's emphasis on the behavioural products of his various experimental manipulations.

EARLY PERIOD

Origins. — Experimental psychology as a systematic study grew out of the work of physicists and physiologists who were compelled to recognize the important part played by the human observer in the results which they obtained from their experiments. Thus it was at first almost entirely concerned with the measurement of reaction times (*i.e.,* the time elapsing between the giving of a stimulus and the making of a prescribed response by the observer) and with a study of the special senses. In a brief survey it is impossible even to mention the names of many pioneers whose work gradually developed modern methods of experiment in psychology.

A very great amount was due, however, to Gustav Theodor Fechner, appointed professor of physics at Leipzig in 1834, who elaborately endeavoured to obtain exact quantitative statements of the relation between the intensity of a stimulus and of the sensation which it evokes. His reasoning never commanded wide assent, but the actual methods of observation mhich he initiated were developed in many ways and became the foundation of a large part of modern experimental procedure. In 1885 Hermann Ebbinghaus published the results of a long series of experiments mhich he had made upon himself in the memorizing of nonsense syllables. He claimed that the use of this kind of material made it possible for the first time to experiment successfully on the "higher mental processes." Although, as in the case of Fechner, there is reason for doubting the validity of many of his claims, his work undoubtedly inspired a large quantity of further research. Near the beginning of the 20th century Oswald Kiilpe took a further step by encouraging a number of researches upon judgment and volition, while throughout the whole period, from Fechner onward, experimental work on feelings and on certain specific psychophysical problems, such as fatigue, were continued.

In England the approach to experimental work in psychology—from the time of Francis Galton—was, in general, by a biological route. The importance of statistics as a method of dealing with experimental results received special attention and in many ways experimental psychology was closely in touch with neurology and medicine.

It is curious that the genuine experimental study of animal behaviour (*q.v.*) is a modern growth. With a few exceptions, and those for the most part resulting from the interest of comparative anatomists in the localization of various bodily functions, the anecdotal method of Aristotle remained predominant in the study of animals till the 20th century. That there arose a flourishing school for the experimental study of animal behaviour was due in the main to U.S. psychologists and in particular to Edward L. Thorndike, Robert Yerkes and John B. Watson.

The study grew until every important university in the world in some way recognized the right of experimental method in psychology to a position in the scheme of higher education and of scientific research. Most of the leading universities provided actual experimental laboratories. A considerable number of journals were established for the publication of the results of experimental research in psychology. Apart from university teaching there arose flourishing organizations for the practical application of psychology in various directions, particularly those of education and industry.

Recognition of the importance of psychological teaching and research in relation to the practice of medicine and law and to the organization of military services grew rapidly. It would be easy to show that the development of this practical aspect of psychology was made possible directly and almost entirely by the use of experimental methods.

Sensory Processes. — The earliest experimental psychologists were physicists and physiologists and consequently a great amount of work in the psychological laboratory became concerned with the special senses of touch, temperature, taste, smell, vision, hearing and movement. Let us select t\\-o groups of these for a somewhat more careful description: those dealing with visual and those dealing with auditory reactions. Here, then, are colour wheels on which disks of different colours may be rotated so rapidly that the resulting sensations combine and the effects of mixing colours in varying proportion can be accurately determined. Special apparatus demonstrates the aftereffects of continued light and colour stimulation and the occurrence of colour-blind or colour-weak zones in the normal eye. A darkroom is provided, designed to show clearly the differences between vision in daylight and in twilight and to bring out some of the theoretically and practically important facts connected with abnormalities of colour vision and with night blindness.

All of these may be seen in the physics laboratory or in the physiological laboratory. But the psychologist came to realize that his main problems and his methods of approach are his own. The physicist is chiefly concerned with an analysis of the stimulus, the physiologist with the mode of reaction of the eye itself, for instance, and with its connections with the central nervous system. The psychologist must be concerned with these also but has all the time to keep clearly in view how the accuracy of the observations themselves is determined. Thus he has to be particularly careful to study the effects of the method and order of presentation of the stimuli. He knows that these and numerous other factors, some of which may be extraneous to the particular experiment involved, determine the observer's attitude toward what is set before him, and that this general attitude, for which there is no obvious or immediately available physical or physiological expression, in turn may powerfully influence his observations.

With the same aim the psychologist carries out experiments on sound. He notices a man's normal reactions to sounds of different pitch, intensity and complexity, studies the results of combining tones in various nays, measures the acuteness of an observer's reaction to sounds of given character and demonstrates how the ears make it possible to judge where a sound has its source. He shows how all these apparently simple responses are in reality exceedingly complex and how an important part of their conditions often has to be stated in terms of what are called the "higher mental processes."

Perceptual Processes. — Obviously the world in which men live is not mainly a world of shifting patches of light and shade. of colour, of isolated sounds, tastes. smells and similar sensory characters. It is a world of things identified, named, referred to some position in space or apprehended as moving in some direction. So the experimental psychologist must try to show the conditions, not only of the relatively abstract sensory response, but of the more concrete perceptual processes that men are constantly carrying out. He has apparatus for the controlled exposure of objects: stereoscopes and devices for the study of the perception of solidity or of distance, and of the various optical illusions; means by which he can demonstrate how sensations of differing kinds may all come together into a single complex perception.

A little study of these perceptual processes is enough to demonstrate that in many instances what is actually perceived at the moment is only a little of what a person reports that he has observed. We fill up the gaps of perceptual data by using images or relying upon some form of recollection of past events, as when a person traveling at high speed in a train sees only parts of things through the window and then reports his observations with much more detail than could possibly have been discriminated at the time. Considering this, the experimental psychologist is led to arrange special situations with a view to the production of mental imagery and to study the types and functions of the imagery produced. Once more employing his exposure apparatus, so that the conditions of reaction can be at least partially controlled, he presents common objects incomplete in some respects, or material arranged in a series which gradually approaches a climax, or material directly designed to produce ambiguous or alternating reactions, or material conflicting with some other simultaneously presented perceptual data, and in these and other ways seeks to arouse mental imagery and so to discover what functions it fulfills. *(See* also PERCEPTION.)

Choice and Feeling. — Throughout the whole range of psychological experiment an observer frequently has to judge, to choose, to decide and he often reports that his reaction processes are accompanied by feelings and emotions. How can these functions of judging. choosing, deciding and feeling be themselves experimented upon? As regards the first three the essential method is to place an observer in some situation nhich presents him with an interesting problem. The solution has to be effected by judgment, choice or decision. Thereupon the experimentalist brings into play apparatus by which he can record some of the physiological changes which accompany these mental processes, such as variations in respiration, in pulse rate or in glandular secretion. At the same time the observer, acting throughout under relatively controlled conditions, gives a verbal report of the processes which seem to him to have led up to the judgment, or the choice, or the volition. The problem situations may be indefinitely varied in complexity, from the simple judgment as to which of two weights is the heavier to decisions upon controversial questions of great difficulty. In regard to feeling, also, some exciting stimulus or situation is presented, and the observer reports verbally the factors which appear to induce his feeling, while changes of respiration, pulse beat, glandular secretion, resistance to passing an electric current through the observer's body, etc., are recorded automatically on polygraph tape. *(See* also FEELING, PSYCHOLOGY OF.)

Reaction Time. — As a part of practically all of the general fields of investigation already mentioned it is often of interest to measure the speed at which the combination of physical, physiological and psychological processes involved takes place. For this purpose the psychologist developed elaborate and delicate reaction-time apparatus by which he can determine accurately the time elapsing between the occurrence of a stimulus and the response to that stimulus in some prearranged manner.

Abnormal Conditions. — Especially interesting questions arise in the investigation of abnormal conditions. What, for instance, are the effects of glare or of flicker in the visual field; of excessive and continued noise or vibration in the auditory and tactual fields; of drugs and fatigue upon psychical processes generally? The study of muscular and mental fatigue (*q.v.*) in particular developed a mass of special apparatus and methods of research and had an immediate practical application.

Learning and Memory. — After 1920 more experimental psychologists devoted their efforts to studying the intricacies of learning and memory, or retention, as later psychologists have generally termed it, than to any other area. The experimental laboratory reflects this interest. For human learning experiments there are tachistoscopes, apparatus for brief exposing of limited amounts of verbal or pictorial material'at a time, with the length of exposure controlled automatically. There are memory drums for presentation of consecutive learning materials at a fixed, but adjustable, rate. There is a wide range of apparatus for learning of motor skills; *e.g.*, the pursuitrotor, complex reaction-time apparatus, a variety of assembly tests and the tno-hand co-ordinator. In soundproof darkrooms there are highly complex apparatus for conditioning eyeblink response, with both photographic and electronic equipment for continuous recording of the stimulation and responses.

A substantial proportion of the modern laboratory is devoted to animal quarters and test rooms. Apparatus for animal learning is extremely diverse. There are mazes, ranging from the straightaway, a single, straight alley with a starting box at one end and a goal box at the other, through mazes shaped like T's or Y's, which require a single choice of path, on through complex mazes having from 3 up to 10 or even 20 sections arranged with cul-de-sacs or blinds. Some of these mazes may be immersed in water so that the animal must swim through the pathways to reach the goal. There is jumping apparatus for training animals to discriminate betneen visual stimuli. the subject being required to jump from a platform at one of two cards. If the animal jumps correctly, the card swings back and the animal drops into a box containing food; if it errs, it hits an unyielding card and drops into a net. There is apparatus for conditioning animals to withdraw a leg to avoid electroshock. There are revolving drums to record activity and shock apparatus for delivering convulsion-inducing electroshocks. There are Skinner boxes, which are cages containing a lever which, when operated, delivers pellets of food or drops of water. And each laboratory has additional special apparatus peculiar to the research interests of the experimenters working there and adapted to the species of subjects being investigated. *(See* also LEARNING: MEMORY.)

Social **Behaviour.**—In one direction in particular experimental psychology advanced rapidly. A great many of the conditions of human behaviour are directly social in character and source. Many attempts were made to observe these under experimental conditions, and the task was by no means hopeless. Experiments were arranged to allow observation of at least some of the effects of such socially derived motives as competitiveness, pugnaciousness, assertiveness, submissiveness, friendliness, liability to suggestion, leadership and co-operation.

The earliest success in the social experimental area was with children in college and university demonstration schools, both in nurseries and elementary grades, which, from about 1920, served frequently for research purposes as extensions of the psychology laboratories. Later, successful research in social relationships was conducted with older subjects through clubs. high school, college and adult extension classrooms, and even special interest and social groups of mature and aged individuals.

Helpful aids in this area have been the combination of a microphone and earphones and a one-way vision window built into one wall of a room which permits observers to sit in another room behind the window and observe activity in the experimental room without detection. Motion-picture and sound-recording equipment also have been extensively used in this area and have facilitated the collection of data. Results obtained in this way inevitably reacted upon the experimentalist's study of the individual, forcing him to investigate not only the operations of the intellectual, cognitive mechanism, but also the extremely important play of temperament and character. One striking achievement of the experimental psychologist was the development of exact methods of studying and ranking "intelligence." Many of the ideas and devices which proved fruitful for this purpose were taken over into the wider field of the study of the social determination of conduct and the influence of individual temperament.

LATER PERIOD

The chief aim of experimental psychology in its early days was to render a description of certain experiences as they were experimentally produced and controlled. On the one hand, the interpretation of the results obtained was dominated by theories taken over from general psychology according to mhich all complex experiences were regarded as made up of unitary elements of a sensory order which had been built together in the course of individual life by the principles of association. On the other hand, the actual methods employed were, as nearly as possible, copied from other experimental fields. Particular forms or varieties of experience. whether of a sensory or of a "higher" order, were, as far as possible, cut off from other kinds and correlated with their immediate physical stimulus. The result was often artificial in the extreme and experimental psychologists were constantly doing or initiating work which could be done much better by physiologists, with their specific training in the technique of the study of relatively isolated bodily activities. The view that complex experiences and reactions are nothing but aggregations of simpler forms practically disappeared. In consequence the problems of the experimental psychological laboratory were brought much nearer those of real life.

Behaviour.—A powerful influence in bringing about this change was the movement known as behaviourism (*q.v.*). Men have always been interested in the study of the behaviour of animals but formerly their interest led them either to' the descriptive type of study attempted by the field naturalist, or to the collection of remarkable animal stories interpreted in the light of human conscious experience. The development of an experimental approach to biology made behaviourism possible. At first, as in the field of general human psychology. experiments were mainly concerned with the special senses, and in particular with an anatomical study of the parts of the central nervous system in which various special sensory reactions of sound, vision, taste. balance and the like may appear to be localized.

Then experimenters began to try to observe exactly how various species of animals learn to discriminate one object from another, or to run successfully more or less complicated pathways in a maze. They decided to avoid explaining animal behaviour in terms of human experience and to limit themselves strictly to relating the conditions of their experiments. as any competent observer mould describe them, to the behaviour of the animals, as that, again, could be described by any instructed onlooker. It seemed possible to do a great amount, and perhaps the whole of this. without once using the notion of consciousness as a causal factor, for these experimenters rightly held that to attribute consciousness to an animal is to go beyond directly observable fact. Their success led them to put forward an exactly similar program for experimental work in general human psychology.

Most experimentalists in psychology. however, maintained their right to include in the conditions of the reactions studied many that are incapable of being expressed in physiological terms. Many continued to try to hold themselves free from any systematic theory about the nature of human experience and, taking up certain specific problems of reaction in human beings, insisted that such reactions must be regarded as partly determined by "attitudes," both conscious and unconscious, by "tendencies" whether instinctive or of a higher level, and by the accumulation of the results of past experience which appear or which function in the form of images, ideas, sentiments and so on. For example, much work continued to be done on the minimal intensity of stimuli of varying quality which mill produce a reaction. The experimental psychologist showed that these threshold values of stimuli of all kinds can be shown to depend in part upon "attitudes," images and like factors occurring during the course of ·the experimental investigation. He held that, independently of any discussion as to their ultimate character, it is impossible to reduce these to physiological and much less to physicochemical terms. Such a vien being admitted, experimental laboratories came to investigate problems over the nhole field of human response. There was a revived interest in the psychology of the special senses, particularly those of vision and hearing. Memory was investigated less as an isolated type of response and more as falling into place in a whole complex learning process which may continually involve also the higher mental activities of judging, choosing, reasoning and the like. On the side of feeling and emotion increased interest in experiment grew out of work on the effects of the secretions of endocrine glands. Methods of registering emotional expression through metabolic change were developed. Encephalography was developed in the physiological laboratory and was much exploited by psychologists.

From 1900 to 1930 experimental psychology and experimental psychologists tried to establish an independent science of behaviour, as indicated above. William McDougall emphasized the fact that purposive or goal-directed behaviour could be studied objectively. but he failed to establish an experimental program bearing out this point of view. John B. Watson stressed the importance of objective measurement in psychology, and his book Behaviorism (1925; rev. ed. 1930) had a great influence on subsequent experimentalists. Watson conducted some rather limited researches on emotional responses and emotional learning in children and maze learning in the rat, but he failed to establish an experimental program. Furthermore, he stressed the importance of the study of isolated responses, and he placed more emphasis upon the biological correlates of behaviour than upon behaviour itself.

By 1920 the research of the Russian physiologist Ivan Pavlov was becoming well-known in Europe and America, and his influence was doubtless greater than it could otherwise have been because of the groundwork laid by Watson. Pavlov's great lasting contribution was the demonstration that learning could be studied objectively in the dog. A second contribution mas the concept of the conditioned reflex, or conditioned response, as it came to be called later. This model of learning dominated the subhuman learning research for several years and remains a formidable method in psychological research. Pavlov chose to investigate a limited kind of learning, the salivary reflex. and his attempt to generalize this specific learning to more complex phenomena, such as those involved in problem solving and thinking, ended in complete failure. Thus, Pavlov remained a neurophysiologist unable to interpret conceptually the problems of the behaviour of the total organism. (See also CONDITIOXIXG; REFLEX.)

Theory. — Theory, of course, played a role in the work of all the early experimental psychologists. The attempts to integrate and explain their data gave rise to hypotheses, and these in turn led to further experiments to check their hypotheses. As the data increased and the scope of experimental psychology broadened, the need for comprehensive theories developed, and this need resulted in the rise of formal systems which attempted to embrace large areas of behaviour.

A number of systems or theories arose and subsided between 1900 and 1930, and all played a part in determining problems to be investigated and the approaches to these problems, and the resulting data led to the development of new systems with new approaches. After 1930 theory became ever more influential in experimental psychology, doubtless because of the maturing of the science.

Thorndike. — Important advances in experimentation and theory were being made by Edward L. Thorndike at the same time Watson and Pavlov were at work. Probably Thorndike's most important contribution was his analysis of the role of motivation in both animal and human learning. His work in this area was to have great influence on a later theorist, Clark Hull, but Thorndike's interpretation of learning as the formation of specific bonds or connections represented a position of limited generality and, thus, was short lived.

Tolman.—In 1932 Edward C. Tolman published his Purposive Behavior in Animals and *Men,* which must be regarded as the first systematic treatise of experimental psychology as it was considered in the late 1950s. Tolman stressed the fact that experimental psychology must be objective and that the only acceptable behavioural data are those that result from direct measurement and recording, whether by observation or mechanical devices. He pointed out that experimental psychology per se was the study of the behaviour of the total, intact organism rather than the investigation of isolated reflexes and the underlying neurophysiological processes. He named the first type of behaviour molar and the second molecular. His view that the psychologist's particular domain lay in the study of molar behaviour later received wide acceptance. Tolman also taught that the behaviour of the total organism is commonly directed to the achievement of objectively determinable ends or goals, and for this reason he used the term purposive behaviour. He mas the first theorist to emphasize the importance of intervening variables in a psychological system, these being processes which intervene between the measurable stimuli which are presented to the subject and the overt behaviour which is directly measured. Tolman's intervening variables included demand, correlated with some maintenance schedule such as food deprivation; appetite, correlated with appropriateness of the goal object such as a particular food incentive; motor skill, correlated with the type of motor response required; and hypotheses, correlated with the cumulative nature and number of training trials. He also established the principle of determining the value of the intervening variable through experiments which systematically varied the correlated environmental variables while holding all other conditions constant.

Tolman and his co-workers were the first to demonstrate the importance of appropriateness of incentives, showing sudden changes in learned performance when a preferred reward was substituted for one of lower preference and when an incentive appropriate for a particular drive state, such as food for hunger, was substituted for one inappropriate, such as water. Furthermore, converse effects were demonstrated under converse conditions. One of his more notable 'discoveries was that of latent learning. In these studies the animal was allowed to explore an apparatus, usually a complex maze with a number of blind alleys, under a particular drive state, *e.g.*, 23-hour food deprivation, in the absence of any extrinsic incentive. After a predetermined number of days food was presented at the end of the maze, and a sharp improvement in performance was found to occur on the subsequent day. Tolman interpreted these data as supporting his position that learning is a process of relating sensory or perceptual processes and that demands and appetites do not affect learning but only performance. In other words, the introduction of an incentive in the latent learning situation does not produce learning but merely provides purpose for the use of previous learning to achieve with minimum effort what has become a desirable goal.

Hull. — Probably no theoretical system has had as great an influence on experimental psychology as that formulated by Clark Hull over a period of 20 years beginning in the early 1930s. He chose the science of physics as a model and developed what was ostensibly a rigid theoretical system based on 16 postulates and the derived axioms. Unlike Tolman, he did not believe that learning was the result of new stimulus-stimulus connections; rather he conceived of learning as the formation of new stimulus-response connections. Also. contrary to Tolman, he assumed that the operation of incentives and drive states was essential to learning per se and not merely to periormance. Indeed, Hull clearly stated that habit strength (*i* **e.,** learning) resulted only in the presence of the need reduction which folloned reinforcement; reinforcement was defined as the attainment of a reward or the reduction of some deprivation state such as hunger.

In actual operation Hull tended to follow the Tolman research model. He placed great emphasis on intervening variables, and he tried to quantify each of these by determining experimentally the effects of systematic manipulation of the independent variables (*i.e.,* the experimental conditions) on the dependent variables, the directly measured responses. Hull differed from Tolman in that his primary intervening variables represented a chain of symbolic and complex interacting constructs.

Hull's system stimulated a large group of research projects employing both subhuman and human subjects. The animal research, mostly conducted with rats, confirmed that it was possible to establish the effect of many variables such as length of deprivation, delay between presentation of the conditioned and unconditioned stimulus. amount of reward and amount of effort required to obtain the reward. Generally, simple response measures were used, such as speed of running down a straight alley or rate of lever pressing in an otherwise barren box. Hull and his associates believed that the results supported his position that learning is fundamentally the formation of new stimulus-response connections arising from need reduction.

Tolman-Hull Controversy.—Because the Tolman and Hull positions appeared to differ drastically, various attempts were made to establish experimental situations demonstrating that one or the other had the greater predictive power. One of these attempts resulted in the continuity-discontinuity learning controversy. Hullian theory would predict that all learning is a gradual, continuous process whereas Tolman had predicted that some learning, at least, was saltatory. Neither group, however, was able to control adequately the conditions essential for a definitive test,

A second attempt to establish a definitive test centred around the latent learning controversy, because latent learning is similar to sudden saltatory learning, at least so far as performance is concerned. One of Hull's associates, Kenneth Spence, argued that the apparent phenomenon of latent learning was the result of inadequate experimental controls and that the phenomenon could not be demonstrated if all controls were adequate. The large number of experiments which resulted from this controversy demonstrated that the latent learning phenomenon existed under limited and prescribed conditions but was voided in similar test situations by such unexpected variables as any condition involving intense deprivation. One of the most heartening results of the latent learning controversy was the realization that even rats were motivated by conditions other than internal, biological drives and that wandering around a maze might of itself represent some need reduction.

Hullian theory led to a series of experiments involving study of the effect of serial position in memorization of nonsense syllables, analysis of the reminiscence effect (improvement in performance after practice has ceased) and the influence of massed and distributed practice on the serial-position effect. In all cases Hull made predictions on the basis of certain of his postulates. and he tested the plotted theoretical curves against those obtained empirically. The general similarities were such as to indicate that Hull's system, primarily established on the basis of subhuman animal experimentation, had considerable power in predicting limited but important aspects of human learning. Another important application of the Hullian theory is found in the researches conducted by Spence and Janet Taylor on the effect of anxiety on the conditioned eyeblink response. Making the assumption that anxiety, as measured on a paper-and-pencil test. would function to raise drive level, they predicted that high anxiety would improve performance on simple learning tasks and lower performance on more complex learning tasks. Again, the results gave general support to the predictions.

Others. — In addition to Tolman and Hull. Edwin R. Guthrie developed a comprehensive theory of learning based on conditioned-response principles, and even though he did not develop the theory to the point at which many specific predictions could be made, the theory did stimulate the collection of experimental data. Also in the same period, Kurt Lewin developed a topological theory using geometric models and physical field theory as illustrative and predictive devices; his technique received attention particularly in experimental social and experimental child psychology. Kurt Goldstein, Max Wertheimer and Norman R. F. Maier independently developed two-factor learning theories which differentiated between so-called conditioned-response type learning and a so-called creative type of learning which has been called reasoning. Another entirely different approach after World War II was the statistical learning theory presented by William Estes and Cletus Burke, and by Robert Bush and Fred Mosteller.

Laboratory Methods. — During the period of 1930 to 1957, B. F. Skinner devised and conducted a series of experiments using a technique by which rate of response is measured instead of errors or latency. Basically this technique involved use of the Skinner box. which is an experimental chamber bare except for a lever (or multiple levers) and an incentive delivery mechanism. After the animal has been trained to depress a lever and receive a reward, it is subjected to various reinforcing schedules, such as a fixed- or variable-interval schedule, in which rewards are given at predetermined periods of time regardless of the number of lever presses, or a fixed- or variable-ratio schedule, in which rewards are given after a predetermined number of lever presses. regardless of time.

The Skinner technique proved useful both in the analysis of the effect of motivational states! such as food or water deprivation, and in the analysis of simple learning phenomena; it was, for example, used extensively by Hull and his associates. In the late 1950s researches were conducted on the ability of the subjects to respond to multiple schedules.

Although the technique was used primarily in analyzing rat and pigeon behaviour, it was also used with monkeys and chimpanzres, The breadth of the method was illustrated by the fact that Skinner adapted it for the study of arithmetical instruction of elementary-school children and behavioural analysis of institutionalized mental patients.

The early comparative psychologists had been quite eclectic in the range of animal species studied, but a tendency later developed in many laboratories to limit researches to the albino rat. Fortunately, however, another trend arose, starting with the establishment of the Anthropoid Experimental station by Robert Yerkes in 1929 (later renamed the Yerkes Laboratories of Psychobiology). There was initiated a comprehensive series of experiments on the psychobiology of the chimpanzee, including collection of data on development, basic sensory capacities, motives and emotions, social behaviour and a wide range of learning abilities. Although the Yerkes laboratories have studied other primates only in incidental researches, a beginning was being made early in the 1930s in the study of other primate species. Carlyle Jacobsen published his ingenious studies on the effect of prefrontal lobectomy on the learning perforinance of the rhesus monkey; W. Trendelenberg and W. A. Schmidt, in Germany, presented their research on colour vision in monkeys; and in 1933, Heinrich Kluver summarized his search on perception and learning in a wide range of monkey species.

At the same time a primate laboratory for the study of monkeys was developed at the University of Wisconsin, Madison, under the direction of Harry Harlow, who by 1945 had developed a series of standardized techniques for measuring a wide range of learned behaviours in monkeys. The research of this laboratory made it quite clear that, at least in the case of the rhesus monkey, it was practical to use primates as subjects in the same kind of formal, rigidly designed experiments that had been popularized in researches nith rats. After 1950 there was an upsurge in the establishment of primate laboratories in the U.S.; and psychological research was undertaken at Yale university, Johns Hopkins university, Baltimore, Md., Emory university. Atlanta, Ga , the University of Texas, Austin. the University of Oregon, Eugene, the University of Pittsburgh, Pa., Stanford university, Calif.. the University of South Dakota, Vermillion, and the National Institutes of Health.

The advantages of using monkeys instead of rats in a wide variety of psychological studies became apparent. The monkey possesses a far wider range of trainable behaviours. It is quite capable of solving complex problems on a level of difficulty unapproached by any subprimate form, and its speed and proficiency in learning simpler problems make possible far more detailed analysis of the mechanisms and developmental processes underlying learning than is possible with subprimate forms.

Studies at the University of Wisconsin on manipulation motivation and on the rhesus monkey's almost insatiable urge to explore its environment visually made it clear that the monkey's motivational structure is far closer to man's than is that of any other animal except the great apes. This does not imply that other animals lack an exploration drive. Such motives were demonstrated in the rat by David Berlyne in Scotland and by Kay Montgomery in the U.S. The differences betneen primates and rodents in the form and range of these behaviours is striking, and the limitations of the rat appear to be as pronounced here as they are in the area of learning.

Areas **of** Interest. — Learning. — In the area of human verbal learning there was continuous research on both serial learning, the learning of a series of words or syllables, and paired-associates learning, the learning of pairs of words or syllables. Among the many investigators in this field may be cited the systematic work of Benton Underwood on the effects of distribution of practice. Underwood found that distribution of practice had a beneficial effect on serial lists of both nonsense syllables and meaningful materials, but that no such effect could be demonstrated for paired associates. Similar research found no evidence for reminiscence with serial lists of nonsense syllables, although this phenomenon had been reported in the past both with serial lists of nonsense syllables and with paired associates.

Thus, the historical inconsistencies from experiment to experiment and from one situation to a similar situation continued to arise. On the basis of 'a detailed review of the literature, Underwood concluded that there was no single theory such as the reactive-inhibition theory or differential-forgetting theory adequate to account for the existing data. One of the most intriguing contributions in this area in many years was a study by Underwood in which he devised a technique for equating associative strength of both fast and slow learners at the termination of practice. He then tested retention 24 hours later and found no differences between the two groups in terms of response probabilities at recall. If this finding proved to be susceptible to generalization, we would have a solution to the problem of relation between speed of learning and amount retained.

Motor Skills. — During and after World War II major emphasis was given to the development of motor skills tests, particularly as devices predictive of pilot proficiency. A large number of specific tasks resulted, such as the pursuitrotor, the two-hand co-ordinator, reversed alphabet printing and block turning, and the effects of multiple variables upon the performance of these tasks have been studied. Investigators found that there are multiple variables influencing performance on all these tests, but no new integrating approach to these problems mas devised.

From the theoretical point of view, most of the work on motor skills revolved around Hull's concepts of reactive inhibition (*i.e.*, inhibition produced by work) and conditioned inhibition, arising from the fact that stimuli associated with the cessation of a response became conditioned or learned inhibitors. A vast array of experiments was conducted dealing with various motor skills performances under conditions of distributed and massed practice, including the phenomenon of reminiscence. Information on the locus — peripheral or central — of the inhibitory effects was provided by a number of investigators. Their findings of significant post-rest gain when subjects shift from the active to the passive hand after rest give support to a central locus.

Unlike the results obtained from verbal learning studies, the differences produced by massed and spaced practice on motor skills are enormous, and the phenomenon of reminiscence appears nith unfailing regularity. The goal of many investigators was to obtain such precise control over their experimental conditions that they could evaluate precisely the role of reactive inhibition and of conditioned inhibition. Both Underwood and Estes doubted not only the ability of investigators to achieve this, but the theoretical possibility of its being done. Indeed. Underwood expressed skepticism about the existence of the Hullian postulate concerning conditioned inhibition.

Children. — Attention to the experimental study of children, normal and abnormal, was focused during this period on learning studies, and attempts were made to integrate the experimental data uncovered in research on subhuman animals with the developing learning abilities of the child. Most of these studies, such as that of transposition in nursery school children by Margaret Kuenne and the studies by Charles Spiker, emanated from Hull's theory or from Harlow's concept of "learning to learn."

Social Psychology. — A renewed interest in experimental social psychology stemmed from the original work of Alex Bavelas, a student of Lewin, on the effects of various communication links on group behaviour. The theory assumes that co-operative action by a group is dependent upon the number and kind of communication links. Various patterns of communication links can be arranged according to definable principles, and their efficiency can be tested on a wide range of task performances by groups of varying size. The effects of different kinds of links on the attitudes of the group members also can be assessed, and the influence of a wide range of conditions, including problem difficulty, distribution of problem-related information, kind of leadership by selected group members, drug states and the efficacy of various types of information feedback were investigated. This communication-pattern model became an instrument for the experimental study of the interactions of small- and medium-sized groups.

Perception. — A new approach to the psychology of perception was provided through the researches of Jerome Bruner and coworkers. They were based on the assumption that perception is a selective process and that it will be influenced by the values which the individual places upon selected perceptual objects, whether these values are determined by past affective experiences or by existing internal states. Specific experiments suggested that favourable values accentuate the physical characteristics of objects, such as the size of coins, and that they selectively sensitize the subject's perceptual system and selectively lower his recognition threshold. Unfavourable values, on the other hand, result in perceptual defense, which elevates his perceptual thresholds and increases his latency response. Furthermore, drive conditions (*e.g.,* prolonged periods of food deprivation) may enhance perceptual selectivity.

Many of these experiments were subject to criticism on the basis of inadequate experimental controls and failure to control the past experience of the subjects.

In whatever realm and with whatever general background of theory he works, the modern experimental psychologist is definitely committed to a biological method of approach. He regards mental processes as falling into their place in a biological adaptation of the organism to its environment, and his problems are thus becoming more and more an inquiry into the functions which such processes carry out, and less and less merely a description or analysis of the processes themselves.

Modern Practical Applications.—The possibility of applying experimental psychological methods to the solution of practical problems, especially in education, was early realized. The movement gained momentum and extended into many fields of human achievement during World War I when almost every belligerent country called upon its psychologists for advice in the organization and training of its military. In industry psychologists devised and widely applied special techniques for vocational guidance, selection and training. Time-and-motion studies made notable contributions to human productivity and industrial organization. Fatigue, accidents and the particular effects upon work of special environmental conditions were studied intensively in a variety of practical fields.

In education the intelligence-test movement grew to enormous dimensions. Medical applications were everywhere exploited. though they were mainly, in this period, confined to the approach through what were called abnormalities. There was even a beginning of experimental investigation of broad problems of industrial management, and there was a burst of interest in the development of new methods for determining the distribution and evaluation of the influence of public opinion.

World War II vastly increased both the amount and the scope of psychological experiment as applied to practical problems. The striking increase of mechanization both in the fighting services and in their attendant industrial processes introduced problems new in magnitude though not in their basic character. In a rapidly increasing number of directions the human operator became an indispensable link in some variety of electrical or mechanical system. Such systems. therefore. had to be devised, and the general and specific conditions of their application determined in accordance with what the normal human individual could reasonably be expected to do with the highest efficiency and the smallest strain.

Experimental psychology became of enhanced interest to the physicist and engineer. Further, since mechanization on the whole tends to increase skill requirements. many hitherto unsolved problems concerned with skill training and skill fatigue were effectively studied. With skill training went a tremendous development of synthetic trainers, the principles in the design and use of which had to be considered as never before from the psychological point of view.

Side by side with all this increased interest in problems of the design and control of the instruments and conditions of work was an increase of activity and scope in vocational and professional selection. Even the broader problems of group and individual morale and of the results of the contact of differently organized social groups began to be approached less from the point of view of dogmatic opinion and more from their factual and partially experimental aspects. PSYCHOLOGY, HISTORY OF. The history of psychology is the history of thought about human consciousness and conduct; that is to say, about reason, perception and memory, and also about action, motives and the other determinants of action. On the one hand. the history of psychology merges with the history of philosophy whenever psychology is regarded as dealing primarily with reasoning, thinking. feeling and perceiving; on the other, it merges with the history of physiology when psychology is considered to be the science of that behaviour which is regarded as a function of the action of the nervous system.

GREEK PSYCHOLOGY

Early Theories.—In the 6th century B.C. the development of medical thought had led to recognition of the importance of the brain and the sense organs in reasoning and in perception, two functions which were distinguished from each other. There also appeared quite early the doctrine of the four basic temperaments, dependent on the admixture of the four bodily humours—the blood, the phlegm, the black bile and the yellow bile. Centuries later the temperaments corresponding to these humours were named, respectively, sanguine, phlegmatic, melancholic and choleric. In early Greek thought there was no recognition of a soul which is an agent in the activities of reasoning or perceiving.

The idea of a soul as something resident in the body but capable of existence apart from it came into Greece with the Pythagoreans about the end of the 5th century B.C. Plato developed it, distinguishing between the nutritive, sensitive and rational functions of the soul, and assigning them, respectively. to plants. animals and men. He held that these functions represent a developmental hierarchy, each higher level including the lower, and that the development of reason in man may introduce conflict between reason, which is possessed only by man: and desire. which exists also at the animal level. Thus we find in Plato the conception of the soul's activity as constitutive of its basic functions? and the notion that simpler activities develop into more complex, sometimes giving rise to conflict. Such conceptions reappear from time to time in the history of psychology, notably in the psychology of G. W. Leibnitz (1704), J. F. Herbart (1825) and Sigmund Freud (1900), the line of development that led eventually to what is called dynamic psychology.

The Greeks also introduced the doctrine of empiricism into psychology, the doctrine that all the contents of the mind are derived through the senses. Heraclitus (5th century B.C.) held that all knowledge comes to man "through the door of the senses," and Protagoras (c. 484–411 B.C.) that the entire psychic life is made up only of sensations. The Stoics used the figure of the *tabula rasa,* the blank wax tablet of the mind upon which experience writes. This is the doctrine that was taken up later in the British school of empiricism.

The Greeks had also a theory of perception. Empedocles (c. 490–435 B.C.) supposed that objects give off from their surfaces or pores effluvia, which act upon the senses to furnish knowledge of the external world. Democritus (5th–4th century B.C.) and Epicurus (*c.* 341–270 B.C.) described these projections as faint images, simulacra or eidola of the objects which. being conducted to the mind, give it acquaintance with the objects which they represent. This view that perception represents an object by being similar to it is so simple and attractive that it continued to persist. in spite of opposition, having been contradicted by Johannes Müller

(1801–58) and by various critics in the 20th century.

Aristotle.—Aristotle (384–322 B.C.) has been said to be the greatest mind in the history of thought. Certainly his recorded wisdom influenced the scholarly thought of Europe more completely and for a longer time than have the writings of any other one man. He was both philosopher and scientist, theorizer and empiricist, and the psychology found in his De *Anima* and other writings determined accepted psychological doctrine down to the end of the 18th century.

In Aristotelian doctrine the body has a pneuma, which is connate with it and pervades it. This pneuma (animus, spirit) effects the integration of the organism by its appropriate movement within the body. Aristotle seems to have believed that the pneuma moved within the blood vessels, for he knew nothing about the nerves. Later psychologists substituted "animal spirits" for the pneuma and assumed that the nerves were their conductors, but the basic idea of integration by an internal pervasive agent was Aristotle's. The soul, according to Aristotle, is the entelechy of the body; that is to say, it is the perfection of unity toward which the functions of .the body are directed. This stress upon the unity of the soul and the importance of considering the total organism in the understanding of perception and action persisted through the ages into modern psychology and is the chief means of distinguishing psychology, which deals with total action, from physiology, which deals with the functions of parts.

Aristotle localized the psychic functions in the heart. That was an error. Plato and Pythagoras had been correct in placing them in the brain. Much later, Galen (*c.* A.D. 130–*c.* 200), one of the greatest physicians of antiquity, synthesized the two views by arguing that the animal spirits are stored in the ventricles of the brain, flow thence to the ventricles of the heart, whence they are distributed to the body by the arteries.

The specification of five separate senses is due to Aristotle. External forces, he held, act upon the body and their effects are transmitted by the pneuma to the sensorium, where the unity of the senses is preserved, as can be seen in such perceptions as those of shape and size: which are common to both sight and touch.

Aristotle distinguished clearly between the cognitive and conative aspects of the soul. On the one hand, he noted a cognitive series of functions from sensation to reason; on the other, a conative series from simple desire through wish to will. The basic conative drive Aristotle called *orexis*. In terms of it he derived a dynamic psychology, which for him included ethics.

Hellenistic Period.—After Aristotle there ensued the Hellenistic period, which was distinguished. among other things, by the brilliance of Alexandrian science in the 3rd century B.C. Herophilos (4th century B.C.) and Erasistratos (c. 304–258 B.C.) discovered the nervous system, the nerves leading to the brain and spinal cord. They even distinguished between motor and sensory nerves, a distinction that was not validated until 2,000 years later. In general, however, Alexandrian science did not promote psychology, for the mind was not then supposed to be understood in terms of natural law, and psychology and physiology became during the course of many centuries more and more widely separated.

The Stoics (c. 300 B.C.) contributed both the notion of instinct and of conscience, the latter signifying an inner sense of conformity with innate reason. In general. the Christian schools took over the pagan philosophy and with it Aristotle's psychology. By the 3rd century A.D. Plotinus (c. A.D. 203–270), promoting a return to Platonism, established psychology as a pure science of experience based upon introspection described without regard to underlying physiological processes. Augustine (A.D. 354–430) continued this tradition, establishing what came presently to be the accepted psychology of the Christian Church. Thereafter, through the middle ages! psychology consisted largely of a repetition and elaboration of the dicta of Aristotle and Augustine.

EARLY MODERN PSYCHOLOGY

All through the history of psychology we find a dichotomy in respect of which the various views and theories about mind and the definitions of psychology can be organized. In the absence of accepted terms, we may call the one the phenomenological approach and the other the mechanistic approach. The phenomenological approach to the problems of mind includes the description of immediate experience, directly as it comes to the observing person. It tends to regard mind as separate from the body and to get along with only minor reference to physiology. It is often an unexperimental psychology, being available to philosophers by their own introspection. The modern representatives of the phenomenological approach are Franz Brentano's intentionalism, Wilhelm Wundt's introspectionism, and Gestalt psychology. The mechanistic approach, on the other hand, deals more with causal relations than description. It is thus forced to look to bodily functions and physiological processes in order that it may subsume psychological events under natural law. Its modern representatives are U.S. functionalism, behaviourism and operationism. In general, up to the year 1910 and even later, the British and German traditions were phenomenological, the French and U.S. mechanistic.

Seventeenth-Century Psychology.—Plotinus and Augustine had left psychology phenomenological and descriptive. In the 16th century, with the tendency to recognize that causal principles determine behaviour, occurred the beginnings of a dynamic psychology. Niccolo Machiavelli (1469–1527) had effectively expounded the thesis that men are controlled more by their passions than by reason, and various other less well-known writers had developed that theme. Still later we find Francis Bacon (1561–1626) promoting a naturalistic view of man's conduct.

Thomas Hobbes (1588–1679), who published his Leviathan in 1651, was essentially a mechanist, a dynamic psychologist. He was primarily concerned with the conduct of man, especially his social conduct. Hobbes distinguished between innate motives and those that are acquired in experience. He observed how pleasure and pain, pride and fear, determine human action. He is perhaps, before John Locke, the originator of British empiricism, because of his stress upon the role of experience in establishing the nature of man; but mostly he was a social dynamic psychologist.

The great founder of the mechanistic tradition in psychology was René Descartes (1596–1650), a philosopher who also performed anatomical dissections and physiological experiments. He established in the common sense of the next three centuries the dualistic notion that mind and body are separate, that mind is unextended substance and body extended substance, the mind occupying the body and interacting with it at a determinate point in the brain. Thus, body affects mind, and mind body. Animals, who have. Descartes thought, no rational souls, are automata, machines which behave in accordance with their properties and the forces which act upon them. Thus, the history of reflex action. as basic to the mechanistic conception of mind, must be dated from Descartes. He called the total motion of the animal spirits along the nerves through the valves of the brain and out again along other nerves to the muscles *undulatio reflexa,* since the nervous system, in redirecting the course of the animal spirits to produce movement, may be regarded as "reflecting" them.

The mechanistic tradition was continued in France during the 17th century by the contributions of Nicolas de Malebranche (1638–1715).

Scientific cognizance was also being given at that time to some of the problems of visual perception. Leonardo da Vinci (1452–1519) had already discussed some of these problems—colour contrast, the relation of light and shade and of aerial perspective to the perception of the third dimension, the problem of the transparency of near objects in binocular vision (caused, of course, by the different angles at which the two eyes view the scene) and the similarity of the eye to a camera. In 1604 the astronomer Johann Kepler (1571–1630) noted that the crystalline object in the eye must be a lens and not the percipient organ, and that it must throw an inverted image on the retina. He, therefore, decided that the retina must be the percipient organ. Kepler then raised the question as to why we see right side up when the retinal image is upside down, falling into the common error of thinking that external objects must be represented by similar patterns in the brain. Later Descartes demonstrated, using the excised eye of a bull, that the inverted image is actually formed by the lens at the back of the eye.

The century saw two other important discoveries in the field of sense perception. In 1638 Galileo (1564–1642) showed that the pitch of tones depends on the frequency of vibration of the air, that the ratio is two to one for the octave and three to two for the fifth. In 1672 Isaac Newton (1642–1727) presented to the Royal society his first paper on colour theory, in which he showed by experiments with a prism that white is a mixture of colours. a discovery that was at first met with incredulity by his scientific colleagues. Newton worked out the laws of colour mixture, and his *Opticks*, after a long delay, was published in 1704.

Eighteenth-Century Psychology.—The French mechanistic tradition was continued by J. O. de Lamettrie (1709–51), who published his *L'homme machine* in 1748; by E. B. de Condillac (1715–80), who is noted for his analogy of the human organism to a statue, which, provided with a single sense, acquires through experience the attributes of a human mind; and by P. J. G. Cabanis (1757–1808), who extended the knowledge of reflex action and argued—he was interested in the reflexes of victims of the guillotine—that consciousness is dependent only on the action of the brain and not of the spinal cord. Contemporaneous with Cabanis was M. F. X. Bichat (1771–1802), who has been called by some the founder of physiological psychology.

The important events of the 18th century occurred, however, on the phenomenological side of psychology, especially in connection with the development of British empiricism and associationism.

In a sense, British empiricism began with Hobbes, but its formal initiation was the publication in 1690 of the *Essay Concerning Human Understanding* by John Locke (1632–1704). Locke's argument was that the mind is constituted of ideas. all of which are gained from experience, most of them by way of the external senses, some of them by reflection, which is the inner sense by which the mind becomes aware of its own operations. Although Locke added a chapter on association of ideas to a later edition of his *Essay*, the doctrine of association became of importance only with his successors.

Bishop George Berkeley (1685–1753), famous for his subjective idealism, inverted Locke's proposition. The problem, he thought, is not how the ideas get into the mind from outside by way of the senses, but rather, since the mind knows nothing other than the ideas of which it is constituted, how we ever obtain a belief in the existence of the external world. Berkeley undertook to answer this question and many other related ones by an appeal to experience and a principle which is essentially that of the association of ideas. He also wrote a *New Theory of Vision* (1709), which contributed both to the systematic theory of empiricism and to the psychology of visual perception.

David Hume (1711–76) comes next in this line of descent. He differentiated impressions, which depend upon a present stimulation, from ideas. which are "faint copies" of the impressions. This is the distinction between sensation and image in later terminology. Hume also undertook to explain the concept of causation as resulting from the habitual sequence of the impressions of two events, thus reducing causation to association. Because Hume lent his great influence to the conception of ideas as mental elements whose compounding explains all of the more involved mental phenomena, he is often regarded as the chief enemy of holism. as it is found in the modern school of Gestalt psychology.

David Hartley (1705–57), while less important than his predecessors in this school, stands out because of the clear, simple and emphatic associationism which his *Observations on Man* of 1749 presents. Taking association from Locke and the notion of transmitted vibratory motion from Newton, he built up a system in which the laws of association of ideas were paralleled by laws of association of vibrations (correlated with sensations) and diminutive vibrations (correlated with ideas. images) in the nervous system. This sharp and uncompromising presentation of the associationistic principles. combined with a simple psychophysical parellelism of mind and nervous action, served to make the nature and implications of associationism clearer than could the more subtle exposition of an abler mind, like Hume's.

The French tended to take over associationism and combine it with their mechanistic psychology. Condillac's statue (*see* above) was supposed to build up its sensations in experience by means of associative principles.

Meanwhile in Germany there was G. W. Leibnitz (1646–1716), Locke's contemporary. Leibnitz's chief contribution to psychology was his insistence on the active nature of the mental units, his "monads," which are forever striving for development according to their pre-established nature. The association of ideas in the British school tended to create the picture of fixed mosaics of mental elements which make up the complexes of the mind. Leibnitz, on the other hand, remained on the side of a dynamic psychology, which insists that activity and purpose are basic in mental life. He believed that his monads develop independently, and that the results of their interrelations are simply coincidences resulting from a harmony pre-established among them and not from causal interaction. The conception of psychophysical parallelism between mind and body grew out of this Leibnitzian notion. Leibnitz also contributed to psychology the concept of apperception, which he held to be the consequence of the summation of many little perceptions. His notion that the apperception of the roar of the sea is the sum of the "petites perceptions" of the noise of every falling drop of water is well known. It gave rise to the concept of the threshold of consciousness as it is found in the writings of Herbart, in G. T. Fechner and psychophysics, in Freud and psychoanalysis.

After Leibnitz the development of German psychology passed into the hands of a number of less well-known men in the Berlin academy, of whom J. N. Tetens (1736–1807) is perhaps the best known. The chief contribution of these philosopher-psychologists was to stress the importance of feeling as a third primary category of psychology. Heretofore cognition and volition. knowing and acting, had constituted chief subdivisions in systematic psychology. Now the affective life was added as a third, and this threefold division of the subject matter of psychology—thinking, feeling and doing—continued as the standard classification all through the 19th century and well into the 20th.

PSYCHOLOGY IN THE 19TH CENTURY

The history of psychology in the 19th century can be viewed as a history of schools of systematic thought about the mind (associationism, introspectionism, intentionalism, evolutionism, functionalism) and of fields of experimentation and research (physiological psychology, experimental psychology proper, phenomenological observation, abnormal psychology and the mental tests in conjunction with the functional psychology of individual differences).

Associationism.—While the Scottish philosophers—Thomas Reid (1710–96), Dugald Stewart (1753–1828) and Thomas Brown (1778–1820)—are not properly classified as associationists. the theory of perception that developed under their thought contributed to the importance of associationism. Bronn's theory is the culmination of the discussion. He distinguished between sensation and perception, holding that perception, unlike pure sensation. refers to or intends an external object. In perception the sensations that first arise suggest—by association. but Brown preferred the word "suggestion" to "association"—other sensations which specify the object which is intended. For example, the smell of a rose suggests the sight of a rose, which is enough to identify the object as a rose. In other words, meaning arises in perception by the compounding of two or more sensory elements, and that theory is really the core of associationism: meaning is given in consciousness by the associative compounding of ideas.

It was James Mill (1773–1836) who expressed this view in simplest and clearest terms in his *Analysis of the Human Mind* in 1829. In fact, he reduced the theory to an absurdity by carrying it to its logical conclusion. At the end of his chapter on association of ideas, he noted that the idea of any object is a fusion of the ideas of its components. "Brick is one complex idea, mortar is another complex idea: these ideas. with the ideas of position and quantity, compose my idea of a wall." Finally, he asked: "How many complex ideas are all united in the idea of furniture? How many more in the idea of merchandise? How many more in the idea called Every Thing?" That was the difficulty: the associationists thought that the idea of everything must be a compound formed by association of every idea of a thing.

John Stuart Mill (1806–73), James Mill's son, made no such error. He avoided the difficulty by noting that a combination of elements often generates something totally new in the compound, so that the parts are lost and the new product gained. This is the theory that Wundt called creative synthesis, that others much later called emergence, that became still later the basis of Gestalt psychology. J. S. Mill also argued that the unrealized potentialities of association play their role in the mental life: an object is, he argued, the "Permanent Possibilities of Sensation"; that is to say, the sensations that it could arouse. As an object, it is believed to be permanent, in spite of the evanescent nature of experience, because these possibilities of sensation are permanent.

Alexander Bain (1818–1903) is the representative of associationism in the latter half of the 19th century. He combined with associationism the growing interest in physiological psychology. Herbert Spencer (1820–1903) represents an influential evolutionary associationism, a doctrine that worked in with the trend of thought in England after Charles Darwin's influence had become dominant. From this point associationism passes over into the introspectionism of Wundt and his followers.

Introspectionism.—Wilhelm Wundt (1832–1920) has been called the founder of the new scientific psychology of the 19th century. Certainly he was its vigorous promoter. He called it physiological psychology and experimental psychology. His *Grundziige der physiologischen Psychologie* was a systematic text and also a general handbook of the new science: and it ran to six editions from 1874 to 1911. Wundt founded the first formal laboratory of psychology at Leipzig, Ger., in 1879. He started the first journal devoted to experimental psychology in 1881. For 40 years he was the most important and influential figure in German psychology.

As a systematist he was an elementist and an associationist, for he described the sensations and feelings that are the mental elements of psychology, and showed how they are compounded by association into ideas and perceptions *(Vorstellungen)* which are meaningful and refer to objects. The turn of events, however, put more emphasis upon Wundt's insistence that introspection—the verbal description of the immediate data of experience—is the chief method of psychology. Although Wundt called the new science physiological psychology, he was insistent that physiological processes parallel and do not constitute the psychic processes. The phenomena of consciousness, he held, are observable without reference to the body to which they belong.

Wundt's position was continued by Oswald Külpe (1862–1915) and E. B. Titchener (1867–1927). They were both his students. Külpe is best known for his attempt to apply the introspective method to the study of thought in the researches of his Würzburg school (1901–09), which showed—this appears to be the verdict of time—that introspection is inadequate to the observation of the unconscious directive tendencies which preserve the purposive nature of thought. Titchener went to the United States in 1892 and there upheld the Wundtian position for 35 years. There can be no doubt that U.S. functionalism was more clearly understood because it contrasted so strongly with Titchener's unyielding introspectionism. Titchener hoped that psychology could eventually get along without any relation to physiology.

J. F. Herbart.—The influence of Herbart (1776–1841) was so great during the first half of the 19th century that separate mention must be made of him. He defended a psychology founded upon experience, metaphysics and mathematics, and denied the possibility of experimenting upon mind. He conceived of ideas as active and struggling, one with another, for a place in consciousness. Thus, as we have already noted, he provided, in following Leibnitz, both psychophysics and psychoanalysis with the concept of the threshold of consciousness and also with the notion of unconsciousness that lies below the threshold. Much of Wundt's work was clarified by his opposition to Herbartian ideas.

Intentionalism.—The traditional psychology that had come down from Aristotle and Augustine was reformulated by Franz Brentano (1838–1917), a Roman Catholic priest and a psychologist of aide influence, as what is called act psychology or intentionalism. The contrast between Brentano's and Wundt's psychologies was heightened by the fact that both men published their crucial systematic texts in 1874. Brentano contended that the conscious mind is constituted of acts—ideating, judging, feeling ("loving-hating"). Wundt had divided mind into more static elements—sensations and the feelings. The acts, Brentano held, have objects which they "intend" or are directed upon, and these objects "inexist" within the act. If I see a green, then the act of *seeing* is the mental datum and the *green,* the object of the act, exists intentionally within the act, thus in part determining its nature.

Brentano's psychology claimed many followers in the late 19th and early 20th centuries, especially in Austria. Kiilpe's later systematic views were affected by Brentano's thinking, as was also the system of Carl Stumpf (1848–1936), who, holding the chair at Berlin, found himself in opposition to Wundt on many occasions.

In England, James Ward (1843–1925) was markedly influenced by Brentano. Ward distinguished between cognition, feeling and conation, finding all three present in the representative psychological act. G. F. Stout (1860–1944) followed the tradition of Ward, and William McDougall (1871–1938), who in 1919 transferred from England to the United States, upheld a purposive psychology that showed this same influence.

Evolutionism.—One effect of Charles Darwin's theory of evolution was to interest psychologists in mental inheritance and in the phylogenetic development of mind. In 1869 Francis Galton (1822–1911) published *Hereditary Genius,* a study which showed that men of eminence in England tend to be related. In those days the data were taken as demonstrating the biological inheritance of mental ability, although later it became evident that these great men owed their eminence at least in part to their education and their socioeconomic status. Darwin himself argued for the phylogenetic development of mind in his *Expression of Emotion in Man and Animals* (1872). Thereafter the versatile Galton conducted other studies on mental inheritance among persons of ability and on the resemblances of twins. He advocated the inventorying of the abilities of the British nation, inventing some simple tests whereby such an inventory could be made (or so he thought). He coined the word "eugenics," meaning by it the improvement of the race by selective parenthood.

G. J. Romanes (1848–94) carried on this interest in England by his studies of animal intelligence and his books on mental evolution in both animals and man. He coined the term "comparative psychology" for the study of the relationships between the minds of different animal species. C. Lloyd Morgan (1852–1936) carried comparative psychology further, and this field of endeavour was then taken up in the United States *(see* PSYCHOLOGY, COMPARATIVE).

British evolutionism also found support in the United States. J. M. Baldwin (1861–1934) was the Romanes of the U.S.. with two important books on mental evolution. G. Stanley Hall (1844–1924) admitted that his many interests in the different phases of human capacity were held together by his abounding faith in the importance of evolution. James McK. Cattell (1860–1944), directly influenced by Galton, coined the term "mental test" in 1888 and lent his support to the development of the psychology of individual differences. In the United States evolutionism formed the background of functionalism.

Functionalism.—In the 1880s and 1890s the United States had the temper of a young nation, a nation still imbued with the practical spirit of conquering a continent. It sent its psychologists to Wundt at Leipzig that they might learn the best of what was new in psychology, but U.S. psychology never accepted the pedantry of the German approach to the subject. The Americans were bound to be practical and functional, to see mind in terms of its use for the survival of the organism in the struggle of the race for existence and in the social competition of the individual for success. Hence, the United States accepted evolutionism enthusiastically and created its own psychology, which was functional.

William James (1842–1910), pioneer of psychology in the United States, introduced the functional approach to the problems of the mind in his *Principles of Psychology* of 1890. Cattell, as has just been noted, supported a functional psychology in his advocacy of the use of mental tests in the 1890s and later. The formal school of functionalism was, however, founded by John Dewey (1859–1952) about 1896 and was continued at The University of Chicago by James R. Angell (1869–1949) and his associates.

Functional psychology admits the data of both consciousness and behaviour to its domain, for it is primarily concerned with what enables the organism to adapt to the varying conditions of its environment. Functional psychology is the psychology of the "Is-for," as Titchener remarked, the psychology of how to be successful, and thus it is appropriately American. The school disappeared after Dewey and Angell left Chicago, and behaviourism was ready to replace it (c. 1916). Nevertheless, the spirit of functionalism, since functional psychology is a natural medium for physiological psychology, animal psychology! differential psychology, normal psychology and applied psychology, came to stay and has characterized most of the psychology of the United States from the beginning. *(See* section on *Functional Psychology* below.)

Physiological **Psychology.**—The century saw great progress in nerve physiology. In 1811 Charles Bell (1774–1842) distinguished between sensory and motor nerves, showing that the two kinds of nerves have separate roots at the spinal cord. François Magendie (1783–1855), the French physiologist, discovered independently in 1821 this same fact, which is called the Bell-Magendie law. As electrical currents and galvanometers became available in the 1840s, the electrical properties of nervous conduction came to be investigated, and the mysteries of the animal spirits were dissipated by the accumulation of observed facts. In 1850 H. L. F. von Helmholtz actually measured the velocity of the nervous impulse along a nerve, a discovery which met at first with as much incredulity as Newton's report in 1672 that white is a mixture of colours.

There was also a great deal of work on the localization of functions in the brain. F. J. Gall (1758–1828), a brain anatomist of considerable ability, formulated the theory of phrenology about 1800, the theory that temperament can be assessed from a study of the conformation of the skull. since the development of crucial areas in the brain would be reflected in the shape of the skull. The popularity of this view was not readily destroyed by the scientific opposition which it received. Pierre Flourens (1794–1867) undertook experiments upon animals to determine more exactly the functions of the various parts of the brain, discovering about 1825 that certain gross areas are essential to certain functions but that fine localization is often (perhaps always) missing. In 1861 Paul Broca (1824–80) discovered the speech centre in the left cerebral hemisphere, and then in 1870 G. Fritsch and E. Hitzig localized motor centres precisely by electrical stimulation of the brain. The last quarter of the century saw the growth of a firm belief in exact cerebral localization, a belief somewhat weakened by the discoveries of the 20th century.

Johannes Müller (1801–58), sometimes known as the father of experimental physiology, affected psychology by his doctrine of specific nerve energies. which he first published in 1826. The doctrine was really a theory of sensory quality, for Müller sought to demonstrate that the sensory quality aroused by stimulation depends on the particular nerve excited and not directly on the nature of the stimulus. Pressure on the eyeball produces a sight, light on the skin elicits warmth and electricity on any nerve arouses the peculiar quality ("energy") that belongs to the nerve. Later Helmholtz extended this doctrine to differences of quality within a given sense, even seeking in the inner ear a means whereby each one of several thousand distinguishable pitches could be put onto a corresponding nerve fibre. Later research indicated that the specificity of different nerves and fibres lies not in a peculiar nervous energy but in points in the brain to which fibres lead.

Experimental Psychology. — Experimental psychology *(q.v.)* proper began with sense physiology, the study of how sensory experience is dependent on stimulation of the sense organs. which is what Fechner later called psychophysics *(see* PSYCHOPHYSICAL METHODS). Newton's discovery of the laws of colour mixture and Galileo's finding about the dependence of tonal pitch on stimulus frequency were psychophysics. In the 19th century the increased interest in sensory physiology advanced psychophysical investigation greatly.

Research on vision predominated. Thomas Young (1773–1829) published his theory of colour vision in 1801, the theory that Helmholtz later established. The poet, J. W. Goethe. in 1810 published his *Zur Farbenlehre,* an elaborate, dictatorial phenomenology of colour; its immediate influence was great because of the enormous prestige of its author. J. E. Purkinje (1787–1869) also wrote a phenomenology of vision (1819. 1825) which contains the first accounts of several important phenomena; for example, the "Purkinje phenomenon" of the changes of hues as illumination shifts from daylight to night vision. Johannes Müller's first important book (1826) was on visual physiology.

In 1834 E. H. Weber (1795–1878) published his experiments on tactual sensibility, experiments which included his finding that magnitudes of stimuli that are just noticeably different in perceived intensity bear a constant ratio to each other. G. T. Fechner later named this principle Weber's law. It is only approximately true.

The century's two most important experimental psychologists were Fechner and Helmholtz. Fechner (1801–87) was, by way of his *Elemente der Psychophysik* of 1860. the founder and promoter of psychophysics, and some say of experimental psychology, although that distinction is generally reserved for Wundt. Fechner was obsessed by his realization that it is possible to measure sensation as well as the sensory stimulus, and to state in an equation the relationship between the two measures. He described, developed and formalized the three fundamental psychophysical methods of sensory measurement. He named Weber's law and worked out the quantitative relationships which it implies. He established the concepts of the absolute limen (just noticeable sensation) and the differential limen (just noticeable difference between sensations), and the methods of measuring them. In short he put sensory psychology on a quantitative basis.

H. L. F. von Helmholtz (1821–94) made the greatest factual contribution of any one man to experimental psychology. The results of his observations and thought appear in the three volumes of his *Handbuch der physiologischen Optik* (1856–67) and the one volume of his *Lehre von den Tonempfindungen* (1863), which for more than half a century remained respectively the standard reference works on visual and auditory psychophysics.

Fechner's methods and Helmholtz's facts helped Wundt in the founding of experimental psychology. The last quarter of the 19th century saw the founding of many psychological laboratories, first in Germany and then in the United States. Wundt's demonstrational laboratory in 1875 was the first to be created, and his institute at Leipzig in 1879 was the first formal laboratory; William James also had an informal laboratory at Harvard college as early as 1875. Research followed the founding of the laboratories — first on sensation and perception. then on action, then on memory and learning, with the bare beginnings of an experimental psychology of thought and attitude showing before 1900.

Abnormal Psychology. — The history of abnormal psychology *(see* PSYCHOLOGY, ABNORMAL) would consist of a history of witchcraft, animal magnetism, hypnotism. hysteria, psychoanalysis and neurosis. Many of the neurotics of the 17th century were considered to be sorcerers or witches. Late in the 18th century F. A. Mesmer (1754–1815) discovered that he could exercise over other persons a peculiar power which he called animal magnetism and which others came later to call mesmerism. Toward the middle of the 19th century James Braid identified this state with some of its scientific conditions, calling it neurypnology which later became hypnotism (*q.v.*). In the last quarter of this century

J. M. Charcot (1825–93) at the school of the Salpêtrière near Paris undertook the study of hysteria, a neurotic state in which the extreme symptoms resemble the symptoms of hypnosis. Charcot thought that only hysterical persons could be hypnotized, but in that belief he was wrong. Charcot's place as the foremost psychopathologist of France was taken by Pierre Janet (1859–1947), who published the classical text on hysteria in 1892.

Sigmund Freud (1856–1939) was also for a brief time a student of Charcot, but Freud's development of the method and concepts of psychoanalysis were his independent doing.

Psychoanalysis (*q.v.*) may be said to have got under way with Freud's publication of his book on the interpretation of dreams in 1900. Its further development and the emergence and establishment of the dynamic psychology of neurosis, which made use of many psychoanalytic terms and concepts, are largely a history of events in the 20th century.

The history of abnormal psychology is, of course, related to the history of psychiatry (*q.v.*). In Germany Emil Kraepelin (1856–1926), one of Wundt's pupils, contributed notably to psychiatry and to the classification of the abnormal states with which psychiatry deals.

Differential Psychology. — We have seen how Galton became interested in individual differences in mental capacities and formed a scheme of inventorying the British nation in order to assess its psychological resources. He invented a number of simple mental tests and Cattell, in the United States, made up some more and promoted their use. Galton's and Cattell's tests were for the most part simple tests of sensory and motor capacity and did not adequately measure intellectual and scholastic abilities. In France Alfred Binet (1857–1911), assisted by Victor Henri, was developing certain concepts of personality and tests of intelligence for children. Out of that work there emerged in 1903 Binet's intelligence tests. which, because they measured more important intellectual capacities, nere accepted in preference to the sensory and motor tests. The history of intelligence testing, and later of testing for special abilities and aptitudes, belongs, however, to the 20th century.

PSYCHOLOGY IN THE 20TH CENTURY

For the most part the history of the psychology of the first half of the 20th century is given in the special articles on psychology.

(See PSYCHOLOGY and cross references there cited.) The following paragraphs give the general perspective.

Schools. — The century began with introspectionism and functionalism well established in the United States, introspectionism and intentionalism dominating the psychology of Germany, abnormal psychology important in France and evolutionism in England. Gestalt psychology began in Germany about 1912 as a reaction against Wundtian introspectionism, and its leaders came to the United States in the 1930s after Adolf Hitler came to power. Behaviourism began in the United States about 1913 as a protest against both introspectionism and functionalism, but actually hehaviourism was not inconsistent with functionalism, and presently it took over the practical and mechanistic values that had been the occasion for functionalism. The attack on old-fashioned analytical introspectionism was successful, and in the late 1920s Gestalt psychology and behaviourism found themselves practically in possession of the field. With their missions thus more or less accomplished, both these schools tended to die out or at least to lose their aggressiveness during the 1930s. Psychological operationism came in at this time to supplant behaviourism as a more sophisticated mechanistic view of psychology, and the outstanding systematic issue in the early 1940s seemed to be whether the Gestalt psychologists could save consciousness, as observed in direct experience, for psychology, or whether the operationists would succeed in having it reduced to the behavioural terms which define the manner of its observation. In general, the operationists tended to support physiological psychology, whereas the Gestalt psychologists relied more often on the modern substitute for introspection which they call phenomenology. (*See* BEHAVIOURISM; PSYCHOLOGY; *see* also special sections on *Functional Psychology* and *Gestalt Psychology* below.)

Trends. — The first half of the 20th century was marked by the shift of leadership in psychology from Germany to the United States, by a decrease in the importance of schools and an increase in the importance of scientific research, by the diversification of psychology into many special fields, each possessed of its own techniques and special knowledges, and by the growth of applied psychology in its various professional aspects, in England and Germany as well as in the United States.

Experimental psychology, the general scientific psychology of sensation and perception, feeling and emotion, learning and thought, response and action, remained the expanding core of modern psychology, although it could scarcely be said to dominate a subject which now had so many special fields. *Animal psychology,* which began the century as an independent field of research, became amalgamated with experimental psychology, at first under the influence of behaviourism, and later because most of the experiments in general psychology, especially the experiments in the field of learning, could be conducted more efficiently with animal subjects. I. P. Pavlov's researches on the conditioned reflex re-enforced this association. *Physiological psychology* required operative techniques and was likewise fairly independent of experimental psychology at the beginning of the century, but also became fused with it.

By 1940 the distinctions among these three fields had almost disappeared. (*See* PSYCHOLOGY, COMPARATIVE; PSYCHOLOGY, EXPERIMENTAL.)

Differential psychology developed steadily from the beginnings of mental testing with Galton, Binet and Cattell. Up to about 1920 the testing of "intelligence" was the most important activity in this field. About that time psychologists began to realize that social. economic and educational factors can affect ability to do well in an intelligence test, and that biological inheritance is less important than had been supposed. C. E. Spearman in England began in 1904 the development of those statistical correlational methods of the analysis of abilities that later resulted in factor analysis. These improved methods of analysis turned attention away from general intelligence toward the factoring out of the personality those special abilities and aptitudes which function independently in the organism's struggle for success. It is obvious that a great deal of the development of differential psychology has thus been functional and in the interests of applied psychology. (See DIFFERENTIAL PSYCHOLOGY; INTELLIGENCE)

Abnormal psychology was quite distinct from general psychology for fully three decades of the century. Since it dealt with the functional disorders and thus with motivation. it got ahead with the problems of personality much faster than did general psychology. *Psychoanalysis* also constituted an attack on the problems of motivation and personality, and its ideology came largely to be accepted by psychiatrists and psychologists, even when they repudiated its techniques and certain of its tenets. It was this development of abnormal psychology throughout the first three decades of the century that gave rise in the 1930s to a vigorous dynamic psychology. (*See* PSYCHOLOGY, ABNORMAL; PSYCHOANALYSIS.)

Dynamic psychology arose because of the great interest in human motivation. By 1925 it was beginning to concern psychologists more and more. Dynamic psychology provides a general background for many applied psychologies, like *clinical psychology,* and the techniques of counselling and guidance.

Child psychology, although it grew out of evolutionism and the interest in genetic psychology in the late 19th century, has been essentially dynamic psychology, and child guidance has become an important branch of applied psychology. (See CHILD PSYCHOLOGY.)

Educational psychology was also principally a growth of the 20th century. It was stimulated by the development of psychological tests and by the general acceptance of the concept of intelligence as the chief intellectual dimension of maturation in childhood and adolescence. Educational psychology has been, of course, closely associated with child psychology and dynamic psychology.

Social psychology has its roots in the *Volkerpsychologie* of the Germans in the 19th century and in the work of certain French writers, especially Gabriel de Tarde and Gustave le Bon. In 1908 William McDougall's *Social Psychology* based social behaviour on the instincts, of which he furnished a classification. After that time social psychology became dependent for its theoretical structure upon those primitive drives or needs which the dynamic psychology of any given period could provide. In the 1930s social psychology was becoming applied, notably through the development of public-opinion polling and the analysis and control of propaganda. In World War II the techniques of the social psychologists were used broadly for the assessment and control of opinion and attitudes and for the gathering of psychological information about large social groups. In such undertakings social psychology was found to be closely related to social anthropology and to certain modern empirical movements in sociology. *(See* section on *Social Psychology* below.)

Applied psychology was the term used for psychotechnical endeavour prior to 1920. Thereafter the special applied psychologies began to make their appearance. We have already noted the modern concern with educational psychology, with clinical psychology, with counselling and guidance of adults and children (as well as the aged) and with applied social techniques. In addition to these there was some development of *legal psychology* and, after 1920, a great deal of interest in *industrial psychology* which, apparent first in England, was promoted subsequently in the United States and greatly furthered by the successful use of psychology in World War II. Industrial psychology is concerned with the selection and training of personnel, and the establishment of the most efficient conditions for work. Efficiency depends upon the proper design of machines, the reduction of fatigue, the promotion of good health and the maintenance of good morale in the relation between worker and employer. Thus, industrial psychology makes use of many of the principles of perception, sensorimotor co-ordination and learning which general psychology develops. and of dynamic psychology, differential psychology and social psychology.

FUNCTIONAL PSYCHOLOGY

Functional psychology is that point of view which emphasizes the biological significance of mental activities, holding that conscious processes, like organic activities, appear and function in response to the needs of the total organism in achieving a more adequate adjustment to its environment. The movement which bears the name functionalism had its roots in the Darwinian evolutionary viewpoint, the biologically oriented psychology of William James, the instrumentalism of John Dewey and the interest in animal psychology. Under the leadership of James R. Angell and Dewey, functionalism, from 1894 on, became the dominant viewpoint of the laboratory of experimental psychology at The University of Chicago. Though its leaders had no intention of developing a unique school, their viewpoint became crystallized through the necessity of defending it against attacks. In stressing the role of conscious processes in everyday living, they seemed to their critics to violate the doctrine, then current, of mind-body parallelism. Their assumption that mental functions develop in response to the organism's adjustmental needs was criticized as teleological; yet, biologists had adopted a similar assumption with impunity. Their attempt to deal with mental functions introspectively met criticism on the ground that functions are meanings, not content, and cannot be objects of introspection. Functional psychology, however, never limited itself to the introspective approach; it investigated activities in terms of what they accomplished, the end product, utilizing both introspection and objective observation. The objection that functionalists use the term function ambiguously, at one time meaning the *process,* at another the *end* served by it, was answered by Harvey A. Carr, who followed Angell as director of the Chicago laboratory. He pointed to a common identity of these two usages in the mathematical term "function," which implies a contingent relation, whether of act to structure, or of means to end. Hence, the distinction made by R. S. Woodworth between primary and secondary functionalism was unnecessary. Carr made mental activity the subject matter of psychology, avoiding any dualistic implications of the term by identifying it with that entire group of psychophysical processes involved in adaptive behaviour; *i.e.,* acquiring, retaining, organizing, evaluating, and subsequently utilizing experiences in the guidance of conduct. By opening the way for the study of behaviour as a legitimate part of psychology and by insisting that mental activity be considered in its practical everyday setting, functionalism paved the way both for the behaviouristic movement and for the phenomenal expansion of the applied branches of psychology in the United States.

GESTALT PSYCHOLOGY

Gestalt psychology deals with mental facts which are ignored when merely analytical procedures are used in psychology. That such facts exist was first discovered in perception. For instance, in customary analysis a visual field was regarded as composed of local sensations, each of which corresponded to a local physical stimulus. But in 1890 Christian von Ehrenfels, an Austrian psychologist, remarked that in this description of the field many visual characteristics such as round, angular and slender were omitted. For their occurrence neither single stimuli nor mere sums of such stimuli can be made responsible. This becomes particularly obvious if, in a given case, all individual stimuli are changed in the same proportion. The characteristics in question are not affected by this measure. When presented in a changed colour, in a different place or in another size, an object remains about as round, angular or slender as it was before. Von Ehrenfels added that in the dimension of time, analysis meets with the same difficulty. Thus, in music the major and the minor characteristics of melodies belong to the melodies rather than to individual tones. Since visual shapes (Gestalten) are the most obvious instances of such phenomena, Ehrenfels called the whole class Gestalt qualities.

But analysis in the customary style also ignored the entities which have such attributes. In vision, for example, retinal stimuli represent a mere mosaic. And yet visual Ehrenfels qualities are for the most part attributes of specific objects such as things and figures. What is the nature of these units? Some authors maintain that the units are established by intellectual processes. However, while intellectual activities may interfere with given objects, there is no empirical evidence that such activities form the objects in the first place.

In 1912 M. Wertheimer was led to a much more radical solution of the problem. He denied the existence of sensory elements as parts of perceptual experience. According to him, the nervous system tends to give a unitary answer to the total stimulating situation with which it is confronted at a given time. But far from being uniform, this answer is for the most part quite articulate. In certain areas the unitary character of the response is greatly enhanced, while at the same time these areas are relatively segregated from their environment. Thus, things, figures, etc., originate. In the temporary dimension the same happens: from the unitary course of experience particular events tend to be segregated which are to this extent analogous to objects. Such events and objects again need not be uniform. Just as they are relatively segregated members of the total field so they may have parts of their own. This term parts, however, no has a particular meaning. Genuine parts of a sensory field or of its objects involve, qua parts, inclusion in the larger units in which they lie. They are experienced as referred to these larger entities. They must also be distinguished from the arbitrarily chosen elements into which traditional analysis would split sensory experience. From the new point of view, analysis is justifiable only if it deals with the genuine parts of a field:

In Wertheimer's writings the specific units or entities which appear in a field are called Gestalten. Although this terminology corresponds to common usage in German it greatly disturbed psychologists in England and in America who translated Gestalt as "shape" (which it may also mean in German). In Gestalt psychology, the substantival connotation of the term plays a much more important part than its adjectival meaning, which refers to shapes rather than to the entities which have shapes. In English, the process of articulation is commonly called organization of the field, a term which may also be used for the outcome of the process. According to the dictionaries, the word "structure" has about the same two meanings as Gestalt has in German.

Although the stimuli which impinge upon sensory surfaces constitute a mere mosaic, there are always factors in this mosaic which give the process of articulation a particular direction. These factors are the formal relations which obtain among the stimuli, such as, for instance, their proximity in space and in time, the degree to which they resemble one another, etc. Other conditions being equal, organization tends to form compact and more or less homogeneous structures rather than widely scattered and heterogeneous units. Again, the process is likely to segregate objects with smooth contours rather than irregularly shaped entities.

From the basic conceptions of Gestalt psychology a great many specific investigations and theoretical discussions developed. Particularly interesting are those in which the new point of view was defended against a rival thesis: the thesis that, after all, elementary sensations are the real material of the sensory world, and that only learning about the unitary objects of the physical and practical world makes things out of sensory atoms. This theory cannot explain the fact that the outcome of sensory organization may be at variance with our knowledge of objects in the practical sense. Thus. well-known objects are not seen, and strange things are seen instead, when the principles of organization favour existence of the latter. Experiments have shown that previous experience has a certain influence upon the organization of given fields. But far from proving that learning fabricates things out of sensory elements, these experiments demonstrate only that familiar forms of organization tend to modify subsequent processes of articulation.

Organization ought not to be interpreted as a mere formation of agglomerates. In the first place, the characteristics of things are generally affected by their inclusion in larger organizations. In other words, organization involves interaction. Such interaction seems to explain colour and brightness contrast, most so-called optical illusions and, also, several perceptual constancies. As an example: When the illumination of an object and of its immediate environment changes, stimulation in the area of the object and its background is correspondingly altered. Nevertheless, the colour of the object tends to remain virtually unaffected. According to the Gestalt psychologists, this constancy of object colour is brought about by interaction between the object and its environment. They claim that, under the circumstances given in a case of constancy, this interaction operates against the effects of changed local stimulation, and thus exerts a compensating influence.

In the second place, organization gives its products characteristics of their own, such as the Ehrenfels qualities. It is, however, not only segregated objects as such which exhibit particular characteristics of this kind. The same holds for their parts. Thus, a certain point in an object is a corner only within this larger unit, a line is a boundary only with reference to a segregated area, etc. One particular characteristic of this class has become famous by an investigation of E. Rubin (1921). He called attention to the difference between figure and ground, between the substantial appearance of objects and the looseness of their homogeneous environment. Equally important is A. Michotte's discovery (1941) that, under certain conditions of successive stimulation, causation is directly experienced as a characteristic of organized developments.

Organization in Physics and Physiology. — Since, as a rule. perceptual organization does not originate within experience, it must be processes in the sensory nervous system which are responsible for the formation of perceptual units. for the change of their characteristics by interaction and for the emergence of Ehrenfels qualities. Thus, Gestalt psychology is under obligation to show that organization occurs in the realm of physical facts; that some particular facts of this kind occur in the nervous system; and that physiological organization in this sense actually underlies all instances of organized experience. As to the first point of this program, such eminent physicists as C. Maxwell, M. Planck and A. Eddington have sometimes clearly stated that a purely analytical approach may not be able to do justice to all phases of physical nature. Actually, whole sets of physical processes are never treated in what could properly be called an analytical fashion. The epistemology of physics has merely failed to recognize this fact, although it is implicit in the physicist's own work. It was first made explicit by W. Kohler (*Die physischen Gestalten in Ruhe und im stationären Zustand* [1920]). He showed that all instances in which physical materials or processes distribute themselves under certain limiting conditions fulfil the principal criteria of organization. For instance, if water streams through a system of interconnected pipes, the flow in each pipe depends upon the flow in all other pipes. For, if an obstruction is introduced in one pipe, the flow in the others is immediately affected. Similarly, if an electric current flows in a network of wires, the self-distribution of this flow is maintained in the system as a whole. Any local change of conditions is at once reflected in a redistribution of the current everywhere. In other words, a physical self-distribution is relationally maintained and relationally determined. This is clearly shown in the mathematical expressions which serve to describe such a process. In any formula which refers to local events within the total distribution, these events are related not only to corresponding local conditions but also to the conditions in all other parts. More particularly, the determining conditions appear in the form of their ratios so that physical self-distribulions remain unaffected if all local conditions are varied in the same proportion. Obviously, this agrees with the criterion which Ehrenfels used when he first called attention to Gestalt characteristics.

In connection with psychological problems, it must be emphasized that physical organization is not restricted to self-distributions which occur in conducting networks. On the contrary, this concept applies most readily to instances in which processes distribute themselves within continuous media.

In trying to indicate what particular processes actually underlie organized experience in perception, Gestalt psychologists propose a change in neurological theory. They do not believe that brain function is limited to the propagation of nerve impulses along separate fibres. Kohler developed a theory of vision according to which organized function in the brain is a matter of electric currents. These currents are supposed to distribute themselves in the brain tissue as a continuous volume conductor. The theory is supported by the fact that organized processes in perception have specific aftereffects which can readily be explained on this ground. The general direction in which Gestalt psychologists attempt to develop neurological theory is indicated by the term "isomorphism." The term means that the facts of organized experience and the brain processes which underlie these facts have precisely the same structures. It would, for instance, follow that to any symmetry in perception there corresponds the same symmetry in the functional interrelations of the underlying process, that segregated units in perception are associated with functional units in brain dynamics, etc.

Organization in Higher Mental Processes.—An early extension of Gestalt psychology beyond the field of perception referred to such concepts as memory traces, association and recall. This development was natural because, when experiences are reactivated in memory, they are on the whole organized in the same sense as are the facts of perception. Gestalt psychology assumes that memory traces are direct products of the processes which underlie primary experience; in other words, that human experience writes down its own history in the nervous system. In the course of time, however, the traces are supposed to undergo changes as a consequence of their inherent dynamics. Interaction within the realm of traces seems to be of the same kind as that which is responsible for primary organization. Any condition which makes for particular clearness in perception also favours retention in memory, and any factor by which clear segregation in experience is impaired strongly operates against recall. This thesis has been amply verified. It has also been shown that the concept of association by contiguity must be given a new interpretation. According to classical association theory, the connection between remembered items is quite analogous to the way in which places are connected by roads, or objects, say, by strings; *i.e.*, the connection as such is assumed to be indifferent to the nature of the connected items, and vice versa. Gestalt psychology maintains that associations are aftereffects of the specific interactions which occur in primary organization. From this point of view, associations must depend upon the characteristics of the items in question because all interaction is a function of the nature of the interacting objects. More particularly, the factors which make for strong perceptual organization of items in pairs must at the same time be factors which favour strong association. Experimental tests have corroborated this conclusion.

A similar reasoning has been applied to the concepts of recognition and recall. Facts in present experience reactivate facts of the past in a highly selective way. It seems that recall begins with a process in which a present experience makes contact with the trace of a similar past event. The way in which similarity here operates as a selecting factor is comparable to the fashion in which resemblance makes for specific organization in perception. From this the conclusion is drawn that recall is initiated by a fact of organization in which a new process interacts with a trace of a similar event in the past. Thus, perception, retention, association and recall are given a unitary interpretation.

The most important extensions of Gestalt psychology refer to higher mental processes. Much in contrast with the view which scientists have of their subject matter, the psychological field exhibits many phenomena of experienced nexus. David Hume's statement that "all events seem entirely loose and separate" does not hold in psychology. According to the German philosopher W. Dilthey, all awareness of relations, but particularly of dynamic relations, proves conclusively that connections among experiences may themselves be experienced. Moreover, such connections tend to have the character of being understandable. When two tones of sufficiently different intensity are given in succession, there may be immediate awareness of the fact that the second tone is louder or softer. This relation is experienced not as a third thing by itself but as being necessary in view of the nature of the tones. In a similar way an emotion is felt to be the adequate and understandable answer to its object; a conclusion emerges as following from its premises, etc. As interpreted by Gestalt psychologists, this means that not only in perception, but also in many other psychological situations, causation is directly accessible to observation, and that it then proves to be identical with the fact that the nature of a given situation requires a certain event to happen. Gestalt psychologists can, therefore, say that in experience certain occurrences "make sense" while others fail to do so. With a more subjective expression, they claim that man may have insight into the "ought" of facts. Thus, in Gestalt psychology, the term insight does not refer to a mental power, nor is it necessarily related to new discoveries. Rather, it is a descriptive term which designates a peculiarity of certain forms of experienced nexus.

In this fashion. the Gestalt psychologists relate the concept of value to that of organization. For it is only within organized mental situations that the phenomenon of requiredness is experienced. The school concludes that ethics, aesthetics and logic deal with, and systematize, principles of requiredness which are implicit in experiences of nexus, but are, in common experience, blended with merely factual admixtures.

On such grounds. Gestalt psychologists have begun to investigate learning and thinking as facts which are directly related to organization. Learning, they declare, is often much less an acquisition and retention of given contents than a development of new contents; namely, of new structures in perception and conception. It is not, of course. denied that learning in this sense involves retention of the new structures. But it is stressed that, before the question of retention is raised, the psychologist ought to realize precisely what is being retained. Some theories of learning ignore the organization which given materials tend to undergo when we learn something about a situation. Often, this is the most important achievement in learning, and without it retention would be of little avail.

M. Wertheimer and K. Duncker applied these concepts to the problem of productive thinking. In such thinking a material and a goal are given while the right way from the situation to the goal is not yet available. With sufficient motivation, such a situation tends to reorganize itself so that either the given material changes its structure or the goal is seen in a new light. As a result, relations which played at first no part in the situation may suddenly become entirely obvious. With their appearance the principle of the solution often emerges. To take one of Wertheimer's examples: The task of computing the sum of the terms of an arithmetic series will be greatly facilitated if the even progress of the series in the ascending direction (*i.e.*, the original structure of the material) is replaced by the conception that from the two ends of the series toward the middle the terms increase and decrease at the same rate. Once this is seen, the series readily splits into a known number of quantitatively equivalent pairs of terms, and the result of their sum can be directly found by multiplication. It will be seen that in productive thinking of this kind the reorganization of the field as a whole and the discovery of the main principle of the solution precede the recognition of any particular steps in which the actual solution is eventually realized. Measures of detail are taken only as required by that principle, and in this sense the solution is found "from above" (Wertheimer). In this respect, the Gestalt psychologists' interpretation of thinking differs widely from that given by associationists, who regard both the concept of organization and that of requiredness with suspicion, and interpret the course of thinking "from below"; *i.e.*, as a play of associations which. in conjunction, happen to give the whole solution. From the point of view of Gestalt psychology, it remains to be seen for what reasons problem situations tend to reorganize themselves in more or less adequate directions when the motivation is sufficiently strong.

SOCIAL PSYCHOLOGY

Social psychology deals with those elements in the ideas, emotions, attitudes and habits of individuals which derive from, and relate to, the fact that man lives in social-cultural relations with his fellows. It studies the behaviour of individuals in so far as their behaviour stimulates others or is itself a response to the behaviour of others. Two main areas of interest emerged in this field: One has to do with the place of social-cultural influences in the rise and functioning of the personality (*q.v.*); the other has to do with the mass or collective aspects of man's thought and conduct.

The Social-Cultural Genesis of Personality.— One basic concept of social psychology, especially as it relates to the development of the personality, is *interaction* or the *social act;* that is, an act which is not completed without the intercession or qualification by the act of another. The earlier systematic psychologists usually took the view that the fundamental habits and thought patterns of the individual are built up, through learning, on the basis of innate neuromuscular potentials, including the drives. and that only later does the individual add social features to his mental and behavioural repertoire. This atomistic viewpoint is rejected by the interactionist school. It agrees with individualistic psychology regarding the importance of biologically inherited drives, of neuromuscular maturation and of learning. But its central theme is that the individual is more or less socially and culturally conditioned at every point from birth on.

This position is defended, first, on the ground that man as a member of the mammalian family is born into a social situation, involving at least the mother and the infant himself. Second, in the early months and years the new member is socially dependent on other members for his food, shelter and bodily protection. Third, within this interactional framework even strictly individualistic, biological reactions such as concern elimination, posture, locomotion and sleep become socialized or conditioned through the tuition of others. In fact, within this social matrix all the basic skills and knowledge develop. The internal organization of stimulus-response patterns (that is, perception, reasoning and concept formation) are all affected by the interplay of the growing child and those who surround him. And in this development communicative as well as overt physical interaction has a part.

Not only is the social impact, as such, basic, but the parents and others bring to the child their culture patterns. These consist of the more or less standardized and expected ideas, attitudes and habits which serve to direct the child's learning and to provide him the content and meaning of his varied experiences. Thus, while the fundamental drives and mechanisms of adjustment are derived from species inheritance, the learning process is social, or cultural, or both, at every step of the way.

The interactionist position derives from the work of J. M. Baldwin, C. H. Cooley and especially George H. Mead and John Dewey. According to Baldwin, the self or personality develops from the give and take of the infant and child with those about him. This he termed the "dialectic of personal growth," operating through imitation, suggestion and accommodation (habit). Cooley's phrase "the looking-glass self" summarized his view that self-feeling, illustrated in pride or mortification, rests upon one's image of himself as he has derived it from others.

It was George H. Mead in *The Journal of Philosophy* (1922) who stated the process of personality formation in interactional terms without positing inherited social instincts. In his words: "The self arises in conduct when the individual becomes a social object in experience to himself. This takes place when the individual assumes the attitude or uses the gesture [or word] which another would use and responds to it himself or tends to so respond. . . ." The growing child introjects into his own stimulus-adjustive-response system the reactions of other individuals with reference to him. He calls out in himself their attitudes and responses as well as his own toward himself. This duplication of the actions of others Mead called role-taking.

At the outset, roles are highly specific. For example, in his play a child may assume the mother's or iather's tones, words and actions toward his toys, dolls and his real or imaginary playmates. In his fantasy he may play many parts. At one moment he is a buyer, at another the clerk making a sale; he may be a gangster for a minute and a policeman arresting himself the next. In taking such roles language has a central place. The child talks to himseli as others have talked to him.

Yet roles do not remain entirely specific. The repetition of the same or similar drives and situations leads particular roles to become generalized. An early general role centres around his age, status and function within the family. The chief general roles of the adult male in our society are those of husband-father-breadwinner, good citizen and solid churchman.

The social seli, however, is not merely a reflection and reorganization of ideas, attitudes and habits which one picks up from others. At all times the drives and action patterns of the individual are present and serve as the dynamic and unique elements in personality. Mead held that these drive-action elements and the specific or general roles together "constitute a personality as is appears in social experience."

Ii one's ideas, attitudes and habits derive irom integrating the roles of others with one's own drive-action systems, it iollows that mind itself must be a social product. The chief medium by which mind is built up is communication through gesture and language.

The thinking function arises as the child rehearses and reorders the interactions—overt and verbal—which have gone on between him and others or which he has observed among those around him. Dewey has aptly pointed out the dramatic (that is, interactional) character of our mental processes. And the investigations of many child psychologists give concrete evidence of the social ioundations of the sense of self and oi the thought processes.

Language as the vehicle of communication sets up expectation or incipient action in the person spoken to, and likewise, in terms of introjection, anticipatory response patterns in the individual speaking. Meaning depends on one's perception and conception of the object of communication as it functions in the other's experience as well as in his own. So, too, the respondent must perceive or conceptualize the idea as it operates in the speaker. As Dewey says in *Experience and Nature* (Open Court Publishing Co., 1925): "To understand is to anticipate together, . . . to make a cross-reference which, when acted upon, brings about a partaking in a common, inclusive, undertaking." In short, meaning always falls within the self-other configuration.

Many social interactionists tended to neglect the place of the content of ideas, attitudes and habits in personal development. But this need was met chiefly from Freudian psychologists in collaboration with cultural anthropologists.

The aim of the culture-personality studies is to compare critically the way in which the basic drives and capacities of the new generation are moulded by culture—chiefly at the hands of family memhers and primary groups; that is, to modify and elaborate them into adult motives, roles and other elements of the self. For example, certain studies show that the masculine-feminine roles as defined in western culture are quite differently organized among other peoples. So, too, co-operative-affectional in contrast to conflictive-aggressive patterns differentially affect personality formation. Among primitives like the Arapesh, Zuni and Hopi, and among certain Christian sects, such as the Amish and Mennonites, the individual is trained irom birth on to be sympathetic and helpful of those around him. Rivalry and personal push are punished. The result is a rather quietistic, mild and nonaggressive person. In contrast, the highly competitive societies like those of the Kwakiutl Indians or the modern United States induct their children into a set of values and habits which stress intense interpersonal struggle, ambition for status and monetary rewards. Or, in militaristic countries like imperial Japan and nazi Germany, the child, especially the male, was brought up in aggressive, conflictive patterns of thought and action.

This does not mean, of course, that aggressive responses are entirely lacking among the Pueblo Indians or among the pietistic sectarians. But they are suppressed and sublimated. Yet among the Zuni vicious gossip provides an outlet for interpersonal antagonism. And some, at least, of the U.S. quietistic sectarians have been known for their sharp competitive business sense.

These comparative analyses show that personal sense of security, presence or absence of inner tensions, the emphasis on introvertive or extrovertive values and activities and other elements of the personality will be greatly influenced by such differentials in training.

A provocative approach in this field was that of A. Kardiner and R. Linton, who examined both primitive and civilized societies in an effort to discover "a group of nuclear constellations in the individual" designated as "the basic personality structure." By applying psychoanalytic concepts to known differences in early child training, especially in the mother-child, father-child and sibling interactions, they traced the integration of ideas, values, attitudes, and habits which form the distinctive modal personality features of all members within any particular society-culture milieu.

The co-operation of workers in psychology and anthropology in tracking down the cultural sources of personality differences marked a step forward toward a science of personality. But there remained many unsolved problems of data, analysis and interpretation. No theory of modal or basic personality for all memhers of a given society can get around the solid facts of individual variation and uniqueness. These differences are based on biological variability as to drive, emotion and intelligence potential, on deviations in acquired skills and knowledge and on variations in interpersonal conditioning at all points. As to the latter, it can be shown that not all social learning is necessarily culturally controlled or directed, unless culture and all interaction are defined as completely synonymous. There is, especially in the early years, a good deal of social learning which occurs outside the framework of the cultural norms and expectancies, and this learning plays a part in the formation of the personality.

Collective Psychology.— Collective psychology deals with group behaviour, in small as well as larger aggregates such as is found in crowds and audiences, in responses to changes in fashion, in public opinion and propaganda and in various manifestations of leadership. However, there is no special psychology oi so-called crowd mind or collective consciousness.

The interactions of individuals in small groups has been studied in order to get at social behaviour which involves, among other things, dominance-submission relationships, degrees of conscious intimacy or hostility among group members, and objects of common or different identification. It is often assumed that generalizations derived from the study of small groups may be applied to similar activities in larger groups. This assumption, however, had not been completely proved at mid-20th century.

Turning to the larger aggregates, a crowd is a relatively temporary congregating of interacting individuals in a limited space. Its typical spatial arrangement resembles the disposition of iron filings around a magnet. There is a centre or focus of attention around which individuals stand or move in varying degrees of verbal, auditory and bodily participation. Unlike the usual face-to-face interactions, the interstimulation of the crowd members is of shoulder-to-shoulder kind.

As to responsiveness, crowds may be further defined as passive or active, the former illustrated by a transitory grouping of pedestrians to watch a dogfight, the latter by the intense emotions and agitated actions of a crowd celebrating the news of a victory, taking part in a lynching or fleeing a fire in panic. Psychologists have given most of their attention to the action crowd.

The principal psychological characteristics of the individual in an action crowd are, first, the expression of strong emotions of love, hate and rage, associated with the basic values of life and security; *e.g.*, bodily survival, sex, property, race, religion, class status and national honour. Second, there is intense ego-expansion in terms of all-or-none, absolutist convictions. Third, a sense of self-righteousness overrides one's habitual sense of guilt and shame. Also, the crowd-man quickly identifies himself with some in-group which stands opposed to some out-group.

Men under these conditions release hidden and suppressed motives. In so doing imitation (*q.v.*) and suggestion (*q.v.*) play a large part, especially in adding a crowd-stimulus or social facilitation to that of the deep-seated drives. Suggestibility and imitative training in copying and conforming to others lead to the inhibition of critical attitudes in favour of doing unwittingly what those around one are doing. There also develops a strong sense of safety in numbers. The prestige and power of numbers fosters anonymity and the "impression of universality." Finally, long training in deference and obedience to leaders and symbols of authority makes for adherence to the emotion and action stimulated by the leader of the crowd. Such interactions as rhythm of bodily movements, whispering, shouting and pushing all add to social facilitation. In short, there is a summation of primary and crowd stimuli which impels the mass along its particular course of action.

It is often said that the crowd-man loses all morality and decency. By traditional standards this is correct; but the self-righteousness of mobs is well known. There arises a primitive morality of survival and group solidarity which temporarily replaces customary conscience. This rudimentary morality even persists, when the violence is over, in the rationalizations which people give for their participation in a mob or panic.

However, a crowd does not act entirely outside the framework of culture. Clearly all kinds of mobbish behaviour have their roots in the faiths and values of the participants. On the American frontier the lynching of cattle thieves was an accepted form of social control. So, too, the lynching of Negroes in the south. Even the periodic mass violence of race and religious riots in the Cnited States, the near east and in India have their original motivations in the values of race, class and religious differences.

An *audience* is an institutionalized crowd which meets for a more or less specific purpose at a predetermined time and place. The polarization and interactional forms vary with the kind of audience. Most audiences may be classified as information-seeking, recreation-seeking and conversional. The first is characterized by a rational aim and function; the other two are loaded on the side of emotion and action.

The psychology of the audience is revealed, first, in the preliminary tuning or prior stimulation, as through advertising and conversation designed to draw out the participants. Second, there are some initial interactions at the time the group forgathers but before the central function begins. Third, the speaker or performers must gain rapport or attention to bring about close identification with the activity. In the informational audience this tends to be by means of logical imagery and abstract ideas. In the other two it is usually a mixture of the rational and the irrational.

Fashion is a prevailing usage, mode, style or manner of expression or presentation of certain cultural elements which are open to, or subject to, relatively rapid change. Fashion ope ates chiefly with respect to clothes, architecture, furniture and modes of transport and communication. *Fad* refers to more superficial, more fleeting and more bizarre forms of such things as decorations or slang. The word *craze* is usually applied to highly transitory, though often widespread, forms of bodily activity, such as certain dances, miniature golf or unconventional gestures or postures.

For the individual, being in fashion provides a curious but pleasing mixture of personal distinction and group conformity. It at once sets one apart from the masses but gives evidence of adherence to one's class by virtue of others also following the fashion parade.

To understand public opinion the meaning of both "public" and "opinion" must be clear. As an adjective, "puhlic" means that which is known, actually or potentially, to all members of a community. As a noun it refers to a relatively large aggregation of persons, not necessarily contiguous, loosely associated together by some common interest. There is not just one public, the political, but actually various publics concerned with any focus of wide community interest. "Opinion" is a judgment or belief based admittedly on ground short of full proof or certainty. Public opinion, then, consists of judgments about some topic of interest in a given public at some particular time and place. It is usually expressed in words and is often related to deeper and more permanent attitudes and values.

The crucial matter of public opinion is its formation and change. While there are some situational variations, the formation of public opinion follows certain stages through time. The first is the rise of an issue or problem confronting a given public. The second is the conversation and discussions by members and leaders who try to define the issue more sharply and perhaps offer some tentative solutions. The third stage appears with the taking of definite positions as to the nature of the solution and the means of attaining it. The final stage is the arrival at consensus. This may mean a compromise of opposing views or it may mean the acceptance by the majority of the views of one side. Consensus may be expressed by written memorials to legislative bodies or executives, by public opinion polls and by legal voting. The overt execution of any decision belongs to action programs and lies outside the strict process of opinion formation.

In democratic societies the formation of public opinion follows this general pattern. Under totalitarianism, opinion formation tends to be restricted to the élite of the dominant party or to party members only. It is not a function of members of the wider community or society. However, this does not mean that amorphous and less vocal publics may not influence opinion formation at any step. Dictatorial governments usually "have their ears to the ground" though they may, by propaganda, attempt to determine the nature and direction of any popular ground swell.

In contrast to conditions in simpler, rural societies, public opinion in highly industrialized, urban societies raises many questions of manipulation and control by political and special interest pressures.

Under such modern conditions propaganda and censorship have especially important bearings on the formation of public opinion.

Propaganda is the deliberate use of symbols, chiefly through suggestion and persuasion, with a view, first, to changing and controlling opinion, attitudes and values, and ultimately to altering overt action along predetermined lines. Also propaganda may be open and obvious to the recipient as in advertising or a public health campaign, or thoroughly hidden and disguised as in the promotion of a revolution or a war.

The essential mechanism of propaganda is suggestion, the aim being acceptance, not logical reflection. Yet in analyzing propaganda it is necessary to know the motive and purpose of the operator, the symbol content he uses and the responses of his would-be recipients in order to find out to what extent their opinions, attitudes and habits have been altered.

Successful propaganda must be related to motivation and culturalized attitudes and habits. While the particular situations vary, among the more common facts which the propagandist must bear in mind are these: (1) It must be linked to basic motives of those to whom it is addressed; (2) the primary appeals should be emotionalized symbols of promise and satisfaction; rarely, and for selected audiences, may rational appeals be used; (3) both the issues and the proposed solutions must be simplified; the promotional artist deals in whites and blacks, in good and evil, not in the intellectual elaboration of a topic; (4) systematic and rhythmic repetition of these few and simple elements is usually effective; (5) innuendo, indirection and implication are frequently preferable to direct statement, especially in the early phases; (6) once the desired motive and bias are established, blunt, declarative and unsupported statements may be used as well as exaggeration, startling accusations and outright falsehood; (7) finally, short-run propaganda may be directed to all age groups, but that designed for more complete and lasting indoctrination should be directed to children and youth. They are the most suggestible since their basic values and attitudes are less deeply rooted.

The tactics just cited deal with the intent and stimuli of propaganda. Accurate knowledge about the effects on those to whom it is directed is more difficult to secure. However, we have some information on the influence of deliberate planting of content in newspapers and of exposure of young people to selected propaganda through the films or radio. The results show that within the limits of previous socia:-cultural learning changes in opinions and attitudes can be effected. There is little if any valid data on the influence of such experimental propaganda on later overt conduct.

Yet, it would be a mistake to hold that propaganda is ineffective. Campaigns to repeal the Corn laws in Britain, the abolitionist, prohibition and populist movements in the United States, Communist and fascist agitation and its use in war—all exemplify its importance.

Leadership is a universal feature of social interaction. It means the determination of certain responses of another or others in line with the leader's wishes.

Attempts to classify dominant individuals are common but difficult to support objectively. Srme writers take their cue from differences in leadership role and status under varying situations. There is the dual classification of leaders into executives, or men oi action, and thinkers, or men of thought. Some writers require more than two categories, as in the division into executive, dominant, persuasive and expert leaders, or into headship, voluntary leadership and status iorms of dominance.

Classifications which attempt to get at psychological characteristics also face difficulties. Followers of Carl Jung's typology often divide leaders into introverts or extroverts; ochers use Ernst Kretschmer's schizothymes or cyciothymes. But most attempts to use these types empirically lead to further assumptions of mixed types as well.

So, too, psychologists who approach personality from the angle of specific traits and attitudes have trouble in deriving any common clusters of these elements which might characterize all leaders, or, for that matter, even those within such social categories as those noted above. One writer tabulated the 79 distinct traits cited in 20 separate studies of leadership. Of the total list, two-thirds of the traits were named but once, and only 5% had as many as four traits in common. The most common trait cited (in ten studies) was intelligence. Initiative was noted by six; extroversion and sense of humour, each by five; and enthusiasm, fairness, sympathy and self-confidence, each by four. Much careiul research needs to be done before any satisiactory generalizations can be made about the psychological traits or types which characterize the dominant individual.

Regarding the relation of psychological characteristics to occupational or other social roles, there is some evidence that men of introspective, introvertive make-up tend to be more successful in science and the arts and that out-going, extrovertive persons are more successful in administrative roles. But cultural expectancies and differential circumstances may serve so to disguise the deeper motives, attitudes and values that any one-to-one correspondence of psychological make-up and social role is difficult to find. Men of the introrertive order are found in executive positions. Furthermore, since mixed types are probably more common than so-called pure types, most individuals may adapt themselves to one role or another without undue inner tension.

The qualities of leadership are definitely affected by the ideas and reactions of followers. The latter invariably attribute certain ideal qualities and powers to the leaders. This sets up expectations as to conduct on the part of leaders which they must follow, or seem to follow, if they would retain their dominance. This projection of ideal qualities is doubtless the reason why the traits of leadership are nearly always put in laudatory, admiring terms. Negative and derogatory traits seldom appear in listing the characteristics of leaders.

Methodology. — Though by no means well-ordered as a logical system, social psychology has developed points of view, hypotheses and methods of empirical research which, in time, should produce a body of systematic knowledge adequate to provide predictions and control of human conduct.

The principal scientific approaches to social psychology are the case- or life-history method and the use oi statistical techniques. An attack on the problems in this field by strictly experimental methods has only recently begun.

The aim of the life history is to discover and analyze the social-psychological processes, operating through time, which cause the emergence or modification of roles, statuses! traits, opinions, attitudes, values and other elements of the personality. In some studies there is an attempt to reconstruct the whole course of personality growth on the assumption that this will permit a fuller understanding of adult behaviour.

The data for the case study are protocols of oral interviews or formal and iniormal writings of the informant. Interviews may be prolonged in time and demand special skills, as in psychoanalysis, or may be relatively short. Free-association techniques or direct questioning may be used in either to elicit forgotten and unconscious memories necessary to reconstruct the genesis and meaning of the factors in personality growth. Formal written reports may be secured by questionnaires or outlines likewise designed to bring out memories of past events. Informal written documents consist of free-flowing autobiographies, letters and diaries or the protocols from projective tests.

The life history is open to question, first. in terms of the assumptions that this device will lay bare the genetic and functioning processes; second, as to the validity of memories on which the data depend; and. third, as to the standardization of procedures, since the difficulties of communication of meaning unwittingly qualify the responses of both informant and observer. Fourth, generalizations are often made on too few cases and with complete neglect of sound sampling.

Yet the case study provides an understanding of motivation and meaning which is often not obtainable through so-called more exact techniques. 4 combination of statistical and case methods, as in some of the projective techniques (*see* PERSONALITY), should, in time, contribute valuable data to a science of social psychology.

The quantitative study of personality derives from the measurement of intelligence. Taking their cue irom mental testing, psychologists and sociologists developed a large number of questionnaires and scales in an effort to measure the manifestations oi personality by tapping a wide variety of traits, attitudes and opinions. Usually there are a series of statements arranged in such form that the respondent may mark his agreement or disagreement and perhaps the intensity of his attitude toward each item. An index is then determined by summation o~ the separate responses or by using such measures as the standard deviation of the distribution. However, the problems of developing equal and interchangeable units on the scale and of composing the scale so as to measure one dimension or cluster of traits, attitudcs or opinions at a time have not yet been satisfactorily solved.

While the more adequate scales are statistically iairly reliable; validity is frequently neglected. The basic test of validity is a high positive correlation oi measured trait, attitude opinion or value with overt behaviour. All too often it is not clear just what outside criteria, if any, were used to validate a questionnaire or scale.

Although public opinion polls and market analyses usually handle the matter of sampling reasonably well, most studies oi traits and attitudes do not. Almost all of them use high school and college student populations, not adults outside. Even so, there is seldom any concern with the representativeness of the sample of this particular universe.

Both from the standpoint of contributing to a scientific knowledge of total personality and of periecting instruments ior predicting specific behaviour, the tests of motives, attitudes, opinions and values have much ground to cover. Yet, with more careful attention to matters of units, reliability, validity and sampling, we may expect,, in time, a body of substantive objective generalizations in social psychology.

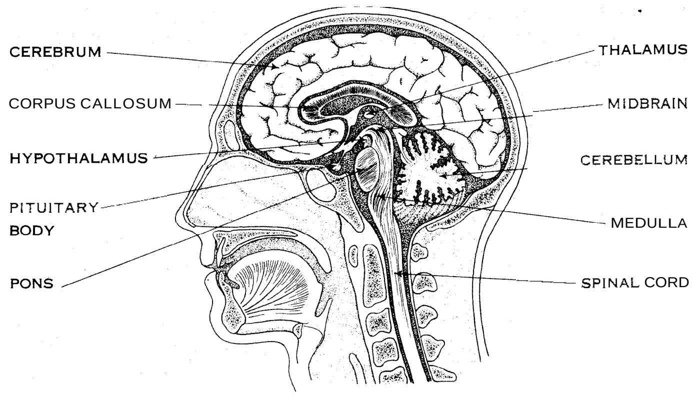
PSYCHOLOGY, PHYSIOLOGICAL, is the study of the biological machinery of behaviour. Primarily it is concerned with how the brain and the rest of the nervous system function to produce the behaviour recognized as characteristic of man and the other animals. Because the nervous system critically depends upon other organs of the body for its normal function, physiological psychology also is concerned with the mechanisms of metabolism, the elaboration of hormones by the endocrine glands, and other regulations of the internal environment. Furthermore, the structural and functional characteristics of the nervous system, as well as of other organs, are determined by the mechanisms of heredity and are affected by diet, drugs and disease. Thus, behaviour may be influenced by all of these things, for the nervous system is the final agent of behaviour.

Although the early philosophers did not understand the nervous system very well, they knew that behaviour and mind were in some way related to the body and its functions. Thus the historic roots



FROM N. L. MUNN, "PSYCHOLOGY" (1951); REPRODUCED BY PERMISSION OF HOUGHTON MIFFLIN CO

FIG. 1.—INTERNAL STRUCTURE AND ORGANIZATION OF BRAIN

of physiological psychology lie in the classical mind-body problem of philosophy (see BODY AND MIND). Aristotle's view of this problem, known as the double-aspect theory, was that mind and body were different aspects of the same thing, that body nas the form or structure and mind the function. This surprisingly modern view did not entirely satisfy Aristotle's folloners, however. Descartes. for example, was impelled to reserve a special realm for the mind of man. He denied mind in animals and viewed their behaviour completely mechanistically, ascribing it entirely to the functioning of the brain and its nerves. For man, however, he argued that while basic reflexes were mechanistically determined, mind was relatively free of the body's influence. For those special occasions when mind and body could influence each other he proposed an interaction theory, holding that the site of the interaction between mind and body was the pineal body.

Even more independence of mind from body was envisaged by Leibniz in his theory of psychophysical parallelism. Leibniz maintained that mental events and bodily events occurred in two separate realms, entirely independent but nevertheless paralleling each other perfectly, as though in accordance with a predetermined plan.

In modern history, the behaviourists under J. B. Watson tried to carry the solution of the problem one step beyond Descartes by denying the existence of mind in man as well as in animals and by embracing a monistic, deterministic philosophy. They tried to strike all mentalistic terms—mind, consciousness and feelings—from scientific use and spoke only of observable behaviour. which they believed was the biological outcome of the activity of the nervous system (see BEHAVIOURISM).

Although mind is still more difficult than overt behaviour to define and specify scientifically, there is actually no need to exclude it from the realm of scientific inquiry, for the term mind is useful to designate certain realy if ill-understood, aspects of man and his experience. Mind is a complex and subtle aspect of behaviour, and ways should be found to investigate it rather than to ignore it. Scientifically, ho ever, mind cannot be regarded as a nonmaterial entity, despite the great emphasis that our philosophical and cultural heritage has placed upon the spiritual. Physiological psychology must begin, then, with the basic concept that mind and behaviour are the result of the structural and functional characteristics of the nervous system. The question is: how?

Basic Properties of the Nervous System.—The anatomy and physiology of the nervous system are discussed fully in the articles BRAIN; SPINAL CORD; NERVE; NERVE CONDUCTION; and NERVOUS SYSTEM. Only a brief review will be given here.

Grossly, the nervous system consists of the brain and spinal cord and their nerves. Coming into the posterior part of the spinal cord are the sensory nerves. These connect with other nerves within the cord which, in turn, connect with motor nerves leaving the anterior region of the cord to go out to the muscles and glands. This simple circuit provides the basis for reflexes such as the automatic withdrawal of a leg from a painful stimulus (see REFLEX). In addition, the incoming sensory nerves send branches up to the brain, and the brain in turn sends motor nerves down to the various segments of the spinal cord. At various levels in the brain, the incoming sensory nerves connect by multitudinous linking nerves to the outgoing motor nerves: making up an infinitely complex mechanism for the integration of behavioural functions, similar in principle to the reflex mechanism.

To understand the complexities of these brain connections and their importance in behaviour? it is necessary to appreciate the gross morphology of the brain and its gross function (see fig. 1 and 2). The continuation of the spinal cord into the brain is called the medulla; it contains, in addition to the major sensory and motor pathways and integrating mechanisms, many groupings of nerve cells that make up the mechanisms controlling the vegetative functions of the body such as respiration and circulation of blood. Above the medulla is the midbrain, serving in many simple visual and auditory reflexes. Behind'the medulla and midbrain lies the cerebellum, a large organ concerned primarily with coordination of posture and locomotion. The thalamus, situated above the midbrain, contains major mechanisms for the integration of incoming sensory nerve impulses and also serves to relay sensory impulses forward in the brain. Belon the thalamus is the hypothalamus, concerned aith control of the pituitary gland and with general vegetative functions, including such complex functions as water balance and thirst, sleep, food ingestion and reproduction. Finally, above the thalamus are the great cerebral hemispheres so prominent in man. The main mass of these hemispheres consists of white nerves entering and leaving the outer mantle of gray nerve cells, known as the cerebral cortex. Actually there are two kinds of cortex: (1) the old cortex, seen in many lower animals as well as in man, which seems primarily concerned with vegetative functions and the emotions; and (2) the new cortex subserving sensory, motor and associative functions. The new cortex may be subdivided into an occipital lobe in the back of the head, concerned with visual function; a temporal lobe on the lower side of the brain, concerned with auditory and language functions; a parietal lobe on the upper side of the brain, integrating sensory information coming from the skin and muscles: and a frontal lobe, including the motor areas controlling discrete movements and postural adjustments; and ahead of them, the frontal poles presumed to serve in complex associative functions.

In this greatly simplified picture of the nervous system, sensory stimulation typically results in activation of integrative mechanisms at all levels, from the spinal cord to the cortex. The major sensory pathways described so far are quite discrete as to the sensory modality aroused and the part of the body or sensory surface stimulated; this gives the nervous system great discriminative powers. In addition, however, all the sensory pathways contribute branches to a feltwork of nerves lying in the centre of the hindbrain or brain stem (medulla and midbrain), known as the reticular formation. The reticular formation relays nerve impulses to all parts of the brain and serves the important function of activating or arousing the brain generally. It is believed that this arousal function is part of the mechanism of wakefulness. attention and emotion, and thus it may be thought of as an important mechanism in the preparation of the brain for the reception of discriminative stimuli.

The great mass of the nervous system just described consists

FIG. 2.— SIDE VIEW OF HUMAN BRAIN. SHOWING MAJOR LOBES AND EXTERNAL SURFACE OF CORTEX

of billions of individual nerve cells, some of which send their tiny filaments all the way from the foot to the head and some of which are not much longer than they are wide. These individual cells of the nervous system connect with each other across tiny gaps between them, known as synapses. Connections may be such that the activity in one cell will arouse activity in a host of connecting cells; or, conversely, activity in many cells may converge on a small number of cells: or there may be reverberatory loops such that a series of cells is activated in turn until the first cell is aroused again and again by the activity it initiated.

The activity of the nerve cells is known as the nerve impulse, a disturbance which may be propagated down a nerve filament at a rate as rapid as 120 metres per second. These disturbances can be accurately recorded electronically with suitable amplification devices, and such recording shows that if a nerve cell is to be activated at all, it must be stimulated by a certain minimal energy, threshold energy; once a nerve cell is activated, it discharges fully in its characteristic pattern of response. From such recording work! it has been learned that the nerve impulse is the mode of communication by which effects are conducted in and out of the brain and spinal cord and from one part of the nervous system to another. Furthermore, it is the combined effects of nerve cells on each other at synapses that provide the mechanism for integration in the nervous system.

Classically, two major integrative mechanisms have been described in the nervous system. One is excitation, the arousal of a nerve to activity; the other is inhibition. the effect of stopping activity in a group of cells. Excitation and inhibition can be illustrated in spinal reflexes where the flection of a limb, initiated by painful stimulation, requires the excitation of the nerves leading to flexor muscles that pull the limb toward the body and the simultaneous inhibition of the nerves leading to extensor muscles.

Given these basic properties of the nervous system, we may now ask how the complexities of behaviour may be mediated. Psychological analysis classically divides behaviour into a number of broad basic categories which will be taken up in turn: (1) sensation and perception; (2) motivation and emotion; (3) learning and intelligence; (4) personality and its disorders.

Sensation and Perception. — One of the oldest questions in physiological psychology is how information is received from the world outside the body and from within the body as well. For man, this is the problem of the anatomical and physiological basis of sensation (*q.v.*) and its attributes: the quality, intensity, spatial and temporal characteristics of sensation following the isolated stimulation of one sensory system. In animals, of course, it is possible to deal only with the capacity to discriminate behaviourally among these attributes of stimulation. Perception (*q.v.*) differs from sensation only in the matter of degree. It is a complex response to stimulation that may involve more than one of the sensory avenues or modalities and that may call into play past experiences that then help to determine the nature of the response or the experience.

The oldest scientific conceptualization of the basis of sensation and perception is the "doctrine of specific nerve energies," first put forward by Johannes Miiller in 1826. While the anatomical and physiological details of this early conception are incorrect, the theory itself has much validity today. What it says, in essence, is simply that sensations or responses to stimulation are determined by the events occurring in the nervous system and not necessarily in the physical world. Thus we see light when pressure is put on the eye with the finger because this pressure mechanically activates the receptors and nerves concerned with vision. So Miiller argued we would see thunder and hear lightning if the nerves from the eye and the ear could be interchanged. Many phenomena support Miiller's doctrine, but its general validity can be seen most easily in the fact that an electrical stimulus, which can activate all the sense organs and nervous tissue. will produce sensations appropriate to the sensory system stimulated, whether it be the eye. the skin, the tongue or some point within the brain to which nerves from these structures go. Thus the sensation experienced or the discriminative response made to stimulation is determined rather specifically by the part of the nervous system that is activated.

To illustrate the point more fully, the case of hearing (*q.v.*) may be considered. The sensation of pitch is determined largely by the frequency of the tone heard. so that the higher the frequency. the higher the pitch. Each tonal frequency vibrates the air at that frequency which in turn vibrates the eardrum. The eardrum passes this vibration through tiny bones in the middle ear to vibrate the membrane of the oval window of the cochlea. As the window moves in and out of the cochlea, it vibrates a fluid in it which, in turn, sets up a standing wave in the basilar membrane, which extends throughout the coiled length of the cochlea. The critical point here is that the standing wave has its maximum effect on the basilar membrane at different places depending upon the frequency of vibration introduced. Low frequencies affect the basilar membrane near the apex of the cochlea. while higher frequencies have their effect near the base. The basilar membrane is lined with the hair cells of the organ of Corti, and as the membrane is moved, the shape of these hairs is distorted. Like crystals that are distorted mechanically, these hairs give off tiny electrical currents, which are believed to stimulate the fibres of the auditory nerve that arise from the vicinity of the hairs. In this way, different fibres of the auditory nerve are activated by the different vibrations produced by tones of different frequencies.

More than that, the different auditory nerve fibres are kept distinct from each other in their course into the brain, at each of the relay stations and at the auditory region of the temporal lobe of the cerebral cortex. Hence it is possible to record electrical activity along different parts of the auditory cortex, representing the different tonal frequencies that stimulate different parts of the basilar membrane. It is even possible in an animal experiment to stimulate different parts of the basilar membrane directly with electrical current and find the same array of different places activated in the cerebral cortex. So the sensation of pitch seems to depend upon the place in the auditory nervous system that is activated by the stimulus.

The other attributes of sound are mediated by somewhat different mechanisms. The loudness of a tone depends upon the energy in it or its intensity, and it is believed that the sensation of loudness is a function of the density of nerve impulses conducted over the nerve fibres serving the frequencies used to stimulate. Density can be increased both by firing individual fibres more rapidly and by the activation of additional fibres of high threshold; *i.e.*, fibres that require a great deal of energy before they will fire.

The temporal pattern of pitches and loudnesses of sounds presumably is given by the temporal pattern of arousal of nerve fibres activated by a frequency- or intensity-patterned stimulus. Finally, the localization of sounds in space depends mainly upon the differences in time of arrival and intensity of a sound from a single source reaching the two ears. These differences are preserved in the brain, for they show up in electrical recordings from the auditory cortex as appropriate differences in time of arrival and amplitude of nerve impulses on the two sides of the brain.

The same general principles apply to the other senses. Thus there are separate fibres and pathways in the spinal cord bearing nerve impulses produced by stimuli that give rise to sensations of pain, touch, heat or cold in the skin. Different patterns of fibres from somewhat different parts of the tongue are activated by sweet, sour, bitter and salty stimuli, and as the tongue is stimulated with stronger and stronger taste substances, the density of the patterns of impulses increases proportionally. In vision, different parts of the receptor surface of the eye, the retina, are sensitive to the wave lengths of light that produce the different colours. Furthermore: there appear to be different combinations of receptor cells in the retina that are maximally sensitive to these different wave lengths that colours emit.

Physiological approaches to the more complex problems of perception can best be illustrated with some of the phenomena of vision such as the perception of real and apparent movement, the perception of depth and visual localization. The visual localization of objects in space, for example, depends upon the part of the retina stimulated and the manner in which that localization or "local sign" is preserved in the brain. Philosophical interest in this problem arose when it was learned that the lens of the eye inverts the image of objects on the retina. The question then became: why do we not see the world upside down? Although this question makes no physiological sense, it nevertheless inspired investigations into the role of early learning that might account for upright localization, and it led to a series of interesting experiments on the inversion of the visual field.

If the eye of the salamander is rotated 180°, the animal will localize 180" out of phase and will snap upward at a lure held below it and to the left at a lure held to its right. Even if the salamander's optic nerve is cut and allowed to grow back, the animal will not reorganize its vision in accordance with its experience! and it will still be 180° out of phase upon recovery. The visual field of man also can be rotated experimentally by placing reversing lenses over the eye. Everything is backward and upside down and never changes from this through long experience with the inverted field, even though man can learn to cope with his reversed visual field and make excellent adjustments to the world around him. Thus it appears that visual localization is a function of the central connections of the retina and is not basically modified by experience.

The role of the brain in perception has been studied in many animal experiments but is shown perhaps most clearly by the complex effects of brain injury on visual processes in man. In such cases, a man with damage to the area around the visual cortex may fail to recognize familiar objects for what they are (visual agnosia), although he may clearly be able to see them and describe their physical attributes. In other cases, such a brain-injured man may totally ignore all visual events occurring in some part of his visual field, although it can be shown by careful tests that he can actually see in that field; or in certain cases he may be subject to gross distortions in that visual field. Thus the brain, and particularly the cerebral cortex, is concerned with the interpretation of sensory impressions.

Motivated Behaviour and the Emotions.—A second problem of historic interest to physiological psychology concerns the basis of feelings, urges and emotions. This is a most difficult area of scientific inquiry, for the very concepts derived classically from the subjective experience of man, and the first attempts to approach the problem in animals came in the study of instincts at a time when instinct implied mysterious forces impelling and guiding the organism. With the advent of objective behaviourism, however, emphasis was placed on the bodily expression of emotion, an approach that applied to animal as well as man and that furthermore provided a basis for scientific measurement. In addition, as efforts were made to uncover the physiological mechanism of emotion, instinct and motivated behaviour, it became apparent that these behavioural expressions had much in common biologically as well as behaviourally.

Behaviouristic analysis divides these complex behaviours into three components: (1) drive, (2) goal-directed behaviour and (3) satiation. Drive ("instinct") is the arousal of the organism to intense activity, measured as an increase in general activity or the appearance of a highly specific activity. Thus the hungry animal becomes restless and hyperactive. Typically. however, the behaviour is goal directed and the drive has a highly specific goal, such as food or a mate; or it might be a bodily expression as in the case of sleep or flight or rage. Upon execution of the goal-directed behaviour, the organism reaches a point of satiation; drive is reduced, hyperactivity ceases and behaviour is no longer directed strongly toward the specific goal. The clinical case of a three-year-old boy with a history of abnormal craving for salt illustrates the points of this analysis. This boy's history showed that his general appetite was poor and that he was restless and upset in his first years, when fed a normal diet. He strongly preferred salty foods such as bacon and crackers, and these seemed to appease him a great deal, but his great craving did not become apparent until he discovered the salt shaker at the age of 18 months and ate salt by the spoonful. Unfortunately, the pathology in this case was not understood at the time, and the child was taken to a hospital for observation and placed on a standard diet; within seven days he died. Autopsy revealed extensive damage to his adrenal glands. It is now known that adrenal damage means that the body cannot retain salt normally. Thus the boy had developed a salt deficiency which produced his strong drive, directed toward the specific goal of salt, when salt was ingested in sufficient amounts, the drive was reduced, and it was thus, in repeated cycles of drive and satiation, that the boy managed to keep himself alive.

This example also serves to make the physiological problem clear. There must be a mechanism in the brain, sensitive to the internal state and to the effects of sensory stimuli as well, which controls the arousal of drive and its specific expression; and there must be a neurological mechanism of satiation. Theoretically, these might be one and the same mechanism, but experimental findings show that there actually may be two interrelated mechanisms, centring in the hypothalamus (*q.v.*): an excitatory mechanism for the arousal of drive and an inhibitory mechanism for its reduction or for satiation. For example. bilateral destruction of small areas in the ventromedial hypothalamus of the rat, cat, monkey and possibly also man results in a doubling or tripling of food intake, leading to great obesity; on the other hand, similar destruction of nearby regions of the lateral hypothalamus, on either side of these first areas, results in refusal to eat and starvation in the presence of customary food supplies. That the first areas in the ventromedial hypothalamus are inhibitory is shown by another experiment in which electrodes, insulated except for their tips, are chronically implanted into this part of the brain. Electrical stimulation through these electrodes in the waking. hungry animal results in inhibition or depression of feeding. Conversely. the excitatory nature of the lateral areas is shown by the fact that electrical stimulation of these regions produces increased feeding.

Similar control mechanisms can be found in the hypothalamus in the cases of thirst, sexual behaviour and sleep. In sexual behaviour it is clear that the hypothalamus also is directly influenced by sex hormones, for it is possible to arouse mating behaviour by introducing minute quantities of hormones directly into the brain through chronically implanted pipettes. The cerebral cortex also makes a contribution to the arousal of sexual behaviour, particularly in the male animal; extensive damage to the cortex may eliminate the possibility of sexual arousal. That the animal is still capable of mating, however, is quite clearly shown by the fact that a massive systemic dose of sex hormones can restore the mating response lost through decortication. Of further interest is the fact that sexual behaviour is independent of any particular sensory modality, including those arising from the genitals, for cutting the nerves from the genital area or surgical elimination of any one other sensory modality does not by itself affect sexual behaviour. In the naive animal, it takes elimination of no more than two sensory avenues at once to preclude sexual arousal; in the experienced rat, however, sexual behaviour may survive the elimination of three modalities, illustrating the role of learning and experience in the physiological control of sexual behaviour. It is important to point out that the mechanism of sexual behaviour must have gone through marked changes in evolution. Comparing animals from rat to man. it is clear that there is a decreasing dependence on sex hormones and an increasing dependence on sensory stimuli, learning and the cerebral cortex.

Much the same physiological mechanism operates in the case of the emotions. Cats deprived of the cerebral cortex are greatly changed in their rage responses. These animals are easily aroused to rage by almost any mild stimulus, but their emotion is short-lived and poorly directed. If only the new cortex is removed, cats become placid; if the old cortex is removed alone, they become fierce. hlonkeys, on the other hand, become strangely placid in the absence of certain portions of the old cortex, particularly the hippocampus and amygdala. These animals show, in addition to placidity, exaggerated sexuality and markedly increased and indiscriminate oral activity, even to the point of putting a snake or a lighted match into the mouth.

That the hypothalamus is also central in the control of emotions is shown by the fact that damage to different parts of it can lead to great increases and decreases in the expression of emotion. Furthermore, electrical stimulation of the waking animal through chronically implanted electrodes will lead to emotional responses such as rage and flight.

Electrical stimulation of the hypothalamus and related structures under somewhat different circumstances illustrates further the physiological mechanisms of motivation and emotion. In this case, the animal is allowed to press a lever which electrically stimulates its brain through chronically implanted electrodes. Such an animal will operate the lever as many as 5,000 times in one hour; under some conditions, pressing the lever is preferred to food, and it has been shown that animals will readily walk through a strongly electrified grid on repeated occasions to depress the lever that produces stimulation of their own brains. Such experiments demonstrate the rewarding nature of this kind of brain stimulation and point to mechanisms that may well be at the physiological basis of all positive emotion and motivation and, indeed, of pleasure itself.

It may be concluded, in general, that the organism is aroused to strong motivated behaviour and emotion as a result of physiological activity in an excitatory neurological mechanism centring in the hypothalamus of the brain. Contributing to this physiological and behavioural arousal are two major influences: (1) sensory stimuli, both learned and unlearned; and (2) internal factors such as hormones, blood temperature. osmotic pressure, salt levels, etc. As the goal-directed behaviour is executed, similar influences arouse the inhibitory mechanism, which then results in satiation or the satisfaction of biological drives. (See also EMOTION; INSTINCT; MOTIVATION.)

Learning and Intelligence. — While many remarkable adaptations to the environment are accomplished through the mechanisms of instinct and motivated behaviour, it is obvious that the greatest factor in the adaptation of the mammal, and especially of man, is the capacity to profit from experience, or to learn. While the mechanism of learning (*q.v.*) is still much of a mystery, it is an article of faith among students of the nervous system that learning and memory (*q.v.*) must depend upon some enduring change in the nervous system. Classically, two scientific questions have been asked in this connection: (1) where does learning take place in the nervous system? and (2) what is the nature of the change?

There are many kinds of learning. but in all of them the organism makes a new response to some specific stimulus or to a general situation. Thus I. P. Pavlov's dog learned to salivate consistently in response to a bell, E. L. Thorndike's cats learned to press a pedal that opened a door when they were locked in a cage and, as is known from common experience, the student of Latin-English vocabulary learns to say "table" when presented with *mensa*. Governing the process of learning and the resultant memory are the "laws of association" (see ASSOCIATION, MENTAL), first formulated by the English association philosophers and expanded through subsequent experimental work: (1) contiguity in time and place; (2) repetition; (3) effect or reinforcement; and (4) interference, leading to forgetting or extinction.

Pavlov, for example, found it necessary to present the bell together in close temporal relationship with meat which naturally elicited salivation; this pairing had to be repeated many times before the bell alone would elicit salivation. The meat functioned as a reinforcement of learning in the sense that the response of salivation to the bell grew weaker and weaker each time it was presented without the meat and gained in strength each time the meat was included. The waning of the strength of salivation to the bell alone is called extinction and is similar to forgetting. Both extinction and forgetting appear to be the result of responses that interfere with the one that was learned, and these interfering responses are favoured when the reinforcement is omitted. Contrary to what one might think on the basis of common experience. there is reason to believe that most learning is permanent; that it is merely covered over or masked by interfering or competitive learning and is not really completely lost.

Many experiments have been directed toward answering the question of where learning takes place in the nervous system. Pavlov believed that even simple learning such as conditioning depended upon the cerebral cortex, but it has been amply shown that animals may be conditioned after the cortex has been removed by experimental surgery. K. S. Lashley demonstrated, in a more complex learning situation, that rats surgically deprived of the visual cortex could learn to discriminate between a white square and a black square. But if an animal had learned this discrimination with the visual cortex intact, subsequent lesion of the visual cortex destroyed the discrimination; as would be expected, the discrimination could be relearned without the visual cortex about as rapidly as it was learned originally. This suggested that the memory for the discrimination was lost as a result of surgery but could be relearned with other parts of the brain. On the other hand, it might be that the memory was not lost, but rather that the animal was incapable of responding to the visual details of the black and white cards after operation and had to learn the problem without the benefit of detail vision; *i.e.,* on the basis of ill-defined light and dark areas. That this may be so is suggested by the fact that the rat without its visual cortex cannot learn to discriminate a triangle from a circle where the difference in detail is the only basis for the discrimination. Conversely, if the animal is required to respond only to brightness change in a large area without any dependence on detail, it can retain a brightness discrimination without impairment after brain surgery.

Lashley also studied the role of the rat's cortex in maze learning and found that the larger the area of the cortex destroyed the poorer the learning and the poorer the retention of the maze learned before operation. It did not matter which parts of the cortex were destroyed and which remained intact, the result was the same: the larger the lesion, the greater the impairment. These findings led to the principles of "mass action" and "equipotentiality," according to which maze learning is a function of the amount of cortex available and the various parts of the cortex are equally potential in subserving learning. Again it seems likely that these results can be understood in terms of impairment of sensory capacities of the animal. It is known from other studies that the more sense organs that are experimentally eliminated in the rat, the poorer the maze learning and retention; furthermore, no one sensory avenue is critical for such learning. Since the rat's cortex is mainly sensory in function, larger and larger cortical lesions would eliminate more and more sensory avenues centrally. and it may be for this reason that larger lesions impair learning and retention more than do smaller ones.

At one time it was thought that the frontal lobes of the brain were critical in the memory processes demanded in the solution of difficult problems. Monkeys without their frontal lobes fail in the delayed reaction test, for example. where they are shown food placed under one of two identical cups and then made to wait for 10–60 seconds before being allowed to uncover the correct cup. Something other than memory is involved in this defect, however, for monkeys without frontal lobes turn out to be quite distractible. If their attention is fixed firmly on the baited cup before the delay, the lobectomized monkeys succeed; if the monkeys are made to keep very still by putting them into darkness during the delay period or by giving them sedatives, they also perform successfully.

The cortex therefore is important in the performance of a learned task, but probably more because of its importance in perception and attention than in learning per se. On the other hand, some of the difficulty in defining cortical function here may be due to the fact that these studies are based only on the method of experimentally damaging cortical tissue. When W. Penfield studied the temporal lobes of epileptic patients whose brains were exposed for surgery under local anesthesia, he found that electrical stimulation could evoke dreamlike sequences that contained familiar episodes from past life. Furthermore, n-hen the temporal lobes are damaged in man, some curious memory defects do show up. While these patients are able to recall events from past life very well, they typically are unable to remember things they learned or experienced a few hours earlier. Closer examination shows that they actually do remember things they learn quite well if they are tested for memory within about 15 minutes, but beyond that the memory fades and is lost. It is as though there were two memory processes separated by the temporal lobe damage: (1) a temporary memory process capable of very short retention that is spared by the lesion; and (2) a more permanent memory process that is impaired by the lesion.

Support for this notion comes from several rather different experiments. In one performed on the octopus the animal was first presented with a crab, dangled in the far end of its tank, every two hours, six times a day. It quickly learned to venture out and eat the crab. Then, on half the tests, a white card was lowered with the crab, and with this cue the octopus learned not to venture out under penalty of electric shock. Thus a simple discrimination was learned. After removal of the vertical lobe of the brain, the octopus could no longer respond differentially in these tests; it kept emerging when the ahite card was presented. Even repeated trials every two hours with the white card and electric shock proved ineffective. But if the trials were run closer together, the octopus was able to perform much better; thus if a test came within 15 minutes to an hour after the octopus was shocked upon approaching the white card. it did not venture out toward the crab and white card. Again it appears as though the capacity to carry a memory over a long period of time was impaired while very short-term memory was left intact.

In studies in which rats were given electroconvulsive shocks at some interval after each daily learning trial, additional evidence for a two-process memory was found. Here there was very little learning if the convulsive shocks were given within an hour after learning. but if the shocks came beyond an hour after each trial, learning was normal. Thus it seems to take some time for the effects of a learning trial to consolidate in the brain to a point of stability. For an hour after a learning experience, memory can be disrupted by convulsive shock, but after that it is not easily disturbed.

The conclusion from all these studies seems to be that the effects of learning are retained in the brain first by some reversible process. but that after some time (nithin an hour) some more permanent change takes place within the brain. It is suspected, therefore. that learning is mediated neurologically by at least two types of processes, and the time course of these processes is partly understood. It is still, however, possible only to speculate as to the nature of the change itself. It has been suggested that the first, temporary and reversible process is a physiological process such as an electrical or chemical change at the synapse or perhaps at a group of synapses, so that a reverberatory loop is activated for some period of time, keeping the memory trace alive. The second, more permanent process has been envisaged by some as an anatomical process consisting of the swelling of nerve terminals or the outgronth of new terminals over short distances so that synapses are enriched in the number of anatomical contacts they have or that new synapses actually are formed. Another possibility, even more speculative, is that in learning there are changes in the chemical structure of nerves, possibly in the structure of complex protein molecules.

As to the locus of the change that takes place in learning, there is still no certainty. Many studies show that the cerebral cortex is not essential for many kinds of learning, but they do not offer a positive clue as to nhere learning might take place outside the cortex. On the other hand, electrical recording studies report that electrical changes take place at many loci in the brain at once during learning. Whether some loci are more important than others, however, still is not known. (For a more detailed discussion of the processes of learning, *see* LEARNING; *see* also MEMORY.)

Related to the problem of learning are the even more complex problems of reasoning, problem solution, intelligence and language. These have been studied primarily in cases of brain damage, particularly in man but to some extent also in animals. First, it should be pointed out that in both man and animal, large amounts of brain tissue may be destroyed without measurable impairment of these complex processes. For example, while removal of one entire cerebral hemisphere results in specific sensory and motor defects, intelligence within the sensory and motor capabilities of the person may be virtually unimpaired. On the other hand, lesions in certain restricted regions of the brain, particularly the cortex. may have devastating effects. Thus following damage in the lateral surfaces of both frontal poles of the brain severe intellectual impairment. as measured by intelligence tests in man and tests such as delayed reaction in monkeys, may result. In man, there are also fairly specific speech areas in the lower parts of the sensory-motor area of the cortex in the dominant hemisphere. Damage here results in aphasia, in which there is an inability to name objects properly or to point to objects named by the examiner, even though in both cases the patient can see the object and say what it is used for. If the lesion is in the temporal, parietal or occinital lobe, there may be difficulty in formulating language, in writing meaningfully (agraphia) or in comprehending written material (alexia).

As mentioned above, lesions in the visual association areas of the occipital lobe produce a visual agnosia in which familiar objects are not recognized even though elementary sensory processes are substantially normal. With parietal lobe lesions, there may be difficulty in recognition of parts of the environmental space, including one's own body, in which case we speak of distortions of the body image. Often in such cases skilled acts such as putting on clothes cannot be carried out even though individual movements can be made normally, a disorder called apraxia. In some cases of frontal-lobe damage there may be a loss in abstract ability. In such an instance, a patient may not be able to go through the motions of drinking from an empty glass, although he can easily drink from a glass with water in it when he is asked to do so. Disorders such as these are not well understood, and there are still many difficulties in making good scientific measurements of such complex behaviour, but it is clear that in many instances relatively small lesions of the brain can lead to major intellectual impairment.

Personality and Its Disorders. — Perhaps the most difficult and perplexing area of human behaviour to study is personality (*q.v.*), and particularly its disorders. For a long time the dominant thought has been that normal personality, neurosis and psychosis are purely psychological matters, the products of life experiences and life stress. But even from the beginning the view also has been held by some that personality is partly a matter of underlying physiological processes, some of which may be determined by heredity. Hippocrates, for example, believed that human temperament was largely determined by humours of the body, and while this view is chemically, biologically and psychologically incorrect, we can see nevertheless many examples in everyday life of the potent role of body chemistry in the expression of personality; consider, for example, the effects of alcohol, mescaline, opium and nitrous oxide on human behaviour.

These drugs affect the functioning of the nervous system, and so also do many naturally occurring chemicals such as vitamins, hormones and enzymes. Furthermore, the morphology of the nervous system and the enzymes directing its metabolism, and therefore its function, are determined by the mechanisms of heredity. For example, the striking case of feeble-mindedness known as phenylpyruvic oligophrenia is caused by a defective gene which produces a defective enzyme. leading to the inability to metabolize phenylpyruvic acid, which in some way impairs brain function. F. J. Kallmann's studies of the major psychoses (*q.v.*) show that heredity is an important factor. When these diseases are found in one identical twin, they are almost certain to occur in the other, even if the two have been reared apart; fraternal twins, having no more similar heredity than siblings, show the same concordance of these diseases as nontwin members of the same family, typically under 16%. Quite clearly the genetic factor predisposes the individual to psychosis; life experience, stress, disease or other factors may, of course, contribute to its precipitation. It is believed that the genetic predisposition is a biochemical defect affecting the nervous system, and the hope in the pharmacological treatment of mental disease with tranquilizers and other inhibitors and exciters of brain chemistry is that the defect may be corrected or counteracted to some degree by drugs (see NEUROPHARMACOLOGY AND PSYCHOPHARMACOLOGY).

Neuroses (*q.v.*) are much harder to understand than psychoses in physiological terms. Here no genetic factor has been demonstrated, and the defect is not so severe and incapacitating as in the psychoses. The work of H. Selye and others. however, indicates that life stress and anxiety can have widespread effects on the physiology of the organism, and it may be possible to understand neurosis as partly a matter of an altered physiological state. Experiments have shown that both physical and psychological stress activate the pituitary gland, in part through the neurosecretory activity of the hypothalamus. The pituitary, in turn, releases hormones that activate other endocrine glands of the body, particularly the adrenal cortex. Once stressed, this system may become more sensitive to additional stresses, and two kinds of disorders may occur: an early one due to oversecretion of the adrenal gland and possibly contributing to such psychosomatic symptoms as hypertension; and a second one, due to adrenal exhaustion and perhaps contributing to symptoms of rheumatism and arthritis, also believed to be partly of psychosomatic origin. Many of these notions are still frankly speculative, and the examples given here do not include many of the important symptoms of neurosis that are not psychosomatic. But the important thing is the physiological principle that seems to be at work which suggests ways in which prolonged emotional stress may affect the physiology of the organism and sensitize it to further emotional disturbances.

PSYCHOPHARMACOLOGY: see NEUROPHARMACOLOGY AND PSYCHOPHARMACOLOGY; TRANQUILIZING DRUGS.

PSYCHOPHYSICAL METHODS. Psychophysics is the science concerned with quantitative relations between psychological events and physical events or, more specifically, with quantitative relations between sensations and the stimuli that produce them. Psychophysical methods are those methods developed for the purpose of specifying and testing such quantitative relations.

Physical science enables us, at least for some of the senses, to measure with accuracy on a physical scale the magnitude of a stimulus. By determining that stimulus magnitude just sufficient to produce a sensation (or a response), it is possible to specify the minimum sensible stimulus or the absolute stimulus threshold (stimulus limen) for the various senses. It is also possible. although practically more difficult, to determine the lowest stimulus magnitude that produces maximal sensation, the terminal threshold; *i.e.,* that point on the physical scale beyond which no increase in stimulus produces any appreciable increase in sensation. Thus are determined limiting stimulus values, between which changes in stimulus intensity are accompanied by changes in sensation. The central inquiry of psychophysics pertains to the search for a lawful quantitative relation between stimulus and sensation for the range of stimuli between these limits.

Psychophysics was established by Gustav Theodor Fechner (*q.v.*), who coined the word, invented the three fundamental methods, conducted elaborate psychophysical experiments and began a line of investigation that still persists in experimental psychology. Fechner's classic book, Die Elemente der *Psychophysik* (1860), may be looked upon as the beginning not only of psychophysics but also of experimental psychology (see PSYCHOLOGY, EXPERIMENTAL). Fechner, trained in physics, became interested in his later life in metaphysics and cast about for a way of relating the spiritual to the material world. He hit upon the notion of measuring sensation in relation to its stimulus. The physiologist Ernst Heinrich Weber (*q.v.*) had discovered that the amount of change in magnitude of a given stimulus necessary to produce a "just noticeable" change in sensation always bore an approximately constant ratio to the total stimulus magnitude. This fact, properly speaking, is Weber's law: if two weights differ by a just noticeable amount when separated by a given increment, then, when the weights are increased, the increment must be proportionally increased for the difference to remain just noticeable. Fechner chanced upon Weber's law and undertook to use it for the measurement of sensation. If R be the stimulus (*Reiz*), and S be the resultant sensation, and Δ signify an increment of either, then Weber's law becomes $\Delta R/R =$ a constant, for the just noticeable difference. Fechner went further and assumed that all equal increments of sensation must be proportional to the same ratio, $\Delta R/R$, that is to say, $\Delta S = c\Delta R/R$, where c is a constant of proportionality. If this equation is integrated, if R be assigned a value of zero corresponding to the absolute stimulus threshold and if the constant be changed to k for common logarithms, the result is $S =$ k log R.

This particular formula Fechner named Weber's law, although it is really Fechner's law and is thus often called the Fechner-Weber law. It expresses the simple relation that the magnitude of a stimulus must be increased geometrically if the magnitude of sensation is to increase arithmetically. For Fechner it meant that the relation between the spiritual and material worlds is statable and that there is therefore only one world, the spiritual; but for physiologists and for many philosophers it meant the measuring of sensation in relation to a measured stimulus and thus the possibility of a scientific quantitative psychology. Fechner got his conception of psychological measurement from J. F. Herbart (*q.v.*), but he was really refuting Herbart in demonstrating that psychology can be experimental.

Fechner's original work stimulated much research and much controversy. It was argued against him that it is introspectively obvious that sensations do not have magnitude (the quantity objection), that "a scarlet is not just so many pinks." This difficulty was met by the Belgian J. R. L. Delboeuf (1831–96), who developed the concept of the sense-distance, holding that sensations, although not complex magnitudes. are separated by variable distances that can be compared as '(greater," "equal" or "less," the three categories of judgment that the psychophysical methods require. In Germany Georg Elias Müller (1850–1934) undertook an elaborate criticism of Fechner and an extension of his work. In the United States E. B. Titchener (*q.v.*) made a historical and practical exposition of psychophysics in the second volume of his Experimental Psychology (1905). F. M. Urban, then also in the U.S., improved one of the methods and developed the concept of the psychometric curve or psychometric function. In England William Brown (1881–) and Sir Godfrey Thomson (1881–1955) were prominent psychophysicists.

Three Classical Psychophysical Methods.—Among the lasting contributions of Fechner are the three fundamental psychophysical methods he invented. Each method is designed to investigate the nature of relationship between the psychological scale and the physical stimulus scale.

Method of Minimal Changes.—This, also called the method of limits or of just noticeable differences, consists of successively adding small constant increments of intensity to a stimulus until a change is noticed. For example, to determine the absolute stimulus threshold of intensity, imperceptible intensities are presented in increasing order until the stimulus is first sensed; then a descending series from perceptible to imperceptible is observed. The results of many such series are averaged to determine a single best estimate of threshold value. To find the difference limen or difference threshold, that difference between two stimuli that marks the boundary between sensed difference and sensed equality, two stimuli always are presented. One, the standard stimulus, is kept constant while the other, the variable, is successively altered by small amounts until a difference between the variable and the standard appears or disappears, according to the direction of change. The difference threshold is the distance from the standard to the average point of change, and there are always both an upper and a lower difference threshold. since change can be noticed on either side of the standard. The method of minimal changes has been used primarily to find intensity thresholds for sounds. odours, tastes. colours. temperature, pain, brightness and tactual stimuli, to name a few.

Method of Average *Error*.—The method of average error, or method of reproduction, also makes use of tno stimuli, a variable and a standard, but in this case the variable is capable of continuous change (in intensity. say) by the turn of a dial The task of the experimental subject is to adjust the variable stimulus until it is subjectively equal to the standard stimulus. Since subjective equality is not physical equality, the results yield an average error (from physical equality), constant for the subject, and also a variable error about his average. The method of average error has been applied most frequently to the study of visual distance, particularly to determine extent of visual illusions.

Constant *Method*.—In the constant method the subject is presented, in random order, a predetermined set of stimuli. for each of which he judges presence or absence of a sensation. In the typical application of the method, each selected stimulus is presented a large number of times. As an example from the cutaneous field, consider determination of the tno-point tactual threshold. With a "touch compass" two points at graduated distances are simultaneously applied to the skin The subject's task is to distinguish between two points and one. Depending upon the part of the body stimulated, the two-point threshold may vary from approximately 1 mm. (tip of the tongue) to about 70 mm. (parts of the back, thigh and upper arm). On the basis of preliminary trials, six or seven distinct distances (stimuli) might be selected so as to include the threshold for a particular subject and a given part of the body. By presenting each stimulus 100 times, a stable estimate for two-point threshold could be obtained. (Due to variability in the conditions of excitation. repeated application of the same stimulus distance is not expected always to yield the same judgment from the subject. However, as the two-point distance increases, the frequency with which the difference is reported increases. The value of that stimulus distance resulting in an equal number of judgments "one point" and "two points" can be taken as the threshold.)

In a somewhat different application of the constant method, two distinct stimuli are presented, either simultaneously or successively, and the subject is instructed to judge whether stimulus B is greater than, equal to or less than stimulus A. Stimulus A might be a standard stimulus, presented on each trial; the second stimulus might have any one of six or seven preselected values.

A classic example is that of lifted weights: on each trial a standard meight is compared with a variable meight, and the subject responds nith one of three possible judgments. Values for the variable stimulus are selected, some to be heavier and some to be lighter than the standard. Each value of the variable stimulus might be presented with the standard 100 or more times, with order of presentation randomized. Relative frequencies of judgments may be plotted as shown in the figure. It may be seen that as the variable stimulus becomes heavier the frequency nith which the variable is judged "less" than the standard decreases. the frequency of "greater" judgments increases. while the judgments of equality become first more. then less frequent. with a maximum near the centre. The loner threshold or limen value of the stimulus is taken as that value where the judgment "less" is as likely as it is not; i e., that point on the stimulus scale corresponding to 50% judgment of "less" The upper liminal stimulus value is similarly defined nith reference to the distribution of "greater" judgments (sometimes called the psychometric function for "greater" judgments). The difference limens are the distances of these liminal values from the standard stimulus (the distances L_l to S and L_u to S). Subjective equality of variable to standard stimulus is usually taken as the point where judgments "less" and "greater" are equally likely; *i.e.*, where the two psychometric functions intersect. Empirically it has been found for a wide range of situations that the observed relative frequencies for "less than" and "greater than" judgments can be fitted reasonably well by the ogives of the normal probability integral, in early psychophysical literature sometimes referred to as the phi function of gamma or the phi-gamma function.

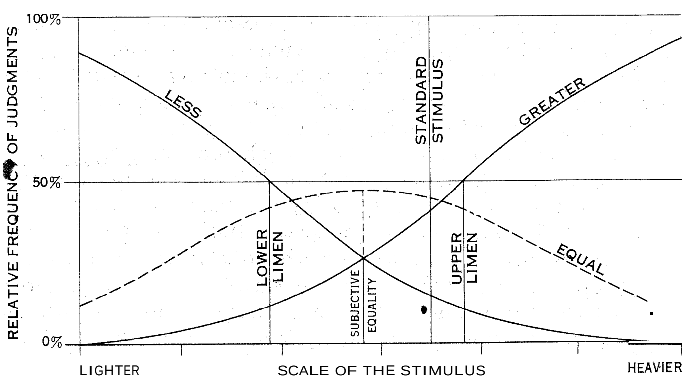

DIAGRAM OF THE CONSTANT METHOD, USING TWO DISTINCT STIMULI

The constant method is regarded as the most accurate and general of the psychophysical methods. While its use has been illustrated here primarily for the estimation of threshold values, it is widely used for other problems of sensory psychology. The method has been found particularly useful for industrial research in the quality control of food and beverage products, where sensory characteristics of the product play a large role in consumer acceptance.

Direct Psychological **Scaling.**—*Method* of Paired *Comparisons.*—Related to but distinct frdm the constant method is the method of paired comparisons, developed in 1927 by the U.S. psychologist L. L. Thurstone (*q.v*). Taken together nith Thurstone's lam of comparative judgment. the method of paired comparisons provides a model by which sensations may be scaled directly, without reference to corresponding physical measurements of stimuli. In the formulation of Weber ($\Delta R/R = c$), the concern is only with the physical measures of the stimulus R Fechner's proposal ($S = k \log R$) explicitly introduced a continuum of sensation, and allowed indirect "measurement" of sensation by using a functional relation between sensation and physical measurement. Thurstone's model allows direct measurement of psychological events without having first established an intervening quantitative relation between psychological and physical events. One striking feature of the method, thus, is its applicability to the scaling of human attitudes, consumer preferences, aesthetic values and other psychological variables associated directly with no apparent physical counterparts.

In the method of paired comparisons, each one of a set of stimuli is presented together with every other stimulus in the set. The subject is asked to make one of two possible judgments to each stimulus pair, either that stimulus A is "*x*'er" than stimulus B or that stimulus B is "x'er" than stimulus A. The quality x is defined by the purpose of the study, so that. judgments might be "heavier," "brighter" or "louder," or could be "more valuable," "friendlier" or the like. Paired stimuli could be presented on many occasions to a single subject or many similar subjects may judge each stimulus pair just once. In either case the result is a matrix of relative frequency showing the proportion of times each stimulus was judged higher on the scale than every other stimulus.

From these basic data, scaling proceeds by the law of comparative judgment. Assuming that a subject's response reflects the momentary subjective value associated with the stimulus, and assuming further that the probability distribution of these momentary values is Gaussian (normal), either over numerous occasions for one subject or over a population of homogeneous subjects, then, applying the simplest case of the law, $\mu_i - \mu_j = z_{ij}$, nhere μ_i and μ_j are the mean psychological values associated with a pair of stimuli. i and j, and z_{ij} is the unit normal deviate associated with p_{ij}—the proportion of judgments that stimulus i is greater than stimulus j (z_{ij} is uniquely determined from p_{ij} and may be read as an entry in the table of the normal distribution function). If the numbers z_{ij} are arranged in matrix (tabular) form, the mean values for the columns provide estimates for the n values, μ_i. For the case where $n = 4$, the table takes the following form (noting that for z_{ij} may be substituted the quantity $\mu_i - \mu_j$):

	$\mu_1 - 1$	$\mu_2 - \mu_1$	$\mu_3 - \mu_1$	$\mu_4 - \mu_1$
	$\mu_1 - \mu_2$	$\mu_2 - \mu_2$	$\mu_3 - \mu_2$	$\mu_4 - \mu_2$
	$\mu_1 - \mu_3$	$\mu_2 - \mu_3$	$\mu_3 - \mu_3$	$\mu_4 - \mu_3$
	$\mu_1 - \mu_4$	$\mu_2 - \mu_4$	$\mu_3 -$ p 4	$\mu_4 - \mu_4$
Sum:	$4\mu_1 - \Sigma\mu_i$	$4\mu_2 - \Sigma\mu_i$	$4\mu_3 - \Sigma\mu_i$	$4\mu_4 - \Sigma\mu_i$
Letting $\Sigma\mu_i = 0$				
Mean:	μ_1	μ_2	μ_3	μ_4

Since the zero point to this scale is arbitrary, $\Sigma\mu_i = 0$ may be defined as above, and this yields the desired solution.

Psychological scaling methods typically allow measurement on a scale characterized by equality of intervals, but one with only a n arbitrary origin or zero point. As upon the centigrade or Fahrenheit scales of temperature, nominal magnitude of zero does not correspond with absolute absence of that which is measured. On such scales ratio comparisons of measures are not valid. (A substance registering a temperature of 40° C., for example. is not twice as hot as a body with measured temperature of 20" C.)

However, the method of paired comparisons has been extended so as to provide a rational zero point. and thus to allow for meaningful ratio comparisons of psychological magnitudes. On a scale of consumer preference, the psychological zero point is that psychological value which, if assigned to a consumer item, would result in consumer indifference toward that item. An absolute scale is established by first assuming the additivity of psychological magnitudes — that (under specified conditions of independence of stimuli) the subjective value for a combination of two stimuli is equal to the sum of the two values associated with the individual stimulus items. The assumption may be stated $\mu_{ij} = \mu_i + \mu_j$, where μ_{ij} is the mean psychological value associated with a composite stimulus and μ_i and μ_j are the mean values associated with the two component stimuli. There is one such equation for every composite stimulus included in a particular study, and it becomes a matter for empirical test to determine whether the several equations are consistent with subjects' judgments scaled by the method of paired comparisons.

Method oj Successive Categories. — Derived from assumptions similar to those for the method of paired comparisons is the method of successive categories. Subjects are instructed to rate each of a set of stimuli by assigning it to one of a group of ordered categories of judgment (usually between five and ten categoriesj. Ratings are to reflect the subjects' judgments concerning the stimulus and are taken as gross indicants of the underlying psychological values associated with the stimulus. Under the assumption that the ratings represent random variables from a normally distributed population of underlying scale values, it becomes possible to estimate the mean and standard deviation of the underlying distribution of subjective values for each stimulus. The method of successive categories has the advantage of requiring just one rating from each subject for every stimulus, in contrast to the method of paired comparisons which requires $n(n-1)/2$ judgments for each of n stimuli.

Results from the two methods generally have been found to be nearly identical.

An Alternative to the Fechner-Weber Law: the Power Function. — One of the earliest criticisms of Fechner's psychophysical approach was that of the Belgian physicist J. A. F. Plateau (1801–83). Plateau reasoned that, since the apparent relations among different shades of gray remain *sensiblement le même* when the general illumination is changed, the ratios among the sensations produced by the grays must remain fixed. This, he argued, is more rational than Fechner's view that it is the differences that remain fixed. While Fechner's formulation entaiis a logarithmic relation between sensation and stimulus, Plateau's assumption entails a power function of the form $S = aR^n$, where sensation (S) is proportional to a constant power (n) of stimulus magnitude (R).

Since the time of Plateau, the power Eunction alternative to the Fechner-Weber law has been revived on several occasions, but never before with such force as that brought to bear by the U.S. psychologist S. S. Stevens. Stevens vigorously attacked the Fechnerian assumption that the just perceptible stimulus difference may serve as a unit of measurement for sensation. As a result of extensive laboratory investigation, a power function has been found to relate psychological magnitude to stimulus magnitude ($S = aR^n$) for more than a dozen distinct psychological continua. Empirical determination of the exponent n has shown it to vary from about 0.3 (for loudness) through unity (for taste, visual length, visual area) and 1.5 (heaviness) to approximately 2.0 (visual flash rate).

The methods utilized in these studies differ sharply from Fechner's psychophysical methods. In the work of Stevens and his students, subjects are required to make direct quantitative estimates of subjective events. The most prominently used of these methods is that called fractionation. The subject is required to adjust one stimulus so as to produce a sensation half (or some other fractional amount) as great as a given standard stimulus.

It seems highly probable that the distinct psychophysical laws, logarithmic and power function, result from application of different measurement methods. By this view! the power function formulation is not necessarily inconsistent with the Fechner-Weber law. Rather, each is valid, but pertains to a unique definition of psychological magnitude, a definition specified by the psychophysical method employed.

For application of the psychophysical methods, *see* PSYCHOLOGICAL TESTS AND MEASUREMENTS.

Titchener, *Experimental Psychology*, vol. ii, parts i and ii (1905). Urban's contributions appear in F. M. Urban, *Application of Statistical Methods to the Problems of Psychophysics* (1908); the work of Brown and Thomson appears as W. Brown and G. H. Thomson, *Essentials of Mental Measurement* (1921). The method of paired comparisons is presented in L. L. Thurstone, "A Law of Comparative Judgment," *Psychol. Rev.*, 34:273–286 (1927). For application of this method to solve for the subjective zero point, *see* L. L. Thurstone and L. V. Jones, "The Rational Origin for Measuring Subjective Values," *J. Amer. Statist. Ass.*, 52:458–471 (1957). Evidence ior the power iunction form of a psychophysical law is summarized in S. S. Stevens, "On the Psychophysical Law," *Psyckol. Rev.*, 64:153–181 (1957). A general summary of psychophysical methods is to be found in J. P. Guiliord, *Psychometric Methods*, 2nd ed. (1954). (L. V. Jo.)

PSYCHOSES. A psychosis is a mental illness in which the patient fails to discriminate between stimuli arising within himself and stimuli received from the external world. The healthy personality accurately perceives and evaluates the environment. When the stress of conflict between the self and the environment becomes too great, however, the perceptive and evaluative (ego; *q.v.*) functions of the personality may break down. In such situations the person appears to distort his concept of the environment into a form which is more satisfactory for him; he organizes it into a less confusing place in order to protect himself. In the process he loses contact with reality and becomes psychotic.

Psychoses are rare until adolescence, but thereafter continue to increase in incidence with the advance of age. There is an especially sharp rise at the older age levels. The problems and conflicts of phases of development and stress, such as adolescence, marriage, pregnancy, parenthood, the involutional period and senility, tend to disturb psychological integration and may precipitate a psychotic disturbance in vulnerable persons.

Psychoses present symptoms that have multiple causations and multiple meanings. These are indicative of underlying conflict and represent ways of trying to deal with the conflict. Symptoms may represent attempts to adapt through protective and safety devices. or else they may appear when defenses collapse and disintegrate. Psychotic symptomatology is a manifestation of both regressive and restitutional phenomena. Initial symptoms, such as world-destruction fantasies, hypochondriasis and depersonalization, often represent regression to earlier behaviour patterns or renunciation of the objective world. Later symptoms, such as world-saving fantasies: hallucinations and delusions, may be evidence of a swing toward restitution or toward reintegration of the psychotic ego. The psychotic appears to oscillate between an almost complete loss of object relationships and a striving to re-embrace them.

Symptoms of Psychosis.—Psychotic symptoms may be considered under the following headings:

1. Disorders of perception. A hallucination (*q.v.*) is a misperception (either auditory, visual, olfactory or, less frequently, gustatory). Something is perceived which has no objective reality; for example, voices may be heard when no sound exists. An illusion is a misinterpreted perception in which a sensory impression is received correctly but then misconstrued so that it takes on an erroneous meaning. For example, the rustling of leaves may be interpreted as whispering reproaches; although the rustling is heard, it is given a specific psychological meaning.

2. Disorders of thinking. In autistic or dereistic thinking the mind appears to operate without regard to reality, building up an unrealistic fantasy life and becoming preoccupied with the fantasy to the exclusion of reality. A ('flight of ideas" is characterized by a rapid digression from one thought to another, often expressed as words or clauses run quickly together without an apparent logical connection. Perseverations are repetitive expressions of an idea and include verbigerations, or repetitions of apparently meaningless words or sentences. A delusion is a false belief which is not susceptible to correction by reason or logic. Thus many patients suffering from delusions of persecution may believe there is an international plot directed specifically against them, and they cannot be shaken from this belief. Patients with delusions of grandeur are convinced they are such exalted figures as Napoleon or Jesus Christ.

3. Disturbances of consciousness. A confusional state usually includes bewilderment. perplexity, uncertainty, disorientation and difficulty in grasping the simplest concepts. Stupor is a state of mind manifested by varying degrees of consciousness but always including diminished responsiveness, either through suspension of thought processes or through intense preoccupation with internal concerns, withdrawal and loss of reality sense. Delirium (*q.v.*) is characterized by combinations of the above plus illusions, hallucinations and intense fear.

4. Disturbances of affectivity and mood. Affectivity or feeling tone are terms signifying the minute-to-minute variations in the subjective feelings of a person. Mood is a sustained feeling tone over a longer period of time. These emotional states range along a continuum from extreme depression through normal affect to extreme elation. In the most extreme elation reality is completely denied, and attitudes of grandeur and peaceful rapture, detachment and power are assumed. Another dimension of affect includes panic, consisting of marked fear and a tendency toward disorganization of the personality. Characteristic of all these affect states (elation, depression, panic) is their inappropriateness; that is, the feeling tone is not appropriate to the patient's life situation.

5. Disturbances of activity. Marked increases or decreases in the rate of mental and physical activity are common. Hyperactivity includes excessive restlessness, pacing, agitation and excitement. The extreme of diminished activity is called waxy flexibility, in which the limbs are maintained in fixed poses for long periods of time.

Defense Mechanisms.—Although the ego defends itself against overwhelming anxiety with defense mechanisms, the mechanisms themselves may become of pathological degree.

1. Rationalization is a form of self-deception by which a person acclaims in a manner acceptable to himself an act, thought or feeling that in actuality has a different and more unacceptable motive. The real reason thus remains obscure. Although rationalization is commonly used by all people, such self-deception may become a full-fledged delusion if carried to an extreme.

2. Projection is a mental technique whereby a person unconsciously externalizes some of his own thoughts or feelings or inadequacies. He thus defends himself from his unacceptable impulse by attributing it not to himself but to another. Thus a person who cannot face his own hostility may attribute it to another and accuse the other of hostile designs against him. This mechanism characterizes the formation of paranoid reactions (see below).

3. Autism, withdrawal into fantasy and regression (a moving back to ard less mature but more comfortable levels of personality development) are protective devices but may lead to psychosis formation.

4. The process of internalization or introjection involves a turning inward upon the self of certain feelings and attitudes which thereby may produce depression. (See also DEFENSE MECHANISMS.)

Causes of Psychosis.—The causes of psychoses appear to be multiple. They include somatic (physical), biological, psychological (intra- and interpersonal) and sociological factors, all of which affect attitudes, feelings and behaviours. Studies of psychological causes stress the importance of the mother-infant relationship, inability and/or lack of opportunity for the child to obtain gratification of his basic needs, and defective development of a sense of reality. Extreme maternal deprivation during the first few months of life, caused either by lack of a mothering figure through loss or by an unusually barren mother-infant relationship, generates unbearable tensions. Since deprived children have had no one with whom to relate when relationship was most important, the warmth and security derived from relating to another human being are lacking. Genetic studies indicate that a specific potential for reacting to personality stresses in a specific way can be inherited; that is, it is possible to inherit a constitutional predisposition to psychosis which is then stimulated or extinguished by other etiological factors.

In addition to the basic determinants, there are a variety of factors that may precipitate a psychosis. These may be obvious reproductions or re-enactments of earlier stresses, or they may be less apparent and seemingly irrelevant events whose relationship to previous stress is obscure. Frequently precipitating factors are organic, such as alcohol and other drugs, infectious processes, endocrine and vitamin deficiencies, physical defects and brain injuries. Other precipitating factors appear to be manifestations of stressful times and events of life, as marriage or pregnancy. Overwork has frequently been implicated, but it is a symptom rather than a cause.

Organic Psychoses.—The psychoses are divided into two main categories, organic and psychogenic (for which see below). according to the presence or absence of discernible organic factors. Organic psychoses result primarily from pathological changes in the central nervous system. They are divided into acute and chronic types. The acute group includes those reactions which come on suddenly, last for a limited time and then disappear. The chronic diseases are slower in onset and tend to produce more lasting effects, which do not appear to be reversible but become stationary or gradually progressive.

The brain is particularly susceptible to physiochemical changes. It is dependent on a large flow of well-oxygenated blood, and since its metabolic activity is high, its oxygen consumption is also high. The brain has a small oxygen reserve and cannot withstand oxygen deprivation very long. It can expand little. yet is suspended and quite movable, subject to injury and sensitive to any noxious stimuli. Thus a state of reduced cerebral competence from whatever cause predisposes the individual to the development of an organic psychosis: (1) personality change, defects in judgment and moral code, tendency toward egocentricity; (2) disturbances in memory, especially for recent events, disorientation for time, place and person; (3) emotional instability, irritability and frequent shifts in mood; (4) exaggeration of previous personality problems (persons who have been aggressive tend to become overwhelmingly hyperactive, whereas persons who have been quiet and reserved tend to withdraw even more); (5) diminished tolerance to medications (more severe reactions to sedatives, other drugs).

In addition to acting as a specific cause or precipitating stress for the development of a psychosis, organic brain disease may interfere with and impinge upon the healthy integration of the personality. The result is impaired ego function, and the symptoms are a manifestation of ego disintegration. A less competent ego then permits the release of previously warded-off impulses which overwhelm the ego and lead to a psychosis.

The following are significant clinical entities:

1. Infectious processes. A meningitis (*q.v.*) may be either intracranial or systemic. Although commonly an acute reaction, some types of meningitis are long-standing. slowly developing diseases. Syphilitic meningoencephalitis (formerly called general paresis; *q.v.*), an infection not only of the meninges but also of the brain itself. may require years to develop.

2. Intoxications. A variety of drugs or poisons produce acute and chronic symptomatoiogy. Bromides, barbiturates, lead and alcohol taken over a prolonged period of time may lead to psychoses. Profuse and frequent imbibition of alcohol followed by sudden withdrawal and accompanied by a nutritional deficiency leads to a condition known as delirium tremens. Korsakoff's psychosis, associated with alcoholism, is in reality due to a severe vitamin B deficiency and is characterized by amnesia, disorientation for time and place and falsification of memory (*see* ALCOHOLISM).

3. Injuries. Severe head injury may produce an acute syndrome known as traumatic delirium or a chronic personality disturbance such as seen in the prize fighter who is "punch drunk."

4. Metabolic disorders such as hypoglycemia (a deficiency of sugar in the blood) and certain swellings or growths (brain tumours and cysts) may bring about a psychosis.

5. Degenerative diseases. Advanced age may be associated with a degenerative disease of the brain which leads to dementia. a psychotic disturbance characterized by progressive impairment of basic mental capacities. In these cases the brain cells literally "wash away" and disappear (see DEMENTIA!.

6. Circulatory disturbances. One of the commonest disease processes expressing itself in both acute and chronic psychotic forms is cerebral arteriosclerosis. In this condition there is gradual or fairly rapid hardening of the blood vessels of the brain, and deposits of fat in the deteriorating vessel wall tend to narrow or almost obliterate the vessel: thereby obstructing the flow of blood. When less blood is carried to the brain its nutritional status is affected and psychosis appears. There is often a fluctuation in the course of cerebral arteriosclerosis, and the patient often recognizes his decline. in contradistinction to other organic maladies where there is no insight.

The treatment of an organic psychosis depends on its cause, and each is handled individually. Both physiological and psychological therapies are employed, ranging from vitamins, medications and surgical procedures to the establishment of emotional security and an increasing sense of self-esteem.

Psychogenic Psychoses.—Disorders of psychogenic origin appear to be free of structural, anatomical or physiological changes and are the result of disturbed psychological experience. The six major psychoses of psychogenic origin are divided into two distinct but by no means mutually exclusive types, the affective reactions and the thought disorders. In the former, mood disturbances are dominant; in the latter, there is a predominant disturbance in the capacity to think and judge and the power to reason. The three affective reactions are involutional depression, manic-depressive psychosis and psychotic depressive reaction. The three thought disorders are schizophrenia, paranoia and paranoid state.

Affective Reactions.—An involutional depression is a depression coming on in the so-called involutional period of life (*i.e.*, approximately 40–60 years of age in women, 45–65 in men). It is often accompanied by agitation, usually represents the person's first "breakdown" and occurs in people whose premorbid personalities are characterized as energetic but inhibited, compulsive and overconscientious, chronically worried, inflexible and sensitive.

A manic-depressive psychosis, as the name suggests, may be made up of both manic (hyperactive, elated) phases and depressive states, alternating with one another or occurring haphazardly without any particular order. Instead of alternating, all episodes may be manic, or all may be depressed. These episodes are usually cyclic in nature and may come on every few months or every few years with reasonable regularity. The disease occurs in young people (early 20s) and may continue intermittently for many years. each attack lasting a few weeks or a few months. The manic phase may represent a defense against a basic depression; certainly the swings from one phase to another give credence to the homogeneity of the two elements. The symptomatology of the manic is characterized by exaltation and excitement. loquaciousness and rapid association of ideas. Psychomotor activity is described as overactive. The depressed phase. on the other hand, is usually characterized by psychomotor retardation; *i.e.*, movement and mental activity are slow and there is an inhibition of the stream of thought.

The prepsychotic personality of the manic-depressive is distinguished by its lability, mood swings and unpredictable oscillations of emotion.

The term psychotic depressive reaction describes a depression of psychotic proportions, arising as a direct result of one or several specific precipitating stresses. It may come at any age, and is often an isolated. single episode in a person's life.

Thought Disorders.—Schizophrenia is a term coined by E. Bleuler in 1911. from two Greek words meaning "splitting of the mind." As with the others, this disorder represents an expression of the total reaction of the person to internal and external stress. There is a breakup in the normal synthesis of thought. and part of the split takes place between the thought process and the affect connected with it. In its most definitive form the schizophrenic syndrome is made up of: (1) a disorder of association—the train of thought does not seem to follow a usual rational pattern: (2) a disorder of affect—the feeling state is inappropriate to the situation, to the particular thought or idea expressed; (3) autistic thinking—withdrawal into self and a fantasy world; and (4) ambivalence—indecision or complete blocking because of two conflicting feelings or two opposing impulses.

Emerging from these manifestations are a host of varied symptoms and signs including poverty and disharmony of feeling tone. inability to relate to another person and delusional or hallucinatory mental content or both. A schizophrenic person may appear dull and apathetic. He may be catatonic and stay in one position over a long period of time. He may exhibit mutism. impulsive or stereotyped behaviour and occasional phases of stupor or excitement; or he may be preoccupied with delusional thoughts with behaviour corresponding to these thoughts. In general there may be mixtures and combinations of symptoms. attitudes. expressions and patterns, so that it is difficult to classify schizophrenics into subtypes or to place them in various subdivisions (see SCHIZOPHRENIA).

The paranoid psychoses are characterized by delusions of a persecutory or grandiose nature. with varying degrees of ego disintegration. In true paranoia there is usually one basic, well-systematized delusion, while the rest of the ego remains reasonably intact. The true paranoiacs are rarely identified. as they usually manage to conceal their delusions and to function adequately. Paranoid states involve a more elaborate delusional system in which the delusions are less believable and more loosely organized and lead to a more disintegrated ego structure. During the paranoid episode the patient may be obstreperous and hostile (see PARANOID REACTIONS).

The bridge between the paranoid psychosis and the schizophrenic psychosis is an entity known as paranoid schizophrenia. In the most serious forms the delusions are poorly organized. bizarre and contradictory. and ego disintegration proceeds at a rapid pace. Paranoid schizophrenics range along a continuum from relatively harmonious ego co-ordination to almost complete ego decomposition and loss of control. The paranoid schizophrenic is potentially dangerous to himself or others because of his feeling that others are against him and because of his bizarre reactions to this thought.

Treatment of the psychogenic psychoses is varied and variable. Several therapies usually are combined in managing a particular syndrome with one or more therapeutic procedures utilized at specific times for specific reasons.

Many patients with psychosis require hospitalization; some do not. Outside a hospital, psychotherapy, environmental manipulation and the administration of drugs are valuable. In a hospital, concomitant with the above, a program that includes individually prescribed activities for the patient and certain helpful attitudes on the part of the ward staff, plus somatic therapies such as insulin, electroshock and lobotomy (surgery on the brain) are employed when necessary. The affective psychoses, particularly the involutional depressions, respond more favourable to electroshock than do the thought disorders. In the paranoid conditions sometimes insulin and occasionally lobotomy have been used, and favourable results with drug therapy have been reported. However, psychotherapy and the provision of a therapeutic milieu are the basic treatment in all the psychoses.

Childhood Psychosis.—Childhood psychosis is an uncommon but severe form of ego disturbance which becomes apparent in the early years of life (before puberty). Onset may be sudden or insidious. Symptoms include withdrawal, negativism (refusal to do whatever is asked, or doing the oppositk of what is expected or desired), anxiety, stereotyped behaviour and a tendency toward an abandonment of reality. In infancy the baby may be apathetic and fail to react emotionally to being approached or when picked up.

Etiologically the lack of an affectional tie between infant and mother appears to be important. Often the mother (or both parents) as nell as the child require treatment. Institutional care for the child is sometimes indicated.

For other types of mental disorders, see NEUROSES. For treatment, see PSYCHIATRY; PSYCHOANALYSIS; PSYCHOTHERAPY; NEUROPHARMACOLOGY AND PSYCHOPHARMACOLOGY. See also PSYCHOLOGY. ABNORMAL, and Index references under "Psychoses" in the Index volume.

PSYCHOTHERAPY in its broadest sense is the systematic effort of a person or group to relieve distress or disability by influencing the sufferer's mental state, attitudes and behaviour. Drugs may be used as adjuncts, but the healing influence is exerted primarily by words and actions that are believed by sufferer, therapist and the group to which they both belong to have healing powers and that create an emotionally charged relationship between them. Psychotherapeutic methods are used to treat all forms of suffering in which emotional factors play a part. These include behaviour disorders of children and adults; emotional reactions to the ordinary hardships or crises of life; psychoses, characterized by derangements of thinking and behaviour usually so severe as to require hospitalization; psychoneuroses, which are chronic disorders of personal functioning often accompanied by bodily symptoms of emotional strain; addictions; and psychosomatic illness, such as gastric or duodenal ulcer and certain skin diseases, in which tissue damage is caused or aggravated by emotional components. Since loss of morale contributes significantly to the degree of disablement of all chronically ill or handicapped persons, psychotherapeutic principles are emphasized in rehabilitation programs.

Historical Survey.—Early psychotherapeutic theories and methods were based on either the religio-magical or the naturalistic view of mental illness. The former, originating before recorded history, regarded certain forms of personal suffering. or of alienation from one's fellows, as caused by an evil spirit that gained entrance into the sufferer because he had sinned or through an enemy's curse. The curse could be lifted or the transgression atoned for, leading to expulsion of the evil spirit, by the participation of the victim and his group in suitable rites, under the leadership of a priest-physician, the medicine man or shaman. Thereupon the victim's health was restored and he was once more accepted by his group. The tradition of supernatural healing remained strong and finds its modern expression in, for example, healing shrines and numberless cults led by healers whose claims are accepted only by their devotees.

The naturalistic tradition viewed mental illness as a phenomenon that could be scientifically studied and treated, like other forms of illness. Treatment consisted in measures to promote bodily well-being and mental tranquility. The earliest surviving expression of this concept is in the writings attributed to Hippocrates in the 5th century B.C. Though largely eclipsed in the middle ages, at the turn of the 19th century it again began to cotne to the fore under the leadership of the great French physician Philippe Pinel. For him, many forms of insanity were the results of excessive exposure to social and psychological stresses, and he tried to help the insane regain their reason through "moral treatment," which included close. friendly contact, intimate discussion of personal difficulties and a planned program of purposeful activities. The popularity of moral treatment depended upon the belief that insanity was curable by psychological influences. As the theory gained ascendance that mental illness was caused primarily by organic disease of the nervous system rather than by the stresses of life, faith in its curability by psychological means declined and, starting in the middle of the 19th century, mental hospitals tended to degenerate into custodial institutions, which most of them continued to be until the mid-20th century.

Psychotherapy of nonhospitalized patients in the naturalistic tradition was not distinguishable from ordinary medical practice until the latter half of the 19th century. The emergence of psychotherapy as a specialized treatment probably is traceable to the dramatic demonstration by Franz Anton Mesmer (*q.v.*) in the late 18th century that many symptoms could be made to disappear by putting a patient into a trance. Although his theories and methods mere soon discredited, mesmerism was the precursor of hypnotism, which became a widely used psychotherapeutic method. Through it Josef Breuer and Sigmund Freud (*q.v.*) made the epochal observations on the relationship to later mental illness of emotionally charged damaging experiences in childhood. From these discoveries grew the theory and practice of psychoanalysis, which, uith its many modifications, immensely influenced the subsequent development of psychotherapy.

Despite the widespread recognition that the groups to which a person belongs powerfully affect his attitudes and behaviour, the traditional medical emphasis on the privacy of the doctor-patient relationship slowed general acceptance of group psychotherapy. Though foreshadowed as early as 1905 by Joseph J. Pratt's group treatment of tuberculosis patients. only a few physicians practised group therapy before World War II. The large numbers of soldiers requiring psychotherapy compelled psychiatrists to try to treat them in groups, and the use of group methods proved so effective that they developed rapidly in the postwar years. During this period, two societies and two journals devoted exclusively to group therapy appeared in the United States alone. The professional acceptance of the importance of group influences led to the development of social or milieu treatment for hospitalized patients, based on the recognition that all aspects of institutional life had therapeutic potentialities. This gradually began to transform mental hospitals from custodial institutions into therapeutic communities.

The rapid growth of group therapy was one manifestation of a striking upsurge of public interest in mental health, especially in the United States following World War II, leading to a demand for psychotherapy that went far beyond the capacity of the medical profession to meet it. As a result, members of related disciplines, particularly clinical psychology and psychiatric social work, received increasing recognition as competent to treat certain types of sufferers.

Psychiatrists continued to have responsibility for treatment of the hospitalized insane and patients in psychiatric clinics. They also enjoyed the highest prestige as private practitioners of psychotherapy. Other physicians continued to practise effective psychotherapy of an informal sort on the large proportion of their patients whose bodily complaints were associated with emotional stress. Clinical psychologists and psychiatric social workers treated patients or their families under psychiatric supervision in mental hospitals and psychiatric clinics for adults and children. In addition. members of each profession used methods analogous to, if not indistinguishable from, psychotherapy in certain institutional settings without medical supervision. The type of person or problem with which psychologists and social workers dealt depended largely on the settings in which they worked. Psychologists in educational institutions counseled children, adolescents and young adults; social workers did casework with clients of social agencies. whose personal difficulties tended to be bound up with environmental stresses. The exact limits of the various fields of competence of these disciplines remained vague and the jurisdictional problem became more acute as psychologists and social workers in the larger cities entered independent private practice in direct competition with psychiatrists.

A significant development during this period was the growing rapprochement between naturalistic psychotherapy and religiously oriented psychotherapy in the form of pastoral counseling. As psychotherapy became more popular, certain persons came to seek it as a means of achieving a fuller life and finding personal solutions to the general problems of human existence. Psychotherapists thus were faced with questions that traditionally lay in the province of philosophy and religion. At the same time, parishioners put increasing demands on their ministers for help with personal problems, leading the latter to turn for help to the newer insights of psychotherapy. Both groups saw resemblances between the moral and spiritual conflicts or emotional responses to the crises of life, which were the primary concern of the pastoral counselor. and the issues raised by patients in psychotherapy.

The variety of therapeutic practitioners was paralleled by a wide diversity of theories of mental illness and methods of treatment. The preferred form of psychotherapy in different cultures seemed to accord with the characteristic pattern of social interaction. Psychotherapy in Germany and the U.S.S.R. tended to be directive, while in the United States permissive, democratic methods had a higher prestige. Within a given culture, furthermore. patients of different socioeconomic levels tended to receive the type of psychotherapy that accorded best with their typical views of treatment. One study of patients in psychiatric treatment in New Haven, Conn., in 1951. for example, found that about half the upper- and middle-class neurotics received insight therapy (see below) as compared with only 5% of the lower-class neurotics. This seemed related to characteristic differences in the conceptions of these classes as to what constituted treatment.

The existence of so many theories and techniques was an indication of the need for research. which received extensive and increasing public and private support in the decade following World War II.

Features Common to **All** Forms of Psychotherapy. — There is no convincing evidence that the results of one form of treatment are better than any other, lending plausibility to the supposition that their underlying similarities might be more significant than their apparent differences. Despite differences in emphasis, most schools of psychotherapy agree that mental illnesses are, at least in part, expressions of chronic states of anxiety and frustration, related to unsolvkd inner conflicts and unsuccessful ways of dealing with other persons Though genetically or physiologically caused vulnerabilities might contribute to the difficulties of these patients, unfortunate early experiences aith family members and other emotionally significant persons are believed to play a major role.

Chances of successful treatment are generally held to be related to the degree of the patient's emotional involvement in the treatment process. This is influenced by the intensity of his suffering and by his faith in the therapist and the treatment method. The patient's expectancy of help is enhdnced by the therapist's ability to convince the patient that he understands him intimately and is dedicated to his welfare. Personal qualities of the therapist and his emotiondl reactions to the patient seem important in the development of a successful therapeutic relationship.

The close, confiding relationship between patient and therapist, including the shared expectancy that the patient will be helped that is common to all forms of psychotherapy, is probably healing in itself. It tends to allay the patient's anxieties and bolster his morale, resulting in direct relief of bodily symptoms due to emotional tension In addition it helps him mobilize the courage necessary to give up habitual but unsatisfactory nays of feeling and behaviour and search for better ones. The search is aided by the fact that the therapist or therapeutic group represent certain values and principles of conduct with which the patient can compare his own and adopt what is helpful to him. This usually occurs not through deliberate choice but more or less unconsciously. just as children take over behaviours and attitudes of their parents, which then become integral parts of their own personalities. Psychotherapy thus is essentially a process of reeducation, both emotional and intellectual. through which the patient develops better patterns of adjustment to life.

Major Forms of Psychotherapy. — Psychotherapies differ primarily in the nature of the activity that mediates the therapeutic relationship. The variety of these activities is bewildering, but they may be classed as individual or group, depending on whether or not the therapist treats more than one patient at a time. Both forms can be divided roughly into methods that seek to alleviate the patient's distress or teach him more satisfactory behaviour through direct interventions, and those that try to facilitate his over-all emotional growth and capacity for responsible behaviour. Many psychotherapeutic methods contain an admixture of both, and most psychotherapists emphasize one or the other with different patients, depending on the nature of their difficulties.

Individual Psychotherapies. — Individual psychotherapeutic methods for influencing patients directly include advice giving, persuasion. suggestion and training in specific curative activities. These include relaxation exercises to combat emotional tension and efforts to inculcate behaviour that is incompatible with that presumably causing the patient's distress. thereby overcoming it. Many of these methods are based on the conditioned reflex theories of I. P. Pavlov (see CONDITIONING; REFLEX). They frequently use hypnosis (*q.v.*) to heighten the therapist's power over the patient, and often include efforts to change his social environment so as to reduce the stresses it places upon him.

Individual therapies that seek to foster the patient's general personality growth emphasize heiping him to gain insight into his feelings and behaviour. They hold that, since symptoms of emotional illness are expressions of flaws in the patient's over-all approach to life, permanent relief requires major personality change. To facilitate this they try to create a therapeutic situation that will enable the patient to express himself with complete freedom, while the therapist maintains a consistent, warm, nonjudgmental interest. Feeling himself understood and accepted by someone whom he admires and to whom he feels close. the patient will progressively dare to reveal those shameful or frightening aspects of himself that he has pushed out of awareness. As his self-understanding increases, his self-esteem will grow and he will become more spontaneous, enabling him to relate more flexibly and appropriately to persons important to him. Thus he will derive increasing satisfaction and security and his distress will diminish, leading to further gain in his sense of self-worth. In this way a beneficial circle is set in motion, resulting in increasingly deep and permanent improvement.

The influential U.S psychotherapeutic school of Carl R. Rogers holds that the consistent, warm "unconditional positive regard" of the therapist for the patient is sufficient to produce these changes. Therapies in the psychoanalytic tradition, while also emphasizing the importance of the therapeutic relationship, try to help the patient understand and master his feelings by labeling and analyzing them. They differ in their concepts and in the relative emphasis placed on different types of rnaterial produced by the patient. Traditional psychoanalysis emphasizes the use of dreams as short cuts to the patient's deeper feelings. It also puts great stress on helping the patient to rediscover, re-experience and "work through" the traumatic emotional experiences of early life in which his current difficulties are believed to originate. Hypnosis may be used to facilitate this, although Freud believed free association (see ASSOCIATION, MENTAL) to be more effective. Later modifications of psychoanalysis put more emphasis on analysis of the patient's current problems. and some emphasize helping the patient to gain a better philosophy of life. Ali agree that in an intimate, prolonged relation with the therapist, the patient will eventually experience toward him the feelings that trouble his relationships with persons emotionally close to him in his past and present life. Since both therapist and patient can observe these "transference reactions," as Freud termed them, exploring their inappropriateness is deemed a powerful means of resolving them.

Group *and Social* Therapies.—Group therapeutic techniques are as varied as those of individual therapy, and similarly tend to stress either alleviation of members' distress by direct measures or creation of a group atmosphere conducive to increased self-understanding and personal maturation. Groups of the first type may have any number of members, up to 50 or more. Some are primarily inspirational in that their chief aim is to raise members' morale and combat feelings of isolation by cultivating a sense of group belongingness through slogans, rituals, testimonials and public recognition of members' progress. Certain of these groups have developed into autonomous movements conducted solely by their members. An outstanding example is Alcoholics Anonymous, organized by chronic alcoholics to help themselves. Two other popular directive methods are didactic group therapy, which seeks. through organized discussions of assigned topics, to stimulate group members intellectually so that they will function more successfully; and therapeutic social clubs, which stress development of social skills through participation in self-organized social activities.

The other class of group methods strives to foster free discussion and uninhibited self-revelation. Most use small face-to-face groups, typically composed of five to eight members. Members are heiped to self-.understanding and more successful behaviour through mutual examination of their reactions to persons in their daily lives, to each other and to the group leader in an emotionally supportive atmosphere. An influential variety of this approach that utilizes larger groups is the "psychodrama" of J. L. Moreno. In this method patients more or less spontaneously dramatize their personal problems beiore an audience of fellow patients and therapists, some of whom also participate in the dramatic production itself. The dramatization is followed by discussion between players and audience.

Social therapy for institutionalized patients represents at once an extension of group therapeutic principles and a revival of the moral treatment of Pinel. Its aim is to make the mental hospital a therapeutic community, all aspects of which will help to restore the patients' mental health. This involves the creation of a cheerful, homelike atmosphere and a full program of occupational, recreational and social activities. It also involves the development of a flexible, democratic social structure in which all members of the treatment staff work as a co-ordinated team and the patients participate responsibly, to the limits imposed by their disabilities. in all phases of hospital life. Through patient government they help make policy decisions, plan and carry out activities and may even have a voice in the handling of deviant or disturbed hehaviour of individual patients.

By heightening the patients' sense of personal worth and instituting social controls of behaviour, social therapy in conjunction with drug therapies may lead to a striking decline in violent or disorganized conduct. This makes possible the reduction or even elimination of physical restraints or locked wards. Social therapy programs lead to a more flexible use of hospital facilities, in that some patients can come to the hospital only during daylight hours. others only to spend the evening and night. In many ways social therapy thus lowers the barrier between mental hospital and community, which improves the morale of hospitalized patients by combating their sense of alienation from the outside world, thereby aiding the recovery process.

Integrated treatment programs finally succeeded in bringing about a progressive decrease in state hospital populations. Though admissions continued to rise, discharges rose even more rapidly. This heartening development enhanced hopes for the increasingly successful treatment of the hospitalized insane.

PTAH, Egyptian god. was originally the local deity of. the town of Memphis (*q.v.*), capital of Egypt in the 3rd millennium B.C.; to its political importance was due the expansion of Ptah's cult over the whole of Egypt. The Asiatic origin of Ptah suggested by some scholars is extremely doubtful and the Semitic words from which it has been allegedly derived appear in Egyptian not earlier than the 3rd century B.C. In Egyptian belief, Ptah was the creator of the universe and maker of things, therefore also a patron of craftsmen. especially sculptors; the title of his high priest was "supreme leader of craftsmen." Consequently, the Greeks identified him with their Hephaestus, the divine blacksmith. Ptah was always represented in purely human form. The connection between him and the sacred bull Apis was artificial, but Apis had his stall in the great temple of Ptah at Memphis and was called "intermediary of Ptah," that is, intermediary between men and the god.

See M. Sandman Holmberg, *The God Ptah* (1946). (J. CY.)

WHITE-TAILED PTARMIGAN, OR MOUNTAIN GROUSE (LAGOPUS LEUCURUS), SHOWING SUMMER PLUMAGE

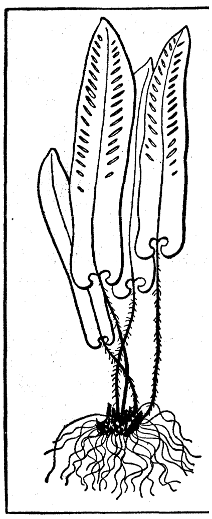
PTARMIGAN (*Lagopus*). A gallinaceous bird of several species inhabiting arctic and sub-arctic regions. In its northern range the plumage becomes pure white; in the southern part the summer plumage of reddish brown barred with black is assumed. The feet are covered with hairlike feathers which aid in walking over snow. From 6 to 12 eggs of various shades of buff marked with brown are laid in a depression in the ground. (K. P.)

PTERIA, the ancient capital of the "White Syrians" of northern Cappadocia, which Croesus (*q.v.*) of Lydia is stated by Herodotus to have taken, enslaved and ruined: after he had declared war on Persia and crossed the Halys (Kizil Irmak). Pteria is mentioned only by Herodotus among the ancients. The identification of Pteria with the modern Bogazkoy, once taken for granted, is quite uncertain. Pteria is probably to be sought in a district nearer to the Black sea.

PTERIDOPHYTA, one of the groups comprising the ferns and their allies. of the second great division of plants. the Archegoniatae, the other being the Bryophyta (*q.v.*). The Pteridophyta thus share with the Bryophyta a middle position between the essentially aquatic Thallophytes and the essentially terrestrial Spermatophytes. Much of their special interest centres round that fact. They include plants well represented at the present day; but many already existed in the early land vegetation of the Devonian period, now known only as fossils; they appeared in greater profusion as fossils of the coal, and many of these early types continued on into the Mesozoic age while their correlatives are included in the flora of the present day. Thus their geological history supports the conclusion that they take a middle position in the evolutionary progression of plant life. in which a transition from life in water to life on land was a striking incident.

Hofmeister first showed that there is essential similarity underlying the life histories of mosses and ferns, and that the same scheme, in modified form, extends to the seed plants also. Since this is so, an account of the Pteridophyta may fitly be introduced by a brief record of the life history of a fern, as an example of the Archegoniatae generally! and of the Pteridophyta in particular. There are two periods in each normally completed life cycle of these plants when the individual is represented by a single cell; and these punctuate the limits between two distinct bodily phases, or generations as they are called. One of these is the leafy *fern plant* which every one knows; the other is a small green scale-like body, delicate in texture, called the *prothallus,* which escapes the observation of most people, though actually common enough. The former is sexless, but bears *spores* in large numbers; it is the *sporophyte* generation. The latter is the sexual generation, and, since it produces *gametes,* it is called the *gametophyte.*

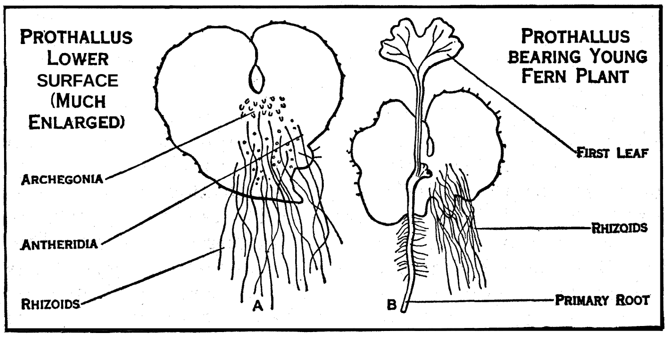
Life-history of a Fern. — The fern plant varies in size from a minute herb to a tree-like body, 60 or even 80ft. in height. It consists of a stem bearing characteristic leaves, usually of large size and delicate outline; the shoot thus constituted is attached by roots to the soil, the whole being traversed by conducting tracts. Since the green leaves serve a nutritional function, the plant is able to subsist as a perennial land-plant (fig. 1). On the leaves the *sori* are borne, of various form and position. In the hart's tongue or the common shield fern they appear as dense groups of brown *sporangia* seated on the lower surface, and covered while young by a membranous indusium. Each sporangium is a stalked capsule containing numerous minute, dry and dusty spores, which are violently ejected when ripe, and each is then liable to be carried away individually by the breeze. The spores are unicellular propagative organs.



FROM STRASBURGER, "LEHRBUCH DER BOTANIK" (GUSTAV FISCHER)

FIG. 1.—HART'S TONGUE (PHYLLITIS SCOLOPENDRIUM)

Each spore germinating on moist soil may grow into a prothallus or gametophyte (fig. 2), which never grows large, though being green it is physiologically independent. It bears the *sexual organs* or *gametangia,* usually on its lower surface (fig. 2, A). Near its base are the male gametangia or *antheridia,* which when ripe consist each of a protective wall of cells surrounding numerous spermatocytes. When bathed by external water (rain or dew) the wall ruptures, and each spermatocyte emits a single spiral *spermatozoid,* which moves in the water by lashing cilia (fig. 3). Near the indented apex of the prothallus the female gametangia or *archegonia* are formed (fig. 2). They are flask-shaped organs, also protected by an external wall; each contains a row of three

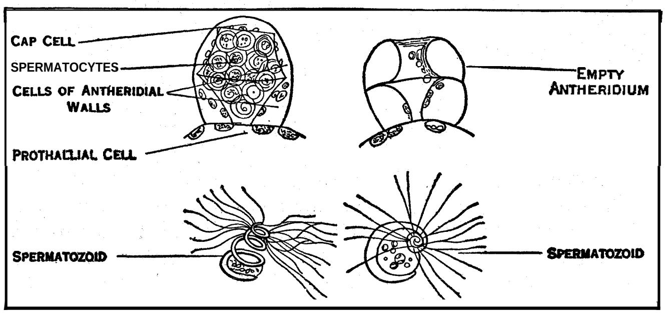


FROM STRASBURGER, "LEHRBUCH DER BOTANIK" (GUSTAV FISCHER)

FIG. 2.— PROTHALLUS OF SHIELD FERN (DRYOPTERIS FILIX-MAS)

cells, of which the lowest and largest is the ovum or egg, sunk in the tissue of the parent (fig. 4). When ripe the archegonium also ruptures on access to external water, the distal cells of the wall parting so that an open channel filled with mucilage leads down to the rounded egg. *Fertilization (syngamy)* consists in the fusion of the spermatozoid with the egg to which it is attracted by soluble substance diffusing from it into the water that bathes the open archegonium. The result of that fusion is the *zygote,* which is the starting point for the development of a new fern plant. This new individual appears first as a spherical mass of delicate cells, nursed in the cavity of the archegonium; but it soon bursts out with its first leaf and root, and its apical bud ready to grow into a new fern, while the prothallus rots away (fig. 2, B).

The central feature in syngamy is the *coalescence of the male and female nuclei;* the resulting fusion-nucleus is then *diploid,* with the $2n$ number of chromosomes *(see* CYTOLOGY*).* That character is then maintained throughout the tissues of the sporophyte. On the other hand, when the fern-plant comes to maturity and forms sporangia, the cells that are to form the spores undergo



FROM STRASBURGER, "LEHRBUCH DER BOTANIK" (GUSTAV FISCHER)

FIG. 3.— ANTHERIDIUM OF POLYPODY (POLYPODIUM VULGARE)

a nuclear change, called *reduction* or *meiosis,* by which they resume that simpler constitution possessed by the nuclei of the prothallus, and described as *haploid (n).* These events normally alternate in regular succession, and they constitute that *nuclear cycle* which underlies all normal life-histories of the Archegoniatae. They stamp structurally the distinction of the two alternating generations. Such alternation, in one form or another, appears in all plants that show sexuality. The Pteridophyta illustrate the cytological cycle with unusual clearness, since the two somatic phases (viz., the haploid prothallus and the diploid fern plant) are so unlike, and so markedly independent the one of the other during their adult existence. It seems probable that in the course of evolution some simple form of alternation present in an algal

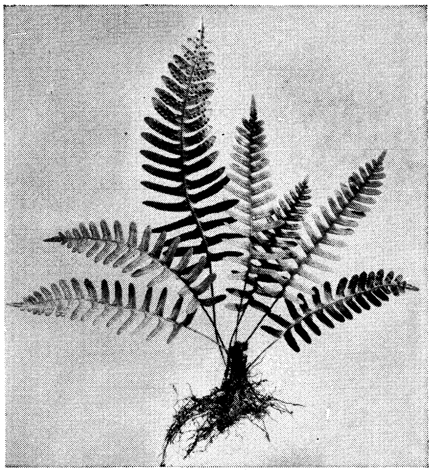
FIG. 4—ARCHEGONIUM OF POLYPODY (POLYPODIUM VULGARE)

ancestry has been regularized and standardized in the Archegoniatae in accordance with a passage from the relative uniformity of aquatic life to the more varied vicissitudes of life on land. In the Bryophyta the gametophyte was more adaptive, and became the dominant generation; on the other hand, in the Pteridophytes, as also in all the higher land-plants, the sporophyte became specialized as the dominant land-living organism. But the Archegoniatae themselves were never wholly emancipated from dependence on external liquid water. They show their amphibious character by their zoidiogamic fertilization; and this confirms their position as primitive land-plants.

For the most part the Pteridophyta are like the Bryophyta in

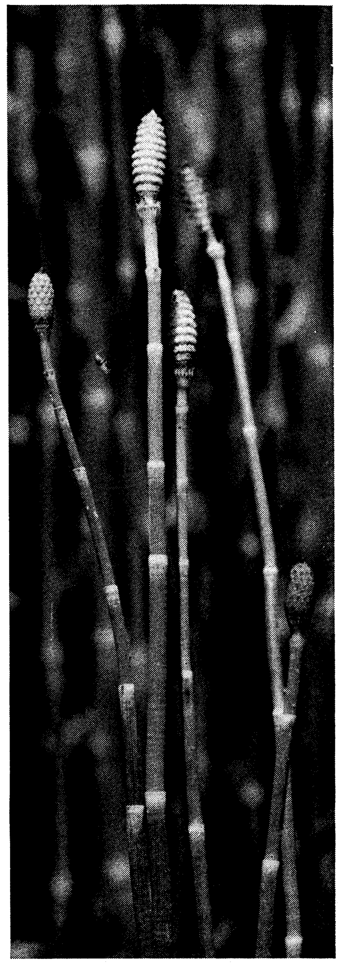
PTERIDOPHYTA

PLATE I

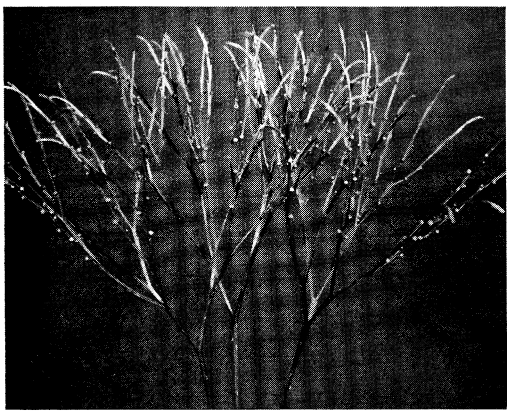


Plant and roots of the common **polypody** (*Polypodium vulgare*), a fern widely distributed in the U.S., Great Britain and Europe

Grape fern (*Botrychium virginianum*), one of the **Ophioglossales** or sucoulent ferns, primitive types limited to four **living** genera



Reproductive stems of rough horsetail (*Equisetum* hyemale), a member of the most primitive of living plant **families** allied to ferns. The plant grows to heights of 5 ft. or more



Psilotum triquetrum, showing spore cases. This plant is of the class **Psilophytinae**, fern allies which do not have true leaves

Detail of the fiddlehead, or crozier, of the **Christmas** fern (*Polystichum* acrostichoides)

Tree ferns, about 20 ft. high, growing on the island of Fernando Po, Spanish Guinea. These are true ferns of the family Cyatheaceae

Leaf of a broad beech fern (*Thelypteris hexagonoptera*)

FERNS AND FERN ALLIES

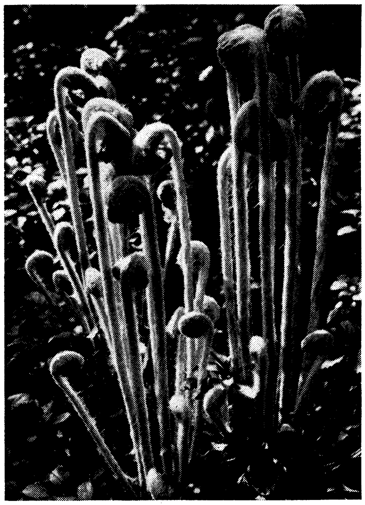
P'I'ERIDOPHYTA

Bulblet fern (Cystopteris bulbifera) usually found on rocky limestone slopes

Bird's-nest fern (*Asplenium nidus*), native to the oriental tropics, is frequently cultivated. This plant was photographed in Polynesia



Croziers of the cinnamon fern (*Osmunda* cinnamomea). Each head unfolds into a leaf

Crested table fern (Pteris *cretica*), a coarse fern of the oriental tropics

Ebony spleenwort (Asplenium platyneuron), a tall fern widely distributed in the U.S.

Maidenhair fern (*Adiantum* pedatum), another fern common to much of the U.S. from the Gulf states to Alaska

Walking fern (Camptosorus *rhizophyllus*), so named because the tips of its leaves often take root and sprout new plants. Note irregular pattern of fruit dots on the underside of leaf at centre

FILICALES: TRUE FERNS

PHOTOGRAPHS, (TOP LEFT, CENTRE, CENTRE RIGHT, BOTTOM LEFT. BOTTOM RIGHT) JOHN H. GERARD, (TOP RIGHT) E AURERT DE LA RUE. (CENTRE LEFT) J. HORACE MCFARLAND CO possessing only one type of spore (*homosporous*); but they produce these in enormous numbers. A common shield fern may ripen over 50,000,000 of them in a season. This is a primitive mode of propagation characteristic of early vegetation.

On the other hand, some few Pteridophyte-types such as *Selaginella* and *Isoetes,* and those curious little fern-derivatives styled collectively the Hydropterideae, possess sexually-differentiated spores, and are described as *heterosporous;* numerous smaller spores (microspores) bear each a rudimentary male prothallus, while a few larger spores (*megaspores*), or only a single one, produce each a massive female prothallus. Ir. this they show a state of specialized advance along lines that have led to the final success of the flowering plants. The Pteridophytes as a whole present the paradox of a great division of the vegetable kingdom that has achieved success by force of numbers, rather than by the more refined methods of physiological adjustment and of propagation even in the higher plants. These paragraphs, of necessity rather technical, will suffice to introduce the Pteridophyta, Vascular Cryptogams, or fern-allies as they are sometimes called. They are represented by six natural groups or classes of organisms, of which four include forms both living and fossil, but two are known only as extinct and very early fossils. Such facts at once confirm their position as representing a primitive vegetation. They may be arranged in rough sequence according to their complexity of form and structure; but this must not be understood as conveying any definite view as to affinity.

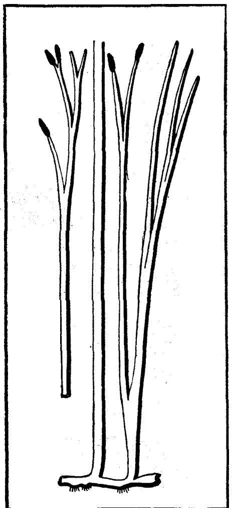
CLASSIFICATION

I. PSILOPHYTALES, comprising only fossil types of simple conformation, from early Devonian rocks.

II. PSILOTALES, represented by two genera of living plants, Psiloturn which is intertropical, and *Tmesipteris* which is confined to Australia.

III. SPHENOPHYLLALES, containing extinct Palaeozoic fossils of small size, which hardly extended into the Mesozoic period.

IV. EQUISETALES, including only the single living genus of the horsetails (Equisetum), but largely represented also by Palaeozoic fossils often of dendroid form (Calamariaceae).



FROM KIDSTON & LANG IN BOWER, "FERNS" (CAMBRIDGE UNIVERSITY PRESS)

FIG. 5.—HORNEA LIGNIERI

V. LYCOPODIALES, or so-called club-mosses, well represented at the present day by the large genera, *Lycopodium* and *Selaginella;* also by *Phylloglossum* and *Isoetes*. But in the Palaeozoic period there existed the giant Lepidodendroid trees, as well as allied plants of humbler dimensions.

VI. FILICALES, or ierns; these comprise not only the living ferns, with about 150 genera and over 6,000 species, but also a rich sequence of fossils, from the Palaeozoic Coenopteridaceae to the most recent strata.

A newer scheme of classification treats the higher cacegoriee in a somewhat different manner. The phyla Pteridophyta and Spermatophyta (Seed,Plants) are united into one group, the Vascular Plants or TRACNEOPHYTA. This includes four subdivisions: (1) the PSILOPSIDA, including the Psilcphytales and Psilotales, (2) the LYCOPSIDA, including the Lycopodiales, (3) the SPHENOPSIDA, including the Equisetales and Sphenophyllales and (4) the PTEROPSIDA, including the Filiciniae, the Filicales of the above treatment, and also the Gymnospermae and Angiospermae, the two large groups of seed plants.

I. **Psilophytales.**—This new class of plants was constituted by Kidston and Lang to receive certain fossils of early Devonian time, discovered by Dr. Mackie at Rhynie in Aberdeenshire. Its name is taken from the old genus *Psilophyton* of Dawson, and the class now comprises a number of other genera of like age, more recently discovered, forming together a very distinctive flora: But of these only the sporophyte is known (fig. S). The vegetative system consists of upward-growing, forked. aerial shoots that spring from a rhizome sometimes creeping, sometimes tuberous and mycorhizic; sometimes the underground branchlets are rootlike, forking in the substratum (Asteroxylon). The erect shoots are cylindrical, and were evidently green, covered by an epidermis, with stomata, and they are traversed by conducting strands of simple structure. Various superficial growths, often with the appearance of thorns or prickles, are borne upon the larger branches, as in *Psilophyton* and Asteroxylon. The plants

FIG. 6.— PSILOTUM TRIQUETRUM. (A) HABIT OF PLANT, SHOWING DICHOTOMOUS BRANCHING (B) PART OF A SHOOT

were of low stature, and growing gregariously they must have looked rather like grass. The genera Hornea, Rhynia and *Asteroxylon,* described by Kidston and Lang were so well preserved that their structure is as well known as though they were modern plants. The class stands conspicuously apart as leafless and rootless vascular plants.

The most distinctive feature of the class for diagnosis is that the large sporangia, protected by a wall of many layers and con: taining numerous homosporous spores, are terminal on the vegetative twigs. The early existence thus demonstrated of leafless, and rootless and homosporous vascular plants, with distal sporangia of primitive construction is a fact of the first comparative importance. It is true it does not demonstrate any nearer connection with the Algae, but as regards other relations the new facts are highly suggestive. Long ago it was remarked that the widest gap in the sequence of plants was that between the Bryophytes and Pteridophytes. It is within this gap that the newly discovered fossils take their natural place, acting as synthetic links for the whole sequence of land-living, sporangium-bearing plants.

II. **Psilotales.**—The Psilotales are represented by two living genera, Psiloturn and *Tmesipteris,* of which both generations are now known. They form a natural family of the Psilotaceae. By their features they appear remarkably isolated among living plants, and their nearest affinity is to be sought among the Psilophytales and Sphenophyllales, both being classes of plants long extinct. These two genera appear in fact as living fossils.

They live epiphytically, or in soil rich in humus, and are rootless. The green, more or less shrubby shoot is fixed in the substratum by much branched leafless rhizomes, which are infected by a mycorhizic fungus. The saprophytic nutrition by these is supplemented by photosynthesis in the green leafy shoots. In Psilotum the aerial stems bifurcate, bearing small and simple scaly leaves, which however pass upwards into bifid "sporophylls," and between the two teeth is seated a large trilocular synangium, containing numerous homosporous spores (fig. 6). *Tmesipteris* resembles it in general character, but branching is infrequent, the leaves and "sporophylls" are larger, and the synagium has only two large loculi. The anatomy of the green stem of *Psilotum,* with its epidermis and stomata, its photosynthetic cortex and conducting protostele, is on the same general plan as that of *Rhynia* or *Asteroxylon;* the bifurcation and presence of minute leaves, and the rootless mycorhizic base all support the comparison with the Devonian types of Rhynie.

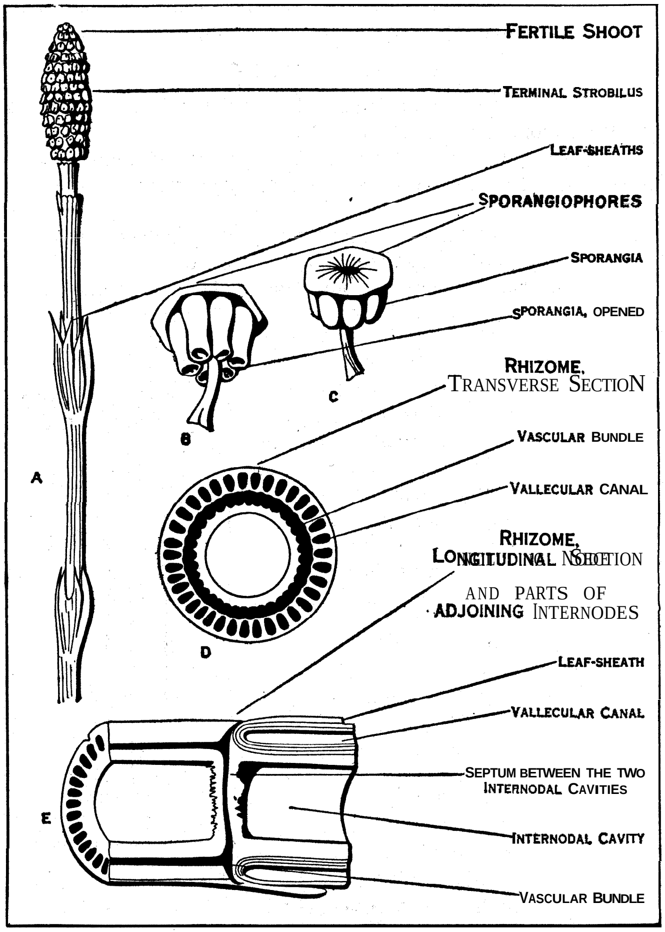
The prothalli of both genera have been discovered since 1914. They are colourless, nourishing themselves saprophytically through fungal agency. In fact these primitive plants conform in their life-cycle to what is seen in many primitive ferns and Lycopods. Moreover, the embryology has been traced in *Tmesipteris;* there is neither suspensor, nor root, nor cotyledon. The embryo with its apex directed, like that of the Bryophytes towards the neck of the archegonium, soon bursts its way out, proceeding to branch distally and form a leafless rhizomic system from which aerial shoots arise later. Such details of the gametophyte link the Psilotales, and indirectly the Psilophytales, with other Pteridophytes as regards alternation on the whole; but the rootless and leafless embryo presents a state that finds its nearest comparison with the Bryophyta.

III. **Sphenophyllales.**—The two genera *Sphenophyllum* and *Cheirostrobus* are the representatives of this class, but in more or less loose association with them are such types as *Pseudobornia* and Hyenia; these suggest that the articulate type of land-plants, which they all illustrate, in common with the horsetails, was well represented in the primary rocks. The existence of the Sphenophyllales extended from the Upper Devonian to Triassic time. (For details of Sphenophyllales see PALAEOBOTANY.)

IV. **Equisetales.**—Those Pteridophyta which have their appendages disposed in successive whorls, with long internodes intervening between them, have been designated the Articulatae. In the distant past this type was strongly represented by the Sphenophyllales, and by the Calamariaceae and others. But it is familiar to us to-day as it is seen in the horsetails, included in the cosmopolitan genus Equisetum, the only species of Equisetaceae, and the only living representatives of the Equisetales. These are semi-aquatic plants; they vary in height from a few inches to 30ft. or more, and are rhizomatous, with erect shoots arising from richly branched, subterranean stems, which are themselves rooted in the soil. The habit of the plants depends upon the method of branching of the shoot rather than upon the foliage, for the leaves are minute (microphyllous), and closely appressed to the stem that bears them. Each whorl of them forms a sheath closely investing the base of the next higher internode, while the teeth projecting upwards from it are all that represent the individual leaves. Their position alternates in successive nodes (fig. 7). The internodes are fluted, the ridges being continuous downwards from the next higher leaves; consequently those of successive internodes alternate. The number of the leaves in a whorl may vary according to the size of the stem, from three to 20 or 30. This is the scheme of the shoot in all species of Equisetum, and the shoot is constantly of radial construction. In some species the branching is sparse (E. *limosum*); in others it is profuse (E. *sylvaticum* and maximum), and the branches may themselves branch again repeatedly. Their number and the degree of secondary branching defines the habit, and justifies for the more bushy types the familiar name of horsetails. The branches arise in the axils of the leaf-sheaths, but they alternate with the leaves themselves. Many of those initiated remain dormant. A root is found at the base of each bud, but it also is frequently dormant, especially in aerial shoots. The structure of the underground rhizome is on the same plan as that of the aerial branches that it bears. Thus the whole plant consists of a succession of shoots, each with a dominant axis, whorls of subordinate leaves, and accessory roots.

In the transverse section of an aerial internode the sinuous outline shows the projecting ridges and depressed furrows of its fluted form, though this is less evident in the rhizomes (fig. 7, D). The centre of the section is occupied by a large air-cavity, surrounded by the remains of the pith. A circle of isolated vascular strands, corresponding in number to the leaves in the next whorl above, is in most species enclosed by a sinuous endodermis, which thus delimits the stele (E. arvense, etc.). Outside this lies the cortex, marked by an equal number of large air-cavities, which alternate with the vascular strands, and correspond to the furrows of the fluting. The vascular strands themselves are opposite the projecting ridges, and are extended upwards into the several leaf-teeth. Between the ridges are regions of green chlorophyll-parenchyma, while the whole is invested by a well-marked epidermis, with curiously elaborate stomata: these are ranged along the furrows, and so are opposite the photosynthetic tissue. The anatomy is clearly that of a semi-aquatic plant with its reduced vascular tissue and large air-spaces.

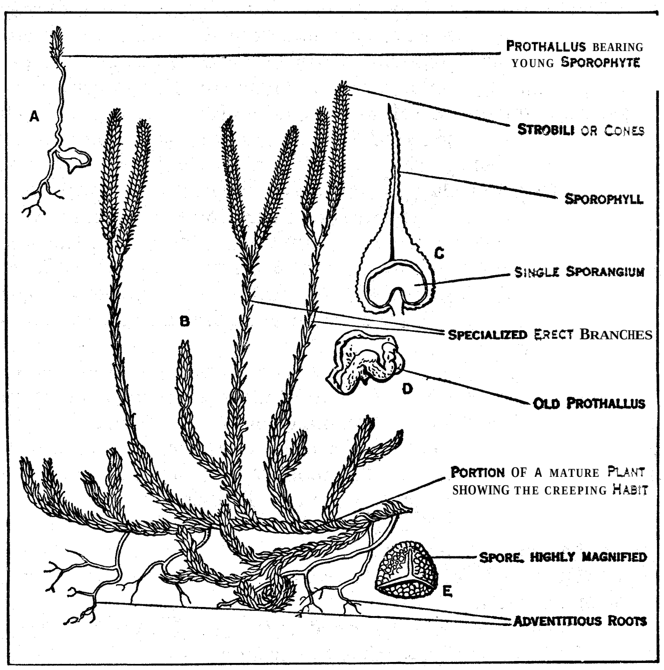
The sporangia of Equisetum are borne upon lateral appendages of the axis, sporangiophores, which are disposed in whorls, and are associated in definite strobili or cones, borne distally (fig. 7, A). Each sporangiophore consists of a stalk that expands into a peltate disc, from the inner surface of which some



FROM (A, B, C) STRASBURGER, "LEHRBUCH DER BOTANIK" (GUSTAV FISCHER)

FIG. 7.—LARGER HORSETAIL (EQUISETUM TELEMATEIA)

six to nine large sporangia hang parallel with the stalk (fig. 7, B, C). A single vascular strand passing through the stalk supplies a branchlet to each sporangium. These arise as massive growths from the first, and each produces a large output of homosporous spores (eu-sporangiate). The spores themselves are large; in ripening the outermost layer of the wall of each splits along spiral lines, giving rise to four elaters that straighten out when dry, and close round the spore in damp air. They are effective in forcing open the sporangium, which dehisces by a longitudinal slit: and those of different spores hooking together, the spores are grouped in germination, a matter of importance since the sexes are usually borne on separate prothalli. The spores germinate at once, producing each a green prothallus, which may be filamentous, flattened, or irregularly lobed. The smaller bear sunken antheridia, each with numerous spermatocytes, from which spermatozoids are liberated on access of water. The larger bear archegonia. The conditions of syngamy and formation of the embryo are essentially as in ferns; but here the embryo has its apex directed to the archegonial neck (exoscopic), and it grows out directly into the apex of the young plant, successive whorls of leaves arising laterally upon it; a root derived from the basal region fixes the young plant in the soil. Notwithstanding the differences of detail, the life-cycle of a horsetail is comparable as **a** whole with that of a fern.



FROM STRASEURGER, "LEHRBUCH DER BOTANIK" (GUSTAV FISCHER)

FIG. 8.—A CLUB-MOSS (LYCOPODIUM CLAVATUM)

A greatly added interest in Equisetum arises from comparison with allied fossils; for not only were these numerous and of early occurrence, but they attained dendroid proportions, while some were heterosporous. They are grouped as the Calamariaceae, which will be specially treated elsewhere (see PALAEOBOTANY).

The Equisetales, thus comprising the Equisetaceae and the Calamariaceae, form a natural and closely reiated class, of which the nearest affinity was with the Sphenophyllales, but with some degree of relation also with the Psilotales; all of these being sporangiophoric Pteridophytes.

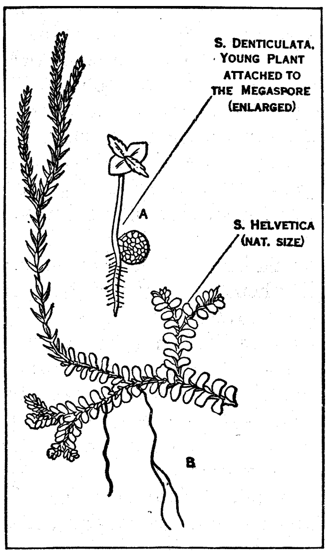
V. **Lycopodiales.**—This class comprises a considerable number of species now living widely distributed upon the earth, and known as club-mosses; though they are in fact vascular plants, and quite distinct from the true mosses. They are all relatively small, and indeed insignificant as features in the present flora, compared with the fossil types which, though they may have included a number of relatively small species, comprised also some of the largest plants of the forests of the coal period. It may be that among the lycopods no actual diminution in size took place as time went on, but rather that the types which were always small survived, while the giant members of the group became extinct.

The features which all club mosses have in common are that the leaves are relatively small and simple in form (*microphyllous*), while the sporangia are seated singly, one in the axil of each leaf of the fertile region, or spreading outwards on its base. This marks off the Lycopodiales clearly from the sporangiophoric Pteridophytes on the one hand, and from the Filicales on the other. As in the former, however, the axis is dominant in the adult shoot, and forks equally or unequally. According to the position assumed by the stem the habit of living club mosses is upright or pendent; but frequently, as in the stag's horn moss common on Scottish hills, with its creeping stem rooted in the soil, and bearing upright fruiting branches (fig. 8, B).

The class is divided systematically according to the presence or absence of a ligule, which is a small scale-like body borne on the upper surface of each leaf, near its base. Those in which no ligule is present, the ELIGULATAE, include Lycopodium and *Phylloglossum*, together with certain early fossils designated *Lycopodites;* those which possess a ligule, the LIGULATAE, include *Selaginella* and Zsoetes, and with these are associated the fossil Lepidodendraceae and Sigillariaceae. The distinction is accentuated by the fact that the former are all homosporous, the latter heterosporous.

A. Lycopodiales Eligulatae. Lycopodium comprises about 100 species of small plants of varied habit, creeping, shrubby or epiphytic. The construction of the shoot is uniformly microphyllous, the bifurcating stem dominating the conformation of the whole plant. The leaves are simple and small, and in some species uniform throughout the plant. In others the sterile leaves are larger than the membranous sporophylls, the latter being associated in definite strobili, or cones (fig. 8, B). The former probably represent the more primitive type. Each of the isolated sporangia is seated at the base of its sporophyll; it is large, and kidney-shaped, with a short massive stalk, and it dehisces like an oyster-shell, in a piane parallel to that of the leaf. The arrangement of the leaves is sometimes in regular whorls, but frequently it is according to some more or less interrupted spiral scheme. The plant is fixed at its base by roots which spring endogenously from the stem, and show bifurcation.

The stem of Lycopodium is seen in transverse section to be surrounded by a bulky and often indurated cortex, and traversed by a stele continued to the apical cone itself, while from each leaf a minute vascular strand passes to its periphery. In the young stem there is a solid woody core, surrounded by phloem and ill-defined sheaths. But in fully-grown stems the core may be invaded by tracts of phloem, moulding it into a cruciform or stellate transverse section, or even separating it into distinct radiating plates, or permeating it to form a sort of woody sponge.



FROM STRASBURGER, "LEHRBUCH DER BOTANIK" (GUSTAV FISCHER)

FIG. 9.—A CLUB-MOSS (SELAGINELLA)

The sporangia are massive from the first, and vary slightly in spread along the leaf-surface, a point of interest for comparison with the ligulate types. Each produces after the usual tetrad-division a large number of homosporous spores, which germinate slowly. The prothalli produced from them, and the embryology that follows, vary more than is usual in a single genus. The prothallus sometimes grows at soil-level and is green (L. cernuum); but often it is underground and wholly saprophytic (L. clavatum, fig. 8, D, A). Whatever its form, the sex-organs are massive and deeply sunk, and both are present on the same prothallus. The antheridia produce numerous biciliate spermatozoids; the archegonia vary in length of neck, and sometimes have numerous canal-cells. But the egg is deeply seated, and produces an embryo with a suspensor. This thrusts the embryo deep into the prothalius, where it often develops juvenile characters of importance for comparison. The most striking of these is the swollen "protocorm," a tuberous growth seen in Hornea, and present also in Phylloglossum. Bursting out from the prothallus the embryo develops shoot and root, the former in the underground types finding its way upwards to the soil-level (fig. 8, **A).**

B. Lycopodiales Ligulatae. Selaginella comprises about 500 species, widely spread through the tropics, some native on temperate hill stations. The latter, chiefly of exposed habit, have radial symmetry, but most *Selaginellas* are dorsiventral and live under shade. The genus shares the leading features of *Lycopodium*, but it differs in the presence of a ligule and in the fact that all the species are heterosporous.

Various *Selaginellas* are favourite greenhouse plants, and the fanlike spread of the delicate branches with their dimorphic leaves is well known (fig. 9, B); also the strange rhizophores springing from points of branching of the shoot, which turning downward give rise to the true roots, being themselves organs of indeterminate morphological nature. It is unnecessary to describe the vegetative organs or their anatomy in detail; the chief comparative interest lies in the propagative process.

The sporangia are borne on radially constructed distal cones. A single sporangium, similar to that of *Lycopodium*, is borne just above the insertion of each sporophyll, with the ligule protecting it from without. The microsporangia are brownish when ripe and the megasporangia pale in colour, and both may be borne on a single cone. They appear all alike up to the stage when the numerous spore-mother-cells are formed. If all the spore-mother-cells undergo tetrad division, numerous microspores resembling those of *Lycopodium* result. But in a megasporangium only one, or at most a few of them, form tetrads, and the resulting spores are large with a rugged wall; the number matured in a single sporangium may vary from one to four, or some multiple of four. On germination each microspore produces a small number of spermatozoids from a very reduced prothallus; but the large megaspore forms a more bulky prothallus, which, projecting from the disrupted wall, bears archegonia. One of these on fertilization develops an embryo with a suspensor. The essentials of the process are as in *Lycopodzum*, though the details are different. As-the sporeling develops its leafy shoot grows upward and its root downward; with the megaspore attached laterally the whole has the appearance of a seedling of some flowering plant (fig. g, A). This is clearly an advance upon *Lycopodium*.

The other genus, *Isoetes*, is peculiar in habit and in habitat, yet shares many of the characteristics of *Selaginella*. It contains about 50 species of tufted herbs, mostly living at the bottom of freshwater lakes, though a few are amphibious or terrestrial. The plant consists of a short, massive, lobed stock, bearing crowded awl-shaped leaves of considerable length. Each bears a ligule on its upper surface, and when fertile, as any one of them may be, a large cakelike sporangium lies between this and the axis. Roots with dichotomous branching arise from furrows between its lobes. The sporangia are heterosporous, and propagation is essentially similar to that in *Selaginella;* but there is no suspensor, and the spermatozoids are multiciliate.

A chief interest in these Ligulate types lies in their comparison with the Lepidodendraceae and Sigillariaceae, for these are also ligulate and heterosporous (*see* PALAEOBOTANY). These fossils attained dendroid dimensions, and, though the primary vascular system was not unlike that of the modern Lycopods, they often differed in having secondary growth with an active cambium. In *Isoetes* there is a sluggish secondary growth in the short stock, which itself shows certain analogies with the Stigmarian trunks of the gigantic fossils. Since any of the leaves of *Isoetes* may be fertile the whole plant appears as a strobilus of the same nature as *Lepidostrobus*, seated upon a Stigmarian base. In fact *Isoetes* is like a telescoped, but still living, fossil.

VI. **Filicales.**—The Filicales may be held as comprising all the living Megaphyllous Pteridophytes, together with such fossils as show essentially similar characters. But the mere fact that their leaves are relatively large in proportion to the stem that bears them is not a sufficient diagnosis. Some Lycopods (*Isoetes, Sigillaria*) share this character, and megaphylly is possible in any of Pteridophytes. But as a matter of fact, excepting *Isoetes*, none such are now living other than the Filicales. The most distinctive feature of ferns, however, is that *on the relatively large leaves many sporangia are borne, either singly or in groups (sori).*

Ferns are represented at the present day by about 150 genera and 6,000 species. Some are minute, others attain considerable size as tree ferns; but none can be reckoned among the largest of living plants, nor is there fossil evidence that ferns ever attained extreme dimensions. Their geographical spread is general; a few are arctic, but ferns increase in numbers both of species and of individuals toward the equator. Most are mesothermal hygrophytes (*i.e.*, they flourish under moist conditions with a moderate temperature), and the majority are shade-loving. Hence their headquarters are in the mountains of the tropics, where they form a considerable part of the undergrowth below the forest canopy. But their habitat is variable; some specialized types are actually aquatic, while others are able to withstand conditions of moderate, some even of extreme, drought. Ferns are much richer in genera, species and individuals than any other living Pteridophytes. They present the climax of successful development in homosporous vascular plants. They show also a high degree of variety both in their vegetative and their propagative characters; these provide good diagnostic features for their classification. They have a full and long palaeontological history that stretches back to Palaeozoic times. The geological record can therefore he used as a valid check upon the conclusions drawn from the comparison of living types.

It has been said that the Palaeozoic period was the age of ferns, and it is true that "fernlike" leaves were then common. But it has now been shown that many of these belonged to seed plants ranked as Pteridosperms, a class long since extinct, which also had fernlike leaves (*see* PALAEOBOTANY). It is not improbable that they represent a stock more distinct from ferns than the similarity of their foliage would suggest, for they had advanced early to seed formation. It may be left as an open question whether or not both may have had far back in their evolution some common origin.

The life history already described at the opening of this article holds for ferns generally, so that the grouping and natural classification of the class must depend upon differences of detail other than the life history itself. A general comparison of them led long ago to the recognition of eight main families, which may here be placed in the reverse order to that first given by Mettenius (1856):

I. Ophioglossaceae.	V. Gleicheniaceae.
II. Marattiaceae.	VI. Hymenophyllaceae.
III. Osmundaceae.	VII. Cyatheaceae.
IV. Schizaeaceae.	VIII. Polypodiaceae.

This grouping in linear sequence places the more robust types first and the more delicate last, while the rest take middle positions. The former were styled by Karl von Goebel the *Eusporangiate ferns*, in which the sporangium is from the first a massive body, in the formation of which many cells co-operate; in the latter each sporangium arises from a single cell, and those ferns in which this is so were styled *Leptosporangiate*. Intermediate states exist, and these suggest that the whole series constitutes an evolutionary progression. If this is true the question arises which is the more primitive and which the more advanced state? The importance of this question is enhanced by the fact that the sporangium is a mere index of a general difference of organization of the two contrasted types. In point of fact *the Eusporangiate ferns are relatively robust in their general constitution, while the Leptosporangiate are relatively delicate.* Thus the question is whether there has been in the course of evolution a progression from a robust to a delicate state, or the reverse. Since the Eusporangiate ferns find their correlatives in the fossils of Palaeozoic time and are relatively few today, while the specialized Leptosporangiate ferns are absent from the Palaeozoic rocks and comprise the bulk of living ferns, it is concluded that the general progression has been from a more robust ancestry toward a more delicate and precise constitution.

Having perceived this general scheme of progressive refinement, it cannot be assumed that the 150 genera and 6,000 species have formed a simple sequence. In testing the question of their relationships it will become necessary to revise the methods in use by systematists, whose aims were primarily classification. They worked as a rule upon few criteria of comparison, drawn almost exclusively from the sporophyte generation. A more exact comparison will be necessary not only as regards external form, but also of internal structure and development, both of the vegetative and the propagative organs, and it must be extended to both generations. The larger the number of the criteria used in comparison the more trustworthy will be the conclusions drawn from them. The criteria currently used in the comparison of ferns are these:

1. The external morphology of the shoot.
2. The initial constitution of the plant-body as indicated by segmentation.
3. The architecture and venation of the leaf.
4. The vascular system of the shoot.
5. The dermal appendages.
6. The position and structure of the sorus.
7. The indusial protections.
8. The characters of the sporangium, and the form and markings of the spores.
9. The spore-output.
10. The morphology of the prothallus.
11. The position and structure of the sexual organs.
12. The embryology of the sporophyte.

By the combined use of these criteria it has been possible to revise the natural groupings of ferns, sometimes amending but more often upholding the decisions of the earlier systematists. The main conclusions may be stated as follows: The *Eusporangiatae* include the living Ophioglossaceae, Marattiaceae and Osmundaceae, together with the fossil Coenopteridaceae *(see* PALAEOBOTANY). All these are Palaeozoic types, though they overlapped into the Mesozoic, and some representatives have even survived to the present day. With them are to be associated also the Schizaeaceae, Gleicheniaceae and Matoniaceae, all of which figured prominently in the Mesozoic, and are well represented among living ferns. In addition to many archaic features of the vegetative system they all possess relatively massive sporangia, which originate simultaneously, being produced either singly or in small numbers in the sori. They are collectively styled *Simplices.* Each sporangium has a relatively large spore-output.

The Ophioglossaceae and Marattiaceae appear to have ended blindly and left no further derivatives. But derivative phyla may be traced by comparison from each of the Schizaeaceae, Osmundaceae, and Gleicheniaceae, while to the Matoniaceae so closely allied to the Dipterids, another phylum may be ascribed. The Schizaeaceae with their solitary marginal sporangia lead to the marginal Dicksoniaceae. The Osmundaceae have many features in common with *Plagiogyria,* while the superficial Gleicheniaceae link on to the Cyatheaceae, these being distinguished by their superficial sori from the marginal Dicksoniaceae. In both of these last-named families the sorus has become *"gradate," i.e.,* after the distal sporangia have been formed on the receptacle, a sequence of further sporangia follows *in basipetal sequence,* the effect of which is that the drain of nutrition is spread over a longer period of time. This may well have been a real factor in the success of these families.

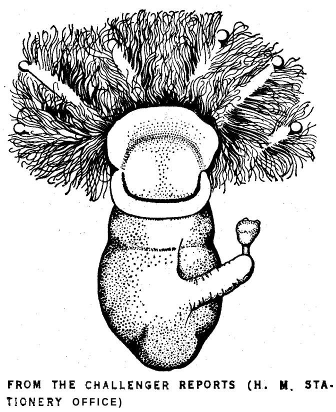
A third state of the sorus, which has a like effect to the last, and may either be initiated independently or by transition from the gradate, is the *"mixed"* state. where sporangia of different ages are irregularly *interpolated between those already present.* This is the final condition seen in the evolution of the Leptosporangiate ferns, and is found in all the more advanced types.

From such intermediate stocks as those mentioned some *six derivatzve phyla of advanced Leptosporangzate ferns* may be distinguished, each centring round some well-known genus. Two of these comparison shows to have been derived from the Dicksoniaceae, viz., the Davallioid ferns centred round *Davallia,* and the Pteroids round *Pteris.* The Gymnogrammoid ferns are naturally grouped round *Gymnogramme,* and may probably be traced from the Osmundaceae, with *Plagiogyria* as a suggestive link. The Cyatheaceae prooably gave rise on the other hand to the Blechnoid ferns, with *Blechnum* as a central type; and the Dryopteroids round *Dryopteris.* Lastly, a quite considerable number of genera may be traced as Dipteroid derivatives, from an ancestry suggested by *Matonia* and *Dipteris.* Thus at least six main evolutionary sequences of advanced Leptosporangiate ferns, with more or less pronouncedly "mixed" condition of their sori, may be referred in origin to types already distinct in Palaeozoic, or certainly in Mesozoic time. Each of these will have pursued its own phyletic advance independently of the others. Comparison reveals that most of them, or in some respects all, show parallel features of advance in form, vascular structure, soral characters, and sporangia, and particularly in the reduced spore-output from each sporangium. There is thus wide evidence of independent *homoplastic, and even convergent evolution* in the several phyla. In no respect is this clearer than in the distinctive feature of heterospory: for the Marsileaceae are referable in origin to a Schizaeoid source, while the Salviniaceae, whatever their actual relation, were of distinct origin from the Marsileaceae.

This brief abstract of the present position of the phyletic study of the Filicales can do no more than suggest how the matter stands to-day. Of all the Pteridophyta the ferns yield the most consecutive results. The living representatives of all the rest appear as isolated survivals, illuminated by fossil evidence, often as fragmentary and isolated as theirs. They raise as many evolutionary questions as they solve. It is only in the Filicales that it is possible, by placing together the evidence from palaeontology and that derived from the living flora, to reconstruct a story which, however incomplete, is sufficiently consecutive to serve as a basis for evolutionary opinion. The sum of it is for the ferns, as also for other Pteridophyta, that they have held their own to the present day as a class which has made the best of their amphibious existence by help of profuse production of homosporous spores. But from the point of view of descent, they have led on directly to no further type of land vegetation. The sources of this must be sought elsewhere.

Eames, *Morphology of Vascular Plants, Lower Groups* (New York, 1936) (F. O. B.; X.)

PTEROBRANCHIA, a very peculiar group of small marine animals, mainly found in the deeper parts of the ocean. They live as colonies, as individuals within a common mass or branching systems, in which they reproduce by budding as well as by sexual reproduction involving eggs and sperm. Their special interest lies in their structure, which seems to relate them to hemichordates such as *Balanoglossus* (*q.v.*) and so possibly to the vertebrate kingdom on the one hand, and, on the other, to the ancient group of fossils known as graptolites. In all likelihood the pterobranchs are the surviving members of an important class of Pre-Cambrian antiquity.



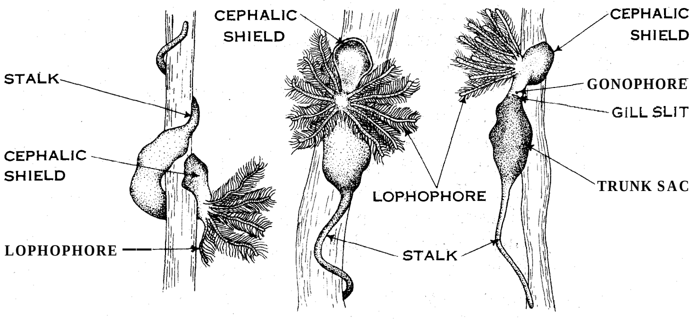
FROM THE CHALLENGER REPORTS (H. M. STATIONERY OFFICE)

FIG. 1.—CEPHALODISCUS DODECALOPHUS AS SEEN FROM IN FRONT; (AFTER MCINTOSH)

The two types are *Cephalodiscus* and *Rhabdobleura.* the former having been discovered by the "Challenger" expedition when dredging in the Straits of Magellan, and by later expeditions all through the southern oceans. *Rhabdopleura,* however, is truly cosmopolitan, ranging from the subarctic to the subantarctic.

A colony of *Cephalodiscus* is generally an orange-coloured gelatinous mass ½ in. to 1 ft, long and composed of numerous branches and layers within which the individual animals, all descended from a single egg, occur in large numbers and wander freely about. Each individual, which may be from one to seven millimetres long, depending on the species, consists of three regions, namely, a broad shield in front, which is used for crawling; a collar immediately behind, which bears featherlike tentacles or gills (hence the name Pterobranchia); and a body with its hind end prolonged as a slender stalk.

Each individual also has its own tube within the colony, and



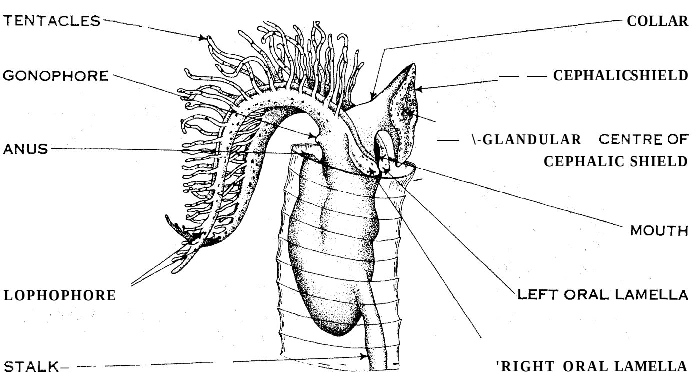
FROM P. GRASSÉ, "TRAITÉ DE ZOOLOGIE," VOL. 11 (1948)

FIG. 2.— ASPECTS OF CEPHALODISCUS HODGSONI ON INDIVIDUAL TUBE HABITATS THAT ARE ASSOCIATED IN LOOSE COLONIES

when wandering about on the surface it keeps the lower end of its stalk attached to the tube to facilitate quick retraction when necessary.

The tentacles. taken together, comprise a broad fan-shaped structure called the lophophore. It serves partly as a gill for respiration but primarily as the feeding organ, for the action of minute cilia on its surface causes a current of water to converge toward the mouth, bringing with it microscopic organisms suitable as food. Such water enters the mouth and is filtered out again through a single gill slit leading from the throat to the exterior on each side. It is the presence of this pair of gill slits that suggests that these primitive simple animals are in some way related to the vertebrates and their more obvious relatives such as Amphioxus and the Tunicata (*q.v.*), for gill slits are a distinctive feature of the group. Within the body, however, the digestive tube is U-shaped, so that bcth mouth and anus are near the front end and the bend of the tube is at the other, a condition characteristic of many other kinds of stalked animals. Even the pair of ovaries or testes open forward, near the base of the lophophore.

The position of the nerve centre dorsal to the mouth is also distinctive, and so are the openings or pores that connect the



FROM P. GRASSÉ, "TRAITÉ DE ZOOLOGIE," VOL 11 (1948)

FIG. 3.— PROFILE VIEW OF RHABDOPLEURA

body cavities of the shield and of the collar region with the exterior. and especially the location of the heart in the shield (proboscis) cavity.

These are all features that place pterobranchs with Balanoglossus and, apart from gill slits and the position of the nerve centre. set them aside as a type uniquely different from all other kinds of animals.

Individuals of *Rhabdopleura* species are very small even when compared with those of *Cephalodiscus*, and probably because of this their structure is somewhat simplified; instead of three to nine pairs of plumelike tentacles constituting the lophophore, only one pair is present, and gill slits are absent altogether.

Otherwise the individuals of the two genera are organized in essentially the same way, except that in *Rhabdoplezira* the individuals produced by budding do not become free but remain attached to one another by a connecting cord. They live in a branching system of minute ringed tubes which are about one-tenth of an inch long.

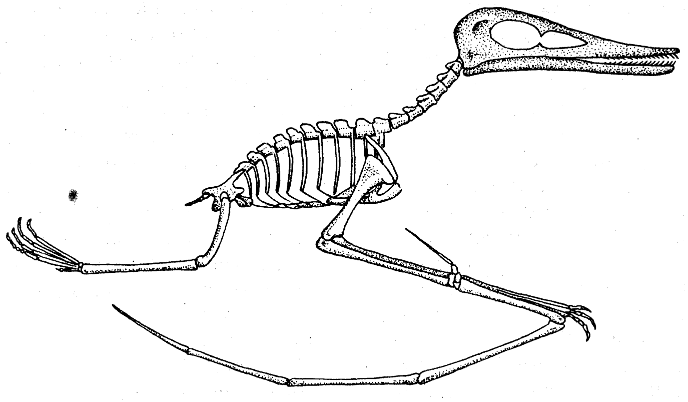
PTEROCLIDAE, a small family of birds of the order Columbiformes.

See Sand Grouse.

PTEROSAUR (Pterodactyl), terms applied to members of a group of flying reptiles that flourished in the Jurassic and Cretaceous periods. between (approximately) 150,000,000 and 70,000,000 years ago. The order Pterosauria is one component of the major reptile group of the Archosauria or "ruling reptiles," to which dinosaurs and crocodilians (*qq.v.*) also pertain and from which birds are descended. Triassic archosaurs tended toward a bipedal gait, thus freeing the "arms" for use in some other fashion, both birds and pterosaurs converted them into wings. In contrast with birds, and as in bats, pterosaurs formed a wing



FROM S. W. WILLISTON'S "THE OSTEOLOGY OF THE REPTILES' (HARVARD UNIVERSITY PRESS)

FIG. I.— SKELETAL RESTORATION OF PTERODACTYLUS

surface by means of a membrane of skin. In bats all the fingers except the thumb support the membrane. In pterosaurs, however, the membrane was attached solely to one elongated finger—the fourth — and extended thence back along the flank to the knee; an accessory membrane lay between the neck and the "arm." The first three fingers were slender, clawed. clutching structures. The pterosaur membrane appears to have been well adapted to soaring and gliding, but lacking in contrast with bat or bird wings, in maneuverability; disadvantageous, too, is the fact that, in contrast with bats. damage to the membrane at any point would affect the entire wing

The body was compact; the hind legs were long but slender and their structure suggests that, unlike birds, pterosaurs were little adapted to upright locomotion or perching but rather like bats hung suspended by the hind limbs when at rest.

The neck appears to have been held upright in flight. with the head attached to it at right angles and pointing foruard The skull was lightly but strongly built with fusion of most of the component bones; there was a long slender beak. The eyes were large, and the eyeball, as in many birds, was reinforced by a series of bony plates (sclerotic ring) lying in its walls.

Casts of the interior of the braincase show that the brain was large and apparently comparable to that of birds in pattern; as in that group, sight rather than smell appears to have been the dominant sense. Most remains of pterosaurs are found in marine sediments; it is probable that they made their livelihood by diving for fish. like terns and gulls, and it is difficult to understand how they could have risen from land or water after alighting.

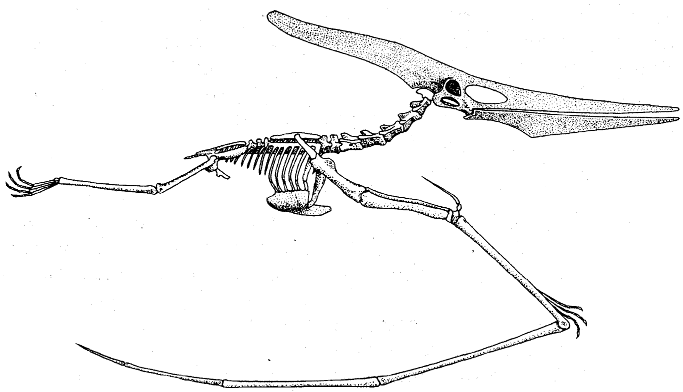
Two major groups of pterosaurs are known. *Rhamphorhynchus* of the late Jurassic Solenhofen slates is typical of the more primitive division, although earlier forms are present in the Early Jurassic (Lias).

Characteristics of this group include the presence of a battery of powerful, sharply pointed teeth in the jaws, relative shortness of the bones supporting the fingers (the metacarpals), and the retention of a long tail, which in *Rhamphorhynchus* is knonn to have had a diamond-shaped rudder at its tip.

Rhamphorhynchus had a wing spread of about two feet, and members of this group, confined to the Jurassic, were generally of similar size.

A second group of pterosaurs appeared in the late Jurassic and continued on into the Cretaceous. The typical Jurassic form is *Pterodactylus,* of which numerous examples are known from Solenhofen. This was a small reptile, some specimens being no larger than a sparrow.

Diagnostic features include the reduction of the dentition to a relatively few small teeth, elongation of the metacarpal bones, and the shortening of the tail to a mere nubbin. Descendants of the pterodactyl type continued on into the Cretaceous, and were



FROM G. F. EATON IN "MEMOIRS OF THE CONNECTICUT ACADEMY OF ARTS AND SCIENCES"

FIG. 2.—SKELETAL RESTORATION OF PTERANODON

generally of much larger size. They are best represented by *Pteranodon* of the Kansas chalk. in which the largest known specimen is estimated to have had a wing spread of 25 ft., making it by far the largest flying animal of which there is knowledge.

The skull was about four feet in length; the long jaws were toothless and presumably covered by a horny bill; a long crest extended back from the point of attachment of skull to body in weather-vane fashion. Despite its great size, the animal was very lightly built; the wing bones consist merely of a thin shell of bone surrounding a central cavity which was presumably air-filled in life.

No pterosaur remains are known beyond the end of the Cretaceous; their place in nature was taken over by their avian cousins. (A. S. Rr.)

PTOLEMAIS, an ancient coastal city of Cyrenaica (the modern Tolmeta in Libya). Naturally attractive, with adequate seasonal rainfall and with arable land and some timber in the neighbourhood, the site was also easily defensible and provided the only safe anchorage between Euhesperides-Berenice (modern Bengasi), 66 mi. S.S.W., and Apollonia (modern Marsa Suza), 61 mi. E.N E. The small settlement that had existed on this site as the harbour for the city of Barca (Al-Marj, 15 mi. inland) since the 6th century B C. was laid out in the early 3rd century B.C. as a city about one mile square, with a gridiron-shaped street plan.

Later in the same century the city received the name Ptolemais from Ptolemy III, who united Cyrenaica with Egypt. It was enclosed with walls and towers ending in an acropolis fort on an adjacent spur of the inland plateau and had five gates. Its economy being based on trade with the interior, the city flourished in Hellenistic times, in the early period of the Roman empire and again from late in the 3rd century A.D., when Diocletian made it the metropolis of the Roman province of Upper Libya.

From the beginning of the 5th century it suffered greatly from raids of the nomadic inland Austuriani, as recorded in the letters of its best-known historical personage, Bishop Synesius. The Byzantine emperors Arcadius, Anastasius I and Justinian I attempted to revive it by rebuilding streets, baths and an aqueduct, using stones of the old city wall to erect forts and blockhouses within.

Some occupation continued after the Arab conquest (A.D. 634) to the 11th century. The small modern Arab town occupies the ancient harbour section.

Italian excavations (1935–42) cleared the main gate, foundations of part of the city wall, a church, a large covered reservoir, a theatre, part of a street with remains of a triumphal arch and an imposing dwelling. American excavations (1956–58) disclosed a villa of the Roman period, a public building and city baths, all apparently rebuilt in the 5th century A.D.

Other remains, visible but unexcavated, included further large reservoirs, a theatre, a temple, a hippodrome, an amphitheatre, fortresses and blockhouses. Sculptures, geometric mosaics, remains of wall paintings, inscriptions and coins were found.

See G. Caputo, "La Protezione dei monumenti di Tolemaide negli anni 1935–42," *Quaderni di archeologia della Libia,* vol. iii *(1954)*; and the report on the American excavations in the series *Oriental Institute Publications.* (C. *H.* Kr.)

PTOLEMIES, a dynasty **of** Macedonian kings who ruled in Egypt from 323 to 30 B.C.

Ptolemy I, the founder, son of Lagus, a Macedonian nobleman of Eordaea, was one of Alexander the Great's most trusted generals, and among the seven "bodyguards" attached to his person.

Ptolemy plays a principal part in the later campaigns of Alexander in Afghanistan and India. At the Susa marriage festival in 324 Alexander caused him to marry the Persian princess Artacama; but there is no further mention of this Asiatic bride in the history of Ptolemy.

When Alexander died in 323 the resettlement of the empire at Babylon is said to have been made at Ptolemy's instigation. At any rate he was now appointed satrap of Egypt under the nominal kings Philip Arrhidaeus and the young Alexander. He at once took a high hand in the province by killing Cleomenes, the financial controller appointed by Alexander the Great; he also subjugated Cyrenaica. He contrived to get possession of Alexander's body which was to be interred with great pomp by the imperial government and placed it temporarily in Memphis. This act led to an open rupture between Ptolemy and the imperial regent Perdiccas. But Perdiccas perished in the attempt to invade Egypt (321).

In the long wars between the different Macedonian chiefs nhich followed, Ptolemy's first object was to hold his position in Egypt securely, and secondly to possess the Cyrenaica, Cyprus and Palestine (Coele-Syria). His first occupation of Palestine was in 318. and he established at the same time a protectorate over the petty kings of Cyprus. When Antigonus. master of Asia in *315*, shoned dangerous ambitions, Ptolemy joined the coalition against him, and, on the outbreak of war, evacuated Palestine. In Cyprus he fought the partisans of Antigonus and reconquered the island (313). A revolt of Cyrene was crushed in the same year.

In 312 Ptolemy, with Seleucus, the fugitive satrap of Babylonia, invaded Palestine and beat Demetrius, the son of Antigonus, in the great battle of Gaza. Again he occupied Palestine. and again a few months later, after Demetrius had won a battle over his general and Antigonus entered Syria in force, he evacuated it.

In 311 a peace was concluded between the combatants, soon after which the surviving king Alexander was murdered in Macedonia, leaving the satrap of Egypt absolutely his own master. The peace did not last long, and in 309 Ptolemy commanded a fleet in person which detached the coast towns of Lycia and Caria from Antigonus and crossed to Greece, where Ptolemy took possession of Corinth, Sicyon and Megara (308). In 306 a great fleet under Demetrius attacked Cyprus, and Ptolemy's brother, Menelaus, was defeated and captured in the decisive battle of Salamis. The complete loss of Cyprus followed. Antigonus and Demetrius now assumed the title of kings; in 305 B.C. Ptolemy, Cassander, Lysimachus and Seleucus, answered this challenge by doing the same. In the winter (306–5) Antigonus tried to follow up the victory of Cyprus by invading Egypt, but here Ptolemy was strong, and held the frontier successfully against him. Ptolemy led no further expedition against Antigonus overseas. To the Rhodians, besieged by Demetrius (305–4), he sent such help as won him divine honours in Rhodes and the surname of *Sotēr* ("saviour"). When the coalition was renewed against Antigonus in 302, Ptolemy joined it, and invaded Palestine a third time, whilst Antigonus was engaged with Lysimachus in Asia Minor. On a report that Antigonus had won a decisive victory, for a third time he evacuated the country. But when news came that Antigonus had been defeated and slain at Ipsus (301) by Lysimachus and Seleucus, Ptolemy occupied Palestine for the fourth time. The other members of the coalition had assigned Palestine to Seleucus after what they regarded as Ptolemy's desertion, and for the next hundred years the question of its ownership becomes the standing ground of enmity between the Seleucid and Ptolemaïc dynasties. Henceforth, Ptolemy seems to have mingled as little as possible in the broils of Asia Minor and Greece; his possessions in Greece he did not retain, bur. Cyprus he reconquered in 295–4. Cyrene, after a series of rebellions, was finally subjugated about 300 and placed under his stepson Magas (Beloch, Griech. Gesch. III. [ii.], p. 134 seq.).

In 285 he abdicated in favour of one of his younger sons by Berenice (*q.v.*), who bore his father's name of Ptolemy; his eldest (legitimate) son, Ptolemy Ceraunus, whose mother, Eurydice, the daughter of Antipater, had been repudiated, fled to the court of Lysimachus. Ptolemy I. Soter died in 283 at the age of 84. Shrewd and cautious, he had a compact and well-ordered realm to show at the end of fifty years of wars. His name for *bonhomie* and liberality attached the floating soldier-class of Macedonians and Greeks to his service. Nor did he neglect conciliation of the natives. He was a ready patron of letters, and the great library, which was Alexandria's glory, owed to him its inception. He wrote himself a history of Alexander's campaigns, distinguished by its straightforward honesty and sobriety.

PTOLEMY II. PHILADELPHUS (309–246) was of a delicate constitution, no Macedonian warrior-chief of the old style. His brother Ptolemy Ceraunus found compensation by becoming king in Macedonia in 281, and perished in the Gallic invasion of 280–79. (See BRENNUS.) Ptolemy II. maintained a splendid court in Alexandria. Not that Egypt held aloof from wars. Magas of Cyrene opened war on his half-brother (274), and Antiochus I., the son of Seleucus, desiring Palestine, attacked soon after. Two or three years of war left Egypt the dominant naval power of the eastern Mediterranean; the Ptolemaïc sphere of power extended over the Cyclades to Samothrace, and the harbours and coast towns of Cilicia Trachea ("Rough Cilicia"), Pamphylia, Lycia and Caria were largely in Ptolemy's hands (Theoc. *Idyll.* xvii. 86 seq.). The victory won by Antigonus, king of Macedonia, over his fleet at Cos (between 258–56; see Beloch, III. [ii.], p. 428 *seq.)* did not long interrupt his command of the Aegean. In a second war with the Seleucid kingdom, under Antiochus II. (after 260), Ptolemy sustained losses on the seaboard of Asia Minor and agreed to a peace by which Antiochus married his daughter Berenice (250?). Ptolemy's first wife, Arsinoe (I.), daughter of Lysimachus, was the mother of his legitimate children. After her repudiation he married, probably for political reasons, his full-sister Arsinoë (II.), the widow of Lysimachus, by an Egyptian custom abhorrent to Greek morality. The material and literary splendour of the Alexandrian court was at its height under Ptolemy II. Pomps and gay religions flourished. Ptolemy deified his parents as the *θεοὶ ἀδελθοὶ* and his sister-wife, after her death (270), as *Philadelphus.* This surname was used in later generations to distinguish Ptolemy II. himself, but properly it belqngs to Arsinoe only, not to the king. Callimachus, made keeper of the library, Theocritus, and a host of lesser poets, glorified the Ptolemaïc family. Ptolemy himseif was eager to increase the library and to patronize scientific research. He had the strange beasts of far-off lands sent to Alexandria. But, an enthusiast for Hellenic culture, he seems to have shown but little interest in the native religion. The tradition which connects the Septuagint translation of the Old Testament into Greek with his name is not strictly historical. Ptolemy had many brilliant mistresses, and his court, magnificent and dissolute, intellectual and artificial, has been justly compared with the Versailles of Louis XIV.

PTOLEMY III. EUERGETES I. (reigned 246–221), son of Ptolemy II. and Arsinoe I. At the beginning of his reign he reunited the Cyrenaïca to Egypt by marrying Berenice the daughter and successor of Mágas (who had died about 250). At the same time he was obliged to open war on the Seleucid kingdom, where Antiochus II. was dead and his sister Berenice had been murdered, together with her infant son, by Antiochus's former wife, Laodice, who claimed the kingdom for her son Seleucus II. Ptolemy marched triumphantly into the heart of the Seleucid realm, as far at any rate as Babylonia, and received the formal submission of the provinces of Iran, while his fleets in the Aegean recovered what his father had lost upon the seaboard, and made fresh conquests as far as Thrace. This moment marks the zenith of the Ptolemaïc power. After Ptolemy returned home, indeed, Seleucus regained northern Syria and the eastern provinces, but the naval predominance of Egypt in the Aegean remained, although there are traces of its being replaced locally, towards the end of Euergetes' reign, by that of Macedonia—in Amorgos, Naxos, Syros, Nisyros, Cos and parts of Crete. (See Beloch, III. [ii.], p. 463.) After his final peace with Seleucus, Ptolemy no longer engaged actively in war.

PTOLEMY IV. PHILOPATOR (reigned 221–204), son of the preceding, was a wretched debauchee under whom the decline of the Ptolemaïc kingdom began. His reign was inaugurated by the murder of his mother, and he was always under the dominion of favourites, male and female, who indulged his vices and conducted the government as they pleased. Self-interest led his ministers to make serious preparations to meet the attacks of Antiochus III. (the Great) on Palestine, and the great Egyptian victory of Raphia (217), at which Ptolemy himself was present, secured the province till the next reign. The arming of Egyptians in this campaign had a disturbing effect upon the native population of Egypt, so that rebellions were continuous for the next thirty years. Philopator was devoted to orgiastic forms of religion and literary dilettantism. He built a temple to Homer and composed a tragedy, to which his vile favourite Agathocles added a commentary. He married (about 215) his sister Arsinoe (III.), but continued to be ruled by his mistress Agathoclea, sister of Agathocles.

PTOLEMY V. EPIPHANES (reigned 204–181), son of Philopator and Arsinoe, was not more than five years old when he came to the throne, and under a series of regents the kingdom was paralysed. Antiochus III. and Philip V. of Macedonia made a compact to divide the Ptolemaïc possessions overseas. Philip seized several islands and places in Caria and Thrace, whilst the battle of Panium (198) definitely transferred Palestine from the Ptolemies to the Seleucids. Antiochus after this concluded peace, giving his own daughter Cleopatra to Epiphanes to wife (193–192). Nevertheless, when war broke out between Antiochus and Rome Egypt ranged itself with the latter power. Epiphanes in manhood was chiefly remarkable as a passionate sportsman; he excelled in athletic exercises and the chase.

PTOLEMY VI. PHILOMETOR (181–145), the elder of his two sons, succeeded as an infant under the regency of his mother Cleopatra. Her death was followed by a rupture between the Ptolemaïc and Seleucid courts, on the old question of Palestine. Antiochus IV. Epiphanes invaded Egypt (170) and captured Philometor.

The Alexandrians then put his younger brother PTOLEMY VII. EUERGETES II. (afterwards nicknamed *Physkon*, on account of his bloated appearance) upon the throne. Antiochus professed to support Philometor, but, when he withdrew, the brothers agreed to be joint-kings with their sister Cleopatra as queen and wife of Philometor. Antiochus again invaded Egypt (168), but was compelled by the Roman intervention to retire. The double kingship led to quarrels between the two brothers in which fresh appeals were continually made to Rome. In 163 the Cyrenaïca was assigned under Roman arbitration to Euergetes as a separate kingdom. As he coveted Cyprus as well, the feud still went on, Rome continuing to interfere diplomatically but not effectively. In 154 Euergetes invaded Cyprus but was defeated and captured by Philometor. He found his brother, however, willing to pardon and was allowed to return as king to Cyrene. In 152 Philometor joined the coalition against the Seleucid king Demetrius I. and was the main agent in his destruction. The protégé of the coalition, Alexander Balas, married Philometor's daughter Cleopatra (Thea), and reigned in Syria in practical subservience to him. But in 147 Philometor broke with him and transferred his support, together with the person of Cleopatra, to Demetrius II., the young son of Demetrius I. He himself at Antioch was entreated by the people to assume the Seleucid diadem, but he declined and installed Demetrius as king. In 145 in the battle on the Oenoparas near Antioch, in which Alexander Balas was finally defeated, Philometor received a mortal wound Philometor was perhaps the best of the Ptolemies. Kindly and reasonable, his good nature seems sometimes to have verged on indolence, but he at any rate took personal part, and that bravely and successfully, in war. Philometor's infant son, Ptolemy Philopator Neos (?)[1], was proclaimed king in Alexandria under the regency of his mother Cleopatra. Euergetes however, swooping from Cyrene, seized the throne and married Cleopatra, making away with his nephew. He has left an odious picture of himself in the historians—a man untouched by benefits or natural affection, delighting in deeds of blood, his body as loathsome in its blown corpulence as his soul. Something must be allowed for the rhetorical habit of our authorities, but that Euergetes was ready enough to shed blood when policy required seems true. He soon found a more agreeable wife than Cleopatra in her daughter Cleopatra, and thenceforth antagonism between the two queens, the "sister" and the "wife," was chronic. In 130–1 Cleopatra succeeded in driving Euergetes for a time to Cyprus, when he revenged himself by murdering the son whom she had borne him (surnamed *Memphites*). Massacres inflicted upon the Alexandrians and the expulsion of the representatives of Hellenic culture are laid to his charge. On the other hand, the monument and papyri show him a liberal patron of the native religion and a considerable administrator. In fact, while hated by the Greeks, he seems to have had the steady support of the native population. But there are also records which show him, not as an enemy, but a friend, like his ancestors, to Greek culture. He himself published the fruit of his studies and travels in a voluminous collection of notebooks, in which he showed a lively eye for the oddities of his fellow kings. The old Ptolemai'c realm was never again a unity after the death of Euergetes II. By his will he left the Cyrenai'ca as a separate kingdom to his illegitimate son Ptolemy Apion (116–96), whilst Egypt and Cyprus were bequeathed to Cleopatra (Kokke) and whichever of his two sons by her, PTOLEMY VIII. Soter II. (nicknamed *Lathyros)* and PTOLEMY *IX*. Alexander I., she might choose as her associate. The result was, of course, a long period of domestic strife From 116 to 108 Soter reigned with his mother, and at enmity with her, in Egypt, whilst her favourite son, Alexander, ruled Cyprus. Cleopatra compelled Soter to divorce his sister-wife Cleopatra and marry another sister, Selene. Cleopatra plunged into the broils of the Seleucid house in Syria and perished. In 108 Cleopatra Kokke called Alexander to Egypt, and Soter flying to Cyprus took his brother's place and held the island against his mother's forces. The attempts which Soter and Cleopatra respectively made in 104–3 to obtain a predominance in Palestine came to nothing. Alexander now shook off his mother's yoke and married Soter's daughter Berenice. Cleopatra Kokke died in 101 and from then till 89 Alexander reigned alone in Egypt. In 89 he was expelled by a popular uprising and perished the following year in a sea-fight with the Alexandrian ships off Cyprus. Soter was recalled (88) and reigned over Egypt and Cyprus, now reunited, in association with his daughter Berenice. This, his second, reign in Egypt (88–80), was marked by a native rebellion which issued in the destruction of Thebes.

[1]Or according to another view, Eupator. On the obscure questions raised by these two surnames, *see* L. Pareti, *Ricerche sui Tolemei Eupatore e Neo Filopatore* (Turin, 1908).

PTOLEMY X. ALEXANDER II.—On his death Berenice assumed the government, but the son of Alexander I., Ptolemy X., entering Alexandria under Roman patronage, married, and within 20 days assassinated, his elderly cousin and stepmother. He was at once killed by the enraged people and with him the Ptolemai'c family in the legitimate male line became extinct. Ptolemy Apion meanwhile, dying in 96, had bequeathed the Cyrenai'ca to Rome.

The Alexandrian people now chose an illegitimate son of Soter II. to be their king, PTOLEMY XI. Philopator Philadelphus Neos Dionysus (80–51), nicknamed *Auletes*, the flute-player, setting his brother as king in Cyprus. The rights of these kings were doubtful, not only because of their illegitimate birth, but because it was claimed in Rome that Alexander II. had bequeathed his kingdom to the Roman people. Two Seleucid princes, children of Soter's sister Selene, appeared in Rome in 73 to urge their claim to the Ptolemai'c throne. Ptolemy Auletes was thus obliged to spend his reign in buying the support of the men in power in Rome. Cyprus was annexed by Rome in 58, its king committing suicide. From 58 to 55 Auletes was in exile, driven out by popular hatred, and worked by bribery and murder in Rome to get himself restored to Roman power. His daughter Berenice meanwhile reigned in Alexandria, a husband being found for her in the Pontic prince Archelaus. In 55 Auletes was restored by the proconsul of Syria, Aulus Gabinius. He killed Berenice and, dying in 51, bequeathed the kingdom to his eldest son, aged ten years, who was to take as wife his sister Cleopatra, aged seventeen.

In the reign of PTOLEMY XII. Philopator (51–47) and Cleopatra Philopator, Egyptian history coalesces with the general history of the Roman world, owing to the murder of Pompey off Pelusium in 48 and the Alexandrine War of Julius Caesar (48–47).

In that war the young king perished and a still younger brother, PTOLEMY XIII. Philopator, was associated with Cleopatra till 44, when he died, probably by Cleopatra's contriving. From then till her death in 30, her son, born in 47, and asserted by Cleopatra to be the child of Julius Caesar, was associated officially with her as PTOLEMY XIV. Philopator Philometor Caesar; he was known popularly as Caesarion. (For the incidents of Cleopatra's reign see CLEOPATRA, ARSINOË.) After her death in 30 and Caesarion's murder Egypt was made a Roman province. Cleopatra's daughter by Antony (Cleopatra Selene) was married in 25 to Juba II. of Mauretania. Their son Ptolemy, who succeeded his father (A.D. 23–40), left no issue'.

See Mahaffy, *The Empire of the Ptolemies* (1895) and *Egypt under the Ptolemaic Dynasty* (1899); Strack, *Die Dynastie der Ptolemaer* (1897); Bouché-Leclercq, *Histoire des Lagides* (1904, 1907); Meyer, *Das Heerwesen der Ptolemäer und Rdmer* (Leipzig, 1900).

(E. R. B.)

PTOLEMY (CLAUDIUS PTOLEMAUS) (fl. 2nd century AD.), celebrated astronomer, geographer and mathematician Virtually nothing is known of his life. but according to Theodorus Meliteniota of Byzantium Ptolemy was born in the Grecian city Ptolemais Hermii. The period during which he flourished is known from the dates of certain astronomical observations which he made His main work was carried out at Alexandria and while he certainly observed between A D. 127 and 145, it may nell be that he was still at work as late as 151. Arabian traditions claim that Ptolemy died at the age of 78.

Astronomical Work.—Ptolemy's astronomical work. which exerted so profound an influence on subsequent generations and, indeed, for more than 1 200 years after it was completed, was enshrined in his great book *The Mathematical Collection (He Mathematike Syntaxis)*. This became known. in due course. as

The Great Astronomer (Ho *megas astronomas*), to distinguish it from a collection of works of Autolycus, Euclid, Aristarchus, Theodosius, Hypsicles and Menelaus which was known as The Little Astronomer. The Arabian astronomers of the 9th century referred to his work by the superlative Megiste and from this term, with the definite article *al* prefixed, its title became known as the Almagest, the name which is still in use today.

The Almagest is divided into 13 books. Book i gives, in broad outline, the geocentric system together with arguments in its favour. Book ii contains a table of chords and what is the equivalent of spherical trigonometry with the theorem of Menelaus (fl. c. A.D. 90) as its basis; sample problems are also worked out. Book iii deals with the motion of the sun and the length of the year. Book iv is concerned with the moon's motion and the length of the month and book v deals with the same subjects, as well as discussing the distances of the sun and moon and giving details for the construction of an astrolabe. Eclipses of the sun and moon are dealt with in book vi, as also are planetary conjunctions and oppositions. The next two books, vii and viii, concern the fixed stars, contain a discussion of precession, Ptolemy's star catalogue and a method for constructing a celestial globe. The remaining five books are devoted to the planets and are, in fact, the most original part of the work.

It was, no doubt, the encyclopaedic nature of the work that rendered the Almagest so useful to those who followed and gave the views contained in it so profound an influence. In essence, it is a synthesis of the results attained by Greek astronomy and is, of course, our one source of knowledge of the work and hypotheses of Hipparchus (*q.v.*); indeed, it is often difficult to determine which results are due to Ptolemy himself and which to Hipparchus. It is, however, incorrect to assume that Ptolemy himself carried out but few observations, for he extended some of the work of Hipparchus and appears to have used somewhat similar instruments—a type of mural quadrant for determining the altitude of the sun, an armillary sphere (in which the circles were set parallel to their counterparts in the sky and from which, utilizing open sights, celestial latitude and longitude could be read off) and an instrument known as "Ptolemy's rules" which was designed for measuring the altitude of heavenly bodies.

While Hipparchus had carried out much work on the stars and had completed the first star catalogue, Ptolemy extended this work. The catalogue of Hipparchus contains 850 stars and that of Ptolemy lists 1,022. However, Ptolemy used the observations of Hipparchus and, in order to bring them up to date with his own, had to make a correction for precession; unfortunately, he erred in the annual value which he adopted for this correction. Hipparchus had discovered precession and determined the value as 45″ or 46″ per year, but Ptolemy obtained a value of 36" which is, of course, far too small (present determinations give 50.26").

On the motions of the sun, moon and planets, Ptolemy followed Hipparchus and took a thoroughgoing geocentric viewpoint, and it was this approach which became dogmatically asserted in western Christendom until, by the 15th century, further detailed observations had made the Ptolemaic system so complex that the validity of such a view became seriously questioned. As is well known, it was Copernicus who took the bold step of proposing a heliocentric system.

Ptolemy considered the earth to be the centre of the universe, and in the Almagest he gives various arguments to prove that it must be immovable. Not least, he showed that if the earth moved, as some earlier philosophers had suggested, then certain phenomena should in consequence be observed, and he was able to show that no such observations had ever been obtained.

He accepted the order: earth (centre), moon, Mercury. Venus, sun, Mars, Jupiter and Saturn. He realized, as Hipparchus had done, that the inequalities observed in the motions of these heavenly bodies necessitated a system of deferents and epicycles in order to keep uniform circular motion as the basis. Yet, even so, the observed phenomena could not be fully taken into account. It was here that Ptolemy showed a brilliant ingenuity by introducing the concept of the equant He supposed that the earth lay a little way from the centre of the deferents for each planet and that the centre of the planet's epicycle described uniform circular motion around the equant which he placed on the diameter of the deferent but at the opposite side of the centre to the earth and at a distance equal to that by which the earth was displaced on the other. He was thus better able to account for the observed planetary phenomena.

Ptolemy also improved substantially the lunar theory of Hipparchus by varying the distance of the centre of the moon's epicycle from the earth. The motion, as with the planetary equant, was uniform, but while the centre of the moon's epicycle rotated around an equant, the position of the latter was on the opposite side of the earth to the centre of the deferent. With this mathematical device he more precisely accounted for the moon's motion and discovered the inequality of the lunar motion known as evection, an inequality which is due to the rotation of the apse line. He then prepared tables of the moon's motion. and these were in use down to the time of Copernicus. 1,400 years later. His value for the evection was close to that accepted today, and although his new theory of lunar motion did not fully account for the observations, Ptolemy made every effort to perfect it. He did not, however, discover any further inequality in the moon's motion, and it was not until the work of Tycho Brahe in the 16th century that any further development of this kind was made.

Ptolemy realized that the planets were much closer to the earth than the fixed stars, and he seems to have believed in the physical existence of the crystalline spheres to which the heavenly bodies were supposed to be attached. Outside the sphere of the fixed stars, Ptolemy proposed other spheres ending with the *primum* mobile or prime mover, the latter providing the motive power for the remaining spheres which constituted his conception of the universe.

Ptolemy's text was translated into Arabic for the caliph al-Ma'mun in 827, and other Arabic translations followed. The *Almagest* was also the subject of many commentaries One in Greek and written by Pappus in the 4th century A.D. is still in existence; a commentary by Theon of Alexandria (fl. 4th century A D) was published in Basel in 1538 and in the same year the first edition of the Greek text was also published there. The Greek text which has now superseded all others is that edited by J. L. Heiberg, published between 1899 and 1907.

Mathematics.—The mathematical work of Ptolemy was important and he was a geometrician of the first order. He proposed a new proof in place of that of Euclid on parallel lines; he showed in "Ptolemy's theorem" (which concerns a quadrilateral inscribed in a circle) how the formulas $\sin(A \pm B)$, $\cos(A \pm B)$ could be derived and how, with this and a few other simple geometrical theorems, a table of chords could be drawn up. Although it appears that the main theorem was actually due to Hipparchus, Ptolemy deals with the whole matter with a conciseness and elegance which it would be hard to surpass, and was able to calculate a table of chords in increments as small as $\frac{1}{2}°$.

In a work entitled Analemma, Ptolemy discussed the details of the orthogonal projection of points on the celestial sphere onto three planes which are mutually at right angles—the horizon, the meridian and the prime vertical. The full Greek text has not survived, but there is a Latin translation made by William of Moerbeke (13th century) from an Arabic original. The *Planisphaerium,* which survives only in a Latin translation from Arabic, is concerned with stereographic projection, and here Ptolemy used the south pole as his centre of projection.

He also prepared a calendar (*Phaseis* aplanon *asteron*) giving the risings and settings of the stars in morning and evening twilight together with weather indications, and a work in two books entitled Planetary Hypothesis (Hypothesis ton planomenon) still exists, the first book in Greek but the second in an Arabic translation only.

Early commentators mention two separate geometrical works. One, On dimension (Peri diastaseos), is concerned with proving that there cannot be more than three dimensions of space; the other contains Ptolemy's alternative proof for Euclid's parallel line postulate. Ptolemy has also been credited by Simplicius (*c.* 6th century) with a mechanical work, On Balancings (Peru ropon), while Suidas (*c.* 10th century) claims that he wrote three books on mechanics.

The *Optics,* which contains Ptolemy's work on optical phenomena, does not exist in the original Greek but only in a Latin translation made from a 12th-century Arabic copy. It appears that the original was in five books. in the last of which Ptolemy deals with a theory of refraction and discusses the refraction suffered by celestial bodies at various altitudes; this is the first recorded attempt at a solution of this observational problem.

He also wrote a treatise in three books on music. This is known as the *Harmonica* and was edited by John Wallis and published in Latin and Greek in 1682.

Geographical Work.—Ptolemy's reputation as a geographer is mainly due to his *Guide to Geography* (*Geographike Huphegesis*), which, like the *Almagest,* exerted a great influence on future generations. Again, this was due to his scientific approach to his subject and the consequent ease of reference which the book possessed. An eight-book manuscript version was prepared in 1400 and was translated into Latin nine years later. Sumerous editions were published in Europe in the zoo years which followed. and the Greek text appeared at Basel in 1533, edited by Erasmus. All these early editions are full of textual errors.

Hipparchus, three centuries earlier, had already pointed out that a map with any pretensions to accuracy could only be prepared by knowing the longitude and latitude of the principal points on its surface. At the time Hipparchus made his suggestions, little information was available and he seems to have contented himself with his method of dividing the then known world into zones. or *klimata* as he termed them. However, Marinus of Tyre (2nd century A.D.). who lived a little before Ptolemy and to whose work Ptolemy refers in his *Guide,* used determinations of position based on itineraries of travelers and other rough methods. In his treatise. which is lost. Marinus discussed the determinations of the authorities he used, but it is not possible now to assess the scientific value of the results he obtained. Ptolemy considered them in general to be satisfactory and used them as a basis for his own work on the Mediterranean countries. although he showed more reserve in accepting them for remoter regions.

Ptolerny's astronomical work and his studies of map projections made him especially fitted for the kind of geographical work he undertook. but his general views were not unlike those of Eratosthenes and Strabo (*qq.v.*). I-Ie continued the method. which Hipparchus had originated. of dividing the equator into 360 parts (degrees) and supposing other great circles (meridians) to be drawn through this. His framework consisted also of parallels of latitude. Although Eratosthenes in the 3rd century B.C. had measured the circumference of the earth and had given a value very close to that accepted today. Ptolemy used the later determination of Poseidonius (*c.* 135–50 B.C.) which was nearly 30% smaller. and so his conclusions as to distances were incorrect by this amount. Moreover, as he plotted the positions of many places purely by using measures of distance. many of his values of latitude and longitude were also incorrect. As prime meridian Ptolemy followed Marinus, taking the great circle through what was supposed to be the most western point of Europe, the Fortunate islands (corresponding approximately to the Canaries and the Madeira group). He placed the equator too far north and his principal parallel was correct only at Rhodes. In addition. it should he noted that there are some contradictions between the text and the maps in the *Guide.*

In spite of all these faults, Ptolemy's monumental work exerted a great influence. His idea that Asia extended-much farther east than is the case strengthened the belief of Columbus that Asia could be reached by traveling westward. and Ptolemy's suggestion that the Indian ocean was bounded by a southern continent was not disproved until the voyages of Captain Cook in 1773. Some of these ideas were prohahly derived by Ptolemy from Hipparchus.

The *Guide* was divided into seven books. Book i begins with general explanations and there follow corrections made from astronomical observations of some of the results obtained by Marinus. The question of maps and their construction is next discussed. beginning with a conical projection in which the meridians are represented as straight lines all meeting at a certain point (a kind of north polej and the parallels of latitude (especially that through Rhodes) as circles with the "north" point as centre. Then follows a more elaborate projection, with meridians as actual arcs of a circle. Books ii to vii contain a list of places tabulated according to longitude and latitude. Ptolemy deals here with Europe and the Mediterranean. then Africa, Asia, Palestine, Mesopotamia, Arabia. India, etc. The work is accompanied by maps (usually referred to as book viii).

As a whole. Ptolemy's geographical work cannot be considered "good geography." No mention is made of climate, natural products, inhabitants or peculiar features of the countries with which he deals. Moreover, although Strabo, for example, was well aware of the geographical importance of rivers and mountain ranges, Ptolemy's treatment of these factors is careless and of little real use. However, it is the profound influence which the *Guide* exerted on later generations which makes this work so important from a historical point of view.

BIBLIOGRAPHY.—Works of Ptolemy ed. by J. L. Heiberg (1898–1907); German trans. of *Almagest* published in *Des Claudius Ptolemaiis Handbuch der Astronomie* (1912–13) by *C.* Manitius. A photographic reproduction of a manuscript of the *Guide* was published by V. Langlois (1867). A 2-vol. ed. by C. T. Fischer and C. Müller was published between 1883 and 1901. Ptolemy's *Catalogue of Stars,* ed. by *F.* Baily, was published as a memoir of the Royal Astronomical Society (vol. 13) in 1843, and by E. B. Knobel and C. H. F. Peters in 1915. (CN. A. R.)

PTOMAINE POISONING is a popular term used to describe food poisoning caused by toxic substances of bacterial origin. The term is misleading since the toxic substances are known to be subitances synthetized by the bacteria with or without obvious evidence of decomposition of the food rather than ptomaines, *i e.,* organic bases. such as putrescine and cadaverine, resulting from bacterial degeneration of proteins. Examples include botulism and staphylococcus food poisoning, a violent but usually nonfatal type of poisoning, generally associated with the eating of éclairs and cream puffs. *See* FOOD POISONING, *BACTERIOLOGICAL.* (F. L. A)

PUBLIC ADMINISTRATION is the application of a policy of a state through its government. Policy is given general legal formulation by legislative institutions in statute law; hut there then remains the defining of that law for specific application. A statute is the product of a law-making agency which is not always in session. whose memhers are usualiy selected to represent general attitudes and opinions rather than to possess expert knowledge. After a statute is adopted, rules are needed for its detailed application in the enforcement of both the statute and rules to the situations it was designed to affect. Thus, a statute adopted to facilitate traffic may authorize in general terms the regulation of the movement of motor vehicles. by specifying reasonahle speeds on public streets and highways with due regard to density of population. location of schools and hospitals and the existence of intersecting streets! and also will prohahly provide for some agency in continuous operation. and presumably with knowledge, experienced personnel and material equipment, with power to translate the general objectives into more specific regulations (*e.g.,* as to coming to a full stop at main arteries or obeying light signals) and to enforce the statute and regulations, with penalties for those who violate them.

Thus, public administration is interrelated with public opinion in that it follows upon the decision of the political leaders to undertake or abandon collective activities or to support or accept laxity in the enforcement of laws; with the legislative process in that effective administration may be rendered difficult or impossible by faulty legislation, and also because the experience and knowledge of the administrative agency are of value to the lawmaker, just as its possible corruption or ignorance may mislead or handicap him; and to the judicial process since the action of the administrator may be challenged in the ordinary or in special courts by a citizen, and the administrative agency may be required, under the terms of a particular statute, to apply to the courts for judicial action against those presumed by the agency to be violating the law. While there is a theory that administration and policy are two separate processes of government, in fact they are constantly merging and interfused. This is because policy-making is inadequate if there is no consideration of the means for making the law effective. and administration of a general objective raises questions of choice, and hence policy. in any specific situation. It is a policeman who arrests a traffic violator, and not a statute, which remains within the covers of a book.

Administration and Policy.—The problems of public administration reflect, therefore, these interrelations with opinion, legislation and adjudication. They also reflect the stage of civilization, the time, place and environment generally of the particular political unit. Thus. at the top of the administrative structure is an official who can speak for, and to, the dominant political power of the society. This need for making the administrative agency subservient to the original intent for which the activity was authorized and the political forces, party or factional or personal, which took the responsibility for the legislation authorizing the program explains why the headship of an administrative agency, at least of national agencies, is generally a politician and nonexpert. He is chosen because he must interpret to the experts what the judgment of those in political power is, and to the politicians and the lay public what the more technical considerations that will affect their political objectives are. The greatest quantity of public administration is in the substantive functions of government such as those of public safety and order, public health, public works, education, the development of natural resources, the facilitation of transportation, the care of the handicapped and the facilitation and regulation of finance, business and industry. Roads and harbours are built. Social insurance payments are made. Forests are guarded from fire or disease. Each field of activity has its accumulated technical knowledge, personnel. forms of organization and procedure, vocational and professional ties, associations and corporate interests, loyalties and issues. For any particular jurisdiction in which a number of these functions are administered. the problem of allocating available revenue to each, of determining priorities and of co-ordinating the application by each agency of policies in which account should be taken of what other agencies are doing is one of the most important responsibilities of the highest administrative authority. At this point in the structure and process of government there is a meeting and mingling of political policy, general management and the conduct of the particular functional departments.

MANAGEMENT

Direction and General Staff.—The heads of the administration in any jurisdiction have a double responsibility of helping to formulate legislation on the one hand, and of directing and co-ordinating the administrative agencies to carry out the authorized policies on the other. This latter task becomes difficult in those stages of civilization in which many functions are undertaken through government since it includes the proper assignment of activity to organization units and the co-ordination of several organization units, each of which has some necessary share in the activity but each of which is also likely to develop its own personality, attitudes and jealousies. Hence, the top administrative policy group, in modern times often called a "cabinet" from the meeting place in the king's quarters (hence his "cabinet council"), and its chairman or chief—prime (*i.e.,* "first") minister, premier or president—need to have the problems presented to them analyzed by persons of integrity, competence and experience. This has come to he called "general staff service" from the influential and famous Prussian general staff. Elements of this important step in the administrative process are to be found wherever government has been effectively used. Thus, planning, inherent in the process of formulating policy, becomes essential also in its wise application, whether in the conduct of war, the prevention of epidemics, the facilitation of transportation or the relief of destitution.

Auxiliary Services.—The responsible political chiefs of administration have been found by widespread experience to need other aids to ensure economical and efficient application of policy. These are agents for obtaining and facilitating the best use of personnel, physical materials and equipment, architectural and engineering services and finances. Since such tools are aids both to general direction and to the operating officials (who are on the front lines in the field, building highways. waging war or constructing irrigation projects), they are frequently called the auxiliary services.

Characteristic auxiliary services are those which recruit and examine applicants for government employment, budget offices which prepare estimates and supervise expenditures authorized by the appropriating and taxing authority, purchasing agencies which prepare specificaiions describing needed materials. purchase them and inspect, store and deliver them and printing, architectural and construction agencies. They are also frequently known as the "housekeeping services" since they perform them for the various operating agencies. Their justification lies in their ability to perform for all the operating departments these specialized tasks more effectively and economically, and to maintain general standards of salaries, prices and procedures.

There is inevitably some clash between such auxiliary agencies with their responsibility to the administrative chiefs for over-all policy, and the particular operating agency with its enthusiasm for and special knowledge of its own field, and hence resentful of controls that are often called "red tape" (used historically to tie up documents for filing). To the operating official, there looms the threat of what is termed in the British civil service the "treasury mind"; its cousin is found in all large organizations in all times and places. To the official zealous in pressing forward his project, the scrutiny of some part of it by another agency which has no immediate apparent responsibility for the success or failure of the project or its initiator, is irksome. The auxiliary or general staff official, however, is equally impressed with the necessity of relating the single project to the other activities of the government, of bringing the enthusiasm of the official within the bounds and standards which the accumulated experience indicates as effective norms and economical expenditures.

Personnel and budget policies illustrate the fact that auxiliary and general staff services (which intermingle through day-to-day activities) are more than narrow technical matters. They are of central importance in the operation of any political system.

Personnel.—Long and varied experience in all parts of the world demonstrated the necessity, for effective administration, of a reservoir of accumulated knowledge of the administration of a function—a knowledge that can be obtained only from persons of ability and integrity who have been given an opportunity for a career, within the appropriate general political, legislative and judicial controls, in administration. That is not the only reason why spoils systems, wherever they exist, have been disastrous (except in situations in which they may have served as alternatives to more costly revolutions). Their primary evil is that they undermine any use of parties and legislatures as reasonably accurate instruments of recording political sentiment and ideas, since they replace the relationship of agency for the public by agency for the chief spoilsman and turn responsible public affairs into irresponsible private rackets. Their administrative evil is that they prevent the accumulation of knowledge that only experience can give. No person of ability and integrity would be willing under spoils conditions to seek a satisfying career, and inevitably the agency sinks in effectiveness and in public confidence and any public objective is lost. Even in revolutionary conditions a new government is generally reluctantly forced to rely upon such officials of experience and knowledge as it can find for carrying on those services necessary for the safety and welfare of populations—especially in a society partly urban. The knowledge referred to here is not only the knowledge of a substantive problem, such as preventive medicine, for example, or highway construction, but the more subtle knowledge for which long experience inside the working of human institutions is required. This is the knowledge of who knows what, of how to use procedures and codes to hasten or delay business, of how to avoid arousing group and individual jealousies, of "moving through the correct channels" and of winning the agreed consent of all those necessary to a policy. The term "bureaucracy" is sometimes given, often in disparagement, to governments in which the "permanent" or "career" officials exercise or condition power. Such a dependence on officials, however, is inevitable and necessary in governments exercising many and interrelated functions.

The selection and training of civil servants has therefore been an important problem of government since early times. The system of widespread recruitment on the basis of examinations in the classics was a feature of the government of China for hundreds of years. The training of officials for the administrative posts in the mediaeval papacy and empire included courses in such universities as Bologna and Naples. The palace school of the Ottoman empire was the nursery of the civil, military and naval officer classes. The ruling families of the German principalities founded universities in which their civil servants (often jealously opposed by the feudal nobility) were educated. In both 19th-century Germany and France, the rise of a larger and more varied civil service was accompanied by the development of opportunities for secondary, university and specialized education that reflected also the enlargement of the middle class. The École Libre des Sciences Politiques in Paris and the development of careers in municipal administration in Germany illustrate these tendencies. The Trevelyan-Northcote report on the civil service in Great Britain in 1853 was influenced by such educators as Benjamin Jowett of Balliol and John Stuart Mill. The expansion in the functions of government in the Cnited States prior to World War I created an interest in the education of administrators which revived strongly with another expansion in the decade 1930–40.

In general, educational qualifications for administration reflect the general social conditions of the time and place and the classification of the positions to be filled. A more fluid and democratic society opens its opportunities for secondary and higher education widely and this tends to prevent the formation of a special official caste sheltered by inherited privileges. The "single-party" system of government tends to create a new form of special privilege dependent upon party allegiance. But in all systems, a job analysis will reveal the need for continuous education after entrance if there is to be an adequate supply of recruits for the higher directive and technical positions. Hence, the questions of "in-service" training, of educational leave and the recruitment through promotion and from outside the service are as much the subject of discussion and experiment as the older question of "pre-entry" training. At this point the interest of students of public administration turns to developments in education and psychology generally as well as to experience in industry and commerce.

The Budget.—The outstanding instrument whereby the total program of a government for a given period of time is set forth by organization unit, types of expenditure and in other detail is the budget. In most states (notably Great Britain, which contributed most to its development as an important tool of government) the budget originates in the executive departments in the form of estimates of proposed expenditures and the revenues to cover them, is submitted to the legislature for investigation, amendment and legal authorization and is then administered by the budget and other finance agencies. The budget process ends with an audit to determine whether expenditures have been properly based upon the legal authorization—an audit frequently made by an agency of the legislature, or otherwise independent of the administrative chiefs. The budget as authorized by the lawmaking process is thus inevitably the total plan for all the activities of the government for the next fiscal period (generally a year), including the provision for personnel and materials. The long evolution of representative government has centred largely in the development of a good budget system, including "the control of the purse strings" by the elected representatives of the people; that is, the submission to them by the executive (usually in name, at least, by the king) of the proposals for expenditure, taxation and loans and the scrutiny and amendment, acceptance or rejection of these by the representatives, sometimes with the aim and result of forcing the king's administrative chiefs and policy advisers from office. The cabinet system, whereby the chief executive officials must possess the support of the majority of the legislature, thus had its origins; while the importance of legislative control over expenditure, and of the appropriation process, is illustrated also by provisions concerning them in the constitution of the United States and in the development of government everywhere.

The Planning Process.—The function of cabinets and chief executives as well as the heads of large departments in the preparation of policy for submission to the legislative authority became complex and difficult with the widening and interdependence of the functions of government. Thus, in a metropolitan area the design of streets and highways, water supply, parks and schools is dependent upon population, industrial, commercial and' technological trends as well as changes in the ideas held by citizens as to standards of living. As a result, the usual budget processes are sometimes supplemented by special staff agencies for investigation and analysis. or by regular and continuing agencies to which the term planning is applied. Planning as an inherent need in the structure and process of administration was diagnosed and recommended by Frederick W. Taylor in his pioneer work in scientific management, although, as noted above, it has been called into existence in some form, as in military affairs, wherever thought has been applied to the problem of the improved preparation of programs.

The "mercantilist" and "cameralist" policies of the early modem state caused the rise of career civil services and methods of training for them. A similar increase in collective services, whether in the U.S.S.R. with its elaborate central, regional and local programs of state action, or a cut-over region of sparse population requiring long-time land policies in the United States, or a great urban agglomeration such as London, Bombay or New York, made desirable and necessary the establishing of planning agencies. Their function is to gather and analyze data concerning the problems of the political organisms they serve and to submit reports on their studies to the political chiefs, the legislatures and the electorate. Sometimes these agencies are also given some operating responsibility and power. Thus, they may be given the enforcement of controls over land use or authority to determine priorities in the allocation of resources to projects. Whether such planning agencies should be exclusively research and advisory in their functions or should have in addition operating functions and powers is a subject of controversy among students of administration. It is agreed, however, that there should be close and sympathetic working relations and an interchange of personnel between them and the budget and other general staff and auxiliary services and the substantive departments.

It may again be stressed that the budget should reflect, as the most comprehensive record of operations proposed for the next fiscal period, the result of the planning process as registered in the working and financial program which the chief executive and his associates are responsibly proposing to the highest lawmaking body of the jurisdiction. Thus, the estimates which are proposed will presumably be supported and justified by the analyzed data. Viewed in this light the planning process in administration is not, as sometimes argued, in opposition to legislative authority but essential to it. A legislature, in fact, may rightly demand that such preliminary collection and analysis of data be undertaken by the executive to ensure a better preparation of proposals placed before it. The use of the fiscal policy of a government to affect general economic conditions by its influence on investment and employment increases the need for careful planning of the estimates.

Internal Operation.—The directive, general staff and auxiliary agencies exist to serve the substantive or operating departments, and it is through them that the functions of a political system are applied. In these basic substantive departments there is a division of labour reflected in an organization of units whose heads are related in some line of responsibility and power. The system may be recorded on organization charts and in standard specifications for every position whereby the duties, qualifications, rates of payment and official titles are set forth. The relation of the different levels, the flow of correspondence, reports, memoranda and dockets of official business and the arrangements for conference between units (bureaus. divisions, sections, branches, regional offices, etc.) may also be guided by written and official codes of procedure. The procedure to be followed in relations with the public generally by correspondence, interview, investigation or inspection, or hearings of an informal or formal type, tends to become standardized and codified. This results in a standardizing of practice that leads to charges of red tape, bureaucracy and the stultifying of initiative, A failure to regularize procedures, however, leads to criticisms of unfairness, capriciousness and abuse of power and an invitation to corruption. The interests affected by the function administered are generally organized in economic or professional associations. Sometimes representatives of these interests are brought into official participation in the administrative process through committees advisory to the agency or committees given some power of administering the program for which the agency is ultimately responsible. At its extreme, such a system might be termed "the corporative state" so much discussed in political theory in recent decades, although never actually embodied in any completeness.

Among the groups involved in the administrative process with some special interest or emphasis of their own are various organizations of the civil servants. Since the number of civil servants in a modern state may be great, collective action in the effort to affect rates of pay and conditions of employment generally developed despite opposition. In some systems, a regular procedure was established (as notably in the "Whitley councils" in the British civil service) for consultation between the directive and personnel officials and the representatives of the civil service organizations.

Thus, the maintenance of some balance in modern administration between the interests and attitudes of legislatures, parties, executive leaders, auxiliary service agencies, interest groups affected and the civil servants themselves is no easy task. The systems appear sprawling, cumbersome and unwieldy and too far removed from the situation from which the call for governmental action originated. Internal operation is complicated further by the relating of decisions taken at the centre to the varied conditions in the field.

The problem of clarifying and explaining the complex task of a department led to increased interest in methods of reporting. Experiments in the use not only of printed and illustrated reports but of the motion picture, the radio, television and direct face-to-face discussion and conference were undertaken. Legislatures are inclined to oppose these on grounds that they may become an alternative to the party system as a means of consulting public opinion and may stimulate public pressure for legislation favourable to the agency employing them.

The problems of internal operation in public administration are in many ways akin to or identical with those in other social institution., including industry and commerce. The comparative study of institutions, including the relation of individuals in the smaller face-to-face groups, brought scholars and administrators together from many fields to share experience and plan and conduct research. Psychologists, personnel managers, anthropologists, sociologists and many other workers find a common field in what is given various names, such as social relations, human relations or the study of the human group. A special challenge was raised by growth of international programs and agencies in which the problems of a substantive field such as health are complicated by the need for co-operation by peoples of different cultures. The training of administrative personnel for such programs began to reflect the new emphasis on human relations, and also the area or regional studies whose origins may be found long ago in the policies of missionary societies and colonial offices, as well as in World Wars I and II.

DECENTRALIZATION AND DEVOLUTION

Whenever the size in area and population of the jurisdiction served by an administrative system is large, the adjustment of general policies and standards to varied local or otherwise specialized circumstances constitutes a major problem. If too great freedom is given to officials to adjust standards to the particular instance, effective general legislation becomes difficult or impossible, and programs may get distorted and special interests may injure the general good. Partisan, sectional, factional or other special favours and corruption may follow. And yet the particular knowledge of the persons whose life work is in an industry, or is concerned with a commodity or profession, or with a particular region or locality, should be employed if a policy is to be wisely administered. The states of the world have in all times, from ancient China or the Roman empire to the present, attempted to meet this problem either by leaving or giving some measure of local self-government to local areas, or by creating regional units in their central administrative agencies to which some discretionary powers for making decisions within the general rule for problems arising within the area are given.

A variant of the same principle is the assigning of powers for the administration of a statute or general policy of the state to a professional, commercial or industrial association or representatives of such interests. Thus, we may find, as in the Germany of the Weimar republic, not only Lander or member states within the Reich but local units within them and also an economic council. Similarly, in Great Britain, which we ordinarily think of as a unitary or relatively centralized state, there are county councils, rural district councils. boroughs and also boards possessing statutory powers in the steel industry or dealing with a commodity such as milk or bacon. In the United States the same problem of relating general policies to the particular situation confronted the constitution makers in 1787, resulting in a federal system, but persists to the present and indeed becomes more complicated as new units such as soil-conservation districts or local housing authorities are created with direct relations with national agencies.

The grant or taking of power by economic groups was advocated perhaps more strongly at about the time of World War I, and a political theory designated "pluralism" or "functionalism" had a period of success. It was indeed supposed to have been reflected in the doctrines of the Russian bolshevists and the fascists in Italy, as well as in the creation of economic councils in France and Germany. Probably local circumstances and situations in the latter two states, just as in the establishment of the National Recovery administration in the United States, with its industrial codes, had a much greater importance, while the Russian and Italian systems quickly revealed themselves as highly centralized single-party controlled governments struggling to secure and retain power and therefore in no position to yield power to regional or commodity or other groups except as forced by circumstances to do so.

The point is, however, that circumstances (*i.e.*, the increasingly complex nature of the activities that go to make up modem economy, the strong pull of neighbourhood and region and all kinds of provincialisms and the necessity to achieve political as well as administrative success for policies) do press for the adjustment of general policies to particular situations and do require the consultation at least by administrators with persons and organizations affected by those policies. It is characteristic of modern legislation affecting industry in some states, for example, that councils on which employers and employees, or members of a profession, are represented, participate in drafting rules and regulations under the act.

Relations of a national or central authority with provincial and local governments are made more complicated by the rise of metropolitan cities that spread over several separate political jurisdictions, the inequality of tax resources of local units, the pressure for national minimum standards of public services and the interdependence of economies. A partial answer to these conditions is found in the grants distributed from national funds to local units on condition of meeting certain required standards, with resulting inspection from the centre, generally entitled "grants-in-aid," and in the employment of officials of one level of government for enforcing the laws of another. The relation of levels of government remains, however, as one of the most difficult and perplexing problems of public administration.

CONTROLS AND STANDARDS

Obviously public administration is certain to be subjected to criticism in part because the objectives sought are disliked or the methods employed are viewed as unjust or inefficient or corrupt.

Over the centuries various devices for its control have evolved. These efforts are designed to confine it to the political objectives for which a particular administration is established, which we may call political control; or to ensure most economical and efficient methods, which we may call executive control; or to ensure observance of the accepted rules of fair conduct as understood by the particular society to apply to the relation of officials with the public, which we may call judicial control; but they necessarily intermingle, and broadly speaking, with the rise of representative government, a somewhat stronger emphasis inevitably was placed in most states upon political control. This is exercised through making the chiefs of administration politically responsible either to the legislature or to the electorate by some form of popular election.

Probably the most famous example of the evolution of political control is the wresting of power from the king and its allocation to a committee of party leaders representing a majority of the house of commons in Great Britain. This system, called "cabinet" or "parliamentary" government, was a model for most states to follow (with varying success). The U.S. "presidential" or "congressional" system makes the chief executive, except in city manager-council government cities, responsible to the electorate. Both systems, however, operate through parties; and at times the British prime minister takes on presidential attributes, and the U.S. president similarly at times plays a role in relation to congress somewhat akin to that of the prime minister in relation to the house of commons.

The more detailed devices of party and legislative control vary greatly; but most legislatures employ committee investigations of administration, scrutiny of budget estimates, the control over expenditure and audit and frequently the questioning of executive chiefs on the floor as well as in committee. These matters are usually topics of discussion at meetings of the Interparliamentary union, the conference of delegates from the legislative bodies of the states of the world.

Executive control is exercised through general staff and auxiliary services as described, and in modern complicated and large structures necessarily employs the techniques of the formulating of general standards, as of personnel, enforced by special auxiliary agencies. Probably the most important control is wielded through the analysis of budget estimates by the central financial control agency of the chief executive and his colleagues.

The struggle of legislatures first for independence of the monarchy and later for supremacy is paralleled historically in many states by a similar effort of the courts for independence; and in some states, notably the United States, the system of written constitutions and a federal distribution of powers has been the basis upon which has been constructed the exercise of judicial review not only of the acts of officials but of the constitutionality of the statutes whereby the officials may have justified their actions.

In many states, notably those influenced strongly by the traditions and precedents of the Roman law, a series of special courts evolved in which controversies involving official acts of civil servants are adjudicated, and the resulting case law, as in France, constitutes an important part of the public law. Administrative law is thus everywhere a branch of public and constitutional law that grows in importance as the extent and complexity of the functions of government increase. Questions of the competence of the authority, the adequacy and justice oi the procedure, the extent of the grant oi discretionary power, the adequacy of the evidence in support of the administrator's action and the finality of the administrative decision are typical issues. The study of comparative government, and in particular oi comparative jurisprudence and administration, is resulting in a greater familiarity on the part of scholars and of some practitioners with the similarities between different systems and a tendency to discover devices in one system that may usefully be adopted in another. Many precedents and theories framed long ago during the struggles with monarchy are being reappraised in the light of the contemporary complexities oi administration.

While legislative, executive and judicial controls are of basic importance, it should not be forgotten that in the daily life of the administrator his own knowledge, character and sense of persona1 and professional responsibility, constituting a series of inner standards and checks, are probably more immediately and intimately influential. Hence, the rise of professional organizations, of research, of in-service training, of journals devoted to administrative questions have increasing importance and constitute a proiessionai control which has operated, indeed, at times in all societies.

The increasing association of citizens through advisory committees with administration, and their sharing in fact with the exercise of some of the discretionary power in rule making, and the necessity for many types of administration of winning the understanding if not the active support of the citizen, characteristic increasingly of many types of administration, is another less recognized but important control over public administration. Many statutes and programs involve matters touching intimately the lives of great numbers of citizens; it is impossible to enforce them (as, for example, systems of social insurance or of highway safety or disease prevention) without extensive efforts to acquaint citizens concerning them. But in that process, the official is often educated himself as to attitudes, habits, capacities and problems of those whom he is supposed to serve; he is probably less concerned with possible legislative, judicial or even higher executive action regarding his work than with the people and problems immediately at hand. In this sense, we may consider administration as moving into a stage in which a two-way educative process is discernible; and while it may seem a far cry from the edicts of ancient rulers, one suspects that even they, too, had sometimes to consider how far they could go with subjects unaware of or opposed to their aims and measures.

PUBLICAN: *see* LICENSED VICTUALLER.

PUBLICANI, the name given in ancient Rome to a body of men who either hired state property or monopolies to farm for their own profit or bought for a fixed sum the right to farm the taxes due to the treasury from the public land in Italy, or the land held by Roman subjects in the provinces. In early times the senate entrusted to officials the control of the sale of salt (Livy iii, 9), and it was a development from this that the state, instead of appointing officials to manage its monopolies, let out those monopolies to individuals. A regular system was established by which the censors who held office every fifth year placed the sources of public revenue in the hands of individuals or companies, who on payment of a fixed sum into the treasury, or on giving adequate security for such payment, received the right to make what profit they could out of the revenues during the five years elapsing before the next censorship. The assignment was made to the highest bidder at a public auction. The same system was applied to the public works, the *publicanus* in this case being paid a certain sum, in return for which he took entire charge of a certain department of the public works. That this system was well. established at the time of the Second Punic War is assumed in Livy's account of the various offers made by the wealthier class of citizens to relieve the exhausted treasury after the battle of Cannae (216 B.C.). On the one hand we have companies offering for branches of the revenue a price which was calculated rather to meet the needs of the state than to ensure any profit for themselves (Livy xxiii, 49). On the other hand individuals are represented as undertaking the management of public works on the understanding that they would expect no payment until the conclusion of the war *(ibid.* xxiv, 18).

Since wealth was a necessary qualification for the post, and wealth at Rome became more and more confined to the commercial class, the *publicani* became identical with the class of capitalists and traders. This was distinct at Rome from the senatorial class, which was excluded from it by definite enactment *(see* SENATE), 'and, except in face of common danger, was often hostile to it. It was in their capacity of *publicani* in the wealthiest provinces that the capitalist or equestrian *iudices (see* EQUITES) became a menace to the provincial governors who represented the senatorial power. When the demands of the equestrian party determined the policy of the state we can trace the interests of the *publicani* as the motive of its action. Thus the fate of the Roman businessmen in Cirta led to the Jugurthine war in 112 B.C.; the disorganization of Asiatic commerce by the pirates led the *equites* to support the proposal to confer extraordinary powers on Pompey in 67 B.C.; and the quarrel over the contracts for the taxes of Asia in 60 B C. led to the downfall of the senatorial party.

Under the empire the *publicani* were subject to close supervision. The name appears as "publicans" in the New Testament.

PUBLIC AUTHORITIES PROTECTION ACT (1893): see PETITION OF RIGHT.

PUBLIC ENTERPRISE. Although there is no standard definition of public enterprise, the term usually refers to government ownership and active operation of agencies engaged in supplying the public with goods and services which alternatively might be supplied by privately-owned profit-motivated firms (private enterprise). Typically, public enterprise operations. the same as private, are financed wholly or largely by receipts from the sale of goods or services.

There is no clean-cut distinction between public and private enterprise, however. Rather. the two concepts may be regarded as the opposite ends of a spectrum, with many mixed forms of enterprise between. On the private enterprise side, the chief motivation and focus of decision is making the maximum of profits for the benefit of owners and managers. On the public enterprise side, the chief emphasis usually is on the welfare of the whole community, rather than upon revenue. Honever. an important objective of many public enterprises in Great Britain and the United States is to produce net revenues for nonenterprise purposes. In the middle of the spectrum are such forms of enterprise as co-operatives (producer and consumer) not operated primarily for profit, and mixed enterprises in which the government supplies part of the capital or participates actively in management. or both.

There have been two basic questions respecting the development and scope of public enterprises in Great Britain and the United States. (1) Which goods and services are better provided under private enterprise and financed by user charges, and which are better supplied by ordinary governmental organizations and financed by taxes? (2) Where goods or services are provided, is public or private enterprise to be preferred?

On the first basic question, there is a case for charging for services or goods if the following conditions are met. (a) The service should be such that a charge (price) can be successfully imposed. Among other requirements, the service must be capable of division into measurable units, as kilowatts of electricity or gallons of water. (b) The immediate benefits of the service should go largely to the individual paying for it. If the community as a whole benefits from the service, there is an argument for financing it by general taxation. From about 1800 there has been a growing recognition of the public benefits attaching to many services (*e.g.*, education) and a corresponding increase in the number and scope of services financed by general taxation. (c) Charges should encourage economy in the use of resources. On the other hand, there is an argument against charges which result in the underutilization of already existing resources.

On the second basic question, there is in Great Britain and the United States a range of views concerning the proper role of government in economic affairs which parallels the range of enterprise forms. At one end is the view that all possible production and distribution should be in the hands of private profit-motivated firms; at the other end is the extreme socialist view that the state should own and operate the means of production.

The case for private enterprise, which found classic expression in Adam Smith's *The Wealth* of *Nations* (1776–99), has always rested on the proposition that private firms in a competitive system are more efficient and venturesome than government enterprise, because of the incentives afforded by the profit motive and the spur of competition, and because of their freedom from the restrictions of government bureaucracy. The case for state socialism has rested on a variety of propositions. Most important are the doctrinaire socialist assumptions that private ownership of the means of production results in inequitable distribution of income and wealth and exploitation of workers and consumers; that the profit motive encourages such unsocial conduct as monopolistic behaviour (see MONOPOLY) ; and that only the state can efficiently plan and direct economic production in the modern highly interdependent industrial society.

Ideological considerations have not predominated in the development of public enterprise in either Great Britain or the United States, except in Britain during the period of nationalization of industry under the Labour government (1945–51). In the main, public enterprises have been established to meet immediate and pressing needs, not as a part of any general plan for a socialized economy.

Public enterprise should be distinguished from other types of direct government intervention in economic affairs—including public regulation—which involve establishing rules of conduct for private firms and policies for stabilizing prices and maintaining employment.

Some government activities are difficult to classify. For instance. the large-scale housing programs both in the United States and Great Britain have been undertaken to promote the welfare of low-income groups. yet the major part of the costs of housing projects in both countries is made up by rentals of dwellings.

Development in the 19th and 20th Centuries.—With the exception of the enterprises operated by the post offices, there mas no instance of an entirely socialized industry in either Britain or the US. prior to the 1920s. The postal services have been generally recognized as appropriate areas of government enterprise and have been operated as government monopolies in both countries. In Britain the post office operates the national telegraph and telephone services, having taken over telegraph in 1869 and telephone in 1911. The U.S. post office during the past century has ordinarily incurred annual deficits, while the British post office, with a greater variety of services, regularly shows an operating surplus, part of which is turned over to the treasury.

Economic undertakings by governments were less common in Britain than in the U.S. during most of the 19th century. Powers of British municipalities to own or trade mere sharply restricted by legislation of the early 19th century, and for some time special acts had to be obtained even for such functions as street cleaning and lighting. The restrictions were in part responsible for the deplorable conditions of towns in the Victorian period. Toward the latter part of that century, the area of municipal enterprise gradually widened, partly as a result of the impact of Fabian socialist propaganda. which began in the 1880s. Such municipal services as sewage disposal, medical officers' and hospital services, vaccination, refuse collection and maternity care were first undertaken on a commercial basis. By the late 1800s, many local governments were starting, or taking over and developing, public utilities—water! gas, electricity and transportation, and later, airports. Ultimately, local authorities came to control about one-third of the gas and two-thirds of the electrical industries.

A forerunner of the public authority device was the Mersey Docks and Harbour board created under an act of 1857, which acquired ownership of the Liverpool and Birkenhead docks and assumed responsibility for conserving, lighting and buoying the harbour and control of pilotage. This organization pointed the way for other local public bodies, including the Port of London authority (1908), and the London Passenger Transport board, established in 1933 to take over the trams, buses, tubes (subways) and suburban railways of metropolitan London.

The national government in Great Britain took small part in public enterprise until after World War I, when a number of new enterprise forms and administrative techniques were developed. The principal new enterprises were: the forestry commission, established in 1919 for the purpose of creating and maintaining state forests to protect national timber resources and supply part of the timber requirements; the British Broadcasting corporation (1927), which monopolized radio and television broadcasting; the Central Electricity board (1927), to construct and operate an integrated national network of transmission lines; the British Overseas Aircraft corporation (1939), to develop and operate air routes outside the United Kingdom and Europe.

With the end of World War II and the coming to power of the

Labour party in 1945, British economy moved toward the socialist objectives of centralized planning and economic controls and nationalization of industry. During Labour's six-year tenure, the Bank of England, the coal industry, civil aviation, overseas telecommunications, electricity, transport, the gas and iron and steel industries were nationalized.

The principal purposes of nationalization, as formulated by the Labour party, were: (1) to remove concentration of economic power from private hands in the interest of a more democratic society; (2) to increase efficiency by expanding operations and improving organization' and interindustry co-ordination; (3) to improve labour relations and provide greater opportunity for promotion and worker participation in management; (4) to permit direct investment of public funds and to lower costs by substituting low interest-bearing government securities for private shares in companies; (5) to give the government greater power to combat unemployment through control over production and power to locate industrial plants in depressed areas; (6) to improve the periormance of private firms by using nationalized industries as models and holding out the threat of iurther nationalization; (7) to eliminate monopolistic practices and to substitute direct public action for regulation of private industries.

The Labour party disavowed any intention of 'taking over all industry, and the nationalization program (despite its ideological motivations) did not involve a drastic reconstruction oi the economy. Of the nationalized industries, electricity, gas, transport, civil aviation, telecommunications and central banking were already closely controlled, as in most advanced economies. Coal was failing rapidly under private ownership, and the way to nationalization had already been prepared by cartelization under close government supervision. Nationalization of iron and steel was the most notable, and most hotly opposed, departure from the private enterprise system.

In 1950, before the iron and steel industry was taken over, nationalized industries employed about 10% of the working population, distributed as follows:

Coal	735,000
Electricity supply	167,000
Gas	135,000
Transport, other than air	906,000
Air transport	24.000
Broadcasting	11,600

The Conservative party came to power in 1951 pledged to reduce economic controls and promote private enterprise. The iron and steel and most of the trucking industries were denationalized, in the face of labour's threat to nationalize them again when it next came to power. But later. government enterprise engaged in another large-scale program —the development of atomic energy ior commercial purposes under the U.K. Atomic Energy authority. Electricity produced by nuclear power was first ied into the national grid in 1956.

As experience accumulated, it appeared that nationalization had fallen short of its original objectives to such a degree that support for further nationalization notably waned, even in the Labour party.

The giant organizations that emerged from nationalization were far greater in scale than business-type organizations of previous experience; only the post office had been comparable in size. There were no precedents ior the type of management organization needed ior enterprise oi such scale or ior the pattern of relations and responsibility between public enterprise inanagements and responsibility between public enterprise managements and parliament. Too little attention had been paid to the many factors which limit efficiency in large organizations. The act of nationalization in itself did nothing to solve worker motivation, industrial efficiency, development of capital plant, adaptability to changing conditions and interindustry co-ordination.

To many workers, nationalization represented only the substitution of one control ior another. Hopes for improved conditions, reduction of income inequalities, greater opportunity ior workers and identification oi the workers' interests with those of the industry were not immediately realized. There remained the question of whether they could be better achieved under the giant public corporations than under smaller private corporations.

Underdevelopment in the United States led to much more government participation in public and mixed enterprise in the 19th century than was the case in Britain. But the responsibility for public improvements was left mainly with the states and the local governments. Except for land grants and financial assistance to transcontinental railways: the federal government did not contribute importantly to the development of public improvements in the 19th century. It participated in the ownership and operation of the first (1791–1811) and second (1816–36) Banks of the United States, and operated iur-trading ventures early in the century; otherwise its role in public enterprise was inconsiderable.

Most of the states and many local governments promoted internal improvements. Unsubsidized enterprise was less important than mixed enterprise in railway building until well into the 1900s. Railways were assisted by state constitutional or legislative provisions for state and local government assistance in the form of loans, stock subscriptions or outright donations. In some cases, the assisting governments actively participated in enterprise management, *e.g.,* Baltimore for many years was represented on the board of the Baltimore and Ohio Railroad company.

Most of the canal ventures were entirely public enterprise. The Erie canal, most important of the early improvements, a-as built and operated by the state of New York. The canal's success stimulated the undertaking of many other canals by states and municipalities. Few of these ventures were long-lived or successful, partly because of the advent of railways.

State governments also engaged in financial enterprises during the early 1800s. Several states established and operated banks, some of which were successful. However, losses on poorly planned and mishandled ventures subsequently led to many financial crises and the repudiation of many state and local government debts. As a result of such conditions many states amended their constitutions and enacted legislation to control public borrowing powers and otherwise to prohibit or restrict government participation in enterprise. In some cases, restrictions were later relaxed as a result of continued pressure ior improvements.

With the growth of cities and development of technology, many municipalities in the United States, as in Britain, began to operate water, gas, electric and public transport systems. In 1955, 74% of municipalities over 5,000 owned water supply and/or distribution systems; 21% owned and operated airports; and 20% owned electric generation and/or distribution systems. Only 1.5% owned and operated public transportation systems, but this number included six of the nation's twelve largest cities. In addition, local governments carried on a variety of other largely or wholly self-supporting activities which could be performed by private enterprise. Incinerator and sewage treatment plants, and such sports facilities as golf courses and swimming pools were common. Municipalities operated public markets, docks, piers, ice plants, coal yards, laundries, cemeteries, liquor stores and telephone systems; some established public corporations to construct and operate toll-financed facilities, including bridges, tunnels and parking lots.

State governments in the 20th century also experimented with various forms of public enterprise. The major enterprises in the 1950s were liquor distribution, insurance, transportation and electric power. Sixteen states operated state liquor store systems in 1954. These systems, all monopolies, served the double purpose of controlling the distribution of liquor and earning substantial revenues for the states. The most important state insurance systems (besides the unemployment compensation systems operated by all states) were workmen's compensation insurance systems, found in 18 states (in seven the state iund was a monopoly). Most states owned the harbour iacilities within their jurisdictions, including docks, wharves and warehouses. A state board of port commissioners operated many facilities serving the port of New Orleans, including grain elevators, coffee terminals, cranes and derricks, a belt line railway and a free trade zone. One of the largest enterprises was formed by a compact between New York and New Jersey, the Port oi New York authority, which operated the tunnels and bridges connecting New York city and New Jersey, the three major airports in the New York metropolitan area, a railway freight terminal, two truck terminals, a bus terminal, several docks and piers and other facilities. Faced with restricted taxing and borrowing powers, several states revived an ancient device, the toll road, as a means of providing needed highways. Toll highways had been built or were under construction in 10 states in 1952. Typically, they were operated by semi-autonomous authorities.

South Carolina, Oklahoma, Texas and Nebraska constructed multipurpose projects involving the production and sale of hydroelectric power. In Nebraska, all production and distribution of electricity was handled by two public power districts. In New York, the state power authority has been given responsibility ior developing and distributing power from large projects on the St. Lawrence and Kiagara rivers.

The U.S. federal government also entered into a number of ventures in the 20th century; by 1950 it owned or was financially interested in approximately 100 enterprises in five major categories: (1) transportation, (2) loans and insurance, (3) enterprises concerned with public lands, (4) miscellaneous manufacturing enterprises and (5) production and distribution of electricity. Most oi the enterprises were established or acquired before World War II.

The government's first major enterprise (other than the post office) was the Panama canal (*q.v.*) and associated enterprises of the Canal Zone, including a railway, fueling plants, public utility systems and other facilities. Other transportation enterprises included the Alaskan railway (begun in 1914); construction and operation of merchant ships, under programs designed mainly for war and defense purposes; operation of barges on the Mississippi, Missouri, Illinois and Warrior rivers—begun during World War I to supplement railway transportation and sold to private interests in 1950.

Many of the federal loan programs, established during the depression' of the 1930s, were designed to assist farmers, home builders and buyers and business firms unable to obtain credit at suitable terms from private sources. The Reconstruction Finance corporation specialized in business loans, and from 1934 to 1954 when it mas terminated, was the nation's largest lender. It was succeeded by the Small Business corporation, with the main function of lending to small firms.

Important insurance agencies include the Federal Housing administration (1934), which insures home mortgages held by financial institutions; the Federal Crop Insurance corporation (1938), which insures crops against natural risks; and the Federal Deposit Insurance corporation (1933), which insures bank deposits up to $10,000.

In its capacity of landlord, the federal government sells rights and privileges to private interests, builds and operates irrigation dams and ditches, operates recreation facilities and carries on numerous other business activities.

Most of the articles manufactured by federal government agencies are ior internal consumption; they range irom naval ships to mail bags. A feu· enterprises sell manuiactured goods to the public, notably the Government Printing office and the Virgin Islands company—organized in 1934 to promote employment—which produces sugar, molasses and rum. During World War II, the government built synthetic rubber plants and a tin smelter, iormer major sources of rubber and tin having been cut off by enemy conquests in southeast Asia. The rubber plants were eventually disposed of to private interests.

The federal government's interest in the production and sale of electricity initially stemmed irom irrigation and flood control projects which could also generate hydroelectric power. In 1906, congress authorized the sale of such power, specifying that preference be given to municipal interests. Activities were on a small scale until the 1930s, when a number of projects were initiated for the development of river valleys; mainly on the Tennessee, Colorado and Columbia rivers, involving such iunctions as flood control, navigation, irrigation and water supply, in addition to power production *(see* **Electric** Power: *United States).*

Under the New Deal and World War II programs, power became increasingly important; hydroelectric facilities were expanded and supplementary steam plants were added to the great federal systems. Federally-owned enterprises in 1930 produced less than 1% of the nation's electricity; in 1954, 12½%.

In the mid-1950s, public enterprise in the United States accounted for less than 2% of the national income. As in Great Britain, the philosophy of the national government administration was antipublic enterprise. However, expansion of the government role appeared inevitable. One reason was the great potential of industries based on nuclear physics and nuclear chemistry, the development of which is directed by the Atomic Energy commission. By 1956, the commission's investments in facilities amounted to approximately $9,000,000,000.

Most public enterprises in the United States and Great Britain are operated by public corporations which own property and are managed by boards or commissions appointed in Britain by the government, and in the U.S. by the chief executive, o'ften with the concurrence of the legislative bodies. A leading problem in both countries has been the working out of democratic controls which assure efficient management, the devotion of enterprise policies to the public interest and accountability ior the use of public funds; while preserving independence from irresponsible political meddling and the complex operating restrictions imposed on regular government agencies, and freedom to meet current situations.

PUBLIC HEALTH.

Elementary efforts to control epidemic disease are mirrored in the early pages of recorded history. The books of Leviticus and Deuteronomy give a fairly complete picture of isolation and quarantine procedures for dealing with "leprosy" and basic essentials of community sanitation. The Romans built great public water supplies, sewers and bath houses. The epidemic of plague in the 14th century led to the establishment of quarantine stations at the principal ports of Europe.

The public health program, in a broad and comprehensive sense, was initiated by Edwin Chadwick's report on *The Sanitary Condition of the Labouring Population of Great Britain* (1842) as a result of two forces set in motion during the 18th century. The first was the development of the fundamentals of modern science, which made it clear that the forces of nature may be controlled by man; the second was the humanitarian movement, which gave a powerful impulse toward the application of such knowledge. First based on primitive empirical theories with regard to sanitation, the public health movement was given its scientific direction by the germ theory of Louis Pasteur and by Robert Koch's isolation of the tubercle bacillus in 1882.

By the beginning of the 20th century, the first two phases of the modern public health campaign were launched: (1) the purification of nater supplies and control of the disposal of wastes and of insect carriers of disease and (2) scientific isolation and quarantine practice and immunization by the use of vaccines and serums. About 1910 the founders of the movement for the control of tuberculosis inaugurated the third and fourth phases by developing programs of health education in the principles of personal hygiene to build up the vital resistance of the human body and by establishing clinics for the early diagnosis and preventive treatment of incipient disease. Movements for the control of venereal diseases and infant mortality, mental disease, heart disease and cancer quickly followed. The visiting nurse became a public health nurse. a messenger of health as well as a minister of healing. The physician became a builder of health and not merely a repairman for disease. The boundaries between preventive and curative medicine began to disappear.

Finally. as the middle of the 20th century approached, the fifth phase of public health opened with a new and vital interest in social and economic factors as they relate to housing, nutrition, medical care and social security.

In the United States, early emergency boards of health were created to deal with imminent threats of epidemics or with particularly offensive nuisances. Boards were created in many large cities in the face of yellow fever epidemics in the early 1800s. Several of these—as in Baltimore, Md., New York city and Philadelphia. Pa.—were made permanent. and Baltimore has probably the oldest health organization with a continuous history, dating back to 1793. It was, however, the reorganization of the New York city board in 1866 which keynoted the more modern developments. H. M. Biggs in New York and C. V. Chapin in Providence, R.I., were outstanding pioneers. From 1915 the American Public Health association rendered notable service in studying and standardizing the techniques of health administrative practice.

UNITED STATES

Local Health Services.— An authority on public health in the United States. Harry S. Mustard, in *Government in Public Health* (New Tork: The Commonwealth Fund and the Harvard University Press, 194j), stated that

> The vast majority oi routine health service received by the people of the United States is delivered by local agencies. The Federal Government may subsidize and indirectly shape local health departments, the state health department may determine major policies for local agencies. set standards, promulgate regulations, and even directly supervise them, but the final determining factor in the effectiveness of a public health program rests with the workers in the locality where the problems are occurring.

The size and scope of local health programs vary, but following are some of the typical functions: (1) control of communicable and chronic diseases; (2) operation of clinics for mothers and children and for various preventive and diagnostic services; (3) provision of public health nursing services; (4) environmental health services, including inspection, supervision and sanitary control of water supplies, sewage disposal facilities, milk production and distribution and food-handling establishments; (5) public health education and information; (6) collection and analysis of vital statistics; (7) operation of community hospitals, nursing homes and rehabilitation centres; and (8) community health planning, consultation and co-ordination.

A modern local health department consists of a corps of health specialists. such as physicians, nurses, dentists, engineers, sanitarians, health educators, psychologists and medical social workers, and supporting technical, statistical and administrative personnel.

The 20th century witnessed a great expansion of local public health services in the United States. In 1915 only 14 counties had full-time health services. By 1953 more than 70% of the 3,070 counties in the United States (which included about 88% of the nation's total population) were organized for full-time local health services or were covered by state health district organizations. However, many of these units were operating with minimum or skeleton staffs.

In addition to the work of official health agencies, other local governmental and nongovernmental agencies often assume responsibility for special health services or activities. For example, boards of education may deal with school health programs, departments of public works with construction and maintenance of sanitation facilities, and welfare agencies with provision of medical and hospital care.

State Health Services.—Within a single state, health services may be dispersed among numerous separate agencies of state government. Every state. however, has a specific agency, usually termed the department of health, which is charged with over-all health responsibilities. State health work ranges from regulatory or advisory activities to the operation of certain direct services.

State governments usually carry on five types of health functions: (1) public health and preventive services. such as demonstrations of new techniques and programs, and supervision over utilities of public health importance; (2) medical and custodial care, such as the operation of hospitals for tuberculosis and mental illness; (3) expansion and improvement of hospitals, medical facilities and public health centres; (4) licensure for health reasons of individuals, agencies and enterprises serving the public; and (5) provision of financial assistance and technical consultation to local units of government for conducting health programs. In addition, most states maintain regulatory authority over most health matters and promulgate rules and regulations which are applicable throughout the state.

Federal Health Services.--Official federal health agencies are responsible for controlling interstate health hazards and for protecting the United States from communicable diseases from abroad. The public health service, for example, maintains inspection and quarantine services at ports of entry to the United States to prevent the spread of infectious diseases. Federal agencies also co-operate with other countries to reduce the danger and stamp out the sources of such infections wherever possible and, through the World Health organization and bilateral agreements, to help the governments of underdeveloped areas of the world to raise their health standards.

Other direct health functions of the federal government include protection of the purity, potency and sanitation of foods, drugs and cosmetics; control of serums, vaccines and other biological products; provision of medical and hospital care for certain designated beneficiaries of the federal government; and conduct and support of research, investigations and demonstrations in the causes, prevention and control of disease. Federal agencies also help, through grants-in-aid and consultative services, to expand and improve public health services throughout the country. Finally, they make national surveys and studies to identify health problems, to determine the need for health facilities and programs and to develop plans of action for meeting family and community health needs.

The U.S. public health service is the chief federal health agency, but several other agencies have health interests and responsibilities related to their broader functions. Prominent among these are the Food and Drug administration, the children's bureau and the office of vocational rehabilitation, all within the department of health, education and welfare, the departments of agriculture, commerce, defense, interior, labour, state and treasury, the Atomic Energy commission, the Federal Civil Defense administration and the Veterans administration.

Voluntary Health Agencies.—The work of official public health agencies in the United States is supplemented and reinforced by voluntary health effort. In the mid-1950s there were more than 20,000 separate agencies concerned with the promotion of public health and preventive services. Most of these agencies operated at the city or county level, but nearly 300 had state-wide activities and about 30 were national in scope. Supported largely through private sources, they make substantial contributions to public and professional education, to research and to programs of medical and hospital care in their respective fields of interest. These interests may centre on a certain specific disease, such as tuberculosis, cancer or poliomyelitis; on safeguarding specific organs or functions, such as vision or hearing; or on promoting the health of speciai groups, such as mothers and children, the aging or the handicapped.

Two other types of nongovernmental or voluntary health organizations in the United States are the agencies which provide hospital and medical care insurance and the nonprofit and proprietary hospitals. Finally, there are a number of other groups which contribute to total health services or resources in the United States. Among these are foundations, private laboratories. professional organizations such as the American Public Health association, schools and universities, industrial and labour groups and civic organizations.

Progress in Public Health.—There is great variety in the type, content, scope and quality of performance of health services in the United States. Moreover, these services are provided by a multiplicity of independent agencies. There is a unifying factor in public health work, however, which gives it form and structure and which makes substantial progress possible. For example, the three levels of government—federal, state and local (city or county)—represent distinct and separate entities. Actually, however, they constitute a working partnership for the protection and promotion of human health. Moreover. they work closely with voluntary agencies, with professional groups, with schools and foundations, with industry and labour and with families and communities to control disease and improve well-being.

As a result, the trend of both individual and community health in the United States has been consistently upward for many years. Measured by the gains in general and specific death rates, the improvement in health was remarkable. In 1900 there were 17.2 deaths from all causes per 1,000 population. In 1954 the estimated rate was 9.2 deaths per 1,000, the lowest in the country's history and the sixth consecutive year in which the death rate was below 10 per 1,000 population. The estimated infant death rate for 1954 was 26.6 per 1,000 live births, compared with 100 per 1,000 births in 1915. In 1935, for each 10,000 live births, 58 mothers died; in 1954 there were fewer than 6 maternal deaths per 10,000 live births.

There was a gain of nearly 20 years in life expectancy at birth after the turn of the century—from about 47 years to $68\frac{1}{2}$ years for the total population.

Most dramatic was the continuing success against communicable diseases, which descended steeply after 1900. In that year the infectious diseases accounted for about 4 of every 10 deaths from all causes. By 1953 the ratio had changed to about 1 of every 13 deaths.

The principal communicable diseases of childhood—diphtheria, whooping cough, measles and scarlet fever—were virtually eliminated as causes of death. Such other infectious diseases as smallpox, typhoid fever, pneumonia, gastrointestinal infections and trachoma were greatly reduced or put under effective control.

Tuberculosis mortality dropped about 95% in the first half of the 20th century in the United States, from a rate of 194 per 100,000 in 1900 to about 10.6 in 1954. From 1945 to 1951 the average annual decline for this disease rose to 10%, and after 1951 there was an average 21% drop in the death rate each year. The venereal diseases also responded favourably to modern control methods in the United States. The death rate for syphilis fell from 16 deaths per 100,000 in 1938 to about 3 per 100,000 in 1953.

Although the communicable diseases were by no means eradicated, the major health problem in the United States in the 1950s was chronic disease. These diseases had been on the rise for several decades. Together, cancer and diseases of the heart and blood vessels accounted for two-thirds of all deaths in the United States in 1954. These, plus diseases such as diabetes, arthritis, rheumatism and mental illnesses, as well as accidents, also caused the most disability, long-term illness and hospital care in the U.S.

Public health agencies in the United States are turning increasingly to the control of these diseases, to the problems of an aging population and to the health problems associated with a complex industrial and social environment. Among these are water and air pollution, hygiene of housing, accident prevention, the dangers involved in the widespread use of chemicals and ionizing radiation, and the promotion of mental health. (X.)

GREAT BRITAIN

The term "public health" as used in Great Britain connotes in the broad sense principles and methods which aim at promoting and safeguarding the health of the community in contradistinction to those nhich are concerned in the main with the treatment of declared disease in the individual It depends for its operation upon the study of disease in the group which is epidemiology. Public health is not synonymous with either preventive medicine or social medicine It makes use of both and seeks to apply all relevant scientific and medical learning to the prevention of ill health and disease and to the promotion of positive health.

Growth of Services.—The 18th century witnessed the early gron th of ideas. official and otheruise, to protect the health of people in Great Britain. Richard Mead of St. Thomas's hospital outlined the measures necessary to prevent the spread of plague in his *Discourse on the Plague* (1720); John Pringle in his *Observations on the Diseases of the Army* (1752), James Lind (1757) and Gilbert Blane(1785). in manuals about seamen, outlined the means to preserve the health of soldiers and sailors; George Baker(1767) studied endemic colic due to lead poisoning in cider drinkers. On the continent Johann Peter Franck from 1779 to the end of the century published the first complete textbook on the public health of a community. As the Industrial Revolution pained momentum the environment of the new conglomerations of human dwellings, particularly in the midlands and north, gave rise to increasing disquiet. Thomas Percival, a Manchester practitioner, emphasizing, as others had done before him the risks. particularly to mothers and children, of overcrowded town living and factory life, pioneered the first British hoard of health(1795).

During the early part of the 19th century when much of Europe had taken active steps to create some protection of the public health by the establishment. at least in the large towns, of councils of health, Britain. absorbed in political reform took no further action. The population grew fast, resulting in great congestion, industrial development produced new hazards especially to women and children, revolutionary changes in agricultural life vastly increased the number of paupers. and epidemics of infection with heavy mortality swept through the towns In 1829 cholera began to spread over Europe and reached Britain in 1831. A central board of health was set up, and attempts were made, not with much success, to establish local boards.

In 1834 the measures taken to reform the poor law were of great significance to the growth of public health, although this was not immediately apparent. Poor law reform was the result of a royal commission of which Edwin Chadwick nas a member and largely responsible for the report. Chadnick s scheme of a centralized machinery with local boards of guardians, very much that of Jeremy Bentham. whose declining years he had shared, was to influence the growth of public health services in Britain for nearly a century. The boards of guardians. operating universally over unions of parishes and made responsible for providing medical care for paupers, appointed medical men in an official capacity. Chadwick nho became secretary to the central Poor Law commission, relied upon this large new body of official medical opinion for his social survey *The Sanitary Conditions of the Labouring Population of Great Britain* (1842).

The boards of guardians were made responsible for the appointment of local registrars of births and deaths under the registration act of 1836, and in 1840 they became responsible for public vaccination. However, the baneful influence of poor lam upon public health was not in the mere fact that the poor law machine undertook these and other forms of public health. or even in that its existence delayed the creation of complete public health cover, but rather because of its dominating note of "repression" and "less eligibility," which were so long to deny the basic needs of public health In later years when the central administration of poor law and public health were fused (from 1871) in the Local Government hoard, poor law became a dominating influence and retained its mastery until the creation in 1919 of the ministry of health.

No sooner had Chadwick succeeded in his designs for refashioning the poor law than he realized that expenditure on the pauper and prevention of disease were two sides of a single coin. This was the burden of his 1842 report. His interests now changed almost wholly to public health. A barrister by profession. he mastered the elements of sanitary engineering. then a little-understood science. He came to the conclusion (1) that health depended upon sanitation; (2) that sanitation was an engineering matter; (3) that an arterial system of water and sewage. nhich alone could solve the problems of the new towns, must entail one local authority to administer all sanitary matters; and (4) that expert advisers in engineering and medical matters were essential. A royal commission appointed in 1843 to inquire "into the state of the large towns" consolidated Chadmick's findings. The course was now set for legislation. The Public Health act, 1848, which followed after an interval of long debate, established the General Board of Health with powers to create local boards.

Medical officers of health now began to be appointed, first under private acts of parliament to Liverpool (William Duncan, 1847) and London (John Simon. 1848). The Public Health act, 1848, authorized their appointment to all local boards. but the appointments were not made obligatory as had been advocated in Chadwick's report of 1842 and by the royal commission of 1843. In 1855 the 38 newly formed London vestries mere required to appoint medical officers of health, and many famous medical men took office. At first no special qualification was prescribed, although Trinity college in 1870 and Cambridge university in 1875 provided diplomas in public health, as regulated by the rules of the General Medical council in 1871. In the Local Government act of 1888 a clause was inserted requiring that after Jan. 1, 1892, every medical officer of health of a county or a district containing a population of 50,000 or more inhabitants should be not only legally qualified in medicine but also the registered holder of a diploma in sanitary science, public health or state medicine. By an order issued by the ministry of health in 1922, this requirement was extended to all medical officers of health.

The General Board of Health. a subject of much controversy, lasted ten years; in 1858 it was dissolved and the powers transferred to the privy council. It created about 183 local boards, covering 3,000,000 persons. This was a relatively small achievement in contrast with the poor law unions. At this time 276 towns with more than 5 000 inhabitants had no health authority. John Simon was appointed medical officer of health to the central government. He remained in office until 1876, witnessing many changes. In 1871 the Local Government board, with responsibility for both poor law and public health. was created. In 1872 the country was divided into sanitary areas. to become later the urban and rural districts, each with a medical officer of health. In 1875 the Public Health act, a charter in environmental hygiene. was passed. The 343 sections of the act were designed to secure (1) wholesome and sufficient water supplies; (2) prevention of pollution of water; (3) provision of sewerage; (4) regulation of streets, highways and new buildings; (5) health of dwellings; (6) removal of nuisances; (7) inspection of food; (8) suppression of disease; (9) sanitary burial; (10) regulation of markets. These were the recommendations of the royal commission of 1869. The Housing act. 1890, the first charter for working-class housing, required medical officers of health to report insanitary houses and areas and gave authorities powers. with appeal to the courts, of demolition and closure. Infectious diseases began to be notifiable (1875, 1889.1899), and many other acts were passed to further environmental hygiene.

By the turn of the century the machinery for dealing with the health aspects of the environment had been laid down and the long and often bitter struggle to remedy the ills of the Industrial Revolution was well advanced. Public health began to grow out into the fields of social medicine. The social surveys of Charles Booth (*Life and Labour of the People in London*, 1889–97) and Seebohm Rowntree (*Conditions in York*, 1901) and the findings of the 1904 interdepartmental committee on physical deterioration strengthened the growing belief in the importance of personal health care, as a counterpart of environmental hygiene. Attention turned first to maternal and child welfare. Infant welfare. with advice centres and trained nurses for home visiting and with antenatal clinics, became a function of the new county and county borough councils created in 1888. The Maternity and Child Welfare act (1918) required these authorities to "attend to the health of expectant and nursing mothers and of children under five years of age not yet at school." The Midwives act (1902), which established the Central Midwives board and began professional midwifery, made county and county borough councils responsible for supervision. The large authorities were also made responsible for the Education act (1907), which began the school health service; the regulations of 1912 and 1916 to establish tuberculosis and venereal disease services; and the Mental Deficiency act, 1913, which required the discovery and care of all mental defectives "subject to be dealt with." Births became compulsorily notifiable in 1915. Two further subjects of great importance to public health, factories and children, were dealt with at this time by the Factory act, 1901, and the Children act, 1908. With the growth of county government, public health functions were divided under separate jurisdiction; environmental hygiene was the duty of the smaller authorities and personal hygiene that of the county council. This dichotomy did not occur in county boroughs.

National health insurance (1911) was at first to have a much deeper significance than that which would arise out of the provision of public medical care. with medical, sickness. maternity, disablement and sanatorium benefits for 16,000,000 workers. It was to be the basis of a new approach to public health in which every doctor in the course of his public work would be concerned to seek out adverse social and environmental factors. The insurance committees. it was supposed, could claim compensation for excess sickness due to remediable factors, where these had been neglected. The Insurance commission, an ad *hoc* body, at the centre. and the insurance committees at the periphery with public health functions, whimsically devised, were testimony to the great dissatisfaction felt with the Local Government board, whose undesirable poor law outlook still persisted 3j years after Simon's resignation.

The same dissatisfaction was expressed in the separate office of the registrar general, in the powers of the privy council both under the Midwives act and for research, in those of the Board of Control under the Lunacy act. and those of the home office under the Children's act and the Factory act. The final eradication of poor law influence at the centre was effected in 1919 by the creation of a ministry of health. with a medical man (C. Addison) as its first minister, a chief medical officer (George Newman) with direct approach to the minister and a permanent secretary (Robert Morant), formerly chairman of the Insurance commission. The new ministry took over most central functions concerned with health. Unfortunately the Board of Control remained in charge of lunacy. It was not until the National Health Service act, 1946, that mental health took its rightful place alongside physical health as a subject for preventive medicine. The home office likewise remained responsible for industrial hygiene, and this service, now under the ministry of labour, was, in 1955, still separately administered.

The ministry of health introduced a scientific approach, hitherto lacking, into public health. It also began to give encouragement and advice to local authorities. Medical officers of health found themselves at last sympathetically linked with the centre. Newman's admirably written annual reports set a new tone and embodied a new spirit of preventive and social medicine. The ministry was advised by a consultative council under a first chairman, Lord Dawson of Penn. This committee produced (1920) the interim report of the Consultative Council on Medical and Allied Services, the first plan for a national health service in which health centres were to play a prominent Dart.

Public health, both environmental and personal, now advanced at a great rate. A succession of Housing acts, 1921, 1923, 1924, 1930, 1935 and 1936, began a spate of new building and slum clearance; the Tuberculosis act, 1921, extended sanatorium benefit to everyone; the Mental Treatment act, 1930, introduced outpatient clinics and voluntary treatment as recommended by the 1926 royal commission on lunacy and mental disorders; the Midwives act, 1936, required all counties and county boroughs to establish midwifery services; existing legislation was consolidated by the Public Health act (1936), the Housing act (1936), the Factories act (1937) and the Food and Drugs act (1938).

In 1929, 650 boards of guardians were abolished and the functions transferred to counties and county boroughs, with a strong recommendation to give assistance wherever possible by other means than poor relief. Poor law infirmaries became the municipal hospitals (the London County council took over 76 institutions with 42,000 beds). Public health now sought to humanize the poor law, hospitals, children's homes and infirmaries, a vast undertaking that was little more than begun before World War II. The Local Government act, 1929, also required county coupcils to frame proposals, in consultation with district councils, for the appointment of full-time medical officers of health precluded from private practice. In the 25 years following this act the reorganization of county public health administration proceeded gradually. For the country as a whole there were in 1955 about 600 medical officers of health in senior positions, of whom about 150 were part-time. A further 1,200 doctors, mostly with diplomas, were employed whole-time, as deputies (119), as senior medical officers (156) and as assistants (981).

After World War II public health was, as it were, engulfed in the flood of social legislation. Acts dealing with education (1944), family allowances (1945), national insurance (1946), national insurance (industrial injuries) (1946), national health (1946), town and country planning (1947), national assistance (1948) and children (1948), all provided the framework of the welfare state in which the problems of community health had to be reassessed. The emphasis of public health began to shift toward the social aspects of disease, a change which was accelerated by the transfer of hospitals to a new authority and by the provision of comprehensive free medical care.

Changing Character of Public Health **Problems.**—*General* Health.—The public health picture of Great Britain has changed over the course of about 200 years from that characteristically exhibited by an "underdeveloped" to that of a "developed" country. High mortalities coupled with a high birth rate, which tended to maintain a small stationary population of about 8 000,000 with large numbers of children and few aged persons, have been replaced by low mortalities and a low birth rate; the present population of about 50,000,000 is again static, with fewer children and more aged persons. In the middle of the 19th century, of 1,000 persons, 66 were aged 65 years and over and about 340 were children under 1j; in 1953 there were 224 children and 113 aged persons in every 1,000. The expectation of life had advanced from around 30 to 40 to between 60 and 70 years. The high specific death rates of the major infectious diseases had diminished to near vanishing point. Of 500,000 yearly deaths. only 12,700 were (1953) attributable to notifiable infectious diseases, and of these 70% were attributable to tuberculosis. The death rate from tuberculosis, which remained a major menace, had declined during the preceding century from 3,000 per 1,000,000 of the population to 200, and as a cause of death it had changed in the incidence of its greatest danger from the young, particularly female, worker to those over 45 years of age.

Infant mortality had declined from near 250 to 28 and the stillbirth rate, since first registered in 1928, from 38 to 22. The largest part of this enormous reduction related to deaths of infants after the first month of life. Of the remaining infant deaths 60% were the result of immaturity and congenital malformations. Thus the major loss of infants had become perinatal; *i.e.*, occurring before, during or shortly after birth. The decline of deaths in children was equally spectacular. William Far', the first compiler of statistics to the registrar general after the Registration of Births and Deaths act, 1836, recorded that between two and three out of five children died before reaching five years of age. The mortality of children from birth up to four years fell from 66 to 6.36. and for children of five to nine years from 9.05 to 0.49, per 1,000 living between 1841–jo and the mid-1950s. In 1850, 64%, and in 1953, 4%, of total deaths were in children under five years of age.

Ninety per cent of deaths in 1953 were in persons over 40 years, 75% in those over 60 years and 50% in those over 70 years. Rather more than half the deaths (255,940) were attributable to diseases of the circulatory system. Neoplasms accounted for 89,860 and diseases of the respiratory system for 62,347. Thus, four out of five deaths were now attributable to conditions that were basically caused by the processes of wearing out. Infectious disease, although not the cause of high mortality, still occasioned much morbidity. The returns of the ministry of national insurance (1952) showed that 41,260,000 days were lost (*i.e.*, more than 25% of the total) from influenza, bronchitis, pneumonia, acute pharyngitis, tonsillitis and the common cold. Most of this resulted from viral conditions.

The amount of mental illness exhibited in psychoses, neuroses and psychosomatic disease is almost certainly very great, although from lack of information there is no exact knowledge. Half the number of hospital beds are filled with patients suffering from mental illness; a large fraction of the absenteeism from industry is attributable to neurosis or psychosomatic disease.

Social, *Occupational* and Geographical Differences.—Disease and death vary greatly in different areas and occupations and among sections and groups of the population. In general the north suffers more. Rural areas of developed counties are more healthful than towns for persons over 40. In particular the toll of degenerative disease is lower in the country. Infant mortality in Britain increases proportionately with density of living. Widely divergent mortalities of various occupations reflect the different nature of hazards: for example, the standardized mortality ratio of agricultural workers is half the average for all workers. whereas that of slate quarry workers is three times as great. Many diseases also vary with social grouping; for example, infant mortalities, including stillbirths and premature births, increase from the professional classes to the unskilled worker; in contrast, coronary thrombosis takes the opposite course.

National Health Service and Public Health.—The Beveridge scheme for social security, which sought to abolish poverty by comprehensive insurance, was based upon the assumption that there would be a national health service designed to reduce sickness, and its disabling effects, to a minimum. The National Health Service act of 1946. which came into operation on July 5, 1948, provided free medical care by general practitioners and in hospital. The service incorporated mental health by placing all the functions of the Board of Control, other than judicial, in the ministry of health and by making local authorities responsible for prevention and aftercare. Unfortunately the industrial medical service was not included and school health remained the function of the education authorities.

Part iii of the National Health Service act placed a variety of duties upon county and county borough councils, acting as local health authorities. These duties were designed to emphasize the expanding functions of public health in the fields of social medicine. They included (1) the provision of a health visiting service to give "advice as to the care of children, persons suffering from illness. and expectant and nursing mothers, and as to the necessary measures to prevent the spread of infection"; the health visitor's work was thus extended to the whole family and the opportunity was given to integrate her social work with medical care by the family doctor; (2) the provision of a home nursing service for those "who require nursing in their own homes"; (3) the provision of a home help service "for providing domestic help for households where such help is required owing to the presence of any person who is ill, lying-in and expectant mother, mentally defective, aged or a child . . ."; (4) responsibility for "the prevention of illness. care of persons suffering from illness or mental defectiveness or the after care of such persons." For the new work in mental health authorized officers were appointed for problems concerning removal to hospital and mental health workers for aftercare work.

The National Health Service act brought about far-reaching changes in the interpretation of public health. Emphasis came to be placed upon the social aspects of disease that can be seen in the new attention to the aftercare of patients leaving all types of hospitals; in the development of a partnership with family doctors for care in the home; in the increasing attention paid to mental health through infant nelfare and antenatal clinics and by aftercare schemes; in the growing understanding of the social aspects of handicaps such as epilepsy, mental deficiency and physical defo ities; in the arrangements, in conjunction with welfare, for the social care of the aged; in arrangements to detect the problem family and to prevent its downhill progress. The medical officer of health of the second half of the 20th century had become a social physician, the partner. not the antagonist as often in the past, of his colleagues in hospital and general practice. Developments in this neu field had been much assisted by the remarkable achievements of social security. backed by national assistance, in eliminating poverty and by the parallel development of free medical care.

The local administration of the service for national health in three distinct parts, hospitals under regional hospital boards, general practitioners under executive councils and public health under local health authorities, proved a handicap to the full development of the social and preventive approach. This could be seen in many different spheres. as, for example, in antenatal care, which could now be given from four different sources—by the midwife, the general practitioner, the welfare centre or the hospital. The difficulties were enhanced by differences of finance, boundaries and electoral systems. Hospital boards and executive councils obtained their money from the treasury, whereas health authorities were supported by the local rate with block grants from the treasury.

Executive councils and health authorities covered the areas of counties and county boroughs. whereas the hospital boards. 14 in England and Wales, covered wide areas often cutting across local government boundaries. Health authorities were elected by popular franchise, whereas hospital boards and executive councils were selected by the minister. Another handicap was the continued dichotomy, within counties, of public health functions, but administrative devices, including divisional administration in counties by the employment of the same medical officer for local and county work, were overcoming these handicaps.

U.S.S.R.

Public health in Russia was almost lacking until the late 19th century. The beginning is to be seen in the introduction of local government by Alexander II in 1864, when district assemblies, known as zemstva, became responsible for organizing medical services in rural areas. The development of local government physicians to give free medical care. of whom there were about 2,000 in 1892, was a remarkable achievement. These salaried doctors formed themselves into public health councils. to advise the district assemblies, but medical care and public health continued at a low level. About 1900 there was an average of one physician to 25.000 persons. In 1918 was formed a commissariat of public health the equivalent of a British or French ministry of health, with more complete control over all aspects of health. The Soviet republics, created in 1922 under the constitution ratified in 1923, established commissariats or ministries throughout the union. In 1936 a central department for the union was established to co-ordinate the health work of the republics. The evolution of services proceeded in a series of five-year plans, which prescribed development schemes for all medical departments. institutions and industries. By 1950 the facilities available for the whole union were approximately as follows: hospital beds 1,470,000 (*i.e.*, about 7 beds per 1,000 persons); medical centres 31,880: tuberculosis dispensaries 1,192; venereal disease centres 1,498 (1941); maternal and child welfare centres 6.190.

Polyclinics—in essence the envisaged health centres of the British system—are designed not only to give medical care but to prevent disease and to promote health. They exist in every district and in every factory of more than 5,000 workers, and the majority of Soviet physicians occupy posts in them. In rural areas they are combined with hospitals and are supported by smaller units in the villages. There are also dispensaries, either associated with polyclinics or separate from them, and serving wide territories, to deal with particular conditions or diseases. From the polyclinic the district visiting physicians undertake therapeutic and prophylactic work. One of the objects of the polyclinic system is to provide frequent medical examinations and yearly "dispensarizations." The term "dispensarization" denotes a full examination by a team of specialists.

Administration.—Under the ministry of health of each republic there exist regional, district and village health departments, each with an elected committee. The health department is in charge of all medical activities both curative and preventive. Village committees supervise local sanitary facilities. undertake health education and a variety of social functions; they appoint guardians for the insane; blind, deaf and dumb and disperse insurance benefits. District committees, of which there are about 3,000 averaging 70,000 population, have a health officer as do also at a higher level the regional committees 'and the autonomous republics that exist within many of the union republics. Larger cities have a status of their own and many have separate divisions. The standards of the polyclinics, the framework of the whole organization of public health and medical care, are laid down by the union ministry to be administered by the republic ministry through a special department; the day-to-day work is conducted by the regional and district health departments. The degree of autonomy of the local committees is restricted.

Special Services and Health Education.—The school health services and maternal and child welfare services, particularly the latter, have been elaborately planned. Antenatal care, preparation for childbirth and insurance safeguards seem to be universal. Occupational health appears to have received considerable attention, with 25 medical institutions for the study of occupational diseases and by the extensive use of industrial polyclinics. The development of services for industry has no doubt been assisted by an industrial expansion which makes use of large factories. Labour codes to protect women and children and limitation of hours of work seem to resemble those of Britain and the U.S.

Health education is regarded as one of the most important means to prevent disease and to promote health. A special department of the union ministry is guided by a central institute for research in health education; routine work is conducted through committees in villages, farms and apartments. A strong cult of health can be seen in many different mays; e g, in the attention given to sports and physical culture, and in the rest homes to which large numbers are admitted yearly for active rest under medical supervision and which form an interesting part of the public health system

Health in the **U.S.S.R.**—Before World War I, Russia exhibited the characteristic health picture of an underdeveloped country, with high general mortality and birth rates, high infant and child mortality much infectious disease with heavy mortalities, low expectation of life and the balance of population weighted toward the younger end. The general death rate averaged 28–30, the infant mortality about 250, and 98% of women had no medical care at childbirth. The present state of public health is largely a matter of conjecture, since published information is scanty. Statements which have appeared in the Russian press suggest a general death rate of 9 in 1953 and an annual excess of births over deaths of 3,000,000 in the period 1949–51.

t'accination against smallpox and tuberculosis and immunization against diphtheria are compulsory. The age structure of the population is probably similar to that of Great Britain in the 19th century. Infant mortality is said to have declined substantially but the exact figure is not stated. It has been claimed, on slender evidence. that there is much less mental ill health in the Soviet Union than in other European countries; on one estimate only 3 per 1,000 have serious mental disorder.

INTERNATIONAL PUBLIC HEALTH ACTIVITY

Historical **Development.**—International action in the field of public health had its origin in attempts to lessen the inconvenience caused by the wide variety of quarantine laws that had developed over several centuries throughout the countries and ports of Europe. By the middle of the 19th century these had become an intolerable nuisance to the expanding steamship routes. The first international sanitary conference was held in Paris in 1851. Before the turn of the century ten such conferences had been held at Paris (1851, 1859), Constantinople (1865) Vienna (1874), Washington (1881), Rome (1885), Venice (1892). Dresden (1893), Paris (1894) and Vienna (1897). By 1890 knowledge of the epidemiology of infection had advanced sufficiently to make it possible to limit the spread of certain diseases. Particular attention was paid in 1892. 1893 and 1894 to the spread of cholera and in 1897 to plague, spread by the Mecca pilgrimages.

In 1903 the first effective convention. as the Lancet said. "to realise and not to theorise," codified previous work: yellow fever was discussed for the first time since the discovery that the mosquito was a carrier As a part of these early arrangements and to some extent preceding them, two regional organizations had been created at Alexandria (1831) and Constantinople (1839) at nodal points of epidemic spread. In 1902 the Pan American Sanitary bureau (originally named International Sanitary bureau) with headquarters at Washington, D.C.. was formed. The first effective office of epidemic intelligence to cover the nhole globe. however. was the Office International d'Hygiène Publique (the "Paris office"). established under an agreement signed Dec. 9, 1907. This centre proved to be effective and although regulated further by revisions of the conventions in 1912, 1926, 1938 and 1944 it continued. undisturbed by later developments elsewhere. until after World War II. Information was distributed through a monthly bulletin and by other publications. The Pan American Sanitary code, in 1924, required the notification to Washington of ten diseases. By 1926 international conventions had extended world-wide control to cover yellow fever, cholera. plaque typhus and smallpox. In 1933 a convention on air navigation was signed.

Health Organization of the League of Nations.—The scope of international public health was widened in 1923 by the creation of the Health organization of the League of Nations. From the new centre at Geneva, Switz., an epidemic intelligence system of greater efficiency was gradually produced. In addition to the Paris office, which continued to function, regional bureaus were set up in Washington Alexandria. Singapore and Sydney. The bureau at Singapore. a focal point in trade routes. was of great value as an intelligence centre for the east. Within the limits of a slender budget. never exceeding E78 500, the Health organization of the League was able also to give some practical assistance, particularly in Greece and China, toward the control of epidemic spread.

For three-quarters of a century international health thus concerned itself mainly with the spread of infectious disease. The time had come to consider international health in a wider sense. The Geneva office extended the work to international standards for the preparation of various biological materials and to international codes of vital statistics; it took an active part in technical discussions on the control of opium. The Commission on Standardization of Sera. Serological Reactions and Biological Products introduced uniformity of potency for the protective serums, hormones and antibiotics The League's Committee of Statistical Experts helped to carry forward the standardization of causes of death which had begun as long ago as 1853, with the first international statistical congress at Brussels The Geneva office also organized international study tours, and it began the system of expert committees. Committees sat to study malaria, cancer leprosy, housing and nutrition. Their findings were to prove of far-reaching importance to public health everywhere. International conferences on rural hygiene (Europe, 1931; far east. 1937) produced %ell-documented statements. There were also two pan-African health conferences. The League was helped in much of its work by the international health division of the Rockefeller foundation.

UNRRA.—World War II greatly interfered with the work of the Paris and Geneva offices. In 1943 UNRRA (the United Nations Relief and Rehabilitation administration) was created to help the devastated norld. For somewhat more than two years. UNRRA acted as an international health organization, with a staff of 1,134 persons. including nationals of 35 countries. It spent more than £58,000,000 and helped the health departments of liberated countries with both advice and practical aid. It administered the maritime and aerial quarantine conventions (1944), which brought up to date the older conventions of 1926 and 1933. These required each signatory nation to notify UNRRA of outbreaks of all communicable diseases which might be a menace to other countries, including the prevalence of the yellow fever mosquito and *Aedes aegypti,* and to report the measures taken to combat their spread. Disinfection, deratization, provision of safe water, destruction of mosquitoes, delousing and vaccination against smallpox could be ordered.

World Health Organization. — In 1946 the Interim commission of the World Health organization. which followed an International Health conference of more than 60 states convened by the United Nations at New York city, took over the functions of UKRRA. A permanent World Health organization, supported at first by 54 states, came into being on April 7, 1948. This absorbed, in addition to UNRRA, both the Paris office of epidemic intelligence and the Health organization of the League of Nations WHO thus became the sole international health organization, excepting the Pan American Sanitary bureau, which continued to work independently but in close association with WHO. In 1947 the U.S.S.R. and the other Cominform countries withdrew from active participation in the work of WHO.

The World Health organization operated, with a high degree of autonomy, as a specialized agency of the United Nations. It had offices in New York city. to maintain liaison with the United Nations and other agencies. but the bulk of the work was carried on by the staff at WHO headquarters in Geneva. The organization was directed by the World Health assembly, which met annually and in which all members might be represented, and by an executive board of 18 persons, representing 18 nations, of whom one-third retired each year. The administration was conducted by a secretariat, headed by a director-general, with 11 divisions as follows: (1) public information, (2) co-ordination of planning and liaison, (3) communicable disease services. (4) organization of public health services, (5) professional education and training services, (6) health statistics, (7) epidemiological services. (8) therapeutic substances, (9) editorial and reference services, (10) management and personnel and (11) budget and finance. There were six regional offices for Africa, the Americas, the eastern Mediterranean, Europe, southeast Asia and the western Pacific.

Article i of the constitution of WHO defined the organization's objective as "the attainment of all peoples of the highest possible level of health." This was to be regarded "as one of the fundamental rights of every human being without distinction of race. religion, political belief, economic or social condition" (preamble). "Governments," according to the constitution, "have a responsibility for the health of their peoples which can be fulfilled only by the provision of adequate health and social measures" (preamble). The relatively small budget, which had risen by the mid-1950s to more than $9,000,000, proved insignificant in comparison with the vastness of the field to be covered. It was spent in (1) giving direct help. (2) publishing information of world-wide significance and (3) organizing expert committees and international conferences to further knowledge of public health matters. Direct help was given in the form of expert guidance, with or without technical aid. In the main the help provided was designed to stimulate further activity. Assistance was given over a wide field; for example, in infant mortality, malaria or syphilis where these presented particular problems. Malaria, tuberculosis, venereal disease, maternal and child welfare, nutrition, environmental sanitation and mental health were given priority in the planning program.

Publications included a newsletter, the *Chronicle;* weekly, monthly and quarterly bulletins of vital statistics; a quarterly digest of health legislation; a quarterly *Bulletin,* the principal scientific periodical; and, in a "Technical Report Series," the findings of expert committees. Committees reported on malaria, tuberculosis, venereal diseases, school health, adoption, alcoholism and mental health among other matters. Many of the international conferences proved of exceptional value; for example. that on malaria held at Bangkok in Sept. 19j3, which 50 persons of 20 different Asian countries attended to pool their experience and to plan programs. An important function of the annual meeting of the assembly was to hold technical discussions on outstanding public health problems, experts in different fields of work presenting their views to the delegates. The World Health organization made a great beginning. The objective of health for the whole world, as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity," still lies far ahead.

PUBLIC HOUSE, in its general English acceptation. a house in respect of which a licence has been obtained for the consumption of intoxicating liquors. Public houses are frequently distinguished as "tied" and "free." A tied house is one rented from a person or firm from whom the tenant is compelled to purchase liquors or other commodities to be consumed therein. A free house has no such covenant.

(*See* LIQUOR LAWS AND LIQUOR CONTROL; PROHIBITION; TEMPERANCE.)

PUBLIC OPINION. There has been little agreement among political scientists, sociologists and social psychologists on the exact meaning of public opinion. The term has been loosely used. sometimes in reference to widespread beliefs, climate of opinion. consensus, the mores and the more settled convictions of a group; at times, to the process of developing opinions, as distinguished from the product; elsewhere to statements that are the result of a reasoned, logical process, as contrasted with those which have been arrived at by illogical means.

A people or group in essential agreement has little to discuss except the sporadic individual variations from the norm. In such a situation, knowledge is limited to the common traditions of the folk, the happenings of the immediate area and the occasional infiltration of alien lore. Hence, there is little public opinion. An opinion is some expression on a controversial point, and a public opinion is that which is formulated in any group of whatever size. This is a logical delineation of public opinion, though not a definition agreed upon by all scholars. A public opinion includes the expressed opinions of all the members of a public. The expression of the majority and also of the minorities constitutes the public opinion. If the differences are so great and persistent that the minorities will not acquiesce in functioning with the majority, then there is no one public—there are several separate publics.

The 19th-century social theorists quite generally included both the materials on which consensus existed and also the controversial items as part of the general content of public opinion. A. V. Dicey wrote of public opinion as a body of convictions, beliefs and prejudices, as well as of what he called crosscurrents due to controversy. But consensus and opinion and proof, fact and opinion may be logically distinguished. Plato confined opinion to that which is subject to change.

Nineteenth-century commentators stressed the rationality of the opinion process; those of the 20th century do not. In 1828. W. A. Mackinnon declared, "Public opinion may be said to be that sentiment on any given subject which is entertained by the best informed, most intelligent, and most moral persons in the community, which is gradually spread and adopted by nearly all persons of any education or proper feeling in a civilized state." Later, A. L. Lowell wrote that, "An opinion may be defined as the acceptance of one among two or more inconsistent views which are capable of being accepted by the rational mind as true" (A. L. Lowell, *Public Opinion in War and Peace,* Harvard University Press, Cambridge, Mass., 1923). After 1900 the developing science of social psychology increasingly emphasized nonrational factors involved in the opinion process; and the manipulative techniques of the practitioners of publicity, advertising and propaganda further eroded faith in rationality. Political democracy, however, holds to the principle that the opinions of some men are based on reason and that it is possible to bring popular judgments to positions that are rationally defensible.

There are relatively stable beliefs which, at any given time; are not involved in the opinion process. A state of agreement following an opinion controversy is a consensus. Publics reach consensus on ethical. political and economic issues. Even large publics may be in substantial agreement. There is consensus of the type that hlontesquieu designated the *esprit général,* that Rousseau spoke of as the *volonté générale* and that the English theorists called "public will." Wilhelm Bauer wrote of organic opinion as the relatively fixed views. aside from the current transient opinions. But one may consider that public opinion deals with those topics which are controversial and discussible within the publics. and not with those aspects of mind-life which are comparatively fixed.

History.—Plato denied the value of any general public opinion. In the main, Roman authors had little respect for mass opinion. It was not until the late 18th century that Alcuin's statement to Charlemagne, *Vox populi, vox Dei* ("The voice of the people is the voice of God"), was quoted approvingly by any substantial group of political theorists. In France. Rousseau and later Necker gave approbation to public opinions and frequently used the term *opinion publique.* In England. in the writings of Jeremy Bentham there was insistence on the significance of public opinion as a basic social control on the excesses of misrule and as a basis for the democratic state.

In the ancient civilizations, public opinion played some part, but the publics were limited in number and size, the mechanisms for expression of opinion were rudimentary and communication was limited. Among the Greeks, public opinion developed to an extent unequaled until modern times. but the publics were the approximately one-third of the adults who were free citizens. Among these. argumentative conversation developed and the art of dialectics was codified. The urban culture and wide-ranging conquests of Rome, the latter of which provided information about many peoples with their values. religions, economic and political systems, gave increased scope for the opinion process. There was a growing emphasis upon news: hence the professional newsmongers and. in the later periods. the publications of the *Acta Diurna.* There was much to discuss, the culture was dynamic, the opinion process was stimulated and the Romans came to speak of the *vox populi.*

Through the middle ages. with diverse, scattered, small groups and agrarian communities and with cultures blanketed under a common religious ideology oriented toward revelation and the supernatural. there could be little of dynamic popular opinion. Rather. there were consensus and traditional mores—popular acceptance of the forms of government and submission to the religious hierarchy, not the support of popular opinion.

The opinion process was vivified when the Reformation questioned clerical authority and emphasized the individual. Arts, letters and science began to cast off the bonds of authoritarian revelation. Public opinion began to develop as larger groups became concerned with religious issues. political systems, relative values and with ideologies in general and the new means of communication, printing. coupled with a slowly growing literacy, distributed the ideas. The enlightenment of the 17th and 18th centuries marked a further turning from the authority of divine revelation to the authority of reason and human understanding. When "natural reason" was posited. then individual opinions became important, and the theorists turned to an examination of the opinion process.

Modern **Public** Opinion.—It is evident that the opinions of large publics became increasingly important during the 20th century. Economic groups depended upon the convincing of large publics by publicity and advertising. Through publicity agents, notable personages attempted to create their own legends in the minds of the general public. Commercial advertising became a partial science and the arts of publicity and propaganda were cultivated. The struggle for power and the control of opinion was conducted by interest groups implemented with the newer means of communication. Authoritarian states meticulously organized propaganda bureaus. while democracies were reluctantly drawn into political and cultural publicity. The problem became one of values. Was the objective the unity of mass opinion for the furtherance of the purposes of the state and of private interest groups? Or was the pre-eminent value the integrity of the individual's psychological experience? For both objectives the modern facilities of press. radio and television provided the channels. Opinions were solicited and expressed upon the widest variety of controversial topics ever presented simultaneously to large publics on matters of morals. religion. education. the details of government. the choice of consumers' goods and the administration of justice. Advertisers of consumers' goods, politicians and representatives of interest groups clamored for attention.

Measurement and Polling.—In the democracies, the many interest groups attempting to mold opinion desired an effective check on their results. The multiplying numbers of publicity agents. advertisers and propagandists wished for instruments to measure opinion. Though there had long been those who sought to discover public opinion by means of interviews and straw votes. it was not until the emergence of the public opinion polls in the mid-1930s that systematic representative sampling of large publics occurred. Two fundamental problems were involved in the measurement of public opinion:

1. Developing tests sufficiently comprehensive to include at least the more typical opinion positions of most of the individuals of a public. Such tests were conducted by interviews, questionnaires. observations of behaviour, "yes"-"no"-type questions, multiple-choice tests. rating and ranking tests and attitude scales, such as those of L. L. Thurstone and Louis Guttman. Motivation research testing for advertising and marketing purposes utilized word tests, picture and cartoon tests. thematic apperception pictures and Rorschach tests (*see* PSYCHOLOGICAL TESTS AND MEASUREMENTS).

2. Developing adequate methods to report on the opinions of large publics. numbering millions of individuals. by means of the smallest possible representative sample. The representative sampling procedure in public opinion surveying is called polling, and early polls on candidates and issues were referred to as straw polls. The pioneer commercial pollsters, or pollers, in the United States were Elmo Roper and Paul T. Cherington, who established the *Fortune* survey, George H. Gallup. originator of the American Institute of Public Opinion, and Archibald Crossley who originated the Crossley poll. They used polling in an attempt to predict the results of the national elections of 1936. The pioneer pollers had had previous experience as market research men. In addition to the commercial pollers, various university-sponsored polling organizations, some polls maintained by newspapers, and a few by governmental agencies, both state and national, were established. Similar polling organizations were later set up in more than a score of other countries.

Sampling.—In public opinion measurement, the objective is the selection and polling of a representative sample of the group which constitutes the public under consideration. The public selected for sampling might be the adult inhabitants of a town, the lawyers of the state of Illinois, the population of the United States or any other of the multithousands of publics. Samples used for the entire population of the United States range from small samples of possibly 2.500 to large samples of 10,000. After the persons to be interviewed are selected (the sample) from the public under consideration (the "universe"). they are questioned by interviewers from the field staff of the polling organization.

Before the use of specially selected samples (made representative by stratified and area-probability sampling), polls were conducted by ballots printed in newspapers or magazines. which could be clipped and returned, by ballots left in stores, by interviews among crowds and on the streets and by mailed ballots sent to address lists variously obtained. In 1936 the *Literary Digest* mailed over 10,000,000 ballots. received back 2,376,523, and incorrectly predicted the 1936 national election by understating the vote for Pres. Franklin D. Roosevelt by 19.3%. Large numbers alone do not assure representativeness of the sample.

More scientific polling stressed the selection of representative samples of publics. Prior to 1952, most pollers used chiefly the quota sampling methods in which the sample was a small-scale model of the larger universe. For example, a sample of 10,000 individuals to represent the entire voting population of the United

States would be selected. The sample would be based on appropriate quotas in proportion to the frequencies in the general population of individuals by age, sex! economic position, community size, past party affiliation and sometimes a few other criteria. These were the strata. The interviewer would then seek for individuals who would fit the requirements of his assigned interviews. Such stratified sampling permits tailoring the sample to those in the population who are expected to be more significantly involved in the particular opinion topic than the generality. This is an advantage. Moreover, stratified sampling can be carried on in smaller geographic areas than area sampling and is, therefore, much cheaper. Also, it is not necessary to call back again and again to interview the person at a particular address as is true of area sampling. But an objection to the method was that it depended upon the often inexpert judgment of the interviewer in selecting the particular individual to be interviewed and also that the poller could not always be certain as to the frequency and significance of the various factors used as the strata.

Probability, or random, sampling. on the other hand, a more recent and less tested procedure, aimed to choose the sample in such a way that theoretically every individual in the universe would have an equal chance to be included in the sample. Such sampling originated from making selections by random methods from finite, discrete objects. Applied to populations, it would mean selecting every *n*th person from the total population as recorded in lists of names or other complete censuses. In polling practice the selection is generally made in terms of location of the individuals in space. From the 3,000 counties of the United States a sample would be drawn; from the counties selected, a sample of rural-urban population drawn; and within these areas, households and individuals would be systematically selected. Area sampling is not based on assignment of quotas, thus eliminating interviewer judgment and possible bias. In area sampling, certain areas (block, section, ward divisions of city or town, section, township or other area of county, county or other division of state) are assigned to the interviewer. Within these areas he interviews every nth individual or member of a family located at an assigned position (the second house from the northeast corner of a block, etc.). The area units are selected randomly in various ways. Due to travel expenses, time consumption for the interviewer in proceeding from one interview to another remote interview and other costs, area sampling is very much more expensive than quota sampling.

The 1944 area sampling procedures of the U.S. census bureau provided the first serious use of area sampling. In 1952 area sampling was first seriously used by commercial pollers to supplement quota sampling in the election of that year. Subsequently it was increasingly used by pollers.

Criticism of Opinion Polling Methods.—Possibilities of error exist at every stage of polling. Sample selection, question selection and formulation, the interview with its possible misunderstandings, the coding and interpretation of answers require experienced, skillful and honest pollers. Prophecy as to future opinion trends, which is involved in election predictions, is an art of a still higher order.

Some political theorists, congressional investigating committees and social scientists object to widespread use of public opinion polls for such reasons as their alleged employment to force premature executive and legislative decisions, the possibly adverse implications for political parties of election predictions. supposed methodological errors, and an inferred desire for vague, unfathomable public mind-life in preference to attempted exactitudes. The partial failures of the pollers on some election predictions have elated some political theorists who really disapproved of the polls on grounds other than their accuracy (for example, the numerous polls might encourage popular, rather than representative, democracy); have aroused partisan politicians who were fearful of the polls' influence on voters; have given some social scientists an opportunity to criticize polling methods; and have delighted many aesthetes, comedians and competing prophets. Others vaguely resent public opinion polls as another threat to privacy in an age in which privacy is already grievously assaulted. The polls may, however, be defended as reasonably accurate reporting on both the significant, matured opinions and the ephemeral sentiments of large publics.

PUBLIC RELATIONS, the activities connected with interpreting and improving the relationships of an organization or an individual with the public. The persons in charge of these activities are usually known as public relations directors, public relations consultants, etc.

Professional associations in the public relations field have maintained that the use of titles of this kind is justified only in the case of those who operate on a policy-making level, so that they have a voice not only in securing publicity for the activities of their employers, but also in making those activities conform to the public interest. However, the term has been widely used by publicity men without regard to this distinction.

The first industries to make general use of the term public relations were U.S. railways and public utilities. For example, the *Electric Railway Journal* for Dec. 13, 1913, said in an editorial that "the subject of the public relations of public utility companies occupied almost exclusively the attention of three important conferences this week in New York." Earlier uses of the term include an address by Dorman B. Eaton on "The Public Relations and Duties of the Legal Profession" to the graduating class of the Yale Law school in 1882. Thomas Jefferson used the term in his address to the 10th congress in 1807, but in the sense of foreign relations.

Forerunners of Public Relations.—While the term public relations did not come into general use until after World War I, many of its basic activities are as old as history. Primitive priests and medicine men performed public relations functions on behalf of their tribes when, in order to eliminate customs that were found to endanger the health or safety of the tribe, they built bodies of legend to give sanctions to their prohibitions.

In the 5th century B.C., the Greek poet Simonides put his muse at the service of publicity, selling songs of praise. This practice seems to have been generally considered in bad taste. However, even the fastidious Pindar accepted money from those he glorified in his odes. Among his patrons were the great merchant princes of Aegina. Plato in his *Republic* attacked poets as special pleaders, and advocated the suppression of all except those hired by the state to serve its welfare.

The Rosetta stone is an example of the governmental public relations work of the priests of ancient Egypt. The inscription, made in accordance with a decree passed by a general synod of priests in 196 B.C., informs the reader that the boy king Ptolemy V has been generous and just, and his policies conducive to prosperity.

In 60 B.C., shortly after he had become consul, Julius Caesar decreed that the acts of the Roman senate should be publicized. A bulletin, the *Acta Diurna,* was posted, and also issued in manuscript form. This publication announced that Caesar had been offered the crown, and had refused it.

Augustus Caesar, foreshadowing a feature of Benito Mussolini's policy ordered publicity gixen in the *Acta Diurna* to citizens who were rearing large families.

Gaius Maecenas, friend and adviser of Augustus, helped direct the genius of Virgil and Horace into channels that greatly enhanced the public prestige of the emperor. John Buchan, in his biography *Augustus* (Houghton Mifflin Co., 1937), sums up the role of Maecenas: "It was his task to feel the pulse of public opinion and to advise the blunter intelligence of the Princeps, and not less to create opinion for his day and for all time."

Under the influence of his friend and patron Maecenas, Horace portrayed Augustus as a symbol of enlightenment and peace. Similarly, Virgil in the *Aeneid* bolstered the pride of citizens by telling that the greatness of Rome had been foretold from the earliest days. In this feat of retroactive prophesy, he included the statement that Rome's ultimate grandeur was to be achieved by the men of the Julian house—the family of Augustus.

In the dark ages. wandering minstrels were made welcome at great castler largely because of the influence on public opinion they were able to exert on behalf of their patrons. The Anglo-Saxon scop or bard had become a respected personage by the 5th century.

The mediaeval guilds performed a public relations function for their members by maintaining the standards and dignity of their crafts. However, in contrast to modern trade associations, which publicize their methods, the guilds emphasized the "mysteries" of their vocations. Thus business became wrapped in a tradition of secrecy nhich tended to leave it defenseless against its critics.

A powerful handicap to the mediaeval businessman was the doctrine of St. John Chrysostom that "whoever buys a thing in order to make a profit selling it. whole and unchanged, is the trader who is cast out of God's temple." St. Thomas Aquinas amended this doctrine to permit a profit, but at a "just price" which involved a small margin.

In Augsburg, Ger.. the house of Fugger, extending its banking and trading interests internationally on a large scale in the early 16th century. was hampered by restrictive laws and adverse public opinion. Jakob Fugger took his problem to Konrad Peutinger, a humanist scholar and an adviser to Emperor Charles V. Peutinger, a great forerunner of the modern public relations man, wrote a series of essays on the moral and legal aspects of trade. He pointed out that merchants were frequently forced to sell their goods at a loss, and maintained that accordingly every trader should be free to get as high a price for his wares as they could command. He argued also against restrictions on monopolies and cartels. Largely because of Peutinger's activities, the Augsburg council voted to do away with restraints on business.

In England, up to the middle of the 18th century, when it became possible for writers to look to the public for their livelihood, it was not unusual for authors who lacked private patrons to be in the pay of political groups. Swift put his talent at the disposal of the Tories Prior and Addison of the Whigs. From 1731 to 1741, Walpole used nearly £50,000 of secret service funds for the pay of writers and printers

In France Racine and Molière were among the distinguished writers who supplemented their incomes by writing eulogies of royalty.

Napoleon Bonaparte made adroit use of opinion-moulding techniques throughout hia career. In 1793, when there was a general revolt by Southern federalists or counter-revolutionaries against the new constitution, Napoleon's regiment was among the units engaged in suppressing the uprising. Sent on a mission to Beaucaire. he wrote a pamphlet, *Souper de Beaucaire,* to prove that the rigours of the revolutionary government were mild compared to the aengeance that the *ancien régime* would exact if disunion opened the way for its return. The pamphlet brought the young officer to the approving notice of the Contention.

In 1796, placed in charge of the army of Italy, Napoleon drafted a proclamation to his unpaid. badly equipped soldiers that gave a dramatic lift to their morale. William Milligan Sloane. in *The Life of Napoleon Bonaparte,* says of the French entry into Milan: "No scene in the history of warfare was more theatrical. The pageant was arranged on the lines of a Roman triumph, and the distances so calculated that Bonaparte was the one impressive figure."[1]

Having used pomp as an effective publicity instrument, Napoleon now showed that he could do likewise with simplicity. On his return to France he dressed plainly, visited minor officials who would normally have been expected to make the overtures—and saw to it that the modesty of his conduct was reported in the official journal, *Le Moniteur universel.*

In colonial America the talent of Samuel Adams for wooing public opinion proved a great asset to the Revolutionary cause. Typical of his practical approach to such questions is the letter he drafted for the Committee of Correspondence on Dec. 16, 1773. "We inform you in great haste that every chest of tea on board the three ships in this town was destroyed the last evening," the letter begins, and continues: "without the least injury to the vessels or any other property."

Developments in 19th **and** 20th Centuries.—In the early 19th century, U.S. newspapers frequently granted the hospitality of their news columns to publicity stories in return for paid advertisements. Other papers, inadequately staffed, accepted contributions without too close a scrutiny as to the motives of the writers. Shortly after the Civil War. land promoters, railroads, politicians and financial groups were making systematic use of such opportunities.

In 1869 James McHenry, press representative of the Fisk-Gould financial group, obtained wide publication of material in their interest. Shortly after this. a number of business and political organizations installed publicity departments, under the name of "literary bureaus."

Promotion-minded businessmen realized that it was possible to create news events that the newspapers mould report as a matter of course. An outstanding instance of this occurred in 1892 when the manufacturers of "Sapolio" sent a 14-ft. sloop to Spain to participate in the 4th centennial of Columbus' voyage to America.

The technique of creating news events had already been brought to England by Thomas J. Lipton, who in 1881 arranged to have the world's biggest cheese manufactured in the United States, and created an effective fanfare of publicity when it reached his main store in Glasgow, Scot.

In the last decade of the 19th century and the first of the 20th, publicity men were multiplying in New York city. Almost all of them were former newspaper reporters. Knowing the ingredients of a lively newspaper story, some of them—particularly theatrical press agents—drew freely on their imaginations.

In 1909 the American Newspaper Publishers association, alarmed at the spread of press agentry, appointed a Committee on Free Publicity. One bulletin issued by it listed 757 "space grabbers."

However, most newspapers continued to use a substantial amount of material from publicity sources. A parallel situation occurred later in Britain. *Report on the British Press,* published by Political and Economic Planning in 1938, stated: "Some newspapers are very much opposed to accepting material from press agencies, and not long ago the Home and Southern Counties Newspaper Federation, representing nearly 300 newspapers, made a concerted attempt to eliminate it. Nevertheless, many of these newspapers continued to print such material, the news-value in them proving too strong a bait."

In both instances the attempted boycotts resulted in a more objective attitude toward publicity. In an article entitled "The Press Agent, His Rise and Decline," published in *Collier's* in 1911 (Crowell-Collier Publishing Co., New York, N.Y.), Will Irwin said: "No more may such as Channing Pollock trick the newspapers by having a popular actress develop a case of aphasia on the steps of the Eden Musee; no more may Toxen Worm draw column after column of space by strewing tanbark before the theatre to 'save the nerves' of an overstrung English star."

Irwin's epitaph for trickery was premature; many years later some of the old press agent devices were still in use, together with

[1]From *The Life of Napoleon Bonaparte,* vol. 1. Copyright, 1939, D. Appleton-Century Company, Inc. Reprinted by permission of Appleton-Century-Crofts, Inc.

such new ones as obtaining mention of clients in syndicated columns by attributing to them witty remarks invented or borrowed for the occasion. However, the article included a defense of the better type of press agent that might well stand as a vindication of his successor. the public relations man:

"A press agent, a special pleader it is true, but perhaps a fair one. helps wonderfully to mutual understanding. . . . The corporation head, associating only with his kind, may be as foolish as any man in misunderstanding the public. The press agent is always a graduate newspaperman. As such, he is an expert on public opinion. He can counsel against these unsympathetic follies; and often he does."

Leaders of business and finance had already begun to think along these lines. Until recently they had been opposed to any publicity except commercial puffs, and had strongly rebuffed newspapermen. The prominent banker George F. Baker told a reporter: "It's none of the public's business what I do." J. P. Morgan said to another "I owe the public nothing." William H. Vanderbilt, when pressed for a statement about reduction of train schedules on his railroad by a reporter who talked insistently of the public interest, exclaimed: "The public be damned!" Associated Press editor Melville E. Stone said in his memoirs that Vanderbilt's ire had been directed at the reporter rather than the public. However, great damage had been done.

The businessman's belief in his right to secrecy was an honest one. rooted in a tradition dating back to the mediaeval guilds. But it was dangerous to rest on real or supposed rights, in view of popular antagonism toward big business. This attitude was equally traditional; in fact, one of the motivations of the Boston Tea Party had been the fear that the British East India company would crush small merchants by selling directly to consumers.

A clash between the two traditions was forestalled for a long time by the availability of homestead lands in the west, which tended to mitigate causes of discontent. The drying up of this source of opportunity was accompanied by an epidemic of attacks on big business.

In 1886 there was a series of strikes, some marked by violence. Edward Bellamy's *Looking Backward, 2000–1887*, published in 1888, held out to a million readers the promise of a future utopia without the debasing effects of trade. In 1894 Henry D. Lloyd attacked the trusts in *Wealth Against Commonwealth*. In 1902 *McClure's Magazine* launched a series of articles indicting municipal politics and big business. Theodore Roosevelt gave the name of "muckraking" to this type of journalism. However, he had given encouragement to it by his rebuke to "malefactors of great wealth."

A series of harrying congressional investigations of big business accompanied the attacks. "We are passing through a reform —yea, a revolutionary period in business affairs," Henry Clews wrote in the *Annals* of the American Academy of Political and Social Science for July 1906. He called on banking and insurance interests to drop their policy of secrecy, which, he said, was "obviously in defiance of public sentiment."

Another development of 1906 was the appointment of Ivy L. Lee, a former newspaperman, as publicity adviser to a group of anthracite operators. The mine owners had stirred the anger of the press by their haughty attitude in labour disputes.' Soon after Lee's appointment it was announced that they would supply the press with all possible information.

Lee then sent to city editors a declaration of his policies, in which he said: "This is not a secret press bureau. All our work is done in the open. . . . If you think any of our matter ought properly to go to your business office, do not use it."

Retained by the Pennsylvania railroad the same year, Lee made information concerning accidents available to the press for the first time. In 1921 his firm issued its bulletin, previously called *Notes and Clippings*, under the title of *Public Relations*.

In 1923 Edward L. Bernays published *Crystallizing Public Opinion*. This book, describing publicity functions and techniques with an emphasis on social responsibility, did much to popularize the term public relations and to gain recognition for specialists in the field.

Meanwhile, men were being hired in the service of the federal government under such titles as "director of information," "editor" and "supervisor of information research." These provided a loop-hole in a congressional act of 1913, which forbade the spending for "publicity experts" of any funds not specifically designated by congress for that purpose.

In Britain, the Empire Marketing board began using large-scale publicity for the promotion of trade in 1924. *Report on the British Press* says of the Empire Marketing board that "before its demise in 1933 it had established the archetype of Government Public Relations Departments."

In Britain, as in the United States, appointment of public relations directors by government departments during World War II was the prelude to increased postwar emphasis on public relations. The British public relations journal *Persuasion* pointed out in its issue for the winter of 1949: "The war made a great difference to the relation between a local authority and its people. . . . When peace came, the climate for formalized public relations was good."

One indication of the greatly heightened interest in the United States was the fact that many colleges were adding courses in public relations to their curriculums. Boston university established the first school of public relations in 1947.

Philosophy of Public Relations.—A realistic view of the public relations field avoids over-idealization on the one hand, or a cynical view on the other.

The basic purposes of a public relations department are the establishment and maintenance of good will. It is obvious that the more the organization does to merit this good will, the easier the task of the public relations director will be. When he invites public attention to his company in connection with some attractive phase of its activities, he cannot be sure of limiting the interest of the press or public to that particular area. The efficient public relations executive therefore works forcefully for the elimination of policies that he believes to be open to criticism.

A typical illustration of this point occurred at a conference in which plans for the construction of a winter resort were being discussed. Business executives associated with the project started with the assumption that it would provide only high-priced accommodations, since inexpensive ones would be unprofitable. The public relations consultant argued that low-priced rooms and meals should be offered also, in view of the fact that the project was backed by a railroad. His view was that a public service corporation would be inviting antagonism if it were associated with an appearance of exclusiveness. This opinion prevailed.

Following is another example of enlightened self-interest in public relations, cited by Glenn and Denny Griswold in *Your Public Relations* (Modern Industry Books, 1948):

"Suspicion and resentment had existed for years between neighboring small towns and agriculture on the one hand and San Francisco and its business interests on the other. . . . Mr. Lundborg" (general manager of the San Francisco Chamber of Commerce) "organized a committee of 83 leading farmers and of businessmen whose enterprises depended on agriculture. They sponsored a program of doing things to help farmers instead of boasting about the city's virtues. First they enlisted the help of newspapers, radio stations and grocery store chains to help dispose of an apple crop so abundant that it threatened ruin to many farmers. Within two weeks the surplus was lifted, prices had been maintained and farmers began to see some good in city business."

A significant sidelight on this story is the fact that it involved the public relations policy with which chain stores were combating campaigns to tax them out of existence. The method of an earlier day would have been merely to fight propaganda with propaganda. In this instance, propaganda was one of the weapons employed; but it was given powerful assistance by an intensive effort to win good will through service. Helping farmers to dispose of surplus crops was part of that program.

The public relations director or consultant frequently needs a high degree of persuasiveness in order to gain a hearing for a long-range point of view in councils concerned with immediate commercial objectives. In order to be an efficient representative of his company he must also be a representative of the interests of its employees, of the local communities in which it has factories, of the retailers who distribute its wares, of the consumers who buy them. and of the public at large. It is not necessary for him to be an altruist in order to do this; he need only realize that it is easier to correct sources of irritation than to justify them.

Public relations consultants have stated that they could not have secured a serious hearing for some of their plans, involving immediate sacrifices for long-range objectives, if not for the respect engendered by their extremely high fees. On the other hand there have been many occasions, before as well as after the term public relations came into use, when businessmen have shown an innate talent in this area. For example, the suggestion box system. which later became a feature of thousands of public relations programs for maintaining employee morale, was used by the William Denny Shipbuilding company of Dumbarton, Scot., in 1880. Denny, after he had given many awards for ideas submitted by employees, said: "The scheme has the effect of making the workmen of all departments into active thinking and planning beings instead of mere flesh and blood machines."

Another Scotsman who showed a keen insight into some phases of public relations was Andrew Carnegie. During his boyhood, when he was an employee of the Pennsylvania railroad, Carnegie submitted to the *Pittsburgh Journal* an article on "the attitude of the city toward the Pennsylvania Railroad Co." In his memoirs Carnegie tells that this article brought him to the notice of the counsel for the railroad. Also, though he shared the weaknesses of industrialists of his era in other ways, he gave a building rent-free for the use of a co-operative store for employees.

Nevertheless, though early parallels can be found for every basic phase of public relations, as an organized activity it represents a major change in the philosophy of business—the recognition of the ultimate authority of public opinion. At the halfway mark of the 20th century, thousands of top-ranking business executives were devoting a major share of their time and planning to an activity that had been trivial or nonexistent in the programs of their companies a generation before.

Publicity as a Public Relations Tool.—When a policy has been set and the public relations representative is seeking publicity for it in news media, he must put his reliance not on techniques of persuasion but on his judgment as to what constitutes an acceptable story.

A story with intrinsic news value, simply and clearly presented, usually receives an objective hearing. A statement made in 1926 by Louis Wiley, business manager of the *New York Times,* is representative of a policy that gained wide acceptance with mass media: "If so-called publicity is legitimate news, it should be printed for the readers of the newspaper regardless of whether it benefits private interests or not. If it is not legitimate news, then it should not be printed, regardless of who may be pleased to have it appear."

In both large and small organizations, public relations departments are usually watchful for such publicity opportunities as anniversaries that may be of local or general interest, public events in which it would be logical for the president or some key official of the company to participate, incidents involving celebrities, and developments susceptible to treatment in text or photography as human-interest stories. In the handling of adverse news, such as that of accidents, experience indicates that the harm is minimized by candid answers to inquiries.

The policy on publicity expressed by Louis Wiley represented an important step forward for the public relations worker; but this did not mean that he was on an equal footing in a newspaper office with the paper's own reporters. The news value of a story had to be such as to be clearly and quickly apparent to the editor, who was constantly being flooded with copy by his own staff and the wire services.

In some cases the solution to this problem was found in the creation of news events—a practice that was not new but which was now followed with much greater respect for the judgment of editors. It became an important factor in the public relations programs of trade groups. For example, a group of soap manufacturers, anxious to combat the statement by some cosmeticians that soap was bad for the skin, turned to a public relations consultant, who advised formation of a cleanliness institute. This was not a dummy organization but one that conducted an actual cleanliness campaign, welcomed in public schools. It received widespread publicity. On another occasion a public relations counsel initiated soap sculpture contests on behalf of the industry. This type of oblique publicity was found to be of great value.

Similarly, when the National Cotton council was faced with the competition of paper bags with cotton ones as containers for feed, its public relations department sent emissaries to show farm wives how they could convert cotton feed bags into attractive dresses. Photography editors of newspapers and magazines were attracted by the novelty of the idea, which proved an effective stimulant for the sale of cotton.

The attitude of many editors toward this type of public relations was summed up by Stanley Walker in *City Editor:* "Once Irene Castle cut her hair, and her photograph was attractive. Barber shops, beauty parlors, hairnet manufacturers, the comb industry and the hat business were affected for better or worse. Businessmen are at the mercy of a million such whims. It is better for them to attempt some intelligent direction of these whims, so that they will know what to expect. Otherwise some morning they may find themselves ruined." [1]

A classic example of the unexplainable whims mentioned by Walker is chronicled by J. Henry Harper in *The House of Harper.* Discussing the publication of the novel *Lorna Doone,* Harper tells that at first this novel attracted little attention. Later, when the marriage of the marquess of Lorne (who had no connection with the book beyond the accidental similarity of his name) was headlined in the press, the novel was somehow associated in the public mind with this glamorous event, and its sales rocketed.

Publicity, which is capable of this freakish power, is a versatile instrument in the hands of a resourceful man or woman with newspaper experience. It proved a major factor in removing a once widespread prejudice against the game of billiards; it helped greatly to popularize bowling and other sports; and it has contributed to the making of fashions and literary and theatrical reputations.

Given an assignment that has a reasonable justification for its existence, a publicity man has many avenues of approach. A favourite one is to interest celebrities in the project, and use their names as a springboard. Another is to devise contrasts of a striking nature.

An illustration of a combination of the two methods occurred in New York city in the early 1920s, when a publicity man, admiring the work of an unknown artist, volunteered to bring it to public notice. A private exhibition was arranged for the artist's work, which included a series of panels depicting a boxing match. Several well-known fighters were then induced to come to a tea at which the pictures were shown. A Sunday newspaper devoted a full page to photographs of the artistic-pugilistic tea.

Publicity of this harmlessly playful type survived as an effective aid to some public relations programs. An instance of this was the formation, on behalf of doughnut manufacturers, of a mock-serious society known as the National Dunking association.

Perhaps the major significance of this type of publicity is that it permits imagination, judgment and energy to do the work of money. It is capable of putting a low-budget public relations office, representing a small business, a college, a church group, or a philanthropy, on a par with the most powerful organization.

Public Relations Advertising.—As some big corporations became increasingly aware of the importance of courting public opinion, they supplemented their publicity efforts with a new type of advertising—one that was not designed to gain business

[1] From *City Editor*, copyright 1934 by Stanley Walker. Published by J. B. Lippincott Company.

but to clarify their policies and improve their relationships with their employees, the local community and the public at large.

The Bell Telephone company was active in this field as early as 1908. After World War II Bell Telephone, unable to supply the demand for new installations, published a series of advertisements explaining why delays were unavoidable. The flood of complaints subsided to a point below the prewar average.

Several public opinion surveys revealed that the average American believed the profit margins of industry to be excessive. However, the popular idea of what constituted a fair percentage of profit proved to be substantially higher than the percentages that industry was actually earning. This was the basis for effective educational campaigns.

In public relations advertising by management in connection with labour disputes, a temperate policy, anticipating the day when the strike will be settled, has been found to be a wise one. During the strike at the General Electric plant in Bridgeport, Conn., in 1946, the company presented the view that wages must be geared to production, but avoided strident controversy. One advertisement was devoted to announcing that the strikers' insurance under the company's employee plan was being kept in force.

Industrial Relations.— Winning the good will of its employees is one of the major objectives of every industrial organization. The morale of a factory's workers affects many economic factors. Among these are the quantity and quality of production; the company's position in competing in a tight labour market for the services of skilled workers; its popularity or unpopularity in the local community, which in turn affects the treatment it receives from the municipal administration; and its reputation through the country as a whole.

No public relations technique can offset substandard wages or unsatisfactory working conditions. However, even a policy that is intended to be equitable may run into trouble if administered in impersonal, bureaucratic fashion. Accordingly, an efficient public relations director makes a strong effort to keep management sensitive to human values. Employees are informed of new developments promptly, before there has been an opportunity for these to be distorted by rumours. They are encouraged to submit complaints as well as suggestions. Advance proofs of institutional advertising are posted on factory bulletin boards. Facts on the company's earnings and prospects are made available. In some organizations, regular "job holders' meetings," similar to stockholders' meetings, are held. Issuance of publications for employees has become a standard practice.

An illustration of the scope of this work in a large organization was provided by the program of the International Harvester company. *Employee Relations*, a report by E. M. Claypool in *Public Relations Handbook*, edited by Philip Lesly, (copyright 1950 by Prentice-Hall, Inc.) states: "Organization of the Harvester employee relations program is divided into six main groups: labor relations, personnel, wage administration, salary administration, education and training, and group insurance. The activities of these groups are coordinated by a vice-president in charge of industrial relations who works in close harmony with the director of public relations. They use such industrial relations techniques as apprentice courses, student training, job training, supervisory training, vacations, collective bargaining, employees' benefit associations, group life insurance, hospital and surgical benefits, accident compensation, and scientific personnel selection and placement.

"An outstanding feature of the Harvester educational program is that any group of reasonable size may arrange for a course in any desired subject, whether the course is related to their present jobs or not. This policy encourages employees to develop hobbies and to broaden their intellectual horizons.

". . . Each plant has its own publication that acquaints employees with persons, departments, and activities removed from their immediate vicinity as well as those with whom they work."

Scope of Public Relations Departments.— Almost every form of the printed and spoken word, and of photography, is used in public relations work. At mid-20th century, many public relations departments included the following activities in their routine responsibilities: issuing news releases to newspapers, radio stations, trade journals and popular magazines; arranging press conferences; answering queries from the press and public; preparing text and illustrative matter for public relations advertising, pamphlets, employee magazines, manuals for the training of new employees, reports to stockholders and form letters; planning documentary motion pictures, recorded television programs, film strips, lantern slides, charts and recorded talks; planning and publicizing exhibitions and "open house" days at factories; and planning research surveys for gauging the opinions of employees, customers, or the general public. In addition, in cases where the product of the company is an expensive one, such as an automobile, the public relations department may have the duty of preparing a magazine for free distribution to listed customers. Some corporations issue special magazines for their stockholders. Public relations directors of trade organizations, long-established companies, and various institutions also have arranged for the publication of books, sometimes by well-known writers, telling the history of the organization or industry. These books are usually placed on sale through normal channels, but often are subsidized to assure the publisher against loss.

Some organizations employ not only a public relations director, with a staff under his supervision, but also a public relations consultant, to provide an outside point of view on questions of policy, or the public relations department of an advertising agency.

Most public relations work involves a combination of logical and psychological methods. Experience has repeatedly proved that exaggeration and distortion defeat their own purpose; but often it is possible to switch from an unpopular concept, expressed in a standardized term, to a popular, or at least an acceptable one, without doing violence to truth. Walter Lippmann, using the word stereotypes to describe these concepts of the mass mind in *Public Opinion*, influenced many public relations experts. An illustration of this type of thinking is the substitution in public relations advertising by labour unions of the term "union security" for "closed shop." Another is the use by manufacturers of "billiards" for "pool," which had taken on the connotations of shabby poolrooms.

Much specialization has developed in public relations work in areas such as banking, agriculture, education, philanthropy, etc. Also, many public relations executives specialize in the use of various media, such as audiovisual materials and stockholder reports.

PUBLIC SCHOOLS. In the United States this term is used to describe free, tax-supported, public controlled and directed, nonsectarian schools. The term public school in England includes not only the schools of ancient foundation such as Eton, Harrow and Winchester, but also schools of comparatively recent creation such as Clifton, Cheltenham and Marlborough. As forming part of the secondary school system of England (see SECONDARY EDUCATION) they are included in the official statistics as non-aided schools.

PUBLIC UTILITIES, a designation for a special grouping of industries legally "affected with a public interest" and conducted under government regulation. They occupy an intermediate position between state services or public works. which are administered as public functions and hence supported by taxation, and the variety of business undertakings usually included under the heading of competitive private enterprise. Public utilities, properly so-called, need not be privately owned. In almost every country a varying number of them are owned and operated by the state. But these publicly managed enterprises, instead of looking to the state for financial support, sell their services to the general public. Both publicly and privately owned utilities sell their services at prices which are not fixed in the open market but are governmentally fixed. This aspect is the most important part of the process known as public-utility regulation.

Although economic and technical evolution is continually changing the character of these industries, besides creating new ones, public utilities may be classified according to the generalized function which they perform in economic life. The main public services supplied through public utilities are: (1) transportation (common carriers), including railroad. highway and local transit, oil and gas pipelines. waterways and air lines; (2) communications —telephone. telegraph, radio and television; (3) power, heat and light—gas and electric; (4) community facilities for water, sanitation and irrigation.

HISTORICAL SURVEY

Public utilities are closely associated with developing civilization, supplying wants so fundamental for communal living that government has at all times subjected them to some measure of control. With the groath of trade in ancient empires facilities providing transport and communication were set up. The governmentally maintained highway system of the Roman empire and its many aqueduct systems are celebrated ancient public works. The need of some system of public communication was so great that even the postal system has its ancient parallel. In the more populous ancient cities. systems of sanitation also became a necessity. With these needs came the recognition that services used collectively should be supplied by the state. Public utilities thus began as state functions. By the middle ages most of the ancient public utilities had declined or virtually disappeared. By slow stages, upon the manors and in the mediaeval cities, these public facilities again appeared. Of great importance in British and American legal history is the fact that out of the economic and legal relationships of feudalism there arose the concept of a "public calling" upon which is based the modern policy of public-utility regulation.

The modern national state gradually supplanted the elements of the feudal system of social control. The expanding domestic system of manufacture was displacing the guild and manorial system of production; foreign trade was growing. National systems of transport involving highways and canals mere undertaken and the regulation of utilities became national rather than local.

Effects of the Industrial Revolution. — The greatest impetus in the expansion of public utilities came with the industrial revolution. Under the stimulus of the factory system cities grew as never before, creating a municipal need of systems of water supply, sanitation, transport, communication, illumination and power. But the philosophy of *laissez faire* was not fertile ground for extending public functions. While the rapid industrial changes intensified needs, the tendency was to give greater scope to private enterprise.

However, the evils of a system which left the supply of basic economic wants to private industry insufficiently regulated by government became too flagrant to be overlooked. Beginning about 1840 the revolt against *laissez faire* doctrines caused an enlargement of the scope of governmental action. The older public utility services were continued for the most part as public enterprises, while the newer services were supplied by private initiative under some form of public supervision and assistance. Thus emerged the modern notion of a public utility, distinct from strictly governmental services and strictly private business.

Need for New Utilities. — The beginning of the modern postal system dates back to the 15th century. In the 18th century England was covered with improved roads built by public authority or by private turnpike companies. The first canal in a new era of canal building was completed in 1761. The first steam railroad was built in 1825, and the first regular steamboat began operation in 1812. The railroads lost a promising source of freight with the development in the 1860s of pipelines for transporting petroleum. The pipeline network for oil was supplemented by pipelines for natural gas after the turn of the century. With the advent of the automobile, highway systems were reorganized on an unprecedented scale. The motorbus and motor truck made use of this development and soon were rapidly cutting into the short-distance traffic of steam railroads. Following World War I railroad traffic was further challenged by the use of the aeroplane for regularly scheduled postal service, passenger and freight traffic. The British introduced regularly scheduled service from London to Paris in 1919.

After 1850 systems of rapid world-wide communication emerged as the telegraph and telephone were perfected. (*See* TELEGRAPH; TELEPHONE.) At the close of the 19th century wireless telegraphy emerged. After 1915 radiotelephony was added to the means of communication developed through public utilities.

Radiobroadcasting systems were introduced both in Europe and in the United States in the 1920s. (*See* BROADCASTING.) The International Broadcasting union, formed in 1925, paved the way to a uniform allocation of wave lengths. The introduction of regular television broadcasting may be credited to the British Broadcasting corporation which inaugurated a daily schedule in Nov. 1936. Commercial television in the United States was started by the National Broadcasting corporation in July 1941. (*See* TELEVISION.)

In the field of municipal public utilities local transportation was supplied to British and American cities by fleets of omnibuses in the 1820s. The horsecar was introduced in the 1830s. Artificial gas for illumination was introduced commercially in London in 1813 and was in wide use by 1840. A new development in water-supply systems was introduced with the completion of the river reservoir which channelled water to London from springs in Hertfordshire. Boston. Mass., in 1652 installed the first modern central water-supply system of the gravity type in the United States. Central water-supply systems became general in large cities by 1820. The systematic treatment of sanitation services as a municipal public utility dates from the 1870s both in England and in the United States.

New public utilities centring in cities developed out of the industrial applications of electric power. In 1882 the first central station for electric lighting began operation in the United States. By 1885 electric power was applied to street railways. The first hydroelectric plant began operation in 1882, the precursor of a new movement in power production.

In this historical survey it is important to note that public utilities were not definitely segregated from public functions until the *laissez faire* philosophy of the 18th century restricted the scope of governmental activity and created institutions and processes so that the supplying of the public needs could be left to private initiative. Public utilities. although privately owned, were subjected to governmental regulation. The term socialization has been chosen to describe this latest phase of utility development because it implies that government may actively promote these enterprises through public ownership or arrive at the same result by creating private agencies and controlling them through well-conceived policies of regulation.

ECONOMIC CHARACTERISTICS

Developments in the engineering arts bring changes in economic organization. For instance: lighting of the home was transformed first from a self-sufficient household industry (as the making of candles) to a commercial competitive industry (the supply of candles, lamps, whale oil and petroleum), and then to monopolistic industry (electric lighting), where central sources of supply satisfy all demands. Perhaps the most significant economic conclusion founded upon these changes is that the social value of public-utility services is increased and the economic cost of rendering them is reduced by a consolidation of enterprises. The individual user of water in urban centres no longer had to depend for his supply upon his own well, nor did he have to buy from one of several competing sources. He resorted to a single common source of supply along with other users. This was found to be more convenient, economical and, indeed, the only practical solution. But this process of integration of supply was a long process. In some public service industries it was not completely realized. The tendency toward monopoly, however, whether the result of a competitive struggle or brought about by legislation, became a fundamental characteristic of public utility business.

Every public utility must be in possession of the natural resource upon v-hich that industry is based. A gas or electric company must have possession of sites for the location of its works; a transportation company must have rights of way and terminal sites. These properties must have strategic locations. Limitation in the choice of this agent of production tends to make the cost of acquiring or leasing these facilities greater than it would be if the industry had a wider range of choice. Furthermore, utilities must make allowances in advance for probable increase in the required capacity. For these reasons utilities are provided with the governmental power of eminent domain which makes possible the compulsory sale of private property. Thus the law recognizes that, socially considered, these properties are being put to the highest uses of which they are capable.

Fixed Capital Characteristics. — The typical public utility—railroad. telephone system or electric power plant — serves an area of the economy where duplication of facilities is regarded as economic waste. Public-utility facilities entail a much higher investment of fixed capital in relation to sales or receipts than is required for industry in general. The liquid capital solicited irom investors is converted into durable, specialized structures and equipment. The facilities must be designed to insure the regular and adequate supply of the utility for which the franchise is granted. At the same time the service must be produced and sold on terms that will provide a return on the invested capital sufficient to permit adequate maintenance and replacement, and to attract additional investment funds for expanding demand. This reconciliation of the interests of the enterprise with the public interest is a basic objective of government supervision of public utilities.

The expansion of metropolitan areas and the interdependence of communities in the use of joint facilities are reflected in the enlarged scope of public-utility operations. These developments have accompanied technological improvements in which fuller advantage is taken of the economies of size. This is exemplified in the utilities supplying power, where economical operation is secured by combining power sources into so-called super power systems in which the power stations are interconnected by transmission lines. The reciprocal sale of power from one system to another is thus possible when the common reserve serves a large area. The co-operative action insures the utilization of surplus power, safeguards the service from interruptions, and secures the advantages of full use of investment by building up the diversity of use.

Availability of Utility Services.—All public utilities must stand ready to supply their services on demand, and utilities may be divided into two classes according to the method by which they meet this situation. The first class, or service type, comprises the utilities that cannot store their services but must adjust to demand variations by maintaining productive capacity equivalent to peak demand, with a resulting tendency toward increased cost of operation. This class includes electric, telephone, telegraph and transportation utilities, as well as the postal service. The second class, the product type, consists of utilities that may be stored, so that output can be uniform and excess production in periods of slack demand set aside for use when customer requirements are high. The ability to limit producing capacity to the equivalent of average demand tends to lower costs, but storage requirements are an added cost item.

The additional cost of being ready to meet all demands without delay must be taken into account in determining the conditions under which the public utility may operate and the rates it must charge to provide reasonable earnings. The problem is to balance the interests of the management and investors with the interest of the community in obtaining the most efficient service.

SOCIAL CONTROL OF PUBLIC UTILITIES

Public service enterprises are regulated by governments throughout the civilized world. It is impossible in this article to trace this development or to outline the modern structure of regulation. Those desiring a detailed presentation are referred to the bibliography. In this summary is mainly given a discussion of the development of social control of public utilities in Anglo-American countries. The regulation of national systems of transportation and communication is also excluded except in so far as their prior development has influenced the course of public-utility regulation.

Munn v. Illinois **Decision.**—A common legal background of public-utility regulation both in the United States and in Great Britain is disclosed by the decision of the U.S. supreme court in *Munn* v. *Illinois* (94 U.S. 113 [1877]). The *Munn* case involved the validity of an Illinois statute fixing maximum rates for storing grain in elevators. Munn had been engaged in the elevator business since 1862, long before the enactment of the statute, and had been in the habit of charging rates fixed by agreement among the elevator owners in Chicago, Ill., and had continued to charge these rates although they were in excess of those fixed by the act. Munn mas convicted and fined in the state courts but appealed to the U.S. supreme court upon the ground that the act violated the 14th amendment in that it deprived him of his property without due process of law.

Chief Justice Morrison Waite, in upholding the validity of the statute, said in substance that under the circumstances in which the elevators were being operated in Chicago (*i.e.*, standing in "the very gateway of commerce and taking toll from all who pass") they had become business "affected with a public interest and had ceased to be *juris private* only." This was not his own language but was quoted from Lord Chief Justice Matthew Hale who had penned it about 200 years before in England. This legal doctrine, he said, had been a rule of the law of property ever since; that under this rule and in exercising the police power of the state, "it had been customary in England from time immemorial and in America from its first colonization to regulate ferries, common carriers, hackmen, bakers: millers, wharfingers, innkeepers. and so forth," and to fix maximum charges. In further explanation of this "public interest" doctrine, the court said that private property is being used "in a manner to make it of public consequence, and affecting the community at large. When, therefore. one devotes his property to a use in which the public has an interest, he, in effect, grants to the public an interest in that use. and must submit to be controlled by the public for the common good, to the extent of the interest he has thus created. He may withdraw his grant by discontinuing the use; but, so long as he maintains the use, he must submit to the control."

In a later case (*Charles Wolff Packing Co.* v. *Court of Industrial Relations of the State of Kansas,* 262 U.S. 522 [1923]), Chief Justice W. H. Taft of the U.S. supreme court gave further precision to this "public interest" doctrine by saying: "In a sense, the public is concerned about all lanful business because it contributes to the prosperity and well-being of the people. The public may suffer from high prices or strikes in many trades, but the expression 'clothed with a public interest' as applied to a business means more than that the public welfare is affected by continuity or by the price at which a commodity is sold or a service rendered. The circumstances which clothe a particular kind of business with a public interest, in the sense of *Munn* v. *Illinois* and other cases, must be such as to create a peculiarly close relation between the public and those engaged in it, and raise implications of an affirmative obligation on their part to be reasonable in dealing with the public."

Between 1923 and 1934, and particularly during the depression years, a series of cases involving the constitutionality of price regulation was decided by the United States supreme court. With a dissenting minority of liberals, the court ruled against the regulation of the resale price of theatre tickets in New York city and of the fees of private employment agencies in New Jersey. Without dissent it forbade the regulation of the retail prices of gasoline in Tennessee. A divided court decided against the regulation of competition among artificial ice plants in Oklahoma. This negation of the extension of regulatory power was halted in 1934 when New York was upheld in its efforts to stabilize the fluid milk supply industry and rescue it from price-cutting tactics through the fixing of minimum prices by a milk control board. The seeming confusion behind these contradictory opinions can be explained by noting that the trend was in the direction of extending the use of the police power in the interests of public health, safety, morals and the general welfare, while the hard core of public-utility regulation in the interests of monopoly control continued without abatement.

Obligations of Public Utilities.—The affirmative obligations upon public utilities arising out of their peculiarly close relation to the public are usually spoken of as that system of rights and duties which constitutes the law of public service undertakings. Briefly, this law places upon a public utility the extraordinary duty to render reasonably adequate service to all who apply. It is required to serve them up to the limit of its capacity, with capacity being defined as the limit of profitableness. It may not let customers' wants go unsatisfied. Nor may it attach unreasonable conditions to contracts for service so as in effect to negative its duty "to serve all comers." Furthermore, it must serve without discrimination all customers similarly circumstanced. Finally, a public utility must observe more than ordinary care in the rendition of service in view of the dependence of the public upon such service and the hazards associated therewith. On the other hand, the same law concedes a public utility the right to collect a reasonable price, to render service subject to reasonable rules and regulations and to withdraw service under prescribed conditions after giving notice to customers. While customers are given the right to demand that a public utility live up to its duties, they are, on the other hand, required to accept reciprocal obligations formally imposed by the regulatory body or implicit in the franchise.

Economic and Legal Determinants.—In determining whether a given industry is subject to this coercive law of public utility the courts have adopted certain practical tests of both a legal and an economic nature. The economic tests look to the presence of elements of natural monopoly in such number and strength that competition cannot work successfully. The power of the state will be used either to regulate industries so as to restore equality of bargaining power by maintaining competition and controlling competitive practices. or used to promote the inherent trend toward monopolistic organization by conferring upon such industries legal monopolies and then controlling their economic relations.

From an economic point of view it is clear, therefore, that the concept of a public utility is made up of two ideas: (1) the idea of monopoly; and (2) the idea of common necessity. Both must be present in order that an industry may become a public utility. Neither alone will suffice. The supply of housing facilities is a necessary economic function, and when it is furnished upon a competitive basis the customer is not coerced. But when, in emergencies such as the acute housing shortage (see HOUSING) during World Wars I and II, the consumer is forced to bargain for a necessity under conditions of temporary monopoly. the courts will uphold the regulation of rents. Yet the character of regulation will be such as to enable the industry to reachieve normal condition. The emergency having passed, as building operations are resumed competition again sets in and the reason for regulation disappears. The housing industry therefore represents a borderline case which, nevertheless, ought not to be classed as a public utility under normal conditions.

When freedom of choice is seriously restricted—that is. when the coercion residing in private property makes itself felt as a monopolistic power—public interest arises in proportion as equality of opportunity to choose is restricted, provided that the wants supplied are recognized as a common necessity. The concept of public utility thus becomes a legal instrumentality to achieve an improvement of the standard of life. In a society which is accustomed to look to governmental initiative for the supply of common needs, the facility will be supplied as a public function. On the other hand, a society which is distrustful of the state will leave the supplying of such common needs to a private agency under a franchise privilege, not as a matter of common right. but as an agency of the state.

Since the law had long recognized the rights and duties of public utilities, this legal conception attained a certain fixity in the form of legal rules. But the number and kind of industries that may be subjected to these rules is not fixed. It may be said that the legal notion of public utility is that of a fixed concept with a changing content. The industries at any time recognized as "clothed with a public interest" are not necessarily the industries which may legally be classified as public utilities at another time. The industrial and political situation as mirrored in public opinion will determine: (1) the number and kind of industries classified as public utilities; (2) the elaboration of the system of rights and duties which make up the institution; (3) the regulating agencies and instrumentalities employed (whether the legal rules and decrees of courts or the charters, special franchises and statutes of legislatures); and (4) the subordinate administrative standards which are evolved in practice. The trend in the development and application of the institution will be a resultant of the amount of social inertia, of the pressure of the economic environment and of the influence of intellectual progress.

Regulation in the United States has been accomplished in three distinct ways: (1) judicially by means of suits at law where the common-law duties and rights of public utilities are applied in specific cases; (2) legislatively by means of corporate charters or special franchises; (3) legislatively by means of the police power of the states or its federal equivalent, the power of congress over interstate and foreign commerce. Judicial regulation is the oldest and constituted almost the only form of control during the first half of the 19th century. Legislative regulation later largely supplanted judicial regulation, but the latter remained in the background as a potential agency which might become active again if legislative regulation should disappear. The function of the judiciary by 1898 had been restricted to the review of legislative and administrative acts.

Legislative regulation by means of the charter or special franchise was the next to be tried. The special franchise is now generally conferred under constitutional or statutory authority by local governments The method of special franchise regulation is applied to so-called local public utilities, furnishing telephone, gas. electric, water and transportation services in local communities.

The weakness of legislative regulation by charter was that the maximum rates therein provided were largely in excess of those actually charged by the companies. Competition of carriers with each other. the decreasing unit cost of operation on account of increased utilization of plant capacity, the decline in the level of prices after the Civil War, continuous improvements in technique made necessary and possible the rendition of service at rates below those fixed in the charters. The failure to provide adequately for financial and accounting control enabled the issuance of more stock and the padding of investment accounts, thus vitiating the control based upon net income. Special franchise regulation followed the procedure applied in the case of carriers. Maximum rates were fixed in the local franchise of telephone, gas, electric and water undertakings. These maximum rates soon became obsolete because the growing business of the companies required more complex and flexible rate schedules. Moreover, the companies began to appreciate that incredsed earnings, both gross and net, could be secured by means of rate reductions.

When state legislatures in the case of national carriers and local councils in the case of local utilities attempted to adjust these rates downward, they were met by the objection that the change would violate a contractual obligation and confiscate the property of the companies. Only when the franchise was silent on rate questions or when the power to alter. amend or repeal the terms of franchises was reserved. could the power to regulate rates or service be exercised by state or local legislatures. Another evil that had crept into the administration of public utilities as a result of the ineffectiveness of rate control was discrimination in rates. This was also induced by the fact that competition had never been entirely eliminated. Added to this, in the case of the limited term franchises of local utilities, was the groning insecurity of tenure. Failing to obtain a renewal the properties would be worth only their scrap value. Often there were no provisions for public purchase or for purchase by some other grantee at the end of the franchise period. The inducement mas too great, therefore, to manipulate operations so as to enable investors to recoup their capital out of earnings.

About 1870–80 a policy was adopted of fixing rates by direct legislation. Legislatures reaiized that statutory regulation should be general rather than specific; that the rate and service problems require continuous attention; that the subject matter of statutes should be the laying down of principles and standards; that the new policy of continuous regulation required an effective agency, sufficiently informed by experience to carry legislative standards and principles into effect. This agency is the modern administrative commission, acting as an agent of the legislature. All states set up regulatory commissions with varying jurisdictions. The first federal agency to regulate a public utility was set up in 1887 to control the interstate commerce of the railroads. As new public-utility industries arose, additional agencies were established or the jurisdictional scope of existing ones broadened. Their authority was strengthened as the need for more adequate control became apparent. Federal regulation in the mid-1950s covered the three major fields of transportation, power and communication. Control over transportation is effected through: (1) the Interstate Commerce commission, established in 188; to regulate the railroads, jurisdiction being extended to cover pipelines other than water and gas (1906), motor carriers (1935), interstate and coastal water carriers (1940), and freight forwarders (1942); (2) the Federal Maritime board and the Maritime administration, set up in 1950 (stemming from the U.S. Shipping board of 1917) to regulate offshore shipping: and (3) the Civil Aeronautics board, created in 1940 (as a reorganization of the Civil Aeronautics authority of 1938), with jurisdiction over air carriers. Authority in the area of power is exercised by the Federal Power commission (organized as an independent commission in 1930) which regulates hydroelectric projects and the transportation and sale of electric power and natural gas. Communication by wire and radio, both interstate and with other countries. is regulated by the Federal Communications commission, established in 1934. In 1935 the Securities and Exchange commission was empowered to regulate transactions in securities and other assets of public-utility holding companies.

With the exception of the Securities and Exchange commission, which is concerned only with financial ownership, these agencies are in general charged with fostering adequate service at reasonable rates. Their powers vary according to the nature of the utility involved but. in addition to regulation of rates, commonly cover such matters as licensing of operations, ruling on maintenance of services, promoting safety regulations and passing on intercompany agreements. The administrative commission applies the common-law rule of reasonableness to the concrete facts in each case and names the particular rate or service regulation deemed appropriate to the circumstances.

Regulation of all public utilities was hampered by the insistence of the courts after 1898. when the epoch-making case of *Smythe* v. *Ames* was decided, upon defining the basis for rate-making which cominissions might use. The major conflict was over the weight to be accorded reproduction costs as compared with actual original costs in the determination of the "fair value" of the investment. With the rise in the levels of prices, particularly after 1914, commissions were inclined to use the standard of actual investment costs while the utilities were contending for reproduction costs. In a series of decisions culminating in *McCardle* v. *Indianapolis Motor* Co. (272 U.S. 400 [1926]) the courts upheld the position of the utilities. But the courts receded from this extreme position after the depression set in and in Federal Power *Commission* v. *Natural* Gas *Pipeline Co.* (315 U.S. 575 [1942]) conceded that the particular formula of rate determination was within the discretion of commissions, so long as the result was not arbitrary or confiscatory. The Hope case (Federal Power Commission v. Hope *Natural* Gus, 320 U. S. 591 [1944]) further strengthened the position of the commissions by specifically rejecting "fair value" as the determining factor in rate-making, thus leaving commissions free to take into account "prudent investment" in fixing rates designed to provide adequate earnings and attract new capital.

REGULATION IN EUROPE

On the continent of Europe practically all telephone and telegraph systems and many railroad systems are nationally owned and operated and there is little opportunity for anything similar to the Anglo-American system of public-utility control. This also holds true in a large measure of local utilities. Where local utilities are privately owned they are operated under franchise contracts with the municipalities.

Great Britain. — Although in Great Britain before World War II the railroads were privately owned but subject to a large measure of regulatory control, a great number of other public utilities, notably local transport undertakings and gas and electricity, were owned and operated by local municipalities. Many had originally been started by private enterprise and later acquired by the local authorities but in the case of transport in particular the municipalities were responsible from the start. Before the war, the trend mas toward increased municipalization through acquisition. Public and private utilities were both subject to considerable statutory regulation but the former enjoyed greater freedom particularly in regard to charges. Establishment of public utilities was by private bill legislation, separate acts being necessary to confer franchises and determine the regulatory conditions of operation of each undertaking. In certain cases of common occurrence special legislation by parliament to establish each public service undertaking was made unnecessary by enabling the appropriate department of the government to issue provisional orders under general legislation after due inquiry. But full parliamentary control was retained by requiring confirmation of provisional orders, either by parliament itself or, in some cases, by an agency such as the board of trade, made effective by resolution of each house of parliament.

The English system of regulation was, accordingly, comparable to the charter or special franchise system in the United States. Laws of this type mere the Gas Regulation act of 1920, and the Electricity Supply acts of 1919, 1922 and 1926. The focal point of control was the regulation of rates. In the case of private gas companies the first method of control, after a brief preliminary period of competition, was the so-called official revision system, Maximum rates and maximum dividends were fixed in special acts but the power to reduce rates was given to the court of quarter sessions. Later another method, the system of sliding scales, was used, the adoption of which was optional. There was established a standard selling price for gas and a standard maximum rate of dividend. Then it was provided that the dividend rate might vary in inverse ratio to the rate of charge.

Local passenger transport undertakings, whether private or public, were made subject to a licensing system under the Road Traffic act, 1930. Regional traffic commissioners were appointed and made responsible for licensing public-service vehicles to regulate competition between road and rail by regulating numbers of vehicles to traffic requirements; by regulating fares, service and frequencies; and by establishing standards of construction, use and maintenance of vehicles. Under the Road and Rail Traffic act, 1933, a licensing system was also introduced to regulate road haulage vehicles operating for hire or reward.

Communication facilities (postal services, telephones and telegraphs) have been a government monopoly since the 17th century. An exception is the city of Hull which operates its own municipal telephone service. Between World Wars I and II cable and wireless services were merged compulsorily and were finally acquired by the state after World War II and handed over to the post office for operation. The British Broadcasting corporation was established in 1927 as a public corporation with a monopoly for sound radio which it retains but a second public corporation, the Independent Television authority, was established in 1955 to provide commercial television in competition with the B.B.C.'s television service.

Between the wars regulation was also directed to creating larger units of operation through amalgamations. Thus the Railways act, 1921, compulsorily merged the railways into four main line companies and the main purpose of the Electricity (Supply) act, 1919, was to bring about mergers and reorganization of the electricity industry to enable more economic generation by larger units. It established an electricity commission of five members, appointed by the minister of transport, to which were transferred many of the regulatory powers previously vested in government departments. The inadequate mandatory powers of the commissioners and insufficient co-operation from the undertakers were largely responsible for the act's failure. It was accordingly superseded by the Electricity (Supply) act, 1926, which vested responsibility for the wholesale distribution of electricity over a national "grid" in the Central Electricity board. This public corporation constructed the "grid"! which it fed with power generated both by itself and by municipal and private concerns. Local distributors remained unchanged until April 1, 1948, when under the Labour government's nationalization program both generation and distribution of electricity were transferred to public ownership. The Central (formerly British) Electricity authority became responsible for generation and the "grid" and its 12 (formerly 14) area boards for local distribution in England and Wales. In Scotland responsibility was transferred to two public boards independent of the central authority. At the same time control of the manufactured gas industry, which had been slower to integrate and comprised 1,056 municipal and private concerns, was transferred to the Gas council and its area boards. The former had mainly supervisory functions as the boards were made responsible for both production and distribution.

Railways, which had been under government control throughout the war, were not returned to their former owners but nationalized, together with their ancillary undertakings, long-distance commercial road haulage and the inland waterways. The British Transport commission was made the responsible body from Jan. 1, 1948. Under the Transport act, 1953, a large section of road haulage was denationalized but the commission retained under a subsequent measure, the Transport (Road Haulage Disposal of Property) act, 1956, a substantial proportion including its nation-wide trunking services.

It can be seen therefore, that in Great Britain regulation of public utilities has evolved from statutory regulation of private and public concerns to direct ownership on a monopoly basis through public corporations. (*See* also GOVERNMENT CORPORATIONS.)

Continental Europe.—Before World War II the trend in continental Europe was toward generation of electricity on a larger scale, particularly in France, Italy and Germany. In Germany "mixed undertakings" were established similar to the German Railways companies with the shares in both public and private hands and frequently with cities served co-operating. After World War II with the great development of hydroelectric power, the trend was toward greater co-operation between the countries of western Europe for exchange of power across frontiers. The Organization for European Economic Co-operation greatly assisted in this.

PUBLIC WELFARE LAW: *see* POOR LAW.

PUBLILIUS (less correctly **PUBLIUS**) **SYRUS,** a Latin writer of mimes, flourished in the 1st century B.C. He was a native of Syria and was brought as a slave to Italy, but by his wit and talent he won the favour of his master, who freed and educated him. His mimes, in which he acted himself, had a great success; he was perhaps even more famous as an improvisatore, and received from Caesar himself the prize in a contest in which he vanquished all his competitors, including the celebrated Decimus Laberius. All that remains of his works is a collection of Sentences (*Sententiae*), a series of moral maxims in iambic and trochaic verse, which has been much interpolated with later extracts.

The best texts of the *Sentences* are those of E. Wölfflin (1869), A. Spengel (1874) and W. Meyer (1880), with complete critical apparatus and index verborum; recent editions with notes by O. Friedrich (1880), R. A. H. Bickford-Smith (1895), with full bibliography; *see* also W. Meyer, *Die Sammlungen der Spruchverse des Publilius Syrus* (1877).

PUBLISHING. Publishing is the selection, reproduction and circulation of written matter. It is older than both printing and paper, though in modern times it has come to depend upon both. Printing from blocks was invented in China some time before the middle of the 9th century; printing from movable type was invented there by the middle of the 11th century. But at neither time was printing thought of or encouraged other than as an excellent device for avoiding the errors of transcription that often marked the work even of the best manuscript scribes and copyists. In Europe, printing from movable type was invented by the middle of the 15th century. But there, as in China, its major advantage over older methods of reproduction was thought to be the standardization of scripture and of official texts. Neither in Asia nor in Europe was printing viewed at first as being useful in the wide dissemination of literature, learning or political or religious discussion. As an instrument of publishing, indeed, printing had to fight its way; it became a great instrument of spiritual and intellectual development and theological and scientific discourse, but the earliest reaction, which persisted for centuries in the west as in the east, was one of opposition by church, government, university or other powerful interests, such as the Brahmin caste in India, to its use in giving wide publicity to certain ideas and information.

The Earliest Books.—Before the invention of printing and of paper, publishing was carried on by means of professional scribes or skilled slaves making numerous transcriptions of manuscripts on papyrus or parchment. Flourishing industries producing papyrus or parchment rolls for sale on which were inscribed the classics of ancient literature, religion and law were to be found in Egypt under the Ptolemies and in the major cities of Greece and republican Rome. Often under the Roman empire, as often under later western kings, princes, parliaments and presbyteries, censorship and intimidation controlled or attempted to control publishers' output, thus interrupting the continuous history of commercial publishing for long stretches. Yet these ancient enterprises were authentic prototypes of modern publishing houses. Their work consisted in selecting manuscripts for reproduction in quantity, in taking the risks of compensating authors in advance of public sale for rights to such manuscripts, in determining the size, price and format of editions of different titles, and in developing markets in which such editions could, by various means, profitably be sold. They were publishers in every modern sense of the word, even though their products were not yet books.

Books in the form with which the world has long been familiar, that is, made up of pages bound together at one side, had a long and obscure development of their own. By the 4th century the bound book had become moderately well-known, at least among the jurists of the later Roman empire. Its first real vogue, however, was in Ireland, two or three centuries later, the climax of the remarkable flowering of intellectual and religious spirit there being the Book of Kells, not infrequently mentioned, according to one authority, as "the most beautiful book in the world."

To distinguish it from the old *volumen,* or "roll" (from which, oddly enough, the word "volume," often used interchangeably with "book," is derived), the early bound book was called a codex. The codex became the typical book of the middle ages, and theological codices were produced in large quantities especially in the monasteries of various church orders, which were the publishing centres of the day. Codices in law, medicine, rhetoric and other fields of learning came from the rising universities which, in certain cities, early grasped control over the publishing industries from the church and the state. In such centres, the second-hand market was as well-known to mediaeval students as it became to those of the 20th century and to 20th-century textbook publishers as well. The difference was that the universities, as publishers but not commercial ones, strove (in these early efforts at price-fixing which became such a feature of publishing in the 20th century) to keep prices down for the students and thus encouraged the use of old copies. This also relieved the universities of producing large new editions every year.

The codex, of course, like the papyrus and parchment rolls that it replaced, was written entirely by hand. In the scriptorium or "writery" of the monastery, scribes more or less devoted to their work toiled during the daylight hours (fear of fire from artificial light prompted the monasteries to forbid work on books at night) copying page after page of ancient classics, thus laboriously accomplishing the great task of preserving them as well as the Bible. "After the scribe had finished his quaternion, or group of four sheets in eight leaves," writes Douglas C. McMurtrie, "his work was proofread in comparison with the original by a second person, and the sheets were then sent to the rubricator, who inserted titles, headlines, chapter and other initials, notes. and the like. If the book was to be illustrated, the sheets next went to the illuminator. After he had completed his work on the volume, it was ready to be bound." This procedure was not very different, in essence, from manuscript preparation in a modern publishing house—except that with modern printing and illustrating methods, these and related publishing tasks need be performed only once for an edition of many thousands, and not over and over again for every individual codex or book.

Printing and Publishing in Modern Europe.—Though the early history of publishing owes nothing to printing, Johann Gutenberg's invention of printing from alphabetical type gave a great boost to publishing in Europe after the middle of the 15th century. Gutenberg probably was not the first European to use movable letter type successfully. After his epochal achievement, however, Mainz, his home in Germany, became the indisputable publishing centre of the continent, and Germany itself the source and fount of subsequent printing and publishing developments in the western world. Before 1500 about 30,000 books were printed in Europe; of these, more than two-thirds came from such great German centres of learning as Leipzig, Cologne. Basel, Nuremberg, Augsburg and Strasbourg. More important, it was Germans, trained in these cities, who introduced modern printing and publishing into Italy about 1460, where it played an important part in the spread of Renaissance culture and trade. Similarly, it was Germans, trained in turn in Italy, who carried the printing industry and modem publishing to France in the early years of the 16th century.

It was only then that a broadening of the lay market for books took place. In 1501 Aldo Manuzio designed the first books in small format, which eventually replaced the huge, elaborate and costly codex, just as the codex had replaced the awkward *volumen.* In succeeding decades, especially in France, much attention was given to typography, and names still commonly used for type faces in the 20th century became –ell-known, from the work, for example, of Claude Garamond and Robert Granjon. A customer of both of these typographical artists, Christophe Plantin, was the most famous of the early printers who became publishers. Born in France in 1514, Plantin fled from Paris in 1548 to escape religious persecution. He settled in Antwerp, Belg., and there made his fortune. In the end he returned to the good graces both of the church and the university, gaining from the Holy See the monopoly of publishing liturgical books for the Spanish empire, and becoming late in life, printer to the University of Leyden, itself a great publishing centre of the time.

Though many early printers remained faithful to the church and to their princes, the publishing of printed works quickly became one of the major means of organizing protestant and radical opinion in the late 15th and early 16th centuries. This naturally led to reprisals against the new publishing industry, especially in Germany, and in self-defense the publishers and printers organized into independent corporations and guilds of their own. These lasted until the 19th century in many countries. Where printing and publishing was not shut down or forced underground, as was the case in Nuremberg and Augsburg early in the 16th century, it was controlled by other means. Thus in France, as early as 1474, the new independent printers and their printed books were brought under the same licensing regulations by which the University of Paris alone had monopolized the work of the old scribes and the publication of their manuscripts. This was indeed a signal recognition of the rapid rise of the printer to publishing eminence: yet it was also an onerous burden to the new publishers who were out of sympathy with officialdom.

Between them, official controls on the one hand and guild restrictions on the other impeded the development of printing and publishing for centuries. On the continent, one result was the emigration of printers and publishers to England where, from 1476 to 1536, it is estimated two-thirds of all printers, binders and stationers were aliens. But even in England from 1534, when the Stationers company or guild was first organized into the monopoly of all English book publishing, to 1710, when the first copyright act was passed in the reign of Queen Anne, there was constant harrassment of publishers, nhich, in due time, was carried across the ocean to America as well. It was on an occasion during this epoch, when some freedom of publishing, bitterly won, was challenged by new efforts at control, that John Milton wrote his *Areopagitica* in 1644.

In France, control was more or less thorough until the revolutionary copyright law of 1793 freed publishing and printing from all existing monopolies. This freedom was short-lived, however, ending under Napoleon's First Empire and not restored until the declaration of the republic in 1870. French restrictions had a salutory effect on the publishing industries in the Netherlands and Belgium where, during the 17th dnd 18th centuries, large editions of the works of Moliere, Boileau, Voltaire, Rousseau and others were issued clandestinely for the French market.

As is usual with excessively rigorous controls, they often were poorly enforced; and as is usual with official monopolies, they often bred strong, if *sub rosa,* competition. Both of these situations, whatever the prevailing atmosphere, permitted printed literature and learning to spread rapidly in Europe between the 16th and 20th centuries, and authorship and publishing to flourish because of it. The English Copyright Act of 1710 freed the individual author and enterprising publisher from monopolistic printers and recognized the right of both to negotiate for the best royalties and other terms for the publication of literary property. But this right had been recognized as early as Roman times, when publishers of the empire bid competitively for the exclusive privilege (for which they paid fees, not royalties) of duplicating literary creations. What was significantly new about the English act was its recognition of the right of the whole public to literary property after a specified term. That is the nub of modern publishing copyright; it protects authors in their rights to literary property and publishers in their acquisition of such rights; but more than that, it gives the public, increasingly eager for great published works, freer access to such property after a limited number of years — under Queen Anne's act the term was 14 years, with the author retaining the privilege of renewing for another 14 years; in the United States in the 20th century, it was 28 years, with the same privilege for another 28 years; in most other countries, the term is the remaining years of the author's life, plus 20 to 50 years.

The development of copyright practice since the early 18th century is an authentic clue to the growth of professional authorship and commercial publishing, and by the protection copyright gave it was a stimulus to both. The limitation in the copyright period, in turn, is an authentic clue to the thirst for learning among the populace who, with the centuries, became more and more literate. Roman usage and common law had acknowledged the author's right—if he could assert it—to his property in perpetuity. English and later continental statutes freed this property for public use after protecting the author and publisher for specified periods of time.

Toward Contemporary Publishing Practice. — Just as the monasteries gradually yielded their monopoly of publishing to the universities, and the universities to the corporations and guilds, and the guilds to the competitive printers, so the printers, under the pressure of this growing market for literary works, gradually surrendered their dominant position to the booksellers.

None of these transitions took place in a day. Even as early as the 1580s in England, the pressure of costs for printing equipment and the like forced printer-publishers to appeal to booksellers for capital and credit. Thus in 1582 Christopher Barker complained to the queen: "The booksellers being growen the greater and wealthier number have nowe many of the best Copies and keepe no printing howse, neither beare any charge of letter, or other furniture but onlie paye for workmanship . . . [with] the artifice printer growing every daye more and more unable to provide letter and other furniture, requisite for any good worke; or to gyve mayntenaunce to any such learned Correctours as are behovefull. . . ." Yet it was not until the 18th century that the bookseller had his great day as publisher. By then the reading public, especially in England, was growing much faster than before and trade in popular new books (as distinct from the earlier staples of the whole industry: Bibles, commentaries, textbooks, dictionaries and the like) was booming. To meet the new demands circulating libraries were established as early as the 1720s, and new authors were developing sufficiently large popular followings to be able to insult and dispense with their former aristocratic patrons. By the late 18th century booksellers whose names continued to adorn modern publishing houses as late as 1950—such as Constable and Longmans — had already become kingpins of the publishing industry. Only a few decades later in the new world itself, Harper, Scribner, Dutton, and Little, Brown had become well-known.

Thus, with the rise of the bookseller, contemporary publishing began, and with the more or less simultaneous rise of the novel and the novelist it flourished. Both developments reflect the ascendancy of the middle classes. and thus had their greatest vigour in England and the United States. They followed more deliberately on the continent, where literacy was slower to become nation-wide and where extremes of wealth and poverty kept the middle-class markets small.

The unity of bookselling and publishing, in turn, persisted far longer in England than in the United States, where the great development of new writers (after piracy of English titles was successfully abated late in the 19th century) gradually stimulated the creation of independent publishing houses which were neither printers nor booksellers. This change brought with it new independent printers, binders and booksellers — the first two to produce, under contract, books arranged for by the new publishers; the third to sell those books to an ever growing public.

By the third decade of the 20th century still newer publishers appeared in numbers in England and the United States and in Germany and France on the continent, devoted almost exclusively to so-called trade books — that is, general books of fiction, popular biography and history, books of memoirs and inspirational psychology, books of sentiment and sentimental learning. Many houses among the older group and some among the newer ones as well continued to have all kinds of special departments for Bibles, other religious books, school and college textbooks, medical books and similar works that once were the foundation of the entire publishing industry. But the newer vogue was the trade publisher as such. The age of specialization had indeed set in, and nowhere more strongly than in the United States, where the industry was less encrusted with old traditions and thus afforded the most suitable soil for the new flowerings.

Subscription Books. — One of the widest and most extensively developed methods of distributing books is by subscription: sales are assured by the canvassing and pledging of subscribers. Today reference works of all kinds — encyclopaedias, sets of children's books, some dictionaries, collections of popular novels — are distributed almost solely by this method and the value of the sales in the United States and elsewhere amounts to many millions of dollars.

Sales by subscription, it is believed, began in the 15th century when William Caxton is said to have initiated this method to finance the publication of *Mirror of the World*. The purpose was to ensure moneys for the production of this work and differed from the traditional practice, of having one sponsor or patron for the book, by enlisting the interest and money of many.

The idea proved attractive to printers and to authors but it was not until the turn of the 17th century that this form of distribution flourished. In most instances, the issue remained a single volume and the cost of production was assured by the persons who promised to buy the book. The method fell into disrepute after a time when some printers, selling a book in advance of publication, sold trash or no book at all.

In the 18th century larger sets of books were distributed by subscription. *Encyclopædia Britannica* in 1768 was one of the first. In some instances, where the cost of the initial production is excessive, prepublication offers are made and subsequent sales are continued under instalment or, as it is known in Great Britain, the hire-purchase plan. Mark Twain in the United States adopted this idea for the distribution of Gen. Ulysses S. Grant's *Memoirs*. Albert Bigelow Paine says in his monumental biography of Mark Twain. that Twain was able to present General Grant, who needed it, the largest single royalty check, $20,000, ever given to an author up to that time, and, of course, before the volumes actually were made.

Perhaps the greatest recent venture in prepublication subscription was the publication of *Great Books of the Western World* in 54 volumes by Encyclopaedia Britannica, Inc., in 1952. It was the generosity of 500 founder prepublication subscribers which facilitated the general distribution of this costly work.

According to the American Textbook Publishers institute the subscription sales of reference books to homes and offices and to schools and libraries in the 'United States alone were estimated at about $125,000,000 for the year 1954.

The Age of Specialization. — In the 20th century in the United States, as elsewhere, the number of new titles published each year grew steadily, except for dips in war years or their immediate aftermaths. At their peaks, about 35,000 new titles were published in Germany, 15,000 in Great Britain and 12,000 in the United States. These figures are not altogether commensurable, since the definition of a book has always remained vague. But whatever the actual figure, the relative size of the industry in the 20th century can be judged by comparing even its smallest annual volume of titles with that of earlier centuries. In the first half of the 18th century in England, for example, it has been calculated that the average annual number of new titles was about 93. The first quarter of the 19th century saw a jump to an average annual total of about 600. By comparison, the 20th-century totals make it clear why specialization in publishing could so readily be supported, indeed, why specialization had to come.

Within trade publishing itself the 20th century saw the development of hard cover reprinters, paper cover reprinters, specialized western story and detective story publishers. science-fiction publishers and others who profited greatly by concentrating on special books for special, but sufficiently large, markets. In distribution, moreover, the old-fashioned bookseller — even the one who himself came to specialize in trade books — was supplemented by the book club, by other types of mail-order houses and by the ordinary newsstand which accounted for the bulk of the sales of the paper cover reprints. While most regular trade publishers still printed editions ranging from 3,000 to 10,000 copies for most of their titles, for book clubs and paper cover reprinters editions often ran to more than 100,000 copies and not infrequently for the latter to more than 200,000 copies. Clearly the old middle-class market had become, by mid-20th century, a mass market, especially but not only in the United States. In the 1950s in the United States a new departure was the publishing in paper covers in editions ranging from 20,000 to 50,000 copies and at prices ranging from 65 cents to $1.95, of reprints of great works of scholarship, science, religion, literature and art. Many had long been out of print; often they had been issued originally by university presses or other specialized publishers and had had total sales of less than 2,000 copies. The great market for these books was found among college students and professors. So successful were these new editions, that many publishers began reprinting their serious books in paper cover editions of their own. Some even issued new learned titles in this form for the new student market. The specialized reprinters and even the publishers of the mass editions of detective stories and the like, in turn, began also to seek original manuscripts of a scholarly nature. In the main, however, those publishers, such as the book clubs and others selling in mass markets, continued to look to the regular publishers for titles to reprint. Thus literary production in the form of books, and hence the literary health of their countries, remained such publishers' responsibility throughout.

Some bore it better than others, but virtually all sought to share it. To discover manuscripts for this publishing industry, new occupations thus became prominent after the first quarter of the 20th century. Two of these were most important: the manuscript scout, who often worked for publishers under contract by which his remuneration was a stated percentage of the retail price (usually ranging from 1% to 2%) ; and the literary agent, who universally worked for authors, handling all their business relations with publishers for compensation in the form of 10% of the author's royalties and other income from his literary production. The growth of the agency business reflected further specialization in the publishing industry by which the publisher, becoming more a business manager, passed over his editorial functions to others. It also reflected the broadening of the market for the work of authors, especially authors of fiction. In the 20th century to the old magazine and newspaper serial rights were added motion-picture rights, dramatization rights, radio rights, television rights, digest rights and a series of others, the sale of which required complicated negotiations and contracts and which, however much it might enrich them, most authors were themselves incompetent to handle.

In facilitating distribution of books, further specialized agencies appeared in many countries in the 20th century. These were advertising agencies, some of which merely added books to all the other products for which they sought to stimulate demand, others concentrating on books alone. In Germany and England, typically, about 5% of a publisher's net return was spent for advertising and promotion; in the United States. the percentage was likely to be ta-ice as high for books of average sales; and the actual amount proportionately even greater. For books with great sales possibilities much more was often set aside. Spending this money most effectively required skill and experience which the publisher often did not have; thus the development of advertising agency business in books.

Though trade books were the fastest growing part of the whole publishing industry in the 20th century. and paper cover reprints the fastest growing part of trade publishing, growth elsewhere also added measurably to the flow of books. Especially notable in the United States was the growth of the federal government as publisher—a development that reflected not only the rapidly increasing number of all kinds of government investigations. but also the growth of federal services to farmers and others not ordinarily reached by regular publishers and regular means of book distribution. Far smaller in volume was the production of the American university presses. Their work was largely in books of importance to science and learning which would, without these presses. probably have gone unpublished and thus unknown.

All told. in 1945, according to the United States census bureau, almost 500,000,000 copies of books were printed in the United States alone. The history of the technological improvements in printing that made such production possible is a long one in itself, including the history of such familiar machinery as linotypes. cylindrical presses, rotary presses and attachments to them. Most of these came in around the turn of the 20th century; subsequent great improvements in their performance allowed them to keep up with the demand for books.

In the 20th century: motion pictures, radio entertainment, television broadcasts. the automobile, the massive illustrated magazines and other vehicles of entertainment and enlightenment occupied the attention of growing populations. All competed with the traditional book; but the book publishing industry itself enjoyed the most remarkable growth in its long and troubled history. In mid-century it was rising on the continent once again from the devastation of two wars. In the United States it remained one of the major channels of communication. one of the major forums from which were fed the spirit and the intellect.

(WI. MR.)

PUCCINI, GIACOMO (1858–1924), Italian operatic composer. was born at Lucca on Dec 22 or 23, 1858, of a family already distinguished in music. his great-great-grandfather Giacomo, great-grandfather Antonio, grandfather Domenico, and father Michele. having all been professional musicians. He was educated at the Milan conservatoire where he studied under Ponchielli In 1889, *Edpar* was performed at La Scala, and in 1893 his *Manon Lescaut* in Turin The former, based on *La Coupe et les lèvres* of Alfred de Musset was a failure, but the latter, founded on the well-known story of the Abbé Prévost (which had been previously treated by three other composers, Halévy, Auber and Massenet) was favourably received, and still holds the stage. Its success was as nothing compared with that of the work which followed it, the sparkling *La Bohème* (Turin. Feb 1. 1896). The libretto is based on Mürger's novel from which four scenes are taken, and the skill and resource and effectiveness with which they are treated leave no room for doubt as to the merits of the work. In La *Tosca* (Rome: Jan. 14, 1900), based on Sardou's tragedy, Puccini had an altogether different task, of which, however, he acquitted himself no less successfully. The work contains some of the strongest and most genuinely dramatic music which he ever wrote, and like *La Bohème* has enjoyed unlimited popularity at the hands of the general public from the first.

Madame Butterfly, on its first performance at La Scala on Feb. 17, 1904, was pronounced an absolute failure. Probably the libretto of the opera, with its unusual setting in Japan. had at least as much to do with this result as its music, but the Milan public's unfavourable verdict was reversed when the work was heard again at Brescia three months later, and since then its popularity has been prodigious and world-wide. If equal success did not attend its successor *La Fanciulla del West* (The Girl of the Golden West), this was accounted for by the unsatisfactory character of its "book" and by the undoubted inferiority of its music, so that the work, though favourably received when first performed in New York (Dec. 10, 1910), has never found general favour. Of the one-act operas *Il Tabarro, Suor Angelica* and *Gianni Schicchi,* which followed, all contain clever and characteristic music, but only the third, based on a most amusing libretto, has kept its place in the general repertory. *Turandot,* not quite finished at the time of Puccini's death, was completed by Alfano, and produced at La Scala, April 25, 1926. While some critics condemn this last work severely, others reckon it the composer's finest achievement.

Puccini died at Brussels on Nov. 29, 1924.

PUDDINGWIFE. A tropical American fish of the wrasse family (Labridae), called also doncella. It has a deep, compressed body, which is covered with large scales except on the head, has strong canine teeth in the front part of the jaw, and attains a length of 18 in. In colour the puddingwife is a vivid blue-green tinged with bronze or soft orange, though varying somewhat with sex and age. Spots and streaks of blue, especially on the head. fins and through the eye, add to its attractive appearance.

PUDDINGWIFE (IRIDIO RADIATUS)

PUDOVKIN, VSEVOLOD ILLARIONOVICH (1893–1953), Soviet film director, one of the greatest of the era of silent films. was born at Penza, Russia, on Feb. 21, 1893. Wounded and imprisoned for three years in World War I, he returned to the study of chemistry but was attracted to the theatre. D. W. Griffith's film *Intolerance* moved him to apply for admission to the State Institute of Cinematography in Moscow. He worked with Lev Kuleshov in certain early film experiments, directed an educational feature *(Mechanics of the Brain)* and collaborated on a comedy, *Chess Fever.*

Pudovkin's best-known theatrical films are *The End of St. Petersburg* (1927), *Storm Over Asia* (1928) and *Mother* (1926), based on Maksim Gorki's novel. He was also occasionally an actor. His sound films included *Deserter* (1933), *General Suvorov* (1941) and *Admiral Nakhimov* (1948).

Pudovkin died on June 30, 1953.

In two books, *Film Technique* and *Film Acting,* written for Russian film classes and first published outside Russia in 1929, Pudovkin explained his principles of scenario, directing, acting and editing. His early films emphasize individuals within the Revolution somewhat more than did Sergei Eisenstein's (*q.v.*), but Pudovkin shared his great contemporary's liking for elaborate crosscutting of images (montage) to represent complex ideas.

(R. D. MACC.)

PUDSEY, a municipal borough (1899) in the Pudsey parliamentary division of the West Riding of Yorkshire, Eng., lying between Bradford and Leeds. Pop. (1951) 30,280. Area 8.3 sq.mi. The trade of the town is principally woolen textiles, but there are tanning mills and light engineering works. Fulneck, in the south of the borough, was chosen in 1743 as a Moravian settlement.

PUDUKKOTTAI, a former princely state of southern India, lying between Tanjore and Madura districts of Madras, with which it was merged in 1948 as part of the Tiruchirapalli (Trichinopoly; *q.v.*) district. The area of the state was 1,185 sq.mi. Pop. (1941) 438,348. The chief, whose title was *tondaman,* was of the Kallan or robber caste. His ancestors received a grant of territory for loyal services to the British during the wars in the Carnatic at the end of the 18th century.

The town of Pudukkottai (pop. [1951] 44,527) is well laid out with several fine public buildings. A college affiliated to Madras university and a training school were established there.

PUEBLA, an interior plateau state of Mexico. Pop. (1960) 1.957.380; area. 13,126 sq.mi., with its capital at Puebla. On the southeast corner of the Anáhuac plateau, Puebla varies in elevation (5.000–8.000 ft.). with numerous fertile valleys formed by the Sierra Madre Oriental which runs through the state. Endowed with a temperate, semihumid climate, crossed by main highways running southward from the national capital, and traversed by rail and air lines, Puebla is one of the most densely populated states of Mexico.

Its strategic location and natural endowments in pre-Hispanic times are attested by innumerable archaeological sites and by its many towns and villages, notably Cholula (*q.v.*), Atlixco and Tehuacán, a noted health resort. Coffee, sugar cane, fibres. maize and cereals are its main crops. Onyx, gold and other metals occur in its richly veined mountains. Numerous short, fast rivers provide hydroelectric power.

Its Nahuatl-speaking native peoples were highly developed at the coming of the Spaniards in the 16th century, and the latter founded many estates in this region, a main focus of their religious and economic activities. In the 19th and 20th centuries Puebla developed as an agricultural-industrial area in the important corridor between Mexico City and its main seaport at Veracruz.

(HD. C.; J. A. CW.)

PUEBLA (PUEBLA DE ZARAGOZA), city of Mexico and capital of the state of the same name. Pop. (1960) 285.284. The centre of an important agricultural and industrial region of central Mexico, Puebla is 80 mi. N. of the federal capital and from viceregal days has been considered the military key to the nation. The city was founded as Puebla de los Angeles by the Spaniards in 1532. According to church chronicles, the site was chosen as the result of a dream by Fray Julian Garcés who saw two angels with a line and rod pacing a beautiful plain flanked by tall volcanoes. Puebla is on a broad, healthful plain 7,050 ft. above sea level in the foothills of the Sierra Madre Oriental within view of Mexico's three highest snow-topped volcanoes, Citlaltépetl, Popocatépetl and Ixtacihuatl.

Puebla is characteristically Spanish with noteworthy architecture similar to that of Toledo, Spain's great fortress city. The sumptuous cathedral, whose interior is rich with onyx, marble and gold, was made a bishopric in 1550 and an archbishopric in 1903. Overshadowing the cathedral is the all gold leaf chapel of the Rosary in the church of Santo Domingo. The Casa del Alfeñique, the "almond-cake house" (now a museum). was built in the 17th century of polychrome blue, white and red tiles with white decorations and black ironwork balconies. The Teatro Principal (1790) was one of the first permanent theatres in the hemisphere. Puebla is the seat of a university, founded 1537.

A conservative, strongly Catholic city, Puebla was often considered politically reactionary in the history of Mexico. U.S. forces under Gen. Winfield Scott occupied the city (1847) during the Mexican War. Most famous of the battles fought in Puebla was the repulse of the French on May 5, 1862. In honour of its defender, Puebla was officially renamed Puebla de Zaragoza after Gen. Ignacio Zaragoza. The French again besieged the city, May 17, 1863, and captured it. Gen. Porfirio Diaz took the city April 2, 1867, and ended the imperialist occupation.

As an industrial centre, Puebla is known for its onyx working, Talavera tiles, cotton and woolen textiles, glass, soap, pottery, leather goods and other light articles. (H. R. HY.)

PUEBLO. The agricultural, town-dwelling Indians of the semidesert southwestern United States. They are of four distinct linguistic groups: (1) Shoshonean, comprising the seven Hopi (*q.v.*) villages in Arizona; (2) Zufii, one town in western New Mexico; (3) Keres, comprising Acoma (*q.v.*), Laguna, Sia, Cochiti, Santa Ana, Santo Domingo, San Felipe, all but the first two in the Rio Grande valley; (4) Tano, consisting of three divisions, all near the Rio Grande; (a) Tiwa, five towns, of which Taos is the most northerly and best known; (b) Tewa, six pueblos (including Hano among the Hopi); (c) Jemez. The aggregate population is not far from 10,000, stationary or slowly decreasing, and approximately equally divided between the four speech groups. At the discovery in 1540 the Hopi, Zuñi and Keres may have been twice, the Tano three or four times, as numerous as to-day; the number of towns has also decreased, though some new ones have been founded. The Pueblos live on ancestral lands and cultivate these much as in the prehistoric period, though they have added wheat to maize and acquired some sheep, cattle, horses and asses; their houses, though larger, are of the old type; their religion has been successfully maintained by the Hopi and Zufii and partly preserved alongside Roman Catholicism by the Keres and Tano. They are peaceable, gentle, unenterprising, quietly industrious and conservative. Physically they are fairly uniform; below average in stature, generally brachycephalic, with the skull somewhat flattened occipitally from the cradle board.

Of all the tribes of the United States the Pueblos are most similar to the advanced native peoples of southern Mexico, and the bases of their culture — maize-beans-squash agriculture, cotton growing and weaving, turkey rearing, painted pottery, masonry architecture, ritualism — are no doubt derived from these Mexican civilizations. They lack, however, a number of accomplishments characteristic of the Aztec, Toltec and Maya, such as metallurgy, political organization, calendrical system, ideographic writing, temples and pyramidal substructures. Since some of these traits have an age of about 2,000 years, the main influences emanating from Mexico are likely to have reached the Pueblos perhaps as much as three millennia ago.

South-western archaeology reveals a development through several stages: (1) Basket maker, possessing maize but apparently no other cultivated plants; no pottery or stone houses; spear thrower, but no bow; the physical type mas long-headed. (2) Post-basket-maker, with crude pottery, slab-lined pit houses, the bow and arrow. (3) Proto-Pueblo, with the short-headed type which has persisted to the present; masonry, painted and neck-corrugated pottery, cotton, the turkey, the essentials of historic Pueblo culture, are already present. (4) Early Pueblo, in small house clusters; black-on-white and body-corrugated pottery; this is the era of most of the cliff dwellings and of the greatest geographical extension of Pueblo culture, ruins in Nevada and well north in Utah belonging to this period. (5) Great Pueblo period, with large towns like Pueblo Bonito and Aztec, centring in the San Juan drainage; the northernmost area had been given up, but the ruins in Chihuahua, like Casas Grandes, seem to be of this epoch. (6) Late Prehistoric Pueblo, with glaze-painted pottery; the San Juan area and Chihuahua extension had been given up, but there were still Pueblos on the middle Rio Grande near El Paso. The Spanish discovery of 1540 falls in this period, which may be assumed to have continued until the influence of the missions became strong in the early 17th century, or until the general Pueblo rebellion of 1680. (7) Historic Pueblo, after the unsettlement caused by the rebellion; pottery is again painted instead of glazed, but both black-on-white and corrugated ware are long since forgotten; domesticated mammals have been introduced and sheep's wool tends to take the place of cotton for clothing.

In general, the Pueblos did not irrigate, although they knew how to choose farmlands containing sub-soil water. They are matrilineal and matrilocal, women owning the houses; but men order all public and religious matters. On the Rio Grande the clans weaken and moieties appear, until in the extreme northern towns clans are, to-day at least, lacking. The religious edifice is the kiva, Spanish estufa, a small semi-underground structure for the performance of esoteric rites. Temporary altars are erected in these, often with ritualistic sand or meal paintings; feathers are "planted" as offerings at outdoor shrines; and for all religious organizations, offices and clans there are fetish bundles. The mythology is characterized by tales of emergence from the lower world and long tribal wandering. Cults take three chief aspects: (1) Youths are initiated into a communal men's society performing masked dances representative of gods and ancestors — kachinas. (2) Men and women are initiated individually into "fraternal" societies whose main function is curing, although there are also war and hunt societies; masks are little used. (3) Hereditary priests fast, entreat and pray for rain for the crops and communal welfare, and ultimately direct not only all religious affairs but the civil oificials.

Ritual symbolism is rich, especially as regards the idea of fertilization and number-colour-direction symbol patterns.

PUEBLO, a city of Colorado. U.S., situated on the Arkansas river at the mouth of Fountain creek, 120 mi. S.E.of Denver, at an elevation of 4.685 ft.; the seat of Pueblo county. Pop. (1960) city 91.181; standard metropolitan statistical area (Pueblo county) 118,707 (for comparative population figures see table in COLORADO: *Population*). Pueblo lies near the great coal fields of the state and is an important manufacturing. retail and trucking centre. At Minnequa, on the mesa south of the city, is one of the largest steel plants in the U.S. The irrigated region of 50.000 ac. adjacent to Pueblo produces large quantities of red clover, onion. squash and cantaloupe seed as well as a major portion of the cucumber seed grown in the C.S. The Pueblo ordnance depot of the U.S. army (established in 1942) is on a mesa 13 mi. E. of the city. The Colorado state fair (established in 1886 and provided for by the state legislature since 1907) is held annually in August. The Colorado State hospital (psychiatric) is in Pueblo. Pueblo Junior college, a public school: was opened in 1933.

The site of Pueblo was visited by Lieut. Zebulon Montgomery Pike, who erected a temporary log breastwork on Nov. 23. 1806. In 1823 John McKnight established a trading post, which was soon wiped out by Comanches. From 1843 to 1854 there was a small settlement of mountain men as well as an adobe fort which was destroyed by Utes. A party of gold seekers located there in 1858. Gen. W. J. Palmer's Denver and Rio Grande railroad reached Pueblo in 1872 and he organized the Central Colorado Improvement company with the purpose of creating an industrial city. Reorganized in 1882 and again in 1892, it became the Colorado Fuel and Iron company and fulfilled the original purpose.

In June 1921 a sudden flood of the Arkansas river struck Pueblo. causing severe property damage and about 200 deaths. A $4,000,000 flood-control system was immediately built, which effectively prevented any recurrence of the disaster.

The city established a council-manager form of government in 1950. (HY. L. C.)

PUENTE GENIL, a town of southern Spain, in the province of Cordova; on the right bank of the river Genil or Jenil, a tributary of the Guadalquivir. Pop. (1950) mun., 30,656. It is on the Cordova-Malaga railway and is the starting point of the line to Linares.

A bridge across the Genil, from which the name of the town is derived, joins the lower part of Puente Genil with the higher. The principal industry is the manufacture of olive oil. There are also flour mills and linen factories.

PUERPERAL FEVER, a medical term implying infection of some part of the genital passages following childbirth or abortion. The infection is most commonly of the raw surface inside the womb left after separation of the afterbirth, but pathogenic organisms may also gain entry through laceration of the mouth of the womb or other parts of the birth canal and may invade the blood stream, causing septicaemia.

History. — The disease has been recognized from the earliest days, and some of the greatest names in medicine have contributed to its study. In the 5th century B.C. Hippocrates stated, "If a woman in childbed have erysipelas of the womb she will usually die"; and this truth was manifest in the appalling mortality from the disease that persisted down to the 1930s. William Harvey (1651) was the first to describe the raw placental site as "one vast ulcer" in cases of puerperal fever. Charles White of Manchester, Eng. (1773), drew attention to the identity of puerperal and "surgical" fever; advised postural drainage of the womb in the lying-in period; and, by his vigorous insistence on cleanliness in the conduct of deliveries and on isolation of cases of puerperal fever, made a famous advance in the art of midwifery. Alexander Gordon (1795) noted that puerperal fever was a contagion, since it seized only such women as were visited or delivered by a practitioner or nurse who had previously attended patients affected by the disease. Jean Louis Baudelocque (1789) noted the greater incidence of the disease when hands or instruments had been introduced into the birth canal. I. P. Semmelweiss (*q.v.*) of Vienna (1847) rediscovered White's teaching and, noticing that the mortality from the disease among women attended by doctors and students who also practised dissection upon cadavers was far greater than among the women delivered by midwives, strenuously advocated washing of the hands in antiseptics before attending women in childbed.

During all this time, contagions were held to lurk in "humours" or miasmata which affected the air and the clothing and were thus borne from. patient to patient directly or by an attendant. But in 1879 Louis Pasteur demonstrated a dotlike microorganism grouped in short chains which he had isolated from the lochial discharge of a woman with puerperal fever, and the bacteriologicdl era of the study of disease had arrived.

These streptococci (Streptococcus pyogenes, S. *haemolyticus*) are only one, although the most deadly. of the causes of puerperal fever; others uncovered later are the anaerobic streptococci (which flourish in dead and dying tissues such as are to be found in the genital tract after long and injurious labour and difficult or injudicious instrumental delivery); the Bacterium coli and Clostridium welchii, inhabitants of the lower bowel; and various staphylococci commonly found on the skin and in skin eruptions of a pustular nature. Many of these organisms can be demonstrated in the vagina during pregnancy, and for some time the endogenous or autogenous theory of puerperal sepsis excused the neglect of rigid antiseptic precautions by the attendants of labour on the grounds that pathogenic germs were already present in the birth canal. However, in 1930 Leonard Colebrook stressed the fact that the anaerobic streptococci do not assume dangerous significance unless provided with the medium of bruised and lacerated tissues in which to grow and multiply and that such a development could be avoided by the utmost skill and gentleness in operative obstetrics.

In 1935 Rebecca Lancefield (U.S.) and Ronald Hare (England) showed that the haemolytic streptococci causing severe puerperal fever, scarlet fever, dangerous wound infections and tonsillitis were all of an easily identifiable group (A) which were not found in the normal birth passage before labour. Leonard Colebrook and his sister, Dora, then showed that in a series of cases of puerperal fever caused by the haemolytic streptococcus the infection had been conveyed by medical and nursing attendants or by other contacts who harboured the organisms in nose or throat. Thus was established overwhelming proof that puerperal fever is an easily preventable infection.

Infection and Symptoms. — The severity of the disease varies with the nature of the infective organism (that is, its powers of invasion of local tissues or the blood stream) and with the local and general resistance of the patient. In the gravest cases, the infecting organisms are commonly the pus-producing haemolytic streptococci and anaerobic streptococci and rarely staphylococci and pneumococci. Infection with the germs of gas gangrene (Cl. welchii) are rare but carry a very high mortality. Milder cases of puerperal fever are caused by infection with the nonhaemolytic streptococci and coliform bacilli.

The symptoms and course of the disease are similar to those of an acute wound infection. Fever with rigours usually arises on the third day after delivery, the pulse rate quickens and general prostration develops. The womb remains enlarged and tender. the discharges from it may be profuse and foul-smelling. Serious symptoms are persistent high fever and pulse rate, repeated rigours, sleeplessness, delirium and diarrhoea. Should the infection remain localized to the genital tract (as with coliform bacteria and nonhaemolytic streptococci), recovery is usual after a more or less severe illness (complicated by pelvic abscesses, etc.); but should invasion of the blood stream or peritoneum occur (as with haemolytic streptococci, anaerobic streptococci, Cl. *welchii*) the disease assumes the utmost gravity and, until about 1935, when sulfonamides were first used, accounted for about half the total maternal mortality in childbearing.

Prevention. — A main concern of those caring for women in childbirth is, therefore, to prevent infection from reaching or spreading among their charges. Until the development of antiseptic principles, the incidence and mortality of puerperal fever were horrifying, and the improvement reached by the first third of the 20th century was still unsatisfactory in comparison with that accompanying the prevention of sepsis after surgical operations. The more natural the labour and the less the interference, the lower the incidence of fever. Conversely, the more prolonged and extensive (*i.e.*, the higher up the genital canal) the interference and the greater the injury caused, the higher the risk of infection. Cleansing of the external genitals, disinfection of instruments and dressings and the wearing of sterilized gloves lessen the risk but will not wholly eliminate infection as it is impossible to render the skin surrounding the external genitals and anus absolutely germ-free. Hence the introduction of hands and instruments into the genital passage carries with it the risk of conveying organisms. Careful antenatal assessment of the size of the maternal passages by radiographic means increasingly prevented the necessity for these dangerous manoeuvres, and the discovery and use of powerful, yet saie, skin antiseptics with a prolonged action greatly lessened their risks. The local resistance of the tissues of the genital tract is lowered by bruising and injury and these can in large measure he avoided. The readiness with which infection may be conveyed by doctors and nurses harbouring organisms in the nose and throat has been clearly realized, and the wearing of an impervious mask over the nose and mouth during ministrations to childbearing women much decreased the danger. Antenatal measures directed to the general health of the pregnant woman — the treatment of coexistent disease such as diabetes, anaemia, tuberculosis or malnutrition — tend to raise the maternal powers of resistance to infection.

Treatment.—Treatment is, therefore, first of all preventive; the most stringent care is taken to adopt the same antiseptic and aseptic precautions in labour as for a major surgical operation and further by antenatal care to maintain the vitality at its best, avoiding all foreseeable complications in labour and generally securing natural delivery without interference. Loss of blood and exhaustion should be prevented or remedied by transfusion and restoratives. Complete emptying of, and free drainage from, the womb are essential, as are good nursing and attention to every detail of the mother's comfort and hygiene in the lying-in period. Until the middle of the 1930s, the curative treatment of puerperal sepsis consisted entirely of the above measures and, as has been said. they were successful in cases where the patient's good power of resistance, or the low virulence of the organisms, prevented the development of a generalized infection. Later, the sulionamide group of drugs, first used by L. Colebrook and Meave Kenny in 1935, specific antidotes for infection by haemolytic streptococci, gonococci and pneumococci and Bacterium *coli,* caused a spectacular drop in the mortality of the disease; and, from the early 1940s, penicillin carried this victory over sepsis still further — more than three-quarters of the women who would previously have been doomed to die in this way now being saved. Before the era of chemotherapy, the haemolytic streptococcus accounted for about 75% of the total mortality froni puerperal infection; the major instrument of death thereafter was the anaerobic group of organisms against which neither the sulfonamides nor penicillin had yet been shown to prevail and for which the only remedy lies in measures directed toward avoiding gross injury of the genital tract in labour. Deaths from puerperal infection by mid-century accounted for about one-sixteenth of the total maternal mortality, but the saving of a woman from death to leave her barren or an invalid is not enough. The incidence of the disease showed some reduction after 1935; but it was likely that the published figures did not present the real picture of the prevalence of the disease since, with sulfonamides and antibiotics, the patient's fever might be restrained below notifiable levels.

PUERTO BARRIOS, the principal port of Guatemala (pop. [1057 est] 19 268). served chiefly by cargo and passenger ships of the United Fruit company Named for Justo Rufino Barrios. president of Guatemala from 1873 to 1885, it was constructed as the Caribbean terminus of the railway, built by foreign contractors from the coast to Guatemala City, which realized a century-old Guatemalan dream of a national commercial outlet through a deep-water Atlantic port. The government became dissatisfied nith control of the facilities by foreign interests. however. and constructed a competing port at Santo Tomás (1955) and a highnay paralleling the railroad. Puerto Barrios is also connected with the capital by air. (W. J. G.)

PUERTO CABELLO is a city and port of Venezuela in the state of Carabobo. Pop. (1959 est.) 46,166. The mean average temperature of the port is 80° F. Puerto Cabello has a well-protected harbour accessible to the largest vessels calling at Venezuelan ports, nith docks, narehouses. a navy yard and dry-dock facilities. The city is connected with Valencia, the capital of the state, by a highway and railway over a 2,000-it pass and is considered a natural outlet for the agriculturally rich and commercially important Valencia basin. Commerce dominates the economy of the city, but there are small processing industries. Ten miles from the city, on the Pan-American highway, is a modern petroleum-chemical plant erected by the government. Puerto Cabello was sacked by pirates many times during the colonial period and was a favoured smuggling centre for the Dutch, operating from Curaçao. The city suffered much damage in the Wars of Independence. Simón Bolivar was defeated there in June 1812. Subsequently the port changed hands several times. José Antonio Páez, national hero and long-time president of the republic, led the attack which forced the final Spanish surrender at Puerto Cabello in 1823. The story goes that the waters of the harbour are so smooth that a single hair (*cabello* in Spanish) could moor a vessel to the dock. hence the name Puerto Cabello. (J. J. J.)

PUERTO DE SANTA MARIA, a seaport of southern Spain. in the province of Cádiz, on the right bank of the Guadalete river, nith a station on the railway from Cádiz to Seville. Pop. (1950) mun. 28.368. Puerto de Santa Maria, commonly called "El Puerto," is probably the Rlenesthei Portus of Ptolemy. Its most important industry is the nine trade; there are also glass, liqueur, alcohol, starch and soap manufactures.

PUERTO LA CRUZ, lying in northeastern Venezuela on the Caribbean is one of the country's outstanding petroleum-handling ports Pop (1959 est) 47,772. It is the petroleum metropolis and the shipping terminal for the large output of the Greater Oficina oil-producing area and for smaller oil fields of the state of Anzoátegui Important oil pipelines from these fields as well as from small ones in the neighbouring states of Guárico and Monagas focus upon Puerto La Cruz. The port is also the site of very large oil storage facilities and of refineries. It is connected aith Barcelona, just 6 mi. distant, by railway. (L. WE)

PUERTOLLANO, a town of central Spain in Ciudad Real province, on the Madrid-Ciudad Real-Mérida railway and at the northeast of the Valle de la Alcúdia. Puertollano is 2,345 ft.

above sea level and has mineral baths. Its population (34,621 [mun.] in 1950) more than doubled in the 20th century.

PUERTO MONTT, city and port of southern Chile, capital of scenic Llanquihue province, occupies a narrow plain between Reloncavi sound and large morrainal hills to the north. It is a popular lake district resort, adjacent Tenglo Island and the superb volcano-dominated scenery being major attractions. Pop. (1960) 64.775 (mun.). The city's strategic position between Chile's core area and the islands to the south makes it an important communications centre. It is a terminus for the state railway, serves as home port for state-owned and other shipping and offers air service to the north and south and to Argentina. There are naval and air stations, an important lumber industry and small-boat yards. The city. named for Manuel Montt (*q.v.*), was founded in 1853 by a group of German immigrants. (J. T.)

PUERTO PLATA, a province in northern Dominican Republic. Area 726 sq.mi. Pop. (1960) 163,896. Its southern boundary is the Cordillera Septentrional (to 3,993 ft.), which is the nation's leading coffee region. Puerto Plata is also one of the leading producers of corn (maize), bananas and tobacco and a significant dairying region. The province was established in 1875. Its capital, San Felipe de Puerto Plata (called Puerto Plata), pop. (1950) 14,843, was founded in 1503 by Columbus. It is the nation's second port and an industrial centre. Thirty miles to the west are the ruins of Isabela (reputed to be the first European town set up in the new world), founded by Columbus in 1493. (D. R. D.)

PUERTO RICO (COMMONWEALTH OF PUERTO RICO, ESTADO LIBRE ASOCIADO DE PUERTO RICO). an island and an independent commonwealth voluntarily associated with the United States. It is the smallest and the most easterly of the Greater Antilles, the major island group of the West Indies (*q.v.*), which form the broken northern boundary between the Caribbean sea and the Atlantic ocean. To the west and just out of sight beyond the 70-mi. Mona passage lies the island of Hispaniola. To the east lie the Virgin Islands, one of which, St. Thomas, can be seen on a clear day from the eastern shore. New York, the main U.S. port of departure for Puerto Rico, lies over 1,500 mi. N.W. Directly south, across about 600 mi. of Caribbean sea, is the coast of Venezuela. Puerto Rico is nearly rectangular with a iength from east to west of 113 mi. and a width of 41 mi. Its area is 3.349 sq.mi. (3,435 including adjacent islands).

This article is divided into the following sections:

I. PHYSICAL GEOGRAPHY

1. Geology and Physiography.— Puerto Rico and the other Greater Antilles are formed by the high parts of a 1.300-mi. chain of mountains whose base and bulk are buried beneath the sea. These mountaintop islands are the oldest of all the land masses in the West Indies. In contrast, the Lesser Antilles. which form the eastern boundary of the Caribbean sea, are of more recent formation, and voicanic activity is sometimes still apparent there. Near Puerto Rico the land mass offers its greatest relief contrast in height and depth. To the north of Puerto Rico, running more or less parallel to the island, exists the deep valley in the Atlantic floor known as the Puerto Rico trough (formerly called the Brownson deep). The deepest part of this trough lies about 75 mi. to the northwest of Puerto Rico; there the floor of the Atlantic goes down 30,246 ft. To the south too the land falls off sharply below sea level. Some 55 mi. S.W. of Puerto Rico the Caribbean reaches a depth of over 17.000 ft. If the base of this chain of mounlains were elevated to sea level, it would become one of the most imposing land masses in the world. Indeed, the highest point in Puerto Rico, Cerro de Punta. 4,389 ft., would attain an altitude greater than that of Mt. Everest.

The island's central mountain chain, the Cordillera Central, rises almost directly out of the sea on the west coast of the island and extends eastward, finally terminating in the Sierra de Luquillo in the northeast and in the Sierra de Cayey in the southeast. While this rugged terrain covers about 70% of the island's area, the fertile coastal plains extend like a fringe between the mountains and the Atlantic on the north and the Caribbean on the south. Geologists agree that while Puerto Rico cannot be considered a volcanic island, in the sense that some of the Lesser Antilles might be so classified, the land mass was formed by early volcanic activity during the upper Cretaceous. In general terms, the Cordillera Central is underlain by lavas and volcanically derived sediments resulting from this igneous activity. In the west a large body of serpentine occurs, and in the central and southeastern areas bodies of coarser plutonic rocks, quartz. diorites and granodiorites are found.

The coastal plain on the south side of the island is not so wide nor so naturally fertile as the northern coastal plain. The north-south drainage divide runs parallel to the Caribbean coast about 10 mi. from the shore line. As would be expected, thus, the southern side of the central mountain chain presents a more precipitous drop to the sea than that found on the north. To the north, most of the principal rivers, such as the Rio Grande de Loiza. Rio de la Plata or Rio Grande de Arecibo, descend to the Atlantic through foothills and slowly declining slopes. The flood plains formed by these rivers are extremely fertile.

2. Climate.— While Puerto Rico lies just within the tropics, its climate is usually agreeable. The average annual temperature is 76.3" F., and the island is without sunshine, on average. for only five days a year. On the coast the winter monthly average is 75°; for the summer months it is 80°. In the interior at an altitude of 1.500 ft. the average winter temperature is 70"; during the summer it is 75". The absolute minimum temperature recorded in Puerto Rico was 39° at an altitude of 3,000 ft. Frost may occur at higher altitudes but has never been officially recorded. The maximum recorded temperature in San Juan is 94". Cool, invigorating sea breezes, constantly brought by the trade winds which bathe the islands of the West Indies, help to soften the effect of the hot sun. During the summer months these winds come directly from the east or slightly southeast. During the winter they shift and come from the northeast. At night, gentle land breezes coming down from the mountainous interior bring cool and refreshing air to the coastal areas, causing a drop of 6° or 7° from the day temperature.

The trade winds also bring abundant rainfall, which for the island averages 74.4 in. annually. It rarely rains for more than a few hours at a time, even during the rainy season, which lasts from May to November. The coastal areas are cooled in the late morning or afternoon by light showers during the warmer months of the year. The variation in rainfall recorded in different parts of the island is much greater than the temperature variation. The rain forest of Sierra de Luquillo, the northeastern branch of the central mountain chain, which receives the trade winds first, recorded an average annual rainfall of 184 in. over a ten-year period. In the southwest corner of Puerto Rico annual rainfall drops to about 30 in. The island is subject to occasional tropical storms. The winds, which reach a velocity of 150–200 m.p.h., are usually accompanied by torrential rains. The storms, which rarely last more than a day, occur from July to October.

3. Vegetation. — The erosive effect of a heavy rainfall on the precipitous slopes of the central mountain range of the island is counteracted by a particularly tenacious soil bound together by clinging and abundant vegetation. The wide variation of rainfall, a fairly rich soil and different altitudes produce a great variety of plant life. Because of the extensive cultivation of the land, the vegetation in a relatively natural state is limited to the insular and national forest reserves located at higher altitudes in the western, central and eastern sections of the island. The tropical rain forest of the Luquillo National Forest reserve, located at the eastern end of the island, is composed of a great variety of trees, clinging and hanging vines and a thick undergrowth of shrubs, ferns and thickets. The junglelike density is almost impenetrable without the aid of a machete, a sharp, long, broad-bladed knife. In this area wild orchids can be found. Trees include bamboo, palm, cedar, ebony, calabash, whitewood, lancewood, boxwood and logwood.

Along the coastal plains, which probably were covered once with a thick forest growth, sugar cane and pineapples are grown. In the northwest corner of the island and in the mountain areas tropical fruits of all varieties are produced. In the western highlands, together with the coffee bush, can be found a great variety of citrus fruits. In addition to the common fruits such as bananas and oranges the island produces papayas, pomegranates, avocados, guavas and mangoes. Spices such as ginger, pepper, vanilla and chicory are also grown.

4. Animal Life. — Physically isolated at an early geological age and densely populated, Puerto Rico has very little wild animal life. Bats, birds, a scarce and harmless species of snake and several varieties of harmless lizards, together with the mongoose and rat, comprise Puerto Rican wildlife. For the patient bird watcher the island offers a wide variety of species of birds, nesting or in transit. About 190 species have been identified, and of these 89 are known to nest. Some 36 birds are endemic to Puerto Rico. Thrushes, tanagers, bullfinches, flycatchers, warblers, plovers, terns and sandpipers are the birds most commonly seen.

The waters around the island are excellent for sport fishing. Yellow-fin tuna, white marlin, sailfish, dolphins, kingfish and wahoo are only a few of the commoner varieties which can be found 2 to 5 mi. from the coast. There are fine black bass in the fresh-water reservoirs of the island.

II. GEOGRAPHICAL REGIONS

Puerto Rico may be divided into three geographical regions, using as the principal criteria the contrasting altitudes.

1. Lowlands and Coastal Plains. — Geographers have calculated that 27% of the island's land can be classified as flat or gently rolling lowlands. With one or two minor exceptions offered by small inland valleys, one near Caguas and the other near Cayey, this region is comprised primarily of land along the coastal fringe of the island. Depending upon the availability of water, the flat or rolling coastal lands are the most fertile areas of Puerto Rico. The abundant rainfall on the north coast assures production, but on the south coast and particularly in the southwest corner, in the Lajas valley sector, the flat rolling land needs irrigation. In the Lajas valley the insular government built an extensive and costly irrigation project which collects in artificial lakes the heavy rain that falls on the nearby highlands, brings the water down over hydroelectric dams and channels the distribution into the previously arid valley.

For the most part the coastal plains produce the bulk of the island's sugar crop. About 30 sugar mills, or *centrales,* located in this region produce more than 90% of the island's sugar. More than 20% of this sugar is produced on the north coast and about 30% is produced on the irrigated plains of the south coast. Some coastal land lacking in rainfall or fertility is used as pasture. Prior to the completion of the irrigation project, the Lajas valley was used primarily in this way. On the north coast about 50 mi. W. of San Juan, near the port of Arecibo, pineapple production has been expanding. The coastal area has some unproductive land in mangrove swamps and in limited areas where sand dunes have moved inland. By far the best of the island's beaches can be found on the sheltered west coast. The north coast also has excellent beaches wherever offshore reefs serve to break the heavy Atlantic surf. The Luquillo beach east of San Juan is perhaps the most popular and widely known.

2. Highlands. — In contrast to the coastal plains is the markedly mountainous terrain of the central part of the island, which accounts for about 36% of the land area. This extensive area is marked by high local relief with little flat land. Most of the slopes range from 30% to over 60% grade. This region, comprised of the Cordillera Central, the Sierra de Cayey and the Sierra de Luquillo, includes the highest peaks of the island drainage divide.

Heavy rainfall and fertile soil permit extensive cultivation of this region in spite of the sharp slopes. Coffee is the main crop in the area uhich extends from near the west coast to the centre of the island. The shrub which produces the coffee bean is very sensitive to temperature variations and grows best in shaded areas between 1,000-ft. and 3,000-ft. altitude; orange and grapefruit trees and the broad-leaf banana plants are utilized for shade. As a result of the cultivation of coffee in the western mountain area, the impression is given of a cleared, well-gardened forest. Two insular forest reserves, Maricao and Toro Negro, nith picnic facilities and lookout towers, can be found in the western and central mountain areas.

The eastern mountainous section, with the exception of the Sierra de Luquillo, receives less rain than the western highlands do, and the vegetation is less thick and the land unprotected by a covering forest. Tobacco is the principal commercial crop. Small farms produce subsistence crops, and extensive pasture areas can be found. The Sierra de Luquillo, where the tropical rain forest is located, has a recreation park with trails, swimming pools and lookout towers.

3. Rolling Hill Land. — The area of the island which lies between the two extremes of the flat coastal plains and the markedly mountain terrain can be described as rolling hill land; it comprises the remaining 37% of the land surface. Foothills adjacent to the central core of mountains are included in this area. In this region the unique limestone belts of the northeastern and north central section of Puerto Rico are found. This area, which is similar to the cockpit area of Jamaica (*q.v.*), is of a more recent geological age than the rest of the island, having been formed during the Tertiary period. The limestone plateau, at one time under the sea, once lifted and exposed to rain and wind erosion, was slowly converted into striking karst topography. The area is characterized by precipitous cliffs, caves and large caverns, deep depressions or sinkholes and undissolved limestone remnants or *mogotes,* which resemble conical haystacks. In this area rivers such as the Tanamá or Camuy disappear suddenly and, running underground, appear just as unexpectedly miles away. In spite of the rugged terrain, the irregular valleys among the *mogotes* and precipices are cultivated with some success by the small farmer. Subsistence crops, vegetables and fruit are the main products.

4. Mona, **Culebra** and **Vieques** Islands. — These small islands are politically and culturally linked to Puerto Rico. Fifty miles southwest of the western port of Mayagüez is Mona Island (*q.v.*), consisting of a limestone plateau of about 20 sq.mi. Light rainfall and infertile soil make Mona an island of poor vegetation

and no permanent inhabitants. Culebra Island (*q.v.*), half the size of Mona, is situated halfway between Fajardo, the east coast port of Puerto Rico, and the port of Charlotte Amalie in St. Thomas, Virgin Islands. Culebra's population of 887 lives mostly in a small town located in the excellent harbour of Puerto Grande. Vieques Island has an area of 57 sq.mi. and is located 10 mi. S.E. of Puerto Rico. While most of the island is used for naval installations by the U.S. government, the small population has struggled to maintain itself by cultivating the sparse soil.

III. THE PEOPLE

1. Racial Characteristics. — Puerto Ricans are mostly descendants of a European stock, specifically Spanish, with an admixture of Negro and some Indian (mainly Arawak or Boriquén) strains. The dominant Spaniards absorbed or eliminated the Indians within a very short time after the conquest of Puerto Rico, but physical characteristics of the aboriginal Indian are still evident in dental formation, colour and texture of hair and even facial structure, particularly of the people in the mountainous interior.

Negroes were introduced early in the 16th century as slave substitutes for the disappearing Indians. However, under the lenient Spanish treatment many of the slaves earned or were granted freedom. Partly as a result of this attitude the slave population was always smaller than that of free coloured people. In 1846, when Puerto Rico's slave population reached the top figure of 51,265, the number of free Negroes was 175.791 and the combined slave and free coloured population was slightly more than 50% of the total population. As Puerto Rico's population increased during the 19th century, with the slave trade effectively halted and slavery abolished, the percentage of Negroes in the over-all population declined rapidly until by the early 1960s less than 20% of the population was classified as nonwhite. However, to be socially considered white, it is not necessary to meet the strict biological requirements of having only white ancestors.

The *jibaro* is the small isolated independent farmer who has struggled for centuries to sustain himself in the rugged Cordillera Central. Within recent years the *jibaro* has been converted into an insular cultural, if not political, symbol.

2. Language. — Puerto Rico draws upon a rich Spanish cultural heritage. The Spanish language is spoken everywhere and is used throughout the school system. English is taught as a secondary language, and in the urban areas and particularly in the commercial establishments, English is commonly heard. Rare would be the businessman who could not carry on a limited conversation in English, and many are fluent bilinguists.

3. Religion. — For the almost 400 years of Spanish control over Puerto Rico the Roman Catholic Church occupied an exclusive place as the state-protected religion. Indeed, Puerto Ricans came to look upon the crown and the church as one. Almost every town on the island has, in true Spanish style, a Catholic church located on one side of the central plaza.

After the change of sovereignty in 1898, evangelical sects became active on the island. Most of their followers are drawn from the lower classes and the expanding urban middle class. Approximately 20% of the population is considered to be active in one or another of the evangelical groups. The cost of the insular evangelical work has been sustained by the various missionary boards in the United States, but the local churches have been encouraged to become economically independent.

A growing number of islanders are believers in some form of spiritualism. These people come from all classes of society but are said to be found most commonly among groups undergoing marked social change.

4. Customs and Culture. — Spanish influence is waning in the social customs of the people of the large towns and cities. The growing industrialization and increasing U.S. influence are converting Puerto Ricans from a two-class, stable, patriarchal, agrarian society to a mobile, three-class, modern, industrial society in which women are achieving a place of equality with men. The rising rate of divorce is an indication of these changing social conditions. Among adolescents of the large cities the chaperon is a thing of the past. Still, in some of the small towns of the interior on Saturday evenings or holidays, the custom of strolling around the plaza, boys in one direction and girls in the other, can be observed. Birthdays, weddings and deaths are occasions for social gatherings. Wakes, *rosarios* (nightly ceremonies in commemoration of a death) and *rogativos* (group supplications) are still observed in rural areas.

In music the fused influence of the African and Latin strains is most notable. Both popular and traditional music have a distinct local flavour. The island has actively cultivated an interest in classical music, and several symphonic groups function, one with the financial backing of the government. A chief contributor to this cultural renaissance was the cellist Pablo Casals.

The island government, concerned at the apparent lack of concerted efforts to preserve the historical and cultural heritage of the island, organized the Institute of Puerto Rican Culture, which, with local branches in all the leading towns, undertook to encourage, through scholarships and prizes, the expression of local artists, musicians and writers. Museums were established, traveling exhibitions were sponsored, drama groups were encouraged, and a series of scholarly publications was initiated, all with the purpose of making Puerto Ricans appreciate their cultural roots.

IV. HISTORY

The first inhabitants of Puerto Rico, originally from the Amazon basin of South America, reached the island by means of the archipelago of the Lesser Antilles some 600 years before the arrival of the Spaniards. These Arawak Indians, living in small villages, were organized in clans and led by a cacique or chief. They were a peaceful people who, with a limited knowledge of agriculture, lived on a variety of domesticated tropical crops such as pineapples, manioc and batatas supplemented by shellfish and other sea food. Anthropologists estimate their numbers to have been between 20,000 and 50,000. On an island naturally fertile, the Arawaks lived an easy life disturbed only by occasional visits from their cannibal Carib neighbours on the islands to the south and east. At the time of discovery, Carib Indians occupied most of the Lesser Antilles, the Virgin Islands and Vieques Island.

In 1493 Christopher Columbus, at the peak of his popularity, left Spain on his second voyage to the Indies with an elaborate expedition of 17 ships and about 1,500 men. At the island of Guadeloupe, the Spaniards rescued several Arawak Indians who had been taken from Boriquen, the Indian name for Puerto Rico, by the Caribs. Columbus agreed to return them to their island, and on Nov. 19, 1493, the expedition anchored in a bay on the west coast of Puerto Rico. Columbus formally took possession of the island in the name of Ferdinand and Isabella, the rulers of Spain, and named it San Juan Bautista. Two days were spent on the island before the ships moved westward to Hispaniola, where the first settlement in the new world was established.

A. Spanish Rule

1. Early Settlement. — For 15 years the island was neglected except for an occasional visit by a ship putting in for supplies, In 1508 Juan Ponce de León (*q.v.*), who previously had accompanied Columbus, was granted permission to explore San Juan Bautista in recognition of his valuable colonizing efforts in eastern Hispaniola. On the north coast, Ponce de León found a well-protected bay which could offer safe harbour for a large number of sailing vessels. The harbour was named Puerto Rico because of its obvious excellent potentialities. In this area was located the most important settlement on the island; through time and common use the port became known as San Juan while the name Puerto Rico came to be applied to the whole island.

The peaceful and friendly relations with the Arawak did not last long. The Spaniards expected the Indians to acknowledge the sovereignty of the king of Spain by payment of gold tribute. The Indians were to be instructed in Christian ways. In return for this education, which was rarely given, the Arawaks were expected to work and supply either more gold or provisions of food. In 1511 the Indians rebelled against the Spanish, who with their superior arms rapidly subjugated them.

Placer mining of gold was continued by Indians brought from other islands and by Negroes introduced from Africa by some of the early traders. After the 1530s, however, gold production markedly declined, and the Spanish colonists, with slave labour, turned to agriculture. By 1550, with financial aid from Spain, several small sugar mills were in operation on the island.

Puerto Rico did not prosper economically, however. Carib Indians from neighbouring islands made frequent raids, carrying off food and slaves and destroying property. The colony continued to lead a precarious existence, ravaged by plagues and plundered by French, British and Dutch pirates. Repeatedly during the mid-16th century the French burned and sacked San Germán, the second community to be established on the island. Under such adverse conditions people began to leave the island whenever opportunity offered.

In the second half of the 16th century Spain, recognizing the strategic importance of Puerto Rico, undertook to convert San Juan into a military outpost. The fortress El Morro, built with the financial subsidy from the Mexican mines, was well constructed and perfectly located to dominate the narrow entrance to the harbour. Later, a stronger and larger fortress was built to the east and on the Atlantic side of the city. In the early 17th century the city was surrounded by a stone mall, 25 ft. high and 18 ft. thick, two parts of which still stand. These defenses made San Juan almost impregnable.

Sir Francis Drake attacked the town in 1595 but failed to gain the harbour. Three years later George Clifford, 3rd earl of Cumberland, had complete military success but was forced to abandon his conquest owing to an outbreak of plague among his troops. In 1625 a Dutchman, Bomdoin Hendrik, burgomaster of Edam, boldly sailed into the harbour, captured and burned the town, but failed to subdue El Morro. .

San Juan as the most exposed military outpost guarding the heart of Spain's new world empire, received political and economic attention from the mother country. However, the rural inhabitants of the interior of the island were ignored by Spain and scorned by the presidia1 residents of San Juan. As the French. English, Danish and Dutch fought over and settled the Lesser Antilles during the 17th and 18th centuries, rural Puerto Ricans, ignoring the edicts of Spain, found profit in clandestine trade. Ginger, hides, sugar, tobacco and cattle from the island were in great demand, and while the colonial authorities of San Juan rarely ventured out of their walled defenses for fear of the reprisals of the buccaneers the rural settlers prospered in a modest way through contacts nith the non-Spanish European traders. No large plantations were established, and the farmer, with little help, cultivated his own land. Contrary to the fears of Spain, this contact with foreigners did not corrupt the islanders, who remained loyal and were willing to participate in aggressive expeditions.

2. Liberal Reforms. — In 1797 the British Gen. Sir Ralph Abercromby, who had captured Trinidad, unsuccessfully attacked Puerto Rico. The British considered the island — a centre of clandestine trade and of operations for quasi-piratical expeditions, and a refuge for runaway slaves — a weak link in the chain of defense of the Spanish empire. The failure of Abercromby was due in part to the important economic and administrative changes in the Spanish colonial empire which were carried out in the latter half of the 18th century by representatives of the Bourbon rulers of Spain. In the case of Puerto Rico it was hoped that the island might become an economic asset rather than a financial drain on the Spanish crown. Trade relations between the island and Spain were liberalized, agricultural production was stimulated, the island as a whole was integrated into the system of military defense, and, above all, concerted efforts were made to break down the social dichotomy which had developed between the walled city of San Juan and the interior.

The liberal reforms of the enlightened despotism of the Spanish Bourbons coincided with and encouraged rapid population growth, introduction of new products and the beginning of commercial agriculture. Population was estimated in 1765 at 45,000; in 1775 at 70,250; in 1787 at 103,051; and in 1800 at 155,426. By the end of the 18th century there were 34 towns on the island. Immigrants from the Canary Islands, French settlers from Louisiana or Haiti and Spaniards from Santo Domingo, which had been turned over to Napoleon, accounted in part for the increase in population. These newcomers brought with them new ideas and methods of producing marketable crops. Coffee, introduced into the island in 1736, became an important export item by 1776. Sugar production, which had always been small, was undertaken on a large scale by augmented slave labour. From 1765 to 1800 the slave population increased from 5,037 to 13,333.

When Napoleon invaded Spain and placed his brother, Joseph Bonaparte, on the Spanish throne (1808), the colonies of South and Central America asserted their right to govern themselves in the name of the imprisoned Bourbon king, Ferdinand VII. This claim to temporary self-rule eventually evolved into a revolutionary movement for independence. In Puerto Rico, however, for various reasons, the sequence of events and their results were different. The communities of the interior of Puerto Rico, with one exception, offered little objection to the strict rules of Spain's mercantilist policy, which for many decades had ceased to have effect on them. Most of the residents of San Juan, on the other hand, dependent upon administrative and military positions, were most willing to follow the orders of the central government of Spain acting in the absence of the king. Puerto Rico, which had asserted its loyalty by repelling the English, undertook to recapture Santo Domingo from the French.

As the revolutions progressed on the southern and central mainlands, loyal Spaniards reluctant to leave the colonies found refuge in Puerto Rico, which was being used as a supply depot for military movements on the continent. In recognition of its loyalty and in a belated move to liberalize an outmoded colonial system, the Spanish government granted Puerto Rico in 1815 ample economic liberties. The island was opened to all non-Spanish Catholics, the ports were permitted to trade with non-Spanish countries, and free land was granted to the new settlers.

3. Economic and Political Development. — By the end of the 19th century the population had increased to nearly 1,000,000, and the value of foreign trade had increased considerably from an estimated $1,000,000 in the 1820s to $30,000,000 annually. During the 1800s imports from the United States rarely dropped below 20% of the total goods received; exports to the U.S. fluctuated between 50% and 15% depending in part upon U.S. tariff restrictions. By 1899 the United States was buying 61% of Puerto Rican sugar production. The area devoted to sugar had been slowly expanding, and the processing was becoming more centralized. Coffee, in the late 19th century, provided the principal source of income for the island; its production quadrupled between 1862 and 1898.

Political development in Puerto Rico during the 19th century was characterized by periods of liberal advance counteracted by long periods of conservative reaction. In part, this was due to the changes occurring in the Spanish government, and in part due to the antiquated Spanish colonial administrative policy.

During the first half of the 19th century, two short periods of relative political freedom were enjoyed. From 1809 to 1814 and from 1820 to 1823 Puerto Rico was declared an integral part of Spain with the right to elect representatives to the Spanish *Cortes*, or parliament. Ramón Power y Giralt, an able liberal, was selected during the first period and succeeded in revoking the absolute powers of the island's colonial governor. In the latter period Demetrio O'Daly secured the separation of the military authority from the colonial administrator. Freedom of the press was also permitted. On each occasion moderate colonial rule was thwarted by the return of royal absolutism in Spain.

In 1837, when a fairly permanent constitutional monarchy was established in Spain, Puerto Rico failed to benefit because it was argued that the colonies were not true Spanish provinces and therefore should be governed by special laws. For more than 30 years Puerto Rico waited for special legislation to ease the despotic rule of military colonial governors. During this waiting period, political thought in the island began to crystallize. A liberal current of opinion, remembering the success of previous periods. requested assimilation into the Spanish government and permission to be represented in and governed by the *Cortes*. A bloc of conservative opinion strongly approved of the status quo. A small third group advocated complete independence.

4. Movements Toward Self-Government and Independence.—A local commission was elected in 1865 to draw up a report on the basis of which a governmental reform might be carried out. The majority report, which declared that the abolition of slavery was the *sine* qua *non* of any political reform, provoked a shocked reaction among the island and peninsular conservatives. The alarmed colonial government took steps to curtail what was feared to be a growing movement of rebellion. Some of the more outspoken and respected islanders were ordered to be arrested and sent to Spain for trial. Thus provoked, a small group of radicals committed to independence attempted an uprising, for which, however. inadequate preparation was made. El *Grito* de *Lares,* the abortive revolt of Sept. 23, 1868, brought forth severe reprisals on all island liberals. However, the abdication of Queen Isabella II of Spain was forced by a republican government, which pardoned all the political prisoners. The first Spanish republic extended to Puerto Rico its third period of constitutional government, 1868–74, during which slavery was abolished.

During the 1880s a movement for political self-government under Spain led by Román Baldorioty de Castro replaced the sentiment in favour of integrating Puerto Rico into the Spanish government. Again a liberal political movement, this time autonomy, was denounced as disloyal and was violently suppressed in 1887, an infamous year in Puerto Rican history. Such treatment only served to solidify the movement for local self-government, and in 1897 the Partido Unionista (Autonomy party), now guided by Luis Muñoz Rivera, through co-operation with the Liberal party in Spain, achieved its objective. The autonomous government granted was parliamentary in form but retained the governor general as a representative of the Spanish king. He was empowered to disband the insular parliament and suspend civil rights. The two-chamber parliament was empowered to legislate for the island, create and control an insular tariff and levy local taxes. Puerto Rico's representation in the Spanish *Cortes* mas also increased. Any change in the governmental organization had to be first approved by the insular parliament.

5. Spanish-American War.—The Spanish-American War (*q.v.*) prevented the islanders from putting into effect the new government. In May 1898 Adm. W. T. Sampson bombarded San Juan for a short time without serious results. Facing token military resistance and with general popular acceptance, Gen. Nelson A. Miles landed a U.S. force of about 3,500 men in July, and after a short campaign hostilities were ended on Aug. 12.

B. Under the United States

1. Early Years.—On Oct. 18, 1898, the island was turned over to the U.S. forces and Gen. John R. Brooke became military governor. Puerto Rico was ceded to the US. by the treaty signed in Paris. Dec. 10, 1898 (ratified by the U.S. senate Feb. 6, 1899). In the work of policing the country, in the accompanying tasks of sanitation, construction of highways and other public works, accounting for the expenditure of public funds and establishing a system of public education, the military control which lasted until May 1, 1900, proved effective in bridging the period of transfer from the control of Spain to the system under the United States civil government. The United States congress passed the Foraker act, under which civil government was instituted in May 1900. Under this act the U.S. element exercised the controlling power; this, however, having proved distasteful to many Puerto Ricans, the Organic law was subsequently amended to give a wider native participation in the government. The Olmsted act, approved by congress on July 15, 1909, placed the supervision of Puerto Rican affairs in the jurisdiction of an executive department to be designated by the president. The people, however, demanded a larger measure of local control. The majority also asked for U.S. citizenship and many other changes. As a result, congress passed a new Organic act (the Jones act), which came into effect on March 2, 1917. Under its terms Puerto Rico became a territory of the United States "organized but unincorporated," and citizenship of the United States was conferred collectively on Puerto Ricans, allowing the right to retain the old status if preferred. Only 288 persons declared in favour of the latter. The local civil government, however, even with modifications, fell far short of the measure of self-government which Puerto Ricans expected in light of the democratic tradition of the United States. Key officials, including the governor, were presidential appointees and thus beyond local control.

In spite of the legal limitations on political autonomy, a climate of freedom was slowly developed as a result of the change of sovereignty. At first this new order, being abrupt, new and imposed from above in some instances, was sometimes mistrusted, resented and misunderstood, but in the long run it was recognized as beneficial and assimilated by the islanders. For example, labourers were allowed to organize for collective bargaining and to affiliate with labour unions in the United States; the Anglo-Saxon legal procedure of assuming innocence until proved guilty brought slowly a feeling of security and freedom from political persecution; the separation of church from state, resulting in open competition for religious adherence, demonstrated the new climate in a practical way; government programs which dealt directly with the vital needs of the people for education, health and sanitation, regulation of working conditions and public facilities all reflected a change designed to remedy centuries of neglect.

2. Economic and Social Changes.—The economic reorientation of the island as a result of the change in sovereignty had almost an immediate and profound effect on all aspects of life. Included within the U.S. tariff walls, Puerto Rican agricultural products, particularly sugar, had a ready market. Aided by the adoption of G.S. currency and by unobstructed financial movement, Puerto Rico experienced within a short period a large capital investment which revolutionized the production of sugar. Sevenfold acreage expansion (1899 to 1939), new disease-resistant plants, rapid transportation facilities, large and efficient cane-grinding mills and complete corporate management within a generation converted the economy of the island into one in which 75% of the population directly or indirectly was dependent upon sugar. Land which had sustained small farmers producing crops and dairy products for local consumption was absorbed by the sugar corporations. The island was forced to import its foodstuffs. Coffee was neglected at a time when weather conditions and transportation problems dictated financial and government aid. Only tobacco production experienced growth, which failed to be sustained after the 1920s when United States smokers shifted from cigars to cigarettes.

The shock of these economic changes might have been absorbed in spite of the island's limited resources if at the same time Puerto Rico had not been undergoing a severe social change as a result of the application of modern sanitation means and medical knowledge to a people with a very high death rate. The population was threatening to double its number in two generations. The two counterpressures—expansion of corporate control over the limited productive land and increasing population pressure—reached an explosive stage at the time when the economic depression occupied the attention of government officials in the United States. Recurring hurricanes joined with declining exports to aggravate the economic distress of the island.

3. Political Development.—With one exception, political parties which had developed since the change in sovereignty had centred their attention on modifications in the political relations between the island and the U.S. federal government. The Republican party limited its program to a plea for statehood for the island. The Union party worked for greater autonomy. In the 1920s the Nationalist party rose to affirm the ideal of immediate independence. The one exception was the pro-U.S. Socialist party, led by the highly respected labour leader Santiago Iglesias. This party had expressed since its foundation a concern for the plight of the labouring classes of the island. Nevertheless, its effectiveness had been hampered by insufficient popular support, due primarily to the concentration of attention upon the issue of the political status of the island.

In the mid-1930s, with Pres. Franklin D. Roosevelt's New Deal policies radically enlarging the previously accepted concept of the function of government as that of maintaining order and protecting the citizens, Puerto Rico was not neglected. More important than the much-needed temporary relief were the steps taken by the Puerto Rican Reconstruction administration (P.R.R.A.), designed to readjust the distribution of economic power on the island. A restrictive quota was placed over sugar production. Legal procedures were initiated to enforce a long-neglected law limiting corporate holdings to 500 ac. Thus the process of increasing the sugar acreage was to be reversed and Puerto Ricans were to be returned to their small farms. A model sugar mill was to run on a co-operative basis to compete with the private mills. Coffee and tobacco growers were to receive long overdue attention.

This radical program provoked the open opposition of the sugar interests, locally vocal through the Republican party. The Socialists accepted the program in a tacit fashion. Their reluctance was due to the fact that the young radical wing of the heirs of the Autonomy party, led by Luis Mufioz Marín, the son of Luis Mufioz Rivera, was recognized in Washington and on the island as the local political proponent of the economic reform.

The success of the New Deal measures was jeopardized by two unconnected factors. Unforeseen administrative and financial problems forced a curtailment of the objectives of the P.R.R.A. No longer was a complete readjustment of the island's economic structure possible; the P.R.R.A. took on a more temporary or experimental nature. The second factor a-as the interjection of the status issue on the political scene by the U.S. government in answer to Nationalist violence. Taking the form of a vindictive offer of independence under adverse economic conditions, the proposal served to realign again the political parties into pro- and anti-independence groups.

The incipient political movement for economic reform originally fostered by the New Deal and temporarily sidetracked was surprisingly successful in the election of 1940. This new political movement took the form of a political party, led by Mufioz Marín, called the Popular Democratic party. Organized to improve the conditions of the louer classes, particularly the hard-working *jibaro* of the mountainous interior, the new party's platform was summarized by the slogan "Bread, land and liberty." The island electorate had agreed that the political status was not in issue and that economic and social problems took precedence. Tenuous control over the island legislature and a new-style colonial governor, Rexford Guy Tugwell, allowed the Popular Democratic party to initiate such economic reforms as redistribution of land, enforcement of minimum wage and hour laws, an enforced progressive income tax law and the establishment of an economic development program. In recognition of partial fulfillment of its announced aims the Popular party was overwhelmingly backed by the island electorate in 1944. In 1946 Pres. Harry S. Truman named Jesús T. Pifiero, a Puerto Rican, as governor, the first Puerto Rican to occupy that post. In 1947 the U.S. congress amended the Organic act of Puerto Rico to permit election of governors by popular vote. Mufioz Marín was elected Nov. 2, 1948, and took office in Jan. 1949. In spite of efforts at economic development, the post-World War II years were marked by large-scale emigration to the eastern United States, mainly New York city.

Governor Muñoz Marín and the Popular Democratic party turned to deal with the temporarily postponed problem of political status. The economic recovery experienced by Puerto Rico under the guidance of the *Populares*, rather than freeing the island from its economic ties to the United States, changed these relations from unrestrained exploitation by absentee sugar corporations to controlled industrial production which allowed the islanders to receive greater benefits from the original capital investment. Obviously any political change had to take into consideration these essential economic relations. The solution was found in the expansion of local political autonomy which did not affect adversely the economy.

4. Establishment of the Commonwealth. — In 1950 the U.S. congress offeredto Puerto Rico for its approval or rejection a series of changes in the law which governed the relationship between the federal government and Puerto Rico. These changes if accepted would eliminate all sections dealing with the creation of the local insular government and would turn over to the people of Puerto Rico the power to create their own government under a constitution of their own making. Under the guidance of Governor Mufioz Marín the islanders accepted the offer of congress and drew up a constitution. Duly approved by the people and the congress, Puerto Rico's constitution mas proclaimed on July 25, 1952, and the Commonwealth of Puerto Rico came into being. (See *Administration and Social Conditions*, below.) After some years of operation the full measure of self-government is still being explored and defined. During this period, Puerto Rican extremists dramatized their desire for independence with an attempt to assassinate President Truman on Nov. 1. 1950, in Washington. They attracted world-wide attention on March 1, 1954, when several members of the Nationalist party shot and wounded five congressmen in the house of representatives in the U.S. capitol. Nevertheless, in the judgment of the general assembly of the United Nations, expressed in a resolution of Nov. 27, 1953, Puerto Rico is a self-governing political unit associated voluntarily with the United States and is no longer considered a colonial territory.

V. POPULATION

The population of Puerto Rico, 2,349,544 in 1960. had more than doubled since 1899, when it was 953,243. The 1950 census gave a population of 2,210,703, of whom about 40% were urban and 60% rural; 79.7% were classified as white and 20.2% as Negro. This small island, with a population density of over 687 per square mile, is one of the most densely populated areas of the world. One of the principal reasons for the growth was the application of modern medical knowledge to a previously underprivileged island, resulting in a radically declining death rate. From 1901 to 1957 the island's death rate dropped from 36.7 per 1,000 to a subnormal 6.9. a lower figure than that in the United States. The birth rate declined at a much slower rate: from 43.2 in 1947 to 32.6 in 1957. The difference (+25.7) between the birth and death rates in 1957 left a high rate of natural increase (a ratio of four births to every death on the average), thus accounting for the high population density. If the United States were this densely populated. it would have 1,500,000,000 inhabitants or about 60% of the world's population. According to the demographers. by the 1960s the population of Puerto Rico should reach its maximum, an estimated 2,500,000 persons. The death rate should rise automatically to a more normal 12 per 1,000 as the age distribution approximates proportionately the same distribution attained in the United States. The birth rate can be expected to continue to decline as the standard of living rises and the middle class increases.

One factor which allowed Puerto Rico to keep pace economically with the rapidly growing population was emigration to the United States. The difference between the numbers of those leaving and those returning to Puerto Rico in the 1950s resulted in a net exodus of about 50,000 a year. This figure was only slightly under the average yearly natural increase of 60,000 for the same period. For the most part, Puerto Ricans who went to the United States were young persons of aorking age with an occupation or skill. Those who returned to the island were older people, already past their productive years.

The metropolitan areas have absorbed much of the island's population growth. The rural inhabitants, particularly in the western highlands where the coffee haciendas are found, have been migrating to the cities on the north and south coasts. Some indication of this migration can be seen in the growth of San Juan (merged with Rio Piedras), which in the 1950s doubled its population to well over 500,000.

VI. ADMINISTRATION AND SOCIAL CONDITIONS

1. Government. — The government of. the Commonwealth of Puerto Rico was established by a constitution drawn up by representatives of the Puerto Rican people meeting in a convention; approved by the electorate of the island, March 3, 1952; and ratified by the congress of the United States. This constitution, proclaimed July 25, 1952, provides for an autonomous form of representative government and guarantees the liberties and rights of its citizens through a bill of rights. The people of Puerto Rico are free to

modify the constitution as long as such modifications do not conflict with the U.S. constitution or the Puerto Rican Federal Relations act, which, as its title indicates, defines to a limited extent the relations between the commonwealth and the federal government. This act was adopted "in the nature of a compact" by the U.S. congress and the Puerto Rican people. To change this compact the consent of both groups would be required.

The constitution provides for a government whose powers are distributed among the executive, legislative and judicial branches. Franchise is restricted to citizens 21 years of age and over. The governor of Puerto Rico is elected by popular suffrage every four years, and unlimited re-election is permitted. He appoints, with the consent of the commonw ealthsenate, the heads of departments, who form, with other agency directors selected at the governor's discretion, his advisory council. Aside from the departments such as labour, education and justice, the commonwealth has a department of co-operatives.

The members of the legislative branch, composed of a senate and a house of representatives, are elected for four-year terms. There are eight senatorial (two members each) and 40 representative districts. Eleven senators and eleven representatives are chosen at large. The common ealth constitution guarantees, by means of automatic appointment based on island-wide voting strength, the representation of minority parties in the legislature.

The island is divided into 76 municipalities, each of which has an elected mayor and assembly whose primary functions are to administer schools, health centres, poor relief and other services of the commonwealth.

The Puerto Rican electorate sends a resident commissioner to the U.S. congress for a term of four years, but he has no congressional vote. Puerto Ricans do not vote in the U.S. presidential elections, but emigrants on the mainland may do so subject to local electoral laws.

2. Taxation. — Since the citizens of Puerto Rico (after one year's residence on the island all U.S. citizens fall into this category) are not represented with a vote in the federal congress, they are not subject to federal taxes. The commonwealth government is sustained in part by the local revenue laws, which in general provide for taxes about one-quarter to one-third lower than those of the mainland. A graduated personal and business income tax, an excise tax and a property tax are the main sources of local revenue. The excise tax, which has produced more than half of the commonwealth's locally collected revenue, was used to reduce spending on nonproductive luxury items, the purchase of which tended to drain off potential local capital.

3. Living Conditions. — The middle- and upper-class living conditions in Puerto Rico are comparable to those of the United States. The expected difference between rural and urban areas is marked, but the standard of living of the agricultural worker has improved. Federal and commonwealth minimum wage laws cover every important industry and areas of agricultural production. Strict enforcement and periodical revisions ensure a just compensation for the working class. The hourly wage received by labourers is considerably lower than that received by workers in similar industries in the United States, but private professional salaries for the growing middle class are generally on a par with salaries for similar occupations in the Gnited States. Government workers such as teachers, clerks or administrators are not so well paid as private professional workers or federal government employees in the U.S.

The labour force of the island has remained for some time slightly over the 635.000 mark. Unemployment, which fluctuates seasonally, has rarely dropped below 15% of the labouring force.

Since more than half the goods and services which Puerto Rico consumes come from the United States, the general price level follows closely the level on the mainland. Local products are naturally less expensive than imported items, but inability to expand local farm production has caused prices of local goods to be increased at a much faster rate than that of imported goods prices. Large supermarkets, including four large consumer co-operatives, serve the San Juan, Ponce and Mayagiiez metropolitan areas.

Faced with the increased migration from the mountains to the cities, particularly to the San Juan area, and a rapidly growing population, the commonnealth government working in close cooperation with the Federal Housing authority was able to undertake during the years after World War II extensive programs of construction of low-cost housing. Although the inadequately serviced housing areas were not eliminated completely, strict enforcement of government laws concerning zoning, new constructions and renovations, coupled with a methodically planned slum-clearing program, improved immeasurably the living conditions of the workers.

4. Welfare Services. — In the late 1950s more than 20% (in 1959, $60,000,000) of the total budget of the commonwealth was spent on providing health and public welfare services for the people of the island. An additional $11,000,000 was contributed by the federal government in 1959.

Several hundred public health clinics, functioning under the supervision of doctors and nurses, offered preventive and curative medical services. Six general district hospitals, six tuberculosis hospitals and a large psychiatric hospital were run by the commonwealth. The health department offered assistance to the aged, needy families and the handicapped. Almost half of those attending public school received free lunches, milk depots were conducted to supply free milk to preschool-age children, and annually about 80,000 pairs of shoes were distributed free to needy students.

All workers, both industrial and agricultural. are completely covered in case of accidents by a compulsory state insurance fund, which has rendered excellent service for over a generation.

5. Justice. — The commonwealth constitution provides for a uniquely unified judicial system consisting of a general court of justice comprised of the supreme court and the court of the first instance. The latter is organized in two divisions, the superior court nith 30 judges and the district court with 55 judges. The uhole judicial system is administered by the chief justice of the supreme court and his office of court administration. This integrated system permits maximum flexibility. Jurisdiction and venue questions do not prevent a case from being considered. Appeals may be carried to the supreme court in Washington.

6. Education. — Compulsory education has been in effect since 1899. To keep pace with the growing population, the commonwealth assigned to education during the 1950s a larger percentage of its budget than did any other Latin-American country, 30%, or $75,000,000 in 1959.

Over 95% of the elementary school-age children are registered and attend classes; about 85% of those eligible attend the secondary schools, and about 50% of those eligible attend high schools. The total attendance in 1958–59 was 573,000 in these three divisions, and in private schools were registered close to 50,000. Teaching is in Spanish in the public school system, but special emphasis is given to the teaching of English as a second language. In the 1950s, partially as a result of a successful adult education program, the island illiteracy rate dropped from 24% to less than 15%. Special English instruction for prospective migrant workers was provided.

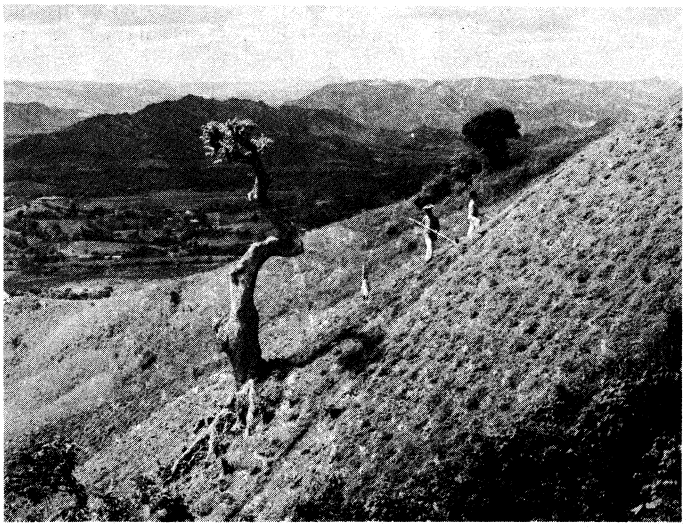
The land-grant government-financed University of Puerto Rico with 18,500 students in 1958–59, several graduate schools and a technical campus with a nuclear reactor in Mayaguez, has an international faculty and student body. The other island colleges include the Roman Catholic Sacred Heart college in Santurce and the Catholic University of Santa María in Ponce, as well as Inter-American university at San Germán which is affiliated with the Presbyterian Church of America.

VII. THE ECONOMY

The economy of Puerto Rico is closely tied to that of the United States. No trade barriers exist to prevent interchange of goods between the two areas. During the first half of the 20th century Puerto Rico's agrarian-based economy functioned primarily from the sale of sugar and its by-products. After 1956 the economy of the island shifted noticeably from one based on agriculture to one based on manufacturing and industry.

1. Agriculture. — The production of sugar, dairy products, to-

bacco, coffee, fruits and vegetables in the late 1950s accounted for about 17% of the island's total net income. Sugar, processed by 32 cane-grinding mills, accounted for 50% of the agricultural income. This production, subject to a federal quota of 1,125.000



BY COURTESY OF THE DEPARTMENT OF STATE, COMMONWEALTH OF PUERTO RICO

CULTIVATING TOBACCO ON A STEEP HILLSIDE NEAR TRUJILLO ALTO

tons annually, supplied about 10% of the sugar consumed in the United States. In 1957, due to adverse weather conditions, the island failed to fill its quota, and the island government extended limited aid to sugar growers. The government planned to stabilize the production of sugar at 1,263,000 tons produced on only 300,000 ac. of the most productive flat coastal land. Coupled with this stabilization is the mechanization of the cane-cutting process. With rising wages and increased rural emigration, large cane growers have turned to machine substitutes for human labour.

Livestock production, second only to that of sugar, contributed 30% of the agricultural income. Accounting for more than half the livestock income was the sale of milk and its by-products. Eggs, beef, pork and poultry accounted for the remainder. With 400 dairies and 13 large pasteurizing plants, the commercial dairy industry was well developed, and it was the only phase of agricultural production in xhich future growth is expected.

Although coffee production declined in the 20th century until it scarcely satisfied local demands, the haciendas in the western mountain area are still numerous. Land dedicated to coffee, 155,000 ac. on the average during the 1950s, produced anywhere from 150 to 200 lb. per acre, depending upon varying conditions. Some 35,000 ac. of tobacco, principally in the eastern central part of the island, brought an annual average return of about $8,000,000 to the growers.

2. Industry. — The remarkable industrial development which occurred in Puerto Rico was due to the government's Economic Development program, particularly that phase known as Operation "Bootstrap." xhich by the late 1950s had established nearly 600 nen factories on the island. These plants represented an investment of more than $400,000,000 and in large part explained why, after the mid-1950s, manufacturing and industrial production, accounting for 20% of the island's total net income, surpassed agriculture as a source of wealth. Stimulated by ten years of grace from taxes, availability of government-built factories for lease or purchase and ready access to the United States market. corporations did not hesitate to establish branch centres of production on the island. At first new industries were those which hoped to profit by low labour costs or mere associated with agriculture. After 1956 textile mills, chemical and metal plants (*i.e.,* industries which involved a higher capital investment) were established in growing numbers. The most important included oil refineries, fertilizer plants and chemical plants to develop petroleum by-products. On the south coast in Ponce there is a large cement factory, and in Santurce, near San Juan, there is an ironworks; both these industries have played an important part in the construction activity which accounts for 5% of the total net income of the island.

3. Power. — The electric power of the island is provided by a government agency, the Puerto Rico Water Resources authority, which came into existence in 1942. As a result of the government's program of rural electrification and a marked increase in industrial demand, the power production of the island during the late 1950s increased to well over 1,000,000,000 kw.hr. annually. Industrial consumption of power increased 134% between 1942 and the late 1950s.

4. **Trade.**—Between 80% and 90% of the value of imports comes from the United States; imports in 195i amounted to 60% of the gross insular product. Puerto Rico imports about 50% of its food, and 43% of consumers' expenditure is for food. Rice, lard, pork and dairy products are the most important imports. The island's expanding industrial climate has required the importation of capital equipment for productive uses, and raw or semi-processed goods for further elaboration and sale. About 40% of foreign imports were raw material, including crude oil from Venezuela and the Netherlands Antilles, to be refined and consumed or shipped to the United States.

All but about 5% of the value of Puerto Rican exports is sent to the United States. The total value exported in 1957 was 42% of the gross insular product. To the older exports of sugar, molasses and rum have been added electrical appliances, textiles, pharmaceuticals and plastic goods.

The deficit in this balance of trade (about $200,000,000 in 1957) is in part made up by payments and expenditures of the federal government on the island. About 90% of this is expenditures of the defense department and payments to veterans. The average capital inflow from 1952 to 1957 for investment purposes was $70,000,000. In 1957 some 186.000 tourists spent $28,000,000.

5. Banking and Currency. — Since Puerto Rico functions economically as an integral part of the United States. the currency of the island is the same as that of the U.S. The island's banking system is also integrated within the U.S. banking structure. A number of local banks, two Canadian banks and three United States banks operate under the close supervision of the insular government. Seven of the banks are members of the Federal Deposit Insurance corporation. The branches of the United States banks are indirectly related to the federal reserve system.

A legal maximum of insular indebtedness, placed at 10% of the aggregate tax valuation of property, has limited the financial operations of the government. Puerto Rico has never defaulted in the payment of principal or interest of the insular debt. Out of the 1959 budget, 5% or $13,800.000 was paid to service the current insular debt, which was estimated at nearly $77,000.000.

6. Transport and Communications. — The island has as extensive system of highways serving every community. In the late 1950s there mere nearly 3.000 mi. of paved streets and highways and more than 150,000 motor vehicles. No railroads for public use exist on the island; during the cane-cutting season some sugar corporations operate local railroads to bring cane to the *centrales.*

Eleven ports of widely varying importance are open for handling freight and some passenger service. San Juan, Ponce and Mayagiiez receive most of the cargo ships. First-class passengers are accepted in limited numbers on the freighters, but no passenger line links the island nith the United States. A French line passenger service connects Puerto Rico with the European continent. Most of the Puerto Rican visitors and migrants travel by air. The San Juan International airport. equipped for jet passenger service, is connected with the important cities on the U.S. Atlantic seaboard from Miami to Boston. British, French, Dutch, Spanish and Latin-American airlines have frequently scheduled flight services connecting Puerto Rico with other points around the Caribbean and abroad.

The Gnited States postal service offers complete service on the island. Three commercial cables extend from Puerto Rico to the mainland. There is a government and commercial wireless service. The island has about 25 small commercial radio stations and four commercial television stations. The government operates an educational radio and television station. *See* also Index references under "Puerto Rico" in the Index volume.

PUFENDORF, SAMUEL, BARON VON (1632–1694), German publicist and jurist: best-known for his treatise on natural law and international law, *De Jure Naturae et Gentium Libri Octo,* was born near Chemnitz, Saxony, on Jan. 8, 1632, the son of a Lutheran pastor. He commenced theological studies at Leipzig university but soon turned to jurisprudence and studied mathematics and natural law under Erhard Weigel at Jena. Leaving Jena in 1657, Pufendorf took service as a tutor in the household of the Swedish minister at Copenhagen. When Sweden declared war. the whole retinue was imprisoned. Pufendorf occupied his captivity of some eight months reflecting on what he had read in the works of Grotius and Hobbes and mentally constructing a system of universal law. On his release, he went to Leiden where he published in 1661 the fruits of his reflections in the work *Elementa Jurisprudentiae universalis,* in the plan and structure of which his mathematical training is very evident.

Karl Ludwig, the elector palatine, to whom the work was dedicated, created a chair of the law of nature and nations for Pufendorf at Heidelberg, the first chair of its kind in the world. His next work was written under a pseudonym, Severinus de Monzanibano: *De statu imperii germanici ad Laelium, dominum Trezolani, liber unus.* It took the form of a bitter attack, supposedly by a Yeronese nobleman, on the constitution of the Holy Roman Empire and the house of Austria, and created a great sensation.

In 1670 Pufendorf left Heidelberg for the University of Lund, Swed., where he produced in 1672 his great work, the *De jure naturae et gentium libri octo,* and, in the following year, the *De officio hominis et cicis* which is in the main a résumé of the *De jure naturae.*

Grotius had pointed out the dualism between a natural and a positive law of nations. Where Richard Zouche stressed the precedence of the latter, Pufendorf followed Hobbes in maintaining the priority of the natural law; he differed from Hobbes however in proclaiming that the natural state was one of peace, not of war, albeit a precarious peace unless given positive support. For, though originating from God in that God created men as social beings, natural law, for Pufendorf, is concerned with man in this life—as he is, with all his failings—and with external conduct. and it derives from human reason alone: man as a prospective citizen of heaven is the concern of moral theology. This search for natural law in the dictates of human reason understandably enables Pufendorf to maintain that international law is the common link of all men, not merely that of Christendom. In public law, while recognizing the state as a moral person, Pufendorf teaches that the will of the state is but the sum of the individual wills that constitute it, foreshadowing Rousseau and the *Corztrat social.*

In 1677 Pufendorf became historiographer royal at Stockholm and thereafter virtually abandoned international and natural lam for historical: political and theological studies. To this period belongs (in addition to, *e.g.,* histories of Sweden and the reign of Charles Gustavus) the *De habitu religionis christianae ad vitam çivilem.* This work, in which he traces the limits between ecclesiastical and civil power, was the basis of the *Kollegialsystem* of church government, which, developed by Christoph Pfaff (1686–1760), was the basis of church and state relations in Germany.

This theory makes a fundamental distinction between the supreme jurisdiction in ecclesiastical matters *(Kirchenholzeit* or *ius circa sacra)* which is inherent in the power of the state with respect to every religious communion and the ecclesiastical power (*Kirchengewalt* or *ius in sacra)* which belongs to the church but which is, in some cases, vested in the state by the consent—express or tacit—of the ecclesiastical body. Though naturally not accepted by the Roman Catholic Church, the theory did in fact facilitate a working compromise between the Protestant governments and Rome.

In 1686 Pufendorf went to Berlin as historiographer to the great elector of Brandenburg. He was created a baron and died at Berlin in 1694.

The value of Pufendorf's work was much underestimated by posterity. Responsibility for this rests largely with Leibniz, who would never recognize the greatness of one who was ever his adversary and whom he dismissed as *vir parum jurisconsultus et minime philosophus* ("a man not enough of a lawyer and scarcely a philosopher at all"). Modern scholarship, however, while conceding that he is not a pioneer in the category of Francisco Vittoria and Grotius, recognizes Pufendorf as a classic writer in the field of international law, and his *Jurisprudence* is the standard one for the 17th and 18th centuries.

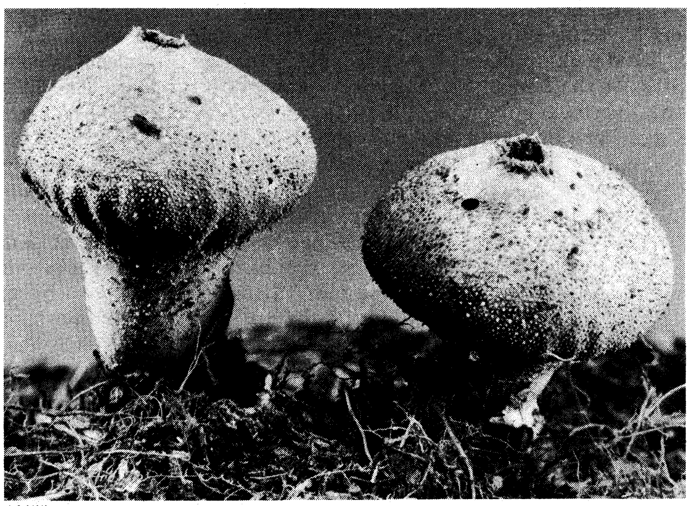
PUFF ADDER: *see* ADDER; SNAKES; VIPER.

PUFFBALL, the popular name of a group of fungi belonging to the Basidiomycetes *(see* FUNGI) and so called because of the cloud of bronn dustlike spores that is emitted nhen the mature plant bursts or is struck a blow. Puffballs are common in meadons and woods and on heaths or lawns, and nhen young resemble white balls, sometimes with a short stalk, and are fleshy in texture. While white and fleshy they are edible.



ROCHE

PUFFBALLS (LYCOPERDON PERLATUM)

The giant puffball, *Calvatia maxima,* may sometimes attain a weight of 15 lb. or more and measure up to four to five feet or more in circumference. It has been estimated that a specimen measuring 15.7 × 11.0 × 7.8 in. will produce approximately 7,000,000,000,000 spores.

PUFFBIRD, the popular name given to the bird family Bucconidae, of the order Piciformes. The order includes also woodpeckers, toucans, jacamars, etc. The Budconidae are confined to tropical America, from southern Mexico to Argentina; in the sub-Andean subregion they are, as regards species, abundant; only two seem to reach Guatemala and only one Paraguay. Most dwell in lightly forested areas near water; a few live in deep forest. The Bucconidae are plainly coloured, and the majority have a spotted or mottled plumage suggestive of immaturity. The smallest, *Micromonacha lanceolata,* of northern South America, is only five inches long. Most puffbirds are very quiet, but the nunbirds, of the same family, often emit whistling notes; typical' of this group is the white-bearded nunbird,,*Monasa morphoeus.*

PUFFIN, a sea bird (*Fratercula arctica*), known also as bottle-nose. coulterneb, pope. sea parrot and tammy-norie. Of old time, puffins were a valuable commodity to the owners of their breeding places, for the young were taken from the holes in which they were hatched, and were "kept salted and reputed for fish." Puffins resort in vast numbers to certain stations on the coast, reaching them in spring with remarkable punctuality. They lay their single egg (white, with a few gray markings at first: but which speedily becomes begrimed by the soil) in a shallow burrow, which they either dig for themselves or appropriate from a rabbit. The plumage of both sexes is glossy black above — the cheeks grey, encircled by a black band — and white beneath; the feet are of a bright reddish orange. The most remarkable feature of these birds is their huge bill. In the breeding season this is very deep, laterally flattened, parti-coloured—blue, yellow and red—and curiously grooved and embossed in places. The puffin's bill undergoes an annual moult, some of its most remarkable appendages, dropping off at the end of the breeding season. The puffin, when feeding its young, manages to arrange crosswise in its bill, a number of fish at a time. In the north Pacific we find the horned (F. *corniculata*) and the crested puffin (*Lunda cirrhata*).

PUGACHEV, EMEL'YAN IVANOVICH (1741?–1775), Russianpretender, the date of whose birth is uncertain, was the son of a small Cossack land-owner. He married a Cossack girl Sofia Nedyuzheva, in 1758, and the same year was sent with his fellow Cossacks to Prussia, under the lead of Count Zachary Chernuishev. In the first Turkish War (1769–74) of Catherine II. Pugachev, now a Cossack ensign, served under Count Peter Panin and was present at the siege of Bender. Invalided home, he led for the next few years a wandering life; was more than once arrested and imprisoned as a deserter; and finally, after frequenting the monasteries of the "Old Believers," who exercised considerable influence over him, suddenly proclaimed himself (1773) to be Peter III. Pugachev asserted that he and his friends had escaped from Catherine, and were resolved to redress grievances, give liberty to the Cossacks and put Catherine in a monastery. He held a mimic court at which one Cossack impersonated Nikita Panin, another Zachary Chernuishev and so on. At the beginning of Oct. 1773 500 roubles was considered a sufficient reward for the head of the troublesome Cossack. At the end of November 28,000 roubles were promised. Still, Catherine, in her correspondence with Voltaire, affected to treat *"l'affaire du* Marquis de *Pugachev"* as a mere joke. By the beginning of 1774 the forts on the Volga and Ural were in the hands of the rebels; the Bashkirs had joined them; and the governor of Moscow reported great restlessness in central Russia. Pugachev captured Kazan, reduced most of the churches and monasteries there to ashes and massacred those who refused to join him. Panin, the conqueror of Bender, was sent against the rebels with a large army, but the innumerable and ubiquitous bands of Pugachev were victorious in nearly every engagement. Not till August 1774 did General Mikhelson inflict. a crushing defeat upon the rebels near Tsaritsyn, when they lost ten thousand in killed and prisoners. Suvorov completed their discomfiture. Pugachev was delivered up by his own Cossacks on attempting to fly to the Urals (Sept. 14), and was brought in an iron cage to Moscow, where he was executed on Jan. 11, 1775.

See N. Dubrovin, Pugachev and his *Associates* (Rus.; Petersburg, 1884); *Catherine II.*, Political Correspondence (Rus. Fr. Ger.; Petersburg, 1885, etc.); S. I. Gnyedich, Emilian Pugachev (Rus.; Petersburg, 1902); also the literature quoted *s.v.* CATHERINE II.

PUGET, PIERRE (1622–1694), French painter, sculptor, architect and engineer, was born at Marseilles on Oct. 31, 1622. He traveled in Italy as a young man, and was employed by Pietro di Cortona on the ceilings of the Barberini palace. On his return to Marseilles in 1643. he painted portraits and carved the colossal figureheads of men-of-war; he also painted numerous pictures for Aix, Toulon, Cuers and La Ciotat; his caryatids for the *hôtel* de *ville* of Toulon were executed between 1655 and 1657. Fouquet employed him to sculpture a "Hercules" for his château in Yaux. In 1655, because of a serious illness, he was forced to give up painting.

In 1660 he was in Genoa, where he executed his French Hercules (Louvre) and the statues of St. Sebastian and of Alexandre Sauli in the church of Carignano (c. 1664.). In 1669, at the summons of Colbert, he returned to France, and took up his old work in the dockyards of Toulon, until in 1685, disheartened by the destruction by fire of an arsenal he was constructing, he returned to Marseilles. There he continued the series of sculptures on which he had been employed by Colbert. His statues of Milo (1682), Perseus and Andromeda (1684) and the bas-relief Alexander and Diogenes (1685) are in the Louvre. In 1688 he visited Paris. but court intrigues obliged him to abandon the project of an equestrian statue of Louis XIV, and he retired to Marseilles, where he died on Dec. 2, 1694.

His best work, the St. Sebastian at Genoa, shows energy and life. In the museum of Aix-en-Provence is the bust of a long-haired young man, believed to be Louis XIV. made by Puget in 1660.

PUGILISM, the practice or sport of fighting with the fists. The first mention of such fighting in literature is found in the 23rd book of the Iliad; another full description is in Yirgil's *Aeneid.*

Although fist fighting was supposed by the Greeks of the classic period to have been a feature of the mythological games at Olympia, it was not actually introduced into the historic Olympic contests until the XXIII Olympiad after the re-establishment of the famous games by Iphitus about 880 B.C. Onomastos was the first Olympic victor.

The rules of Greek boxing were strict. No wrestling, grappling. kicking nor biting mere allowed: and the contest ended when one combatant owned himself beaten. On this account pugilism was forbidden by Lycurgus, lest the Spartans should become accustomed to an acknowledgment of defeat (Plutarch, *Lycurgus*). Moreover. it was strictly forbidden to kill an adversary, on pain of losing the prize.

Boxing was evidently in vogue in very ancient times in Italy, imported, in all probability, from Greece. During the republic boxing was cultivated as a gentlemanly exercise. The art remained popular in Italy down to a late period of the empire.

Pugilism in England. — The first references to boxing in England as a sport occur toward the end of the 17th century, but little mention is made of it before the time of George I. when "prize fighters" engaged in public encounters for money. The most celebrated of these fighters and the one who is generally considered to have been the first champion of England, fighting with the bare fists, was James Figg. who was supreme from 1719 to 1730. Figg was succeeded by Pipes and Gretting, both of whom made way in 1734 for Jack Broughton, who built the amphitheatre for public displays near Tottenham Court road and who was undisputed champion until 1750. Broughton seems to have been a man of intelligence, and to him is ascribed the scientific development of the art of boxing. During his time the sport became truly national and the prize fighter the companion of the greatest in the land. Among Broughton's successors were Slack, "Big Ben" Brain, Daniel Mendoza, J. Jackson, Tom Cribb, Jem Belcher, Pearce (called the "Game Chicken") and John Gully, who afterward represented Pontefract in parliament.

From the time of Cribb the English champions were Tom Spring (1824), Jem Ward (1825), Jem Burke (1833), W. Thompson, called "Bendigo" (1839–45), Ben Caunt (1841), W. Perry the "Tipton Slasher" (1850), Harry Broome (1851). Tom Sayers (1857–60), Jem Mace (1861–63), Tom King (1863) and again

Mace until 1872. In the U.S. boxing began to be popular about the beginning of the 19th century. The first recognized national champion was Tom Hyer (1841–48). who was followed by James Ambrose (born in Ireland), called "Yankee Sullivan"; John Morrissey (afterward elected to the U.S. congress); John C. Heenan; Tom Allen (of England); Jem Mace (of England); J. Kilrain; John L. Sullivan (1882–92). Sullivan was the last of these to fight with the bare fists. Pugilism (*i.e.,* fighting with the bare fists) was driven out in favour of boxing (*i.e.,* fighting with the glove) by public opinion and by the general adoption after 1866 of the Marquis of Queensberry rules.

See BOXING.

PUGIN, AUGUSTUS WELBY NORTHMORE (1812–1852), English architect, who worked on the designs for the Houses of Parliament, was born in London on March 1, 1812, and died on Sept. 14, 1852, at Ramsgate. In the office of his father, Augustus Charles Pugin, he helped prepare a series of works on the Gothic buildings of England. He was a skillful etcher, and made numerous drawings and sketches, in pen and ink or with sepia monochrome, perfect in their delicacy and precision. After his reception into the Roman Catholic Church in 1833, he became a leader in the English Gothic revival. In 1837–43 he assisted Sir Charles Barry in working out the details for the new houses of parliament at Westminster; and though his exact share was the subject of bitter controversy, there is no doubt that the excellence of the details was partly due to him and to his training of the masons and carvers. Many of his executed works, such as the cathedral of St. George at Southwark and the church in Farm street, Berkeley square, London, suffered from later alterations. The cathedral of Killarney and the chapel of the Benedictine monastery of Douai best express his original conception. He also designed his own house at Ramsgate and the stately Adare hall in Ireland built for Lord Dunraven.

Pugin published Contrasts; or a Parallel Between the Architecture of the 15th and 19th Centuries (1836); True Principles of Christian Architecture (1841); Glossary of *Ecclesiastical* Ornament (1844); and Treatise on Chancel Screens and Rood Lofts (1851).

See B. Ferrez, Recollections of *A. W. Pugin* and *His* Father (1861); Paul Waterhouse, "The Life and Work of Welby Pugin," Architectural Review, iii, iv (1898).

PUGLIA (or APULIA), a region (*compartimento*) of southern Italy, extends from the Fortore river in the northwest to Cape Santa Maria di Leuca, the "heel" of the peninsula, in the southeast. It has a total area of 7,470 sq mi., a population (1951) of 3,220,483'. and is composed of the provinces of Bari, Brindisi, Foggia, Lecce and Taranto (*qq.v.*). The northern third of the region is centred on the Foggia plain, or Tavoliere, flanked by the Gargano massif in the north and the Keapolitan Apennines in the west. The central third is occupied by the low plateau of the Murge Salentine, limited in the west by a depression, the "fossa premurgiana," while in the east it slopes gradually to the narrow coastal plains of the Adriatic. The southern third, southeast of the Taranto-Ostuni line, is the Salentina peninsula, consisting of the lowland of Lecce and the low plateaus east of Taranto and south of Lecce. The predominant rock material of Puglia is limestone, and karst phenomena of underground drainage and large cave formations are present in many areas.

The coast line for the most part is low and sandy, except in the Gargano peninsula and in the southeasternmost tip of Puglia The only rivers of significance are the Fortore and the Ofanto, but there are numerous springs, some under the sea near the coast line. The absence of surface water over large areas led to the construction of the Apulian aqueduct, the largest of its kind in Italy, that traverses the entire region as far as Cape Leuca (see AQUEDUCT).

Wheat and oats are the principal cereals, raised in the Foggia plain and in the more fertile parts of the plateaus; olives, grapes, almonds and figs are grown intensively in the coastal and some inland areas; tobacco is a speciality of the Lecce plain. The wines of Puglia are among the strongest of Italy and are used to fortify other, lighter varieties. Fishing is carried out in many ports; those of the Gargano, of Barletta, of Monopoli and of Taranto are the most important. Salt is produced from sea water at Margherita di Savoia, near Foggia. About 1,000,000 sheep once grazed on the plain but owing to cultivation it only supports half that number today. Bari is the largest city and the leading port, as well as the biggest industrial centre (especially chemicals and petrochemicals); other, lesser industries are located in Brindisi, Taranto and Foggia. The largest railroad centre is Foggia, with lines connecting it to Naples-Rome, Bologna-Milan, and Bari- Taranto- Brindisi- Lecce. The so-called "Ionian" railroad follows the Ionian coast from Taranto to Reggio di Calabria. After World War II Puglia became one of the principal areas of Italian land reform, and numerous small farms were created from the old landed estates, new farm houses and rural service centres built, new roads and aqueducts constructed, transforming the face of the land.

The southeastern extremity of Puglia was Roman (not modern) Calabria. For archaeology, Roman and early history see APULIA; CALABRIA. After the tumultuous times following the disintegration of the Roman empire, Puglia was ruled by the Byzantines for over two centuries, and came to know its greatest glory under the Hohenstaufen emperors. It was a favourite of Frederick II (1220–50) and cathedrals and palaces witness the flowering of Puglia at that time. Thereafter a long period of decline set in, accentuated by neglect by distant rulers (Aragonians, Spaniards, Keapolitans) and by slave raids along the coast. In 1860 Puglia became part of the Italian kingdom. (G. KH.)

PUISNE, a term in law meaning "inferior in rank." It is pronounced "puny" and the word. so spelled, has become an ordinary adjective meaning undersized. By the Supreme Court of Judicature act, 1877, a "puisne judge" is defined as a judge of the high court other than the lord chancellor, the lord chief justice of England, the master of the rolls, the lord chief justice of the common pleas and the lord chief baron and their successors respectively. The last two offices have been abolished.

PUKET, officially spelled PHUKET (the Chinese name is TONGKAH), leading Thai port on the west coast of the Malay peninsula, on Junk Ceylon Island (also called Puket) in 7° 50' N. and 98° 24' E. Pop. of Port (1957 est.) 25,847.

The island constitutes one of the 71 changwats (provinces) of Thaiiand. Pop. (1956 est.) 64,637, nearly half Chinese. Rich tin deposits have been worked by Chinese from ancient times. A European company commenced modern dredging operations in 1907. Among other exports are rubber and betel nuts.

European merchants began trading at Puket in the 16th century. It was besieged by the Burmese during the 18th century wars between Burma and Thailand, but was relieved by troops from the mainland.

PULA (Italian POLA), a seaport of Yugoslavia situated at the southern tip of the Istria peninsula at the head of the Bay of Pula with a safe, commodious and almost landlocked harbour.

The history of Pula begins with its capture by the Romans in 178 B.C. It was destroyed by Augustus because of its espousal of the cause of Pompey, but was rebuilt under the name of Pietas Iulia. In A.D. 198–211 an amphitheatre 79 ft. high, 400 ft. long and 320 ft. wide was built in honour of the emperors Septimius Severus and Caracalla and could accommodate 23,000 spectators. In the middle ages Pula became the capital of the margraves of Istria and in 1148 was captured by the Venetians. In 1379 the Genoese, after defeating the Venetians in a great naval battle off the coast, took and destroyed Pula, which disappeared from history for the next 450 years. It remained, however, under Venetian supremacy until 1797 and fell under Austria in 1815. During the 19th century it became Austria-Hungary's principal naval harbour and arsenal. Occupied by the Italians in Nov. 1918, it was transferred to Italy in 1919 by the treaty of St. Germain.

The modern town of Pula lies round the base of a hill formerly crowned by the Roman capitol and later by a castle of the 17th century. Besides the castle the chief buildings are the cathedral, burned down in 1923 and reconstructed on the lines of a 6th-century Ravenna basilica, and the 14th-century Franciscan church. On March 3, 1945, the Yugoslav army took Pula after heavy fighting during which the cathedral and many other buildings suffered damage. From June 12. 1945. to Sept. 15, 1947, the town was under Allied military occupation. On Feb. 10, 1947. the date of the signing of the Italian peace treaty, a 34-year-old woman, Maria Pasquinelli, at Pula assassinated Brig. R. W. M. de Winton, commander of a British infantry brigade, the nearest representative. she declared, of the Big Four who had ',betrayed" Italy.

As the Italian peace treaty stipulated that Pula was to be ceded to Yugoslavia, about 28,000 Italians out of a population of 34,090 (1938) left for Italy. The 1953 census revealed a population of 28,512, entirely Yugoslav.

PULASKI, CASIMIR, COUNT (1748-1779), Polish soldier, was born in Podolia in 1748, and took a prominent share. under his father, Count Joseph Pulaski, in the formation of the confederation of Bar and in the military operations which followed, becoming ultimately commander in chief of the Polish patriot forces.

Driven into exile about 1772, Pulaski went to America and joined the army of Washington in 1777. He distinguished himself at Brandywine, was made a brigadier general and chief of cavalry by congress, and fought at Germantown and in the battles of the winter 1777–78, after which he raised a mixed corps called the Pulaski legion, with which he defended Charleston in May 1779. Pulaski, mortally wounded at Savannah, died Oct. 11, 1779.

PULCI, LUIGI (1432–1484), Italian poet whose name is chiefly associated with *Morgante,* one of the outstanding epics of the Renaissance, was born in Florence, Aug. 15, 1432. For many years he lived under the protection of the Medici family, especially Lorenzo il Magnifico, who first introduced him into the circle of poets and artists which was gathering round him and later, after assuming power, entrusted him with various embassies and diplomatic missions. Nevertheless, poverty and other hardships caused him, nhen about 38-40, to enter the service of a northern *condottiere,* Roberto Sanseverino, with whom he remained until his death at Padua in Nov. 1484.

Pulci's literary output, all in Italian. was very large. Among minor works, his *Lettere* (mod. ed., 1886) and *Sonetti* (mod. ed., 1932) are worthy of mention as revelations of his extravagant character, wide but not always deep cultural interests and biting criticism of contemporary Florentine writers and philosophers. But his masterpiece is the *Morgante* or *Morgante Maggiore,* a chivalrous epic in 23 cantos, later expanded to 28, begun about 1460, of which the earliest surviving complete edition is dated 1483. The plot of the poem is simple. Orlando, the hero, driven from the court of Charlemagne, goes to Pagania, where he meets three giants, two of whom he kills. The third, Morgante, is converted and becomes his faithful squire. Orlando and Morgante are joined by Rinaldo, who has also quarreled with Charlemagne, and the poem then recounts their episodic adventures in Africa and Asia, which continue until Orlando and Rinaldo, hearing that the Saracens have reached the borders of France, hasten to its defense. The story ends with the battle of Ronceveaux and the death of Orlando. The predominantly comic and burlesque tone is varied by a more serious mood in which the author expresses at times deep and sincere feeling, at times a bitter experience of life. Similarly, Pulci's amoral attitude, typical of an age which considered success as the only criterion of salvation, contrasts aith his deeply felt religious problems, which constitute a large part of the poem. It is this complexity and richness of feeling which makes the *Morgante* both one of the most original poems in Italian literature, and an essential text for understanding of the Renaissance.

Modern editions of the *Morgante* include those by G. B. Weston (1930), G. Fatini (1948) and F. Ageno (1955).

PULITZER, JOSEPH (1847–1911), U.S. editor and newspaper proprietor. was born in Mako, Hungary. April 10. 1847. Educated privately in Budapest he was induced by a U S. agent to emigrate as a recruit for the Cnion army. He was discharged from the army on July 7, 1865, and went to St. Louis, where he arrived penniless. In 1868 he became a reporter on the German-language daily newspaper, the *Westliche Post.* He was elected in 1869 to the lower house of the Missouri legislature. where he gained a reputation as a reformer, and in 1871–72 he helped organize the Liberal Republican party in Missouri and was one of the secretaries of the Cincinnati convention that nominated Horace Greeley for president.

Pulitzer became a newspaper proprietor in 1871 by buying a share of the *Westliche Post* on liberal terms. This he soon resold for $30,000, using part of the proceeds for an extended tour of Europe. On his return in 1874 he purchased a moribund German daily, the *St. Louis Staats-Zeitung,* and sold its Associated Press franchise to the *Globe* for $20,000. In 1878 he laid the foundation of his fortune by purchasing at auction the dying *St. Louis Dispatch,* and merging it with the *St. Louis Post* as the *Post-Dispatch,* which soon dominated the St. Louis evening field. The paper was independent in politics and devoted to "hard money" and tariff reform. In 1880 Pulitzer became sole owner, but unfortunately in Oct. 1882 his chief editorial aid, Col. John A. Cockerill, shot and killed Col. Alonzo W. Slayback, a lawyer, in a bitter political quarrel. Public reprobation was so great that the *Post-Dispatch* lost revenue and Pulitzer departed for the east in the spring of 1883. nhere he bought the *New York World* from Jay Gould for $346,000.

Under its new management the World won prosperitv. its annual earnings by 1886 rising to more than $500 000 In 1887 Pulitzer established the *Evening World.* To the *World,* as to the *Post-Dispatch,* Pulitzer gave a tone of aggressive editorial independence He supported Grover Cleveland for the presidency in 1884, 1888 and 1892. He was sympathetic to labour; in 1892 he took the side of the striking steel workers at Homestead, Pa He opposed William Jennings Bryan for the presidency in 1896 and became an advocate of aar with Spain.

The *World* was largely responsible for bringing on the New York state legislative investigation of insurance companies in 1905. In 1909 the U S. government successfully sought an indictment against Pulitzer for criminally libeling Pres. Theodore Roosevelt J P. Morgan, Elihu Root and others in connection with allegations about the disposition of the $40,000,000 paid the French Panama Canal Co. The case was never prosecuted

In his later years Pulitzer's health compelled him to live as an invalid, but he kept in intimate touch with the *World* until within a few weeks of his death in Charleston, S.C., Oct. 29. 1911.

Pulitzer was elected to the U.S. house of representatives from New York in 1885, and served briefly in congress. During his lifetime he endowed the school of journalism of Columbia university, opened in 1912.

He also established the Pulitzer prizes, awarded annually for fiction, drama, history, biography, poetry, music and various categories of newspaper work.

PULLEY AND BELT, a mechanical arrangement for transmitting torque from one shaft to another. The torque originates at a wheel or drum, called the drive pulley, that applies torque to a continuous, flexible member called the belt. The belt passes around and delivers torque to a second wheel or drum, called the driven pulley.

A pulley may be made fast to a shaft by a setscrew or key in the pulley hub, or by a tapered bushing drawn between shaft and hub; or the pulley may turn freely on a shaft as an idler. Pulley rim and hub may be one solid piece connected by a flange, web or tapered arms, depending on the pulley diameter. Pulleys whose peripheral surfaces are grooved are called sheaves.

Belt drives are used when one or more of the following conditions prevail: (1) The distance between shafts is large; (2) flexibility is desired to absorb shock; (3) overloads can be absorbed by belt slippage without damaging machine parts; (4) low cost is desired; (5) quietness is desired.

Belts are suitable for approximate velocity ratios only, because overload causes slippage between the surfaces of the belt and each pulley; even when slippage does not occur, creep takes place. Creep is a small backward movement of the belt relative to the pulley because of belt elasticity. The higher tension of the belt (T_1) reduces to the lower tension (T_2) as the belt travels around the drive pulley (see fig. 1), hence the length of belt leaving the pulley is less than the length entering. Creep alone reduces operating speed about 1%, and slippage causes loss of another 2%.

In addition, excessive slippage causes belt damage. Belts are operated at about 5,000 ft. per minute; above this speed most of the belt strength is needed to withstand the tension from the centrifugal force rather than the load.

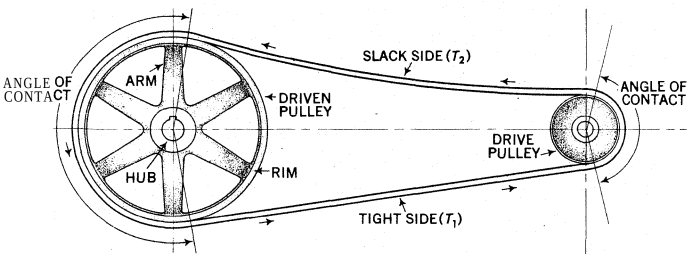

FIG. 1.— BELT ON PULLEYS

Solid pulley (at right) is driving a larger pulley (at left) with rim connected to hub by arms. In arranging pulleys, the slack side of the belt should be on top to increase angles of contact. (See text)

Both tight (T_1) and slack (T_2) sides of the belt pull on the pulley and result in a net force of their difference ($T_1 - T_2$) acting at the pulley surface to produce torque. The torque is dependent upon the ratio of effective forces which according to theory is $\frac{T_1 - T_c}{T_2 - T_c} = \epsilon^{\left(\frac{fa}{\sin\theta}\right)}$, where T_c is centrifugal force of one foot of belt, $\epsilon = 2.718$, f is the coefficient of friction between surfaces and a is the angle of contact in radians between belt and pulley, and θ is one-half the groove angle. The maximum value of T_1 is limited by the tensile strength of the belt.

Transmissive capacity is dependent upon the effective force ($T_1 - T_2$), hence will be greatest when the ratio of effective tensions, equal to $\epsilon^{\left(\frac{fa}{\sin\theta}\right)}$, is greatest. The frictional resistance to slip depends upon the coefficient of friction, the normal contact force and the angle of contact between belt and pulley. Combinations of materials, form of belt and angle of contact are selected to give the required capacity.

Types of Belts.—Belts are made of any material having suitable strength and flexibility and of any shape resistant to slipping (fig. 2). Combinations of material and cross section used are: flat leather operating on a flat or crowned pulley; round leather wedged in grooves of a sheave; V-belts or trapezoidal or sharp V section consisting of cotton cords, cotton sheets or steel wire vulcanized in rubber with a sheave; woven fabric on a pulley; spiral steel spring with a sheave; flat steel on a pulley for high speeds; hemp or Manila rope wedged into sheave grooves; stranded steel rope resting without wedging in the padded bottom of grooves in a sheave.

Leather Belts.—Leather belts of best quality are made of strips from the rear, back and sides of steer hides. The hide is cleaned, cured, dehaired, defleshed and then tanned in a solution of tannin to make the leather strong and pliable. Oak bark is used to produce a tannite solution in which the hides are cleaned. worked, "stuffed" with grease and stretched. Mineral salts such as chromium salts may be used for tanning. Chrome-tanned leather has greater tensile strength, a higher coefficient of friction (particularly until oak-tanned leather is used a while), greater flexibility and greater resistance to water, steam and certain chemicals. It is. howe er, softer than oak-tanned leather and lacks the lateral stiffness required to shift a belt by applying force at its edge. Combinations of oak and chrome tanning give a product with some of the advantages of each.

After preparation, the centre portion of the hide, which possesses the tightest texture, is cut into strips and squared. Pieces are then selected according to soundness and thickness. The pieces are scarfed to a feather edge and cemented together under pressure to make a continuous roll of belt. Belts of hide thickness are called "single ply." Double ply and triple ply belts for heavier loads are made by cementing together a number of strips. Belt thickness depends upon the hide thickness and varies from $\frac{1}{8}$ to $\frac{7}{32}$ in. for single ply, $\frac{1}{4}$ to $\frac{3}{8}$ in. for double ply, and $\frac{7}{16}$ to $\frac{9}{16}$ in. for triple ply.

Oak-tanned belting is the most generally used leather belt. Sandwiches of oak- and chrome-tanned belting have been used for special purposes, but such combinations are rare. Leather is used also for round belts. V-belts and link belts composed of overlocking leather links connected by steel pins.

Rubber Belts.—Rubber belts are made of natural and synthetic rubber, generally in combination with a load-carrying core. Flat belts are composed of plies (or layers) of cotton duck impregnated with a slow-aging rubber compound. Most generally used weight is 32 oz. cotton duck. The duck is folded to the desired number of plies and then vulcanized together. The rubberized cords may be left exposed or encased in a protective covering of rubber. Other constructions use load-carrying members of parallel longitudinal cords of fabric or steel within a vulcanized rubber covering. Strength is about 325 lb. per ply per inch.

V-belts of rubber are made of layers of duck or of various combinations of cotton cords encased in a rubber body of trapezoidal cross section, the strength of the belt depending upon the fabric rather than uwon the belt cross section. The layer type has raw edges. whereas the cord type body is covered with a rubberized fabric. Because the V-belt is stiff due to its depth, some constructions flute the inner edge to give flexibility without sacrificing contacting surface. Endless V-belts are molded in a press with five standard cross-section sizes available in various lengths. Multiple V-belt drives use a number of parallel belts of the same length running in parallel grooves in the pulley face. The belt does not bottom in the groove. Unreinforced rubber belts of round cross section are used for light loads a-here considerable elasticity is desired.

Other Types of *Belts*.—Balata belting is similar in construction to rubber belting. Balata is a gum from the bullet tree (*Manilkara bidentata*, formerly known as *Mimusops* balta) of Guiana and the West Indies. The belting is nonelastic and can be made waterproof.

Steel bands, carefully made and balanced, may be used as belts on accurately aligned pulleys. The high strength-weight ratio of steel allows large force transmission at high speeds with a relatively small reduction from centrifugal force.

Belt Fasteners.—Belt lengths may be connected by the following separate fastenings, accompanied, however, by a reduction in strength as indicated: machine wire lacing, 10%; hand wire lacing, 18%; lacing with rawhide strips, 40%; metal hooks. 65%.

Metal belt loops are bent into the end of each belt, the hooks placed side by side and a pin of leather or steel inserted through the loops to provide a connecting pivot. A stamped sheet may be used instead of separate wires.

The belt must be stretched over the pulleys and made into a continuous strip. The joint may be cemented together in position by stretching with screw clamps and cementing the prepared ends together. Cemented joints develop practically the full strength of the belt, which is about 4,000 lb. per square inch. The maximum working load is usually limited to about 400 lb. per square inch for safety.

Construction and Stresses of Pulleys.—Pulleys are usually made in one piece of cast iron. The hub has an outside diameter about tnice the bore and is fastened to the shaft by a key, setscrew or compression bushing. The width of the hub is approximately the same as the width of the pulley. The hub is connected to the rim by arms that are elliptical in cross section and tapered from hub to rim. The rim surface is adapted to the form of belt used.

Because of centrifugal force the rim, if free. is subjected to a tensile hoop stress of $\frac{12wv^2}{g}$ where w is the weight of one square inch of section, v is the rim velocity in feet per second, and g is 32.2 ft. per second per second. For cast iron this stress in pounds per square inch is closely $\frac{v^2}{10}$. The rim is partially restrained by the arms and so is subjected to a lesser hoop stress but, consequently, also to a bending stress. The resultant stress is difficult to assess but is greater than the full free hoop stress alone. An unannealed pulley contains shrinkage stresses of unknown amount, so a close calculation of working stress is of little practical use. The arms should be sufficient in number to limit the unsupported length of rim. Four to six arms are sufficient in most instances.

Surface speeds of cast iron pulleys are usually limited to 4,000 ft. per minute. Under favourable conditions webbed cast iron pulleys might be used up to 10,000 ft. per minute. Wooden built-up pulleys of maple have been used for high speeds because wood is lighter for its strength than cast iron. Pressed steel pulleys are lightweight and have a high strength-weight ratio but are more easily deformed because of the thin sections of which they are made.

Motor pulleys are made of wood, rawhide or pressed paper held between metal end plates. The diameter of a pulley for leather belts is recommended to be not less than 30 times the belt thickness to limit the flexing of the belt as it goes on and off the pulley. The rim of a pulley for a flat belt is made slightly wider than the belt. For cylindrical pulleys in the same plane the belt must be of the same length along each edge and must be mounted on pulleys which are properly aligned. If the pulley centres are not parallel the belt will ride toward the tight side and off the pulley. The belt lies flat on the pulley surface and, because of its lateral stiffness, is tilted toward the high side of the pulley. Thus each successive point of the approaching belt is nearer to the high end of the pulley face. Drive pulleys are crowned by being made with a larger diameter at mid-section; the crown amounts to about $\frac{1}{8}$ in. per foot of width and makes the belt run centrally (fig. 2). Thus the pulley surface is geometrically two

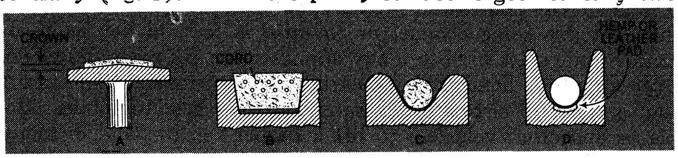

FIG. 2.— BELT AND PULLEY FORMS
(A) flat belt on crowned pulley; (B) V-belt on sheave; (C) round belt on sheave; (D) steel rope on sheave

slight cones base to base, and the belt rides to the greatest diameter in mid-face. Idler pulleys and pulleys on which the belt is shifted are not crowned.

Belt Arrangements. — An open belt arrangement rotates the driven pulley in the same direction as the driver. Crossed belts cause the driven pulley to rotate opposite to the driver. A crossed belt has considerably greater contact angle than an open belt, hence will transmit greater torque. Such an arrangement is usually avoided, however, because the belt surfaces rub together at the point of crossing and cause wear.

Pulleys with shaft centres in the horizontal plane transmit the greatest torque. As the line between centres departs from the horizontal the transmissive capacity is reduced. The slack side should be on top so that sag in the belt will increase the angle of contact.

Belts afford a simple means of connecting shafts which are not in the same plane. In order for the belt to stay on the pulleys the centre line of the approaching belt must lie in the centre plane of the approached pulley. This arrangement is shown in fig. 3. Note that if the direction of belt travel is reversed the required relationship is no longer satisfied and the belt will run off the pulley.

The addition of an idler pulley in accordance with the above rule would permit travel in either direction.

V-belt sheaves have grooves of the same angle as the belt section used with them. The grooves are deeper than the belt so that it contacts the sides and does not bottom. Wide wedge-shaped belts are used between adjustable sides so that as the sides are moved apart the belt lies lower on the sides and the pitch diameter decreases. As the lie of the belt is lowered, the belt velocity must be increased if the angular velocity of the pulley is to remain the same.

Belt Adjustments. — Short-centre drives are frequently employed when an electric motor is used to drive a machine. The small angle of contact on the smaller pulley caused by the short centre distance of the pulley limits the torque that can be transmitted. The driving motor may be mounted on a base that can be adjusted by a screw so the permanent stretch of the belt may be taken up by separating the pulleys. This adjustment can be made only occasionally and does not maintain tightness because the belt length changes elastically with load. One method of maintaining tightness and increasing the angle of contact is to use a gravity- or spring-loaded idler pulley. Another method is to use a motor base pivoted so the weight of the motor produces balancing tensions on the belt in an amount equal to the desired maximum capacity. The tight side of the belt should be between the pivot and the pulley centre.

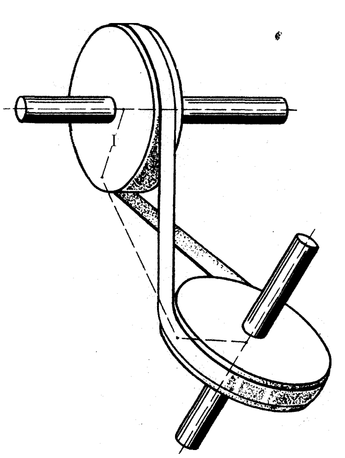

FIG. 3.—BELT CONNECTING SHAFTS IN DIFFERENT PLANES

(E. S. A.)

PULLMAN, GEORGE MORTIMER (1831–1897), U.S. industrialist and inventor of the Pullman car, was born at Brocton, Chautauqua county, N.Y., on March 3, 1831. He moved to Chicago in 1855, accumulated some capital as a contractor and began to work on his earlier idea of devising a better sleeping car. The first real Pullman car appeared in 1865, embodying Pullman's conviction that if he produced something better than anyone else, regardless of expense, someone would pay the price. He was president of the Pullman Palace Car company, organized in 1867, which built cars and operated Pullmans under contracts with railroads. His widely discussed social experiment, a paternalistic model town for his workmen, located south of Chicago, came to grief when a strike broke out that precipitated the great Pullman strike of Eugene Debs's American Railway union in 1894. The state later forced the company to give up control of the town. Pullman died on Oct. 19, 1897.

BIBLIOGRAPHY.—George A. Mortimer, in ***Dictionary of American Biography***, vol. xv (1935); Almont Lindsey, ***The Pullman Strike*** (1942), includes critical appraisals of Pullman and his model town; Joseph Husband, ***The Story of the Pullman Car*** (1917), is laudatory.

(D. L. McM.)

PULP: *see* PAPER.

PULPIT, a raised platform with enclosed front, from which sermons are delivered. The pulpit probably derived from the ambo (*q.v.*) in the early Christian church. There are many old pulpits of stone, though the majority are of wood. Those in churches are generally hexagonal or octagonal; some stand on stone bases, and others on slender wooden stems, like columns. The designs vary according to the periods in which they were erected, having paneling, tracing, cuspings, crockets and other ornaments. Some are extremely rich and ornamented with colour and gilding. A few also have rich canopies or sounding boards. Their usual place is in the nave, mostly on the north side, against the second pier from the chancel arch. Outdoor pulpits were common in the medieval period, and stood near a road or cross. Pulpits, for reading during the meals of the monks, are found in refectories. After the Reformation the English canons ordered pulpits to be erected in all churches. Many of the time of Elizabeth I and James are beautifully carved, and of Flemish workmanship. The pulpits in mosques, known as "mimbars," are canopied and approached by a straight flight of steps. These have a doorway at the foot, with an enriched lintel and boldly molded head; the work is of wood, often inlaid, gorgeously painted and gilded.

PULQUE (PULQUE FUERTE), the national beverage of the Mexican natives. It is prepared by fermenting the juice of a number of species of the agave (Agave americana, etc.). The cultivation of the agave for purposes of pulque manufacture constitutes a considerable local industry. Pulque has a heavy flavour, resembling sour milk, but it is esteemed by the natives because of its cooling and, according to them, nutritious properties. See AGAVE.

PULSE, throbbing or beating; in physiology the rhythmical beating due to changes of blood tension in the arteries consequent on expansion and contraction of their elastic tissues in response to the ejection of blood by the heart (see CIRCULATION OF BLOOD). In botany, a collective term for beans, peas, lentils and other members of the family Leguminosae (*q.v.*).

PULVERIZED FUEL: see FUELS.

PUMA (Felis concolor), which occurs only in the western hemisphere, is exceeded in size among cats of the new world only by the jaguar. Besides the term puma, which is derived from usage by the Incas of South America, it is also known by the following names: cougar, deer tiger, Mexican lion, panther, painter (corruption of panther), mountain lion and catamount. Sixteen geographic races of the puma are recognized; they range widely, from British Columbia in the north to Patagonia in the south, and formerly ranged coast to coast from the Atlantic to the Pacific. Man has eliminated pumas in many locations; they are now generally restricted to wilderness areas away from dense human populations.

WILFORD L. MILLER FROM NATIONAL AUDUBON SOCIETY

PUMA OR MOUNTAIN LION (FELIS CONCOLOR)

A wide range of coloration exists among puma races, from pale buff to reddish brown. The ears and tip of the tail are generally dark, while the belly as well as the rump extending to the first hind leg joints are white. There is no mane. Weights of adult puma range from about 75 to 275 lb.; shoulder height may be 2–24 ft., the males being larger than the females. From one to six kittens are produced after a gestation period of 90–96 days; they may be born in any month of the year. The young have rows of small, irregular black spots, which disappear at maturity.

The puma exists on a wide range of foods, its favourite, when available, being deer. When killing, the puma brings its victim to the ground with the stunning impact of its entire weight, generally attacking at the throat and breast. See also CAT. (S. P. Y.)

PUMICE, a very porous, frothlike, volcanic glass. Pumice has long been used as an abrasive, in cleaning, polishing and scouring compounds. After 1945 its uses multiplied in applications as railroad ballast and as a lightweight aggregate in precast masonry units, poured concrete, insulation and acoustic tile and plaster.

Pumice is an igneous rock which was almost completely liquid at the moment of effusion and was so rapidly cooled that there was no time for it to crystallize. When it solidified the vapours dissolved in it were suddenly released and the whole mass swelled up into a froth which immediately consolidated. Had it cooled under more pressure it would have formed a solid glass or obsidian (*q.v.*); in fact if we take fragments of obsidian and heat them in a crucible till they fuse they will suddenly change to pumice when their dissolved gases are set free. Hence it can be understood that pumice is found only in recent volcanic countries. Any type of lava, if the conditions are favourable, may assume the pumiceous state; but basalts and andesites do not so often occur in this form as do trachytes and rhyolites.

Pumices are most abundant and most typically developed from acid rocks, for which reason they usually accompany obsidians; in fact, in the Italian island of Lipari and elsewhere the base of a lava flow may be black obsidian while the upper portion is a snow white pumice.

Small crystals of various minerals occur in many pumices; the most common are feldspar, augite, hornblende and zircon. The cavities of pumice are sometimes rounded, and may also be elongated or tubular owing to the flowing movement of the solidifying lava. The glass itself forms threads, fibres and thin partitions between the vesicles. Rhyolite and trachyte pumices are white, contain 60% to 75% of silica and the specific gravity of the glass is 2.3 to 2.4; andesite pumices are often yellow or brown; while pumiceous basalts, such as occur in the Hawaiian Islands, are pitch black when perfectly fresh.

Good pumice is found in Iceland, Hungary, Teneriffe Island in the Canaries, New Zealand, Pantelleria Island and the Lipari Islands of Italy, West Germany and Greece. In the United States pumice is mined in Kansas, the Rocky mountain and Pacific coast states (as California, Nevada, New Mexico, Wyoming), Alaska and Hawaii. Pumice occurs, among the older volcanic rocks, but usually has its cavities filled up by deposits of secondary minerals introduced by percolating water. Pumice, in minute fragments, has been shown to have an exceedingly wide distribution over the earth's surface. It occurs in all the deposits which cover the floor of the deepest portion of the oceans, and is especially abundant in the abysmal red clay. In some measure this pumice has been derived from submarine volcanic eruptions, but its presence is also accounted for by the fact that pumice will float on water for months, and is thus distributed over the sea by winds and currents. After a long time it becomes waterlogged and sinks to the bottom, where it gradually disintegrates and is incorporated in the muds and oozes which are gathering there. After the great eruption of Krakatoa (*q.v.*) in 1883, banks of pumice covered the surface of the sea for many miles and rose in some cases for four or five feet above the water level. In addition much finely broken pumice was thrown into the air to a great height and was borne away by the winds, ultimately settling down in the most distant parts of the continents and oceans. See also TUFF; VOLCANO.

(J. S. F.; X.)

PUMP, a device for increasing the pressure of a fluid, usually a liquid. The increase in pressure, or head, is used to move the fluid through some channel or to raise it to a higher level, or both. Pumps are used in many applications; for example, to deliver water for home and industrial use; to transport oil across the country; to circulate oil, water and fuel in automobiles, airplanes and other vehicles; to lift a barber's chair; and in many industrial plants where fluids are used for power transmission or in manufacturing processes. In a pump, mechanical work is transformed into fluid energy; by contrast, in a turbine, fluid energy is transformed into mechanical work at some rotating shaft.

Pumps may be divided into two main types: the positive-displacement or static type; and the dynamic or kinetic type. In the positive-displacement type the characteristic action is a displacement by a decrease in volume in the working chamber of the pump. The increase in fluid static pressure is developed by a displacement action rather than by a velocity change or a kinetic energy change. The reciprocating pump, the rotary pump, the gear pump and the vane pump are illustrations of positive-displacement pumps. In the kinetic or dynamic type there is a kinetic or dynamic action between some mechanical element and a fluid; a force acting on the fluid causes a significant velocity change. The centrifugal pump and the jet pump are examples of the dynamic type.

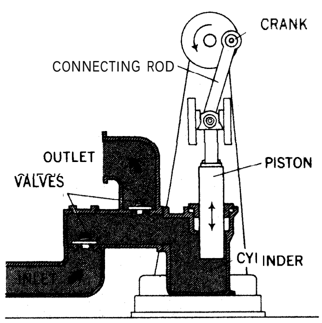

FIG. 1. — RECIPROCATING PUMP

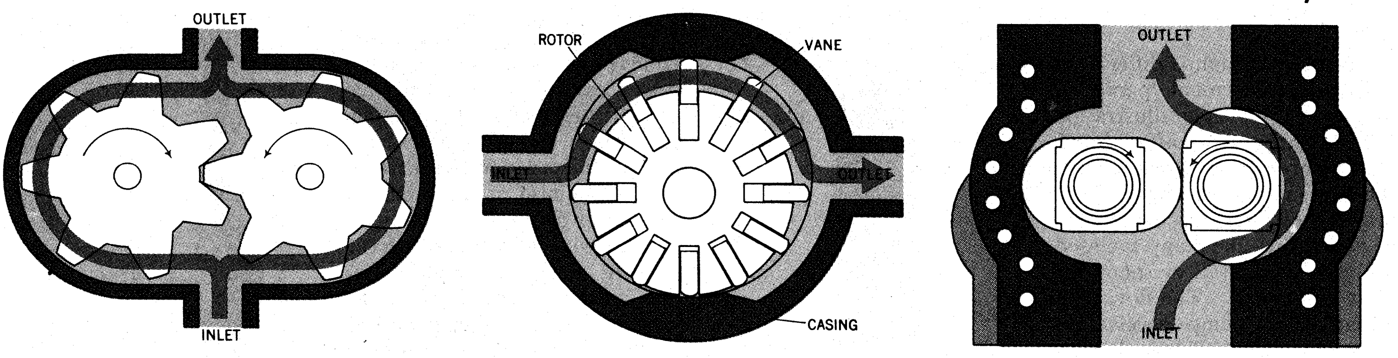
Reciprocating Pumps. — In the common reciprocating pump a piston moves back and forth in a cylinder. An example is the hand bicycle pump, in which, as the hand pushes the piston back and forth, air from the atmosphere enters the cylinder and is pushed out of the cylinder into the tire by the piston action. Suitable valves are necessary to control the flow properly.



RIGHT, AFTER E. F. WRIGHT, "PUMPS," "MECHANICAL ENGINEERS' HANDBOOK"; REPRODUCED BY PERMISSION OF MCGRAW-HILL BOOK COMPANY, INC.

FIG. 2.— SCHEMATIC DIAGRAM OF (A) ROTARY PUMP; (B) HYDRAULIC VANE PUMP OR MOTOR: (C) LOBE PUMP

Fig. 1 illustrates the case in which the piston is moved back and forth in the cylinder by an arrangement of crank and connecting rod. As the piston moves toward the right, the outlet check valve is open, the inlet valve is closed, and the fluid flows from the cylinder through the outlet or discharge pipe. As the piston moves toward the left, the inlet check valve is open, the outlet valve is closed, and fluid enters the cylinder. If leakage past the piston is neglected, then the piston delivers the volume of fluid it displaces in moving through the cylinder; this explains the term positive-displacement.

A single-acting pump, in which fluid is pumped only by one side of the piston is illustrated in fig. 1. This can be turned into a double-acting pump—in which both sides of the piston are in contact with the fluid, and both sides pumpsimply by adding inlet and outlet pipes, with suitable valves, at the other end of the cylinder (and, of course, providing a proper seal at the opening where the piston rod enters the cylinder).

For a given volume rate of flow through the pump, the pressure at the pump outlet may be high or low, depending on the pressure necessary to force the fluid through the system connected to the pump; thus the discharge pressure is governed by the load or piping system. The pressure that a reciprocating pump can develop is limited only by the strength of the pump components and the power of the driving unit.

On some reciprocating pumps there is an air chamber on the discharge. The air trapped in the chamber acts as a cushion, making the pump operation smooth and quiet. Generally speaking, reciprocating pumps are best adapted for relatively low rates of flow, high pressures and high suction lifts. They are built of a wide variety of materials and for many different types of service. Reciprocating pumps are not well suited for pumping very dirty or very viscous liquids, because of the possibility of clogging.

Various methods are used for reciprocating the piston, such as different mechanical linkages or a fluid under pressure. For example, steam may be used on one side of the piston to drive it while water or some other liquid is pumped by the other side of the piston.

Diaphragm Pumps.—If, instead of the movable piston in fig. 1 a circular diaphragm–of rubber or other flexible material—is fixed at its outer edge to the cylinder, and if the crank and connecting rod linkage is fastened at its centre, the result will be a diaphragm pump. The central portion of the diaphragm is moved back and forth to provide volumetric displacement, and the inlet and outlet valve arrangement is similar to that of the reciprocating pump. Because there is no possibility of liquid bypassing the diaphragm and coming in contact with the connecting rod or other pump parts, diaphragm pumps are used for handling such materials as thick pulps, sewage sludge, acids, alkaline solutions, mine waters and fruit juices.

Rotary Pumps.—The rotary pump is classed as a positive-displacement pump, although its action is one of rotation, not reciprocation. It should not be confused with the centrifugal pump. The gear pump in fig. 2, an example of one type of rotary pump, has a pair of meshed gears in a casing. As the gears rotate, fluid is caught between their teeth and the casing, and is carried from inlet to outlet, the volume of fluid delivered during each revolution depending on the amount of space between the teeth and the case. Delivery is fairly steady, in contrast to the pulsating delivery of the reciprocating pump.

Rotary pumps are most suitable for applications requiring only low and medium delivery pressure. The absence of valves is an advantage in pumping heavy viscous liquids but because of the close clearances between gears and case, rotary pumps are not suitable for liquids containing any abrasive material that might damage the metal surfaces.

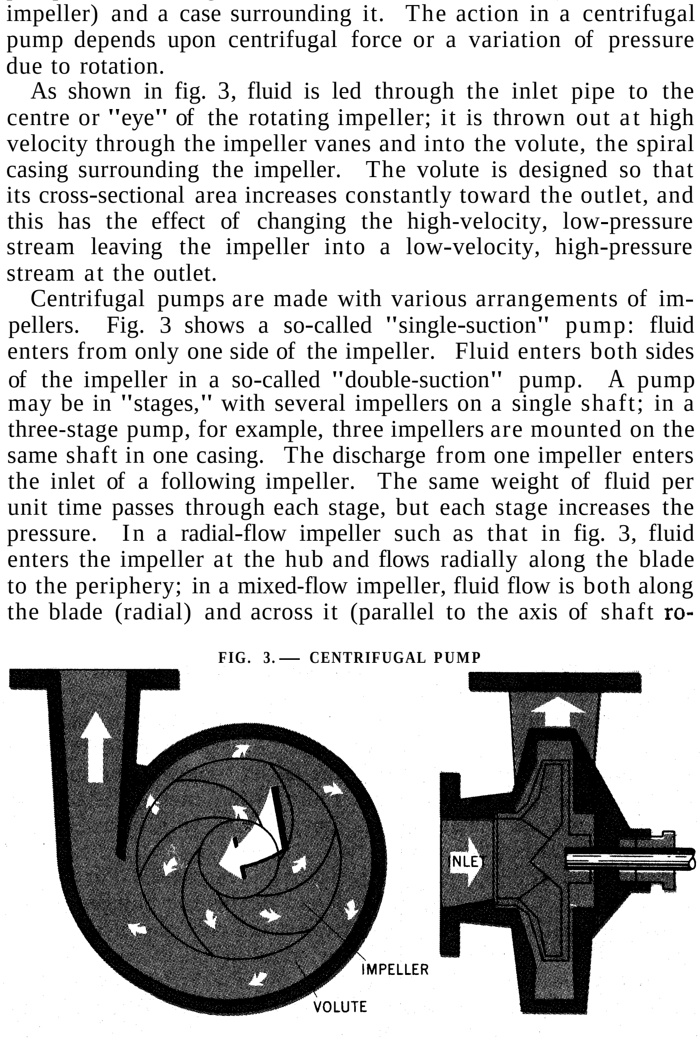
Different types of rotary pumps are available. In some pumps, rotating members with two or more lobes are used instead of gears. In the vane type of pump, there is a rotor set off-center in a casing. The rotor is fitted with vanes which slide in and out radially. The entering liquid is trapped between the vanes, which ride on the inside of the case, and is carried to the outlet.

Centrifugal Pumps.—The essential parts of a centrifugal pump are a rotating member with blades or vanes (the so-called impeller) and a case surrounding it. The action in a centrifugal pump depends upon centrifugal force or a variation of pressure due to rotation.

As shown in fig. 3, fluid is led through the inlet pipe to the centre or "eye" of the rotating impeller; it is thrown out at high velocity through the impeller vanes and into the volute, the spiral casing surrounding the impeller. The volute is designed so that its cross-sectional area increases constantly toward the outlet, and this has the effect of changing the high-velocity, low-pressure stream leaving the impeller into a low-velocity, high-pressure stream at the outlet.

Centrifugal pumps are made with various arrangements of impellers. Fig. 3 shows a so-called "single-suction" pump: fluid enters from only one side of the impeller. Fluid enters both sides of the impeller in a so-called "double-suction" pump. A pump may be in "stages," with several impellers on a single shaft; in a three-stage pump, for example, three impellers are mounted on the same shaft in one casing. The discharge from one impeller enters the inlet of a following impeller. The same weight of fluid per unit time passes through each stage, but each stage increases the pressure. In a radial-flow impeller such as that in fig. 3, fluid enters the impeller at the hub and flows radially along the blade to the periphery; in a mixed-flow impeller, fluid flow is both along the blade (radial) and across it (parallel to the axis of shaft ro-

FIG. 3.— CENTRIFUGAL PUMP



tation).

Centrifugal pumps differ from positive-displacement pumps in various ways. As an illustration, the discharge valve of a centrifugal pump can be closed without the pressure rising above a certain value; if the discharge valve of a reciprocating pump is closed, the pump will stall or some part of it will break. The flow from a centrifugal pump is relatively smooth and steady, and these pumps can handle various liquids, sewage and liquids containing sand, gravel and stones of moderate size.

Centrifugal pumps are sometimes classified as volute or diffuser types. Fig. 3 shows a volute type, the fluid being discharged directly from the impeller into the volute. In the diffuser type, there is a series of fixed vanes, surrounding the impeller, that reduce turbulence in the volute by smoothing the flow of fluid and lowering its velocity; there is a decrease in kinetic energy and an increase in static pressure in the vane diffuser.

FIG. 4.—SUBMERSIBLE PUMP

Axial-flow Pumps.—An axial-flow pump is a dynamic machine which may consist of a single runner in a cylindrical casing or of a runner with one or two sets of fixed guide vanes. In an axial-flow pump the fluid passes through the runner without essentially changing its distance from the axis of rotation (in principle and design, the axial-flow pump is much like a gas turbine). There is practically no centrifugal force effect within the true axial-flow pump. Generally speaking, the centrifugal pump is best suited for producing relatively high pressures and low rates of flow, while the axial-flow pump is best for producing relatively low pressures and high rates of flow.

Deep-Well Pumps.--Various types of pumps have been developed for pumping water or oil from deep wells. One, called the plunger pump, is essentially a reciprocating pump with a long piston rod. In the so-called turbine deep-well pump, a motor at the surface turns a vertical rotating shaft; this shaft drives a multistage centrifugal pump (with impellers rotating in a horizontal plane) which is installed in the well below the surface of the water or oil. For high lifts, the pump may have 20 or more stages.

Fig. 4 illustrates a submersible-motor pump; the motor is mounted below the centrifugal pump. The elongated, small-diameter electric motor operates submerged in the well liquid. The liquid being pumped does not come in contact with the electric parts or motor bearings, because these are enclosed in an oil-filled case which has a mercury seal where the rotating shaft passes through the top to the pump.

The pump and motor form a compact assembly that is fastened to and supported by the outlet pipe. A liquid-tight armoured cable connects the motor leads to the power supply at the surface, and a small copper tube provides a lubrication inlet at the surface for larger models; small models are provided with "permanent" lubrication and require no attention.

Each type of deep-well pump has its advantages. For a specific application in a well of moderate depth, the plunger pump usually is least expensive; and since it is the only one of the three that can be operated directly by a windmill it has often been used in remote locations. As in the case with the turbine pump, the power source is at the surface and readily accessible for maintenance. However, in both cases, trouble with the pumping unit necessitates withdrawing and disconnecting, section by section, the plunger rod or turbine shaft, to raise the pump to the surface; this is true also of the submersible-motor pump.

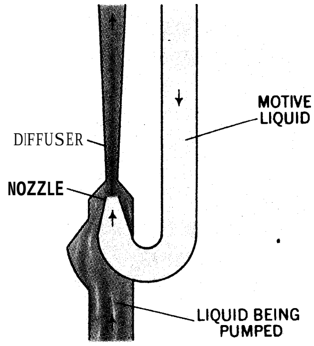

FIG. 5.—LIQUID JET PUMP

The limit of depth at which the plunger pump will operate economically. is reached when the power unit is expending almost as much, or more, energy lifting a long plunger rod than lifting fluid; and this type of pump does not work well except in very straight well bores. The economical limit of the turbine pump is reached when more energy is expended in overcoming bearing friction in the long shaft than in lifting fluid (the shaft must be supported at frequent intervals by "spiders" or frameworks that fit against the sides of the well bore and are fitted with bearings to keep the shaft centred in the bore); the turbine pump will work in an out-of-plumb well, but any deviation from straightness increases frictional losses at the bearings.

The submersible-motor pump overcomes some of these disadvantages (it will work in a very crooked bore, for example, the amount of deviation being limited only by the angle through which the pump unit and outlet pipe can be inserted and withdrawn easily), but it introduces disadvantages of its own. Principal among these is the fact that malfunctioning of either pump or motor necessitates withdrawing the entire unit from the well.

Jet Pumps.—In the reciprocating, rotary and. centrifugal pumps, there is a moving mechanical part which does work on the moving fluid. However, there is a dynamic type of pump which does not have any moving mechanical parts: it is called variously a jet pump, injector or ejector. In this type of pump the pressure of a fluid is increased as it flows through an arrangement of fixed channels. A "motive fluid" is used to pump, or induce the flow of, some other fluid.

Jet pumps are found in many applications, pumping many different fluids. A common type is one in which water is the motive fluid and water is the fluid being pumped; such pumps are used on domestic water well systems. As illustrated in fig. 5, water passes through the converging nozzle with a high velocity and acts as a motive or driving fluid; at the end of the nozzle the velocity is high and the pressure is low. The mixture of motive fluid and liquid being pumped, or induced, then passes through the diffuser where the velocity is reduced and the pressure is increased.

A number of pumping devices can be explained by reference to the venturi tube. As illustrated in fig. 6, the venturi tube consists of a converging nozzle and a narrow portion or throat. As motive fluid passes through the converging portion, the velocity is increased and the pressure is decreased, and this decrease in pressure can be used to move some other fluid. In the usual aspirator pump, water passes through a venturi channel, and air is drawn into the venturi throat by the low pressure; in the common atomizer, air passing through a venturi tube lifts liquid from the attached container, mixes with the liquid, and ejects it as a fine spray.

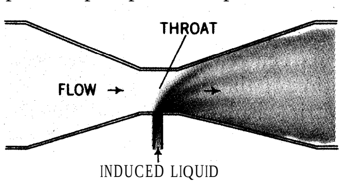

FIG. 6.—VENTURI PUMPING DEVICE

Air or Gas Lift Pumps.—In this type of pump there is a vertical lift pipe arranged with its lower end submerged in the liquid to be raised and its upper end connected to a discharge pipe or tank. Air or gas from a compressor is led through a separate pipe to the lower end of the lift pipe, where it bubbles through the liquid to form a gas-liquid mixture that has a lower density (or specific weight) than the surrounding liquid. The resulting buoyant force moves the lighter mixture (of gas and liquid) to the top of the vertical pipe. In this type of pump, air may be used to pump water, or a gas may be used to pump oil. The pumping action depends on the air or gas used, the nature of the liquid, the depth of submersion of the lower end of the lift pipe, and the manner of forming the bubbles.

Vacuum Pumps. — Atmospheric pressure is the force exerted on a unit area due to the weight of the atmosphere. The word "vacuum" is frequently used in referring to pressures below atmospheric. In many cases it is desired to exhaust or evacuate air (or some gas) from a vessel or a piece of equipment. The aspirator pump can be used to develop a partial vacuum; other types, to produce higher degrees of vacuum, are described in the article VACUUM.

Magnetic Pumps for Liquid Metals. — Certain characteristics of liquid metals make them attractive as heat-transfer liquids for cooling nuclear reactors. The electromagnetic pump has proved suitable for the circulation of some of these liquid metals.

The electromagnetic pump uses the same principle on which the electric motor is based; namely, that a conductor in a magnetic field, carrying a current flowing at right angles to the magnetic field direction, has a force exerted on it in a direction mutually perpendicular to both the field and current. In the electromagnetic pump, the fluid being pumped is the conductor, and the resultant force acts to propel the fluid if suitable arrangements are made. The current and field can be produced in many ways.

In one electromagnetic pump, the D.C.-Faraday type, the liquid metal flows through a thin-walled duct of square or rectangular cross-section. A constant magnetic field is passed through the fluid on an axis perpendicular to the flow direction. The magnetic field is developed by windings, carrying direct current, that are mounted on a magnetic core with pole faces that provide a magnetic return path through the fluid metal. Current is passed through the fluid by establishing a voltage drop along the axis of the duct, mutually perpendicular to both the flow direction and the magnetic field direction. In theory, the operation of this pump is similar to that of a direct-current shunt motor.

PUMPKIN, the fruit of certain varieties of Cucurbita pepo or of *C.* moschata, members of the family Cucurbitaceae. The names pumpkin and squash, especially in America, are applied rather inconsistently to certain varieties of both these species. The quick-growing, small-fruited bush or nontrailing varieties of C. pepo (see SQUASH) are called squash in America, while the long-season, long-trailing, large-fruited varieties are called pumpkin. The fruits are large, generally 10–20 lb. or more, yellowish to orange in colour and vary from oblate through globular to oblong. The rind is smooth and usually lightly furrowed or ribbed; the fruit stem is hard and woody, ridged or angled, and in C. pepo not flared at its point of attachment to the fruit. The very largest varieties of "pumpkin" are more properly designated as winter squash, *C.* maxima, and may weigh 75 lb. or more. Varieties cross-pollinate readily within each of the three species, but the species do not cross naturally. A few interspecific crosses have been recorded but the hybrids were highly self-sterile and set no fruit with their own pollen. Neither pumpkins nor squashes will cross with cucumbers or with melons.

Pumpkins are commonly grown in North America, Great Britain and Europe for human food and also for livestock feed. They are used in the U.S. as Halloween decorations, the pulp being removed and a light inserted which shines through cut-out eyes, nose and mouth. The varieties commonly called pumpkin produce very long vines and are usually planted in hills of two to three plants each, about 8 × 8 ft. apart. They are also planted at wide intervals in fields of corn. Pumpkins mature in early fall and can be stored a few months in a dry place well above freezing. They are prepared for food in a variety of ways. (V. R. B.)

PUN, a witty play upon two or more meanings for the same word, or on two words with identical sounds. Example: "She was a good cook as cooks go, and as cooks go, she went." — H. H. Munro. This form of wit has been in and out of fashion many times. It was highly respected in Shakespeare's age, but Oliver Wendell Holmes, the poet, dubbed it "the lowest form of wit" — in which he freely indulged. It can be used seriously, as metaphor, as when Emerson says the poet "apprises us not of his wealth, but of the common wealth." With mingled humour and pathos Shakespeare declared: "Golden lads and girls all must,/ As chimney-sweepers, come to dust." See FIGURES OF SPEECH: Play Upon Words. (G. W. A.)

PUNAN. The name applied to a number of peoples in Borneo, all of them, except the Punan Ba, forest nomads in the area of the headwaters of the major rivers. They live in isolated groups of 30 to 40, subsisting on the wild sago palm and game hunted with the blowpipe. Physically and culturally they are very similar to the other peoples of the island; none of them is Negrito or demonstrably aboriginal in Borneo. Some of the groups differ widely from each other; as a result of the similarity of name European accounts of them are almost inextricably confused. Three "Punan" peoples, however, are certainly distinct. the settled Punan Ba of western Borneo; the Penan (wrongly named Punan) of the Baram and Balui; and the Punan Aput and Busang of the northern Apo Kayan. (R. NM.)

PUNCH, the abbreviated form of PUNCHINELLO (Italian Policianelo, *Pulcinella;* French, Polichinelle), the most popular of the marionettes and glove puppets and the chief figure in the Punch and Judy show. Many modern authorities tend to accept the opinion that the whole family of Italian maschere (masked characters of the commedia *dell'arte; e.g.,* Arlecchino and Brighella) are modified survivals of the principal Oscan characters of the atellanae, and that Pulcinella is the representative of Maccus, the country bumpkin, or Bucco, the comic servant (see ATELLANA FABULA). But there is a gap of 1,000 years between the last records of the Atellan farces and the first of the commedia dell'arte, and it would be ingenuous to follow the antiquaries of the 18th century in accepting a clear connection between the two. At the same time it is interesting to compare a bronze of Maccus with 17th-century pictures of Pulcinella in Italy and France.

It is not certainly known who was the first Pulcinella. Claims have been made on behalf of Silvio Fiorillo and Andrea Calcese, both of whom were performing at the beginning of the 17th century. But some facts of his early history are definite. One of the *zanni,* the comic servants of the company, he was indispensable when the troupe played in Naples but did not always appear in other localities. His characteristics were not clearly marked at first, and the hooked nose, the humped back, the tendency to wife-beating and outrageous lawlessness typical of the English Punch were acquired only gradually. This is clearly seen from the first pictorial representations. The earliest. in which he is called Policianelo, is dated 1618 and is one of a series made from birds' feathers by Dionisio Minaggio, the gardener of the governor of Milan. The second, in 1622, is of Pulliciniello in Jacques Callot's I *Balli di Sfessania.* In both he is depicted as large, shambling and stupid-looking, dressed in a loose white shirt and very full trousers.

PUNCH

From a drawing which appeared on a music cover of the mid-19th century

The Italian actors soon began to travel abroad. A few of them were in Nottingham, Eng., in 1573. The Gelosi, one of the most famous companies, visited Paris in 1577. It is not known exactly when Pulcinella arrived in these countries, but the French version, Polichinelle, was firmly established in France by the middle of the 17th century. When the actors came from Italy the puppet showmen came with them. By 1649 a showman called Jean Brioché, probably an Italian named Briocci, was displaying a puppet Polichinelle near the Pont Neuf in Paris. The marionette was grotesque, humpbacked and hook-nosed, but its origin may not have been entirely Italian. There was a French tradition of hunchbacked fools, as can be seen from a print of the entertainment at the marriage of Henry IV with Marie de Médicis in 1600, and the popularity of the Polichinelle puppet in France may be due to the fusion of these two traditions.

Similarly a tradition of the humpbacked fool existed in England when the first Italian puppeteers arrived after the restoration of Charles II. In 1662 a showman called Signor Bologna, alias Pollicinella, was performing in London, and by 1667 a more elaborate entertainment of Punchinello was established at Charing Cross by Antonio Devoto. In 1672 the king gave his patronage to this theatre, and then performances with human actors were permitted. Already the shortened form of the name had passed into general usage. Samuel Pepys mentions (1669) some people who called their fat child Punch, "that word being become a word of common use for all that is thick and short." This general popularity was probably caused by the traveling showmen, who carried puppets to the country wakes in the summer and visited London for the fairs in August and September.

Early in the 18th century Punch became famous in political circles through the use of the name by Martin Powell, a marionette showman, in a scurrilous attack on Robert Harley. This pamphlet, entitled *A Second Tale of a Tub* (1715), furnishes some details of Punch performances and has a frontispiece of Powell with Punch and his wife. But it was in the 1790s that the revival occurred which caused the preservation of Punch and Judy: as the marionettes at the fairs lost their popularity, there was a new interest in the humbler glove puppets, and in this form the Punch and Judy play became a success. *See* also COMMEDIA DELL'ARTE; PUPPETS AND MARIONETTES.

PUNCHING AND SHEARING MACHINES: *see* MACHINE TOOLS.

PUNCTUATION. The consistent use of conventional signs for the division of the stream of speech into parts are, in the main, of modern origin. Early manuscripts are usually devoid of punctuation, and careful legal documents are still drawn in such a way that punctuation may be omitted without affecting the meaning. Ancient inscriptions either have no punctuation whatever or use interpuncts as separators between words. But the origin of the signs used in most European languages (and in their expansions overseas), their gradually increasing use and consistency of use, may be traced as far back as the pre-Christian era, yet the practice was neither standard nor obligatory before the middle ages. Moreover, since phrasing within a sentence varies in different languages, practice also varies, and details must be sought in the grammars of different languages, or in the rules established by printing houses to guide typesetters, proofreaders and editors. Some of the rules taught in schools, and particularly in secretarial schools, are artificial, not being in accord with the natural pauses of utterance.

PUNIC WARS, a name specially appropriated to the wars between Rome and Carthage in the 3rd and 2nd centuries B.C. The origin of these conflicts is to be sought in the position which Rome acquired about 275 B.C. as suzerain and protector of all Italy. Her new obligation to safeguard the peninsula against foreign interference made it necessary that she should not allow the neighbouring island of Sicily to fall into the hands of a strong and expansive power. Carthage, on the other hand, had long been anxious to conquer Sicily and so to complete the chain of island posts by which she controlled the western Mediterranean.

First Punic War (264–241 B.C.[1]).—The proximate cause of the first outbreak was a crisis in the city of Messana, commanding the straits between Italy and Sicily. A band of Campanian mercenaries, which had forcibly established itself within the town and was being hard pressed in 264 by Hiero II. of Syracuse, applied for help to both Rome and Carthage. The Carthaginians, arriving first, occupied Messana and effected a reconciliation with Hiero. The Roman commander nevertheless persisted in throwing troops into the city, and by seizing the Carthaginian admiral during a parley induced him to withdraw. This aggression met a declaration of war from Carthage and Syracuse.

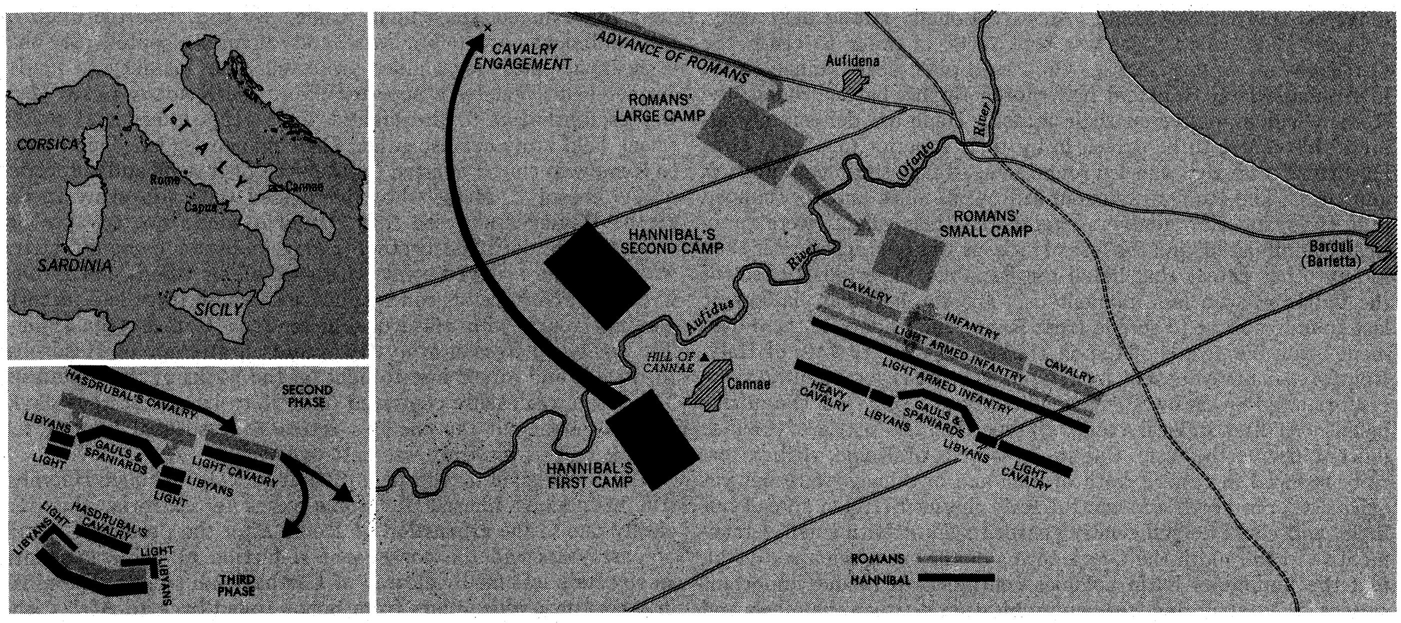
Operations began with a joint attack upon Messana, which the Romans easily repelled. In 263 they advanced with a considerable force into Hiero's territory and induced him to seek peace and alliance with them. In 262 they besieged and captured the enemy's base at Agrigentum. But they made little impression upon the Carthaginian fortresses in the west of the island and upon the towns of the interior.

In 260 the Romans built their first large fleet of standard battleships. At Mylae, off the north Sicilian coast, their admiral C. Duilius defeated a Carthaginian squadron of superior maneuvering capacity by grappling and boarding. This left Rome free to land a force on Corsica and expel the Carthaginians (259), but did not suffice to loosen their grasp on Sicily. A large Roman armament sailed out in 256, repelled the entire Carthaginian fleet off Cape Ecnomus (near Agrigentum) and established a fortified camp on African soil at Clypea. The Carthaginians, whose citizen levy was utterly disorganized, could neither keep the field against the invaders nor prevent their subjects from revolting. A single campaign compelled them to sue for peace, but the terms which the Roman commander Atilius Regulus offered were intolerably harsh. Accordingly they equipped a new army in which, by the advice of a Greek captain of mercenaries named Xanthippus, cavalry and elephants formed the strongest arm. In 255, under Xanthippus' command, they offered battle to Regulus, who had taken up position with an inadequate force near Tunis, outmaneuvered him and destroyed the bulk of his army. A second Roman armament, which subsequently reached Africa after defeating the full Carthaginian fleet off Cape Hermaeum, withdrew all the remaining troops.

The Romans now directed their efforts once more against Sicily. In 254 they carried the important fortress of Panormus (Palermo) by an attack from the sea; but when Carthage threw reinforcements into the island the war again came to a standstill. In 251 at last the Roman general L. Metellus brought about a pitched battle near Panormus in which the enemy's force was effectively crippled. This victory was followed by an investment of the chief Punic base at Lilybaeum by land and sea. The besiegers met with a gallant resistance, and in 249 were compelled to withdraw by the loss of their fleet in a surprise attack upon the neighbouring harbour of Drepanum (Trapani), in which the admiral Claudius Pulcher was repulsed with a loss of 93 ships. Meanwhile other losses in storms on the high seas so reduced the Roman fleet that the attack upon Sicily had to be suspended. At the same time the Carthaginians, who felt no less severely the financial strain of the prolonged struggle and had a war in Africa on their hands, reduced their armaments and made no attempt to deliver a counter-attack. The only noteworthy feature of the ensuing campaigns is the skilful guerrilla war waged by a new Carthaginian commander, Hamilcar Barca, from his strong positions on Mt. Ercte (247–244) and Mt. Eryx (244–242) in western Sicily, by which he effectually screened Lilybaeum from the Roman land army.

In 242 Rome resumed operations on sea. By a magnificent effort on the part of private citizens a fleet of 200 warships was equipped and sent out to renew the blockade of Lilybaeum. The Carthaginians hastily collected a relief force, but in a battle

[1]The chronology here given is the traditional one, but recent researches tend to show that many events have been antedated by one year.



PLAN OF THE BATTLE OF CANNAE. 216 B.C.

A major battle of the Second Punic War (218–201 B.C.) in which Hannibal was victorious over the Romans. Inset at lower left shows the second and third phases of the battle

fought off the Aegates or Aegusae islands (west of Drepana) their fleet was caught at a disadvantage and mostly sunk or captured (March 10, 241). This victory, by giving the Romans undisputed command of the sea, rendered certain the ultimate fall of the Punic strongholds in Sicily. The Carthaginians accordingly opened negotiations and consented to a peace by which they ceded Sicily and the Lipari islands to Rome and paid an indemnity of 3,200 talents (about £800,000).

The Interval Between the First and Second Wars **(241–218 B.C.)**.—The loss of naval supremacy not only deprived Carthage of her predominance in the western Mediterranean, but exposed her oversea empire to disintegration under renewed attacks by Rome. The temper of the Roman people was soon made manifest during a conflict which broke out between the Carthaginians and their discontented mercenaries. Italian traders were allowed to traffic in munitions of war with the mutineers, and a gross breach of the treaty was perpetrated when a Roman force was sent to occupy Sardinia, whose insurgent garrison had offered to surrender the island (239). To the remonstrances of Carthage the Romans replied with a direct declaration of war, and only withheld their attack upon the formal cession of Sardinia and Corsica and the payment of a further indemnity.

From this episode it became clear that Rome intended to use her victory to the utmost. To avoid complete humiliation Carthage had no resource but to humiliate her adversary. The recent complications of foreign and internal strife had indeed so weakened the Punic power that the prospect of renewing the war under favourable circumstances seemed remote enough. But the scheme of preparing for a fresh conflict found a worthy champion in Hamilcar Barca, who sought to compensate for the loss of Sicily by acquiring a dominion in Spain where Carthage might gain new wealth and form a fresh base of operations against Rome. Invested with an unrestricted foreign command, he spent the rest of his life in founding a Spanish empire (236–228). His work was continued by his son-in-law Hasdrubal and his son Hannibal, who was placed at the head of the army in 220. These conquests aroused the suspicions of Rome, which in a treaty with Hasdrubal confined the Carthaginians to the south of the Ebro, and also guaranteed the independence of Saguntum, a town on the east coast which pretended to a Greek origin. In 219 Hannibal laid siege to Saguntum and carried the town in spite of a stubborn defence. It has always been a debatable point whether his attack contravened the new treaty. The Romans certainly took this view and sent to Carthage to demand Hannibal's surrender. But his defiant policy was too popular to be disavowed; the Carthaginian council upheld Hannibal's action, and drew upon itself a declaration of war.

Second Punic War **(218–201 B.C.)**.—It seemed as though the superiority of the Romans at sea must enable them to choose the field of battle. They decided to embark one army for Spain and another for Sicily and Africa. But before their preparations were complete Hannibal began that series of operations by which he dictated the course of the war for the greater part of its duration. Realizing that so long as Rome commanded the resources of an undivided Italian confederacy no foreign attack could beat her down beyond recovery, he conceived the plan of cutting off her supply of strength at the source by carrying the war into Italy and causing a disruption of the League. His chances of ever reaching Italy seemed small, for the sea was guarded by the Roman fleets and the land route was long and arduous. But the very boldness of his enterprise contributed to its success; after a six months' march through Spain and Gaul and over the Alps, which the Romans were nowhere in time to oppose, Hannibal arrived in the plain of the Po with 20,000 foot and 6,000 horse, the pick of his African and Spanish levies (autumn 218: for details see HANNIBAL).

His further advance was here disputed by some Roman troops which had been recalled from the Spanish expedition. But the superiority of the Carthaginian cavalry and the spread of insurrection among the Gaulish inhabitants forced the defenders to fall back upon the Apennines. At the end of the year the Roman army was reinforced by the division from Sicily and led out to battle on the banks of the Trebia (*q.v.*). Hannibal, by superior tactics, repelled the assailants with heavy loss, and thus made his position in north Italy secure.

In 217 the campaign opened in Etruria, into which the invading army, largely reinforced by Gauls, penetrated by an unguarded pass. A rash pursuit by the Roman field force led to its being entrapped on the shore of Lake Trasimene (*q.v.*) and destroyed with a loss of 40,000 men. This catastrophe left Rome completely uncovered; but Hannibal, having resolved not to attack the capital before he could collect a more overwhelming force, directed his march towards the south of Italy, where he hoped to stir up the peoples who had formerly been Rome's most stubborn enemies. The natives, however, were everywhere slow to join the Carthaginians, and a new Roman army under the dictator Q. Fabius Maximus ("Cunctator"), which, without ever daring to close with Hannibal, dogged his steps on his forays through Apulia and Campania, prevented his acquiring a permanent base of operations.

The eventful campaign of 216 was begun by a new aggressive move on the part of Rome. An exceptionally strong field army, estimated at 85,000 men, was sent forth in order to crush the Carthaginians in open battle. On a level plain near Cannae (*q.v.*) in Apulia, which Hannibal had chosen for his battle-ground, the Roman legions delivered their attack. Hannibal deliberately allowed his centre to be driven in by their superior numbers, while Hasdrubal's cavalry wheeled round so as to take the enemy in flank and rear. The Romans, surrounded on all sides and so cramped that their superior numbers aggravated their plight, were practically annihilated, and the loss of citizens was perhaps greater than in any other defeat that befell the Republic. The moral effect of the battle was no less momentous. The south Italian nations at last found courage to secede from Rome, the leaders of the movement being the people of Capua, the second greatest town of Italy. Reinforcements were sent from Carthage, and several neutral powers prepared to throw their weight into the scale on Hannibal's behalf. At first sight it seems strange that the battle of Cannae did not decide the war. But the resources of Rome, though terribly reduced in respect both of men and of money, were not yet exhausted. In north and central Italy the insurrection spread but little, and could be sufficiently guarded against with small detachments. In the south the Greek towns of the coast remained loyal, and the numerous Latin colonies continued to render important service by interrupting free communication between the rebels and detaining part of their forces. In Rome itself the quarrels between the nobles and commons, which had previously unsettled her policy, gave way to a unanimity unparalleled in the annals of the Republic. The guidance of operations was henceforth left to the senate, which by maintaining a persistent policy until the conflict was brought to a successful end earned its greatest title to fame.

The subsequent campaigns of the Italian War assume a new character. Though the Romans contrived at times to raise 200,000 men, they could only spare a moderate force for field operations. Their generals, among whom the veterans Fabius and M. Claudius Marcellus frequently held the most important commands, rarely ventured to engage Hannibal in the open, and contented themselves with observing him or skirmishing against his detachments. Hannibal, whose recent accessions of strength were largely discounted by the necessity of assigning troops to protect his new allies or secure their wavering loyalty, was still too weak to undertake a vigorous offensive. In the ensuing years the war resolved itself into a multiplicity of minor engagements which need not be followed out in detail. In 216 and 215 the chief seat of war was Campania, where Hannibal vainly attempted to establish himself on the coast but experienced a severe repulse at Nola. In 214 the main Carthaginian force was transferred to Apulia in hopes of capturing Tarentum. Though Croton and Locri on the Calabrian coast had fallen into his hands, Hannibal still lacked a suitable harbour by which he might have secured his oversea communications. For two years he watched in vain for an opportunity of surprising the town, while the Romans narrowed down the sphere of revolt in Campania and defeated other Carthaginian commanders. In 212 the greater part of Tarentum and other cities of the southern seaboard at last came into Hannibal's power. But in the same year the Romans found themselves strong enough to place Capua under blockade. They severely defeated a Carthaginian relief force, and could not be permanently dislodged even by Hannibal himself. In 211 Hannibal made a last effort to relieve his allies by a feint upon Rome itself, but the besiegers refused to be drawn away from their entrenchments, and eventually Capua was starved into surrender. Its fall was a sign that no power could in the long run uphold a rival Italian coalition against Rome. After a year of desultory fighting the Romans in 209 gained a further important success by recovering Tarentum. Though Hannibal still won isolated engagements, he was being slowly driven back into the extreme south of the peninsula.

In 207 the arrival of a fresh invading force produced a new crisis. Hasdrubal, who in 209–208 had marched overland from Spain, appeared in north Italy with a force scarcely inferior to the army which his brother had brought in 218. After levying contingents of Gauls and Ligurians he marched down the east coast with the object of joining hands with his brother in central Italy for a direct attack upon Rome. By this time the drain of men and money was telling so severely upon her confederacy that some of her most loyal allies protested their inability to render further help. Yet by a supreme effort the Romans raised their war establishment to the highest total yet attained and sent a strong field army against either Carthaginian leader. The danger to Rome was chiefly averted by the prompt insight and enterprise of the consul C. Nero, who commanded the main army in the south. Having discovered that Hannibal would not advance beyond Apulia until his brother had established communications with him, Nero slipped away with part of his troops and arrived in time to reinforce his colleague Livius, whose force had recently got into touch with Hasdrubal near Sena Gallica (Sinigaglia). The combined Roman army frustrated an attempt of Hasdrubal to elude it and forced him to fight on the banks of the Metaurus. The battle was evenly contested until Nero by a dexterous flanking movement cut the enemy's retreat. Hasdrubal himself fell and the bulk of his army was destroyed.

The campaign of 207 decided the war in Italy. Though Hannibal still maintained himself for some years in Calabria, this was chiefly due to the exhaustion of Rome after the prodigious strain of past years and the consequent reduction of her armaments. In 203 Italy was finally cleared of Carthaginian troops. Hannibal, in accordance with orders from home, sailed back to Africa, and another expedition under his brother Mago, which had sailed to Liguria in 205 and endeavoured to rouse the slumbering discontent in Cisalpine Gaul and Etruria, was driven back on the coast and withdrawn about the same time.

Campaigns in Sicily and Spain.—Concurrently with the great struggle in Italy the Second Punic War was fought out on several other fields. It will suffice merely to allude to the First Macedonian War (214–205) which King Philip V. commenced when the Roman power seemed to be breaking up after Cannae. The diversions which Roman diplomacy provided for Philip in Greece and the maintenance of a patrol squadron in the Adriatic prevented any effective co-operation on his part with Hannibal.

In view of the complete stagnation of agriculture in Italy the Romans had to look to Sardinia and Sicily for their food supply. Sardinia was attacked by a Carthaginian armament in 215, but a small Roman force sufficed to repel the invasion. In Sicily a more serious conflict broke out. Some isolated attacks by Punic squadrons were easily frustrated by the strong Roman fleet. But in 215 internal complications arose. The death of Hiero II., Rome's steadfast friend, left the kingdom of Syracuse to his inexperienced grandson Hieronymus. Flattered by the promises of Carthaginian emissaries the young prince abruptly broke with the Romans, but before hostilities commenced he was assassinated. The Syracusan people now repudiated the monarchy and resumed their republican constitution, but they were misled by false threats of terrible punishment at the hands of Rome to play into the hands of the Carthaginians. The attacks of a Roman army and fleet under Marcellus which speedily appeared before the town were completely baffled by the mechanical contrivances of the Syracusan mathematician Archimedes (213). Meantime the revolt against Rome spread in the interior, and a Carthaginian fleet established itself in the towns of the south coast. In 212 Marcellus at last broke through the defence of Syracuse and in spite of the arrival of a Carthaginian relief force mastered the town by slow degrees. A guerilla warfare succeeded in which the Carthaginians maintained the upper hand until in 210 they lost their base at Agrigentum. They were dislodged from their remaining positions, and by the end of the year Sicily was wholly under the power of Rome.

The conflict in Spain was second in importance to the Italian war alone. From this country the Carthaginians drew large supplies of troops and money which might serve to reinforce Hannibal; hence it was in the interest of the Romans to challenge their enemy within his Spanish domain. Though the force which Rome at first spared for this war was small in numbers and rested entirely upon its own resources, the generals Publius and Gnaeus Scipio by skilful strategy and diplomacy not only won over the peoples north of the Ebro and defeated the Carthaginian leader Hasdrubal

Barca in his attempts to restore communication with Italy. but carried their arms along the east coast into the heart of the enemy's domain. But eventually their successes were nullified by a rash advance. Deserted by their native contingents and cut off by Carthaginian cavalry. among which the Numidian prince Massinissa rendered conspicuous service, the Roman generals were slain and their troops were destroyed in detail (212 or 211).

Disturbances in Africa prevented the Punic commanders from reaping the full fruit of their success. Before long the fall of Capua enabled Rome to transfer troops from Italy to Spain, and in 209 the best Roman general of the day, the young son and namesake of the recently slain P. Scipio, was placed in command. The new leader signalized his arrival by a bold and successful coup-de-main upon the great arsenal of Carthago Nova (see CARTAGENA). Though he was unable to prevent Hasdrubal Barca from marching away to Italy, Scipio profited by his departure to push back the remaining hostile forces the more rapidly. A last effort by the Carthaginians to retrieve their losses with a fresh army was frustrated by a great victory at Ilipa (*q.v.*), near Corduba, and by the end of 206 they mere driven out of Spain.

The War in Africa.—In 205 Scipio, who had returned to Rome to hold the consulship, proposed to follow up his victories by an attack upon the home territory of Carthage. Though the presence of Hannibal in Italy at first deterred the senate from sanctioning this policy, the general popularity of the scheme overbore all resistance. Scipio was granted a force which he organized and supplemented in Sicily, and in 204 sailed across to Africa. He was there met by a combined levy of Carthage and King Syphax of Iiumidia, and for a time penned to the shore near Utica. But in the winter he extricated himself by a surprise attack upon the enemy's camp, which resulted in the total loss of the allied force by sword or flame. In the campaign of 203 a new Carthaginian force was destroyed by Scipio on the Great Plains not far from Utica. their ally Syphax was captured, and the renegade Massinissa (*q.v.*) reinstated in the kingdom from mhich Syphax had recently expelled him. These disasters induced the Carthaginians to sue for peace. but before the very moderate terms which Scipio offered could be definitely accepted a sudden reversal of opinion caused them to recall Hannibal's army for a final trial of war. and to break off negotiations. In 202 Hannibal assumed command of a composite force of citizen and mercenary levies stiffened with a corps of his veteran Italian troops. After an abortive conference with Scipio he prepared for a decisive battle at Zama (*q.v.*), an inland site not yet identified with certainty. Scipio's force was smaller in numbers, but well trained throughout and greatly superior in cavalry. His infantry. after evading an attack by the Carthaginian elephants. cut through the first two lines of the enemy, but was unable to break the reserve corps of veterans. The battle was ultimately decided by the cavalry of the Romans and their new ally hlassinissa, which by a manoeuvre recalling the tactics of Cannae took Hannibal's line in the rear and completely destroyed it. The Carthaginians having thus lost their last army again applied for peace and accepted the terms which Scipio offered. They were compelled to cede Spain and the Mediterranean islands still in their hands. to surrender their warships, to pay an indemnity of 10,000 talents (about £2,400,000) within 50 years and to forfeit their independence in affairs of war and foreign policy.

The Second Punic War, by far the greatest struggle in which either power engaged, had thus ended in the complete triumph of Rome. This triumph is not to be explained in the main by any faultiness in the Carthaginians' method of attack. The history of the First Punic War. and that of the second outside of Italy, prove that the Romans were irresistible on neutral or Carthaginian ground. Carthage could only hope to win by invading Italy and using the enemy's home resources against him. The failure of Hannibal's brilliant endeavour to realize these conditions was not due to any strategical mistakes on his part. It was caused by the indomitable strength of will of the Romans, whose character during this period appears at its best, and to the compactness of their Italian confederacy, which no shock of defeat or strain of war could entirely disintegrate. It is this, spectacle of individual genius overborne by corporate and persevering effort which lends to the Second Punic War its peculiar interest.

The Third Punic War (149–146 B.C.).—The political power of Carthage henceforth remained quite insignificant, but its commerce and material resources revived in the 2nd century with such rapidity as to excite the jealousy of the growing mercantile population of Rome and the alarm of its more timid statesmen. Under the influence of these feelings the conviction—sedulously fostered by Cato the Elder. the Censor—that "Carthage must be destroyed" overbore the scruples of more clear-sighted statesmen. A *casus belli* was readily found in a formal breach of the treaty, committed by the Carthaginians in 154, when they resisted Massinissa's aggressions by force of arms. A Roman army was despatched to Africa, and although the Carthaginians consented to make reparation by giving hostages and surrendering their arms, they were goaded into revolt by the further stipulation that they must emigrate to some inland site where they would be debarred from commerce. By a desperate effort they created a new war equipment and prepared their city for a siege (149). The Roman attack for two years completely miscarried, until in 147 the command was given to a young officer who had distinguished himself in the early operations of the mar—Scipio Aemilianus, the adopted grandson of the former conqueror of Carthage. . Scipio made the blockade stringent by walling off the isthmus on which the town lay and by cutting off its sources of supplies from oversea. His main attack was delivered on the harbour side, where he effected an entrance in the face of a determined and ingenious resistance. The struggle did not cease until he had captured house by house the streets that led up to the citadel. Of a population probably exceeding half a million only 50,000 remained at the final surrender. The survivors were sold into slavery; the city was razed to the ground and its site condemned by solemn imprecations to lie desolate for ever. The territory of Carthage, which had recently been much narrowed by Massinissa's encroachments, was converted into a Roman province under the name of "Africa."

BIBLIOGRAPHY.—1. *Ancient Authorities.* For the First Punic War Polybius, bk. 1, provides a trustworthy and impartial account, but owing to his conciseness leaves many problems oi chronology and strategy unexplained. For the Second War bk. 2 and 3 of Polybius present a complete and detailed record down to Cannae; bk. 7–15 contain fragmentary notices of which the most continuous deal with the campaigns of Scipio. Livy (bk. 23–30) gives a continuous and detailed narrative, partly based upon Polybius and other good authorities, partly upon untrustworthy Roman annalists. The Third War is described in Appian's *Res Libycae,* ch. 67 *sqq.*, and the fragments of Polybius, bk. 36–39.

The subsidiary authorities are: Diodorus, bk. 20–27, 32; Appian, *Res libycae, hispanicae, hannibalicae;* Zonaras' epitome of Dio Cassius, fr. 43, 54, 57; Plutarch's *Lives of Fabius and Marcellus;* Cornelius Nepos's *Lives of Hainilcar and Hannibal,* and short references in Justin, Eutropius, Aurelius Victor and Orosius. The sources and methods of composition of these authors hare been discussed in numerous articles and dissertations, mostly German, of which the most important are mentioned in Niese's work (quoted below). These essays have brought out few certain results. but they trend to show that the narratives, so far as they are not based on Polybius or earlier authorities, are of little value.

2. *Modern Works. a.* For general accounts *see* the respective passages in the general histories of Rome, especially Mommsen (Eng. trans., 1894, vol. ii), Ihne (Eng. trans., vol. ii) and de Sancti's; also C. Neumann, *Das Zeitalter der punischen Kriege* (Breslau, 1883), and R. B. Smith, *Rome and Cartlzage* (1881).

The battles are methodically examined in J. Kromager, *Antike Schlachtfelder* (1912 *et srq.),* and in Kromager-Veith, *Schlachten-Atlas zur antiken Kriegsgeschichte* (Leipzig, 1922). *See* also H. Delbrück, *Gesch. der Kriegskunst* (1901–07).

PUNISHMENT, the infliction of some kind of pain or loss upon a person for a misdeed. *i.e.,* the transgression of a law or command. See CRIMINAL LAW; CRIMINOLOGY; CAPITAL PUNISHMENT; PRISON, etc.

PUNJAB (land of the "five rivers"; viz., the Jhelum, Chenab. Ravi. Beas and Sutlej, all tributaries of the Indus), in the Indo-Pakistan subcontinent, is the name given primarily to the triangle of country of which the Indus and the 'Sutlej form the two sides and of which the base is the lower Himalayan hills between those two rivers. From 1848 to Aug. 1947, when British responsibilities were transferred to India and Pakistan, the Punjab formed a British province, with changing boundaries. Until 1901 it included the whole area stretching from the Jumna in the east to the Sulaimans (Suliman) in the west and the Himalayan region lying on either side of the state of Jammu and Kashmir. From its territories the North-West Frontier province was created to the west of the Indus in 1901 and the Delhi enclave in the southeast in 1912. The remaining territory of the province was divided in 1947 into two parts. the East Punjab and the West Punjab, occupied by India and Pakistan respectively. Later both India and Pakistan changed the names of their provinces to Punjab. At the time of the 1951 census the area of the Pakistani Punjab (excluding Bahawalpur) was 62,245 sq.mi. Pop. 18,828,015. The area of the Bharati Punjab was 37,378 sq.mi. Pop. 12,641,205. The Pakistani Punjab province was merged in West Pakistan in Oct. 1955. The Bharati Punjab forms the Indian-state of Punjab, and is the only remaining political entity bearing this name. (*See* also below.)

The geographical area of the Punjab, in addition to the British province in its final form, comprised 43 states under the personal government of rulers who had treaty relations with the Punjab government or the government of India. The largest of these was Bahawalpur (pop. [1951] 1,823,125; area 17,471 sq.mi.), which at the time of the partition acceded to Pakistan. The remainder which all lay in the East Punjab joined India. These were formed into two groups: the Patiala and East Punjab States Union (PEPSC) (pop. [1951] 3,493,685; area 10,078 sq.mi.), a "B" state under the constitution of the republic of India; and the Himachal Pradesh (pop. [1951] 1,109,466; area 10,904 sq.mi.), a part "C" state under that constitution. administered by a lieutenant governor appointed by the government of India. As a result of the reorganization of Nov. 1, 1956, PEPSU was incorporated in Punjab, which was grouped with the northern zone.

The total population of the two Punjab areas (including states) according to the census of 1951 was about 39,000,000. The Jats form the backbone of the cultivating community, though large numbers of them have become Sikhs or Mohammedans in the tracts where those religions predominate. The Rajputs comprising tribes of different religions and social systems are also an important element in the population. By religion they are about 40% Mohammedans, about 40% Hindus and 20% Sikhs. The Gujars are an important agricultural and pastoral tribe. Baluchis and Pathans are strongly represented in the southwest and west.

Physical Features.—The mountain regions of the Punjab fall into four separate groups. To the northeast of the country lies the Himalayan system, with the fringing range of the Siwaliks at its foot. In the southeastern corner the Aravalli system sends out insignificant outliers, which run across Gurgaon and Delhi districts. The southern portion of the western frontier is constituted by the Sulaiman chain; while the northwestern districts of the old province are traversed by the Salt range which cuts off the Potwar plateau from the plains.

The "five rivers" of the Punjab are each of large volume but their wide sandy channels and shifting shoals make them worthless for steam navigation, though they all support a considerable boat traffic. They have been much utilized for irrigation purposes and many canals have been cut from them.
