Source: M. Segi, "Cancer Mortality for Selected Sites for 24 Countries," No. 5, August 1969.

Squamous-cell epithelioma, sometimes called epidermoid carcinoma, arises from the prickle cells (the cells with hairlike projections that allow them to interlock with each other) of the epidermis. A senile keratosis, which is a harsh dryness of the skin accompanying old age, often is the forerunner of this variety of skin cancer. After months or even years, the lesion suddenly starts to grow peripherally or inwardly. High cure rates are achievable if treatment is instituted early.

The lung. Cancers of the lungs may arise in the bronchial tree (the branching complex of air passages) leading to the lungs, or in the tissues of either or both of the lungs. The most common forms arise either in the flat, scaly cells of the bronchial epithelium and are called squamous-cell carcinomas, or in the glands or ducts and are called adenocarcinomas.

Two types of lung cancer

The incidence of adenocarcinomas is about the same in both sexes, whereas more men than women have squamous-cell lung cancers. Cigarette smoking does not usually appear to be a cause of adenocarcinomas in the lung, but is frequently associated with squamous-cell carcinomas of the lung. Spread to both lungs is more likely to occur in bronchial adenocarcinomas than in squamous-cell carcinomas.

Cancer of the lung may metastasize widely to the lymph nodes in the neck and chest, the pleura (the membrane lining the chest and covering the lungs), liver, brain, bone, esophagus, and adrenal glands. The average survival of persons with untreated lung cancer is nine months. With successful surgical removal of one lung or the lobe containing the tumour, the affected person can be expected to live longer. Currently, only five to ten percent of affected persons survive five years.

The breast. Most breast cancers, especially among older women, arise from the epithelium of the mammary ducts (milk channels). These cancers usually grow slowly and may remain localized by connective and elastic tissue for some time. Among younger women, breast cancers are frequently made up of undifferentiated (unspecialized) cells from the epithelium of the acini, the small saclike dilations at the ends of the mammary ducts. These tumours may spread widely and quickly. In either type, the tumours are often advanced upon detection, and the exact cell type of origin is obscured. With the best of modern methods, breast cancer in a majority of cases can be successfully treated.

The esophagus. Most cancers of the esophagus are undifferentiated epidermoid carcinomas. They may arise in the upper, middle, or low portions of the passage and often develop in the form of bulky, fungus-like growths that rapidly close the esophagus. Others may ulcerate superficially and spread on the surface of the structure without much obstruction. Cancers of the esophagus often metastasize early. With the present methods of treatment, cures are not frequent.

The stomach. In most instances, cancers of the stomach are adenocarcinomas that arise from the mucus-secreting cells of the stomach lining and vary only in their degree of differentiation. They can arise in the upper, middle, or lower sections of the stomach and extend along its surface or travel to other sections. Occasionally, lymphomas or sarcomas also occur in the stomach. Surgery is the treatment of choice and may be temporarily helpful. In about nine percent of persons in whom the cancer is identified at an early stage, surgery may be curative. Lymphomas can sometimes be successfully treated with radiation.

Treatment of stomach cancer

The liver. Primary cancers in the liver are carcinomas consisting of liver cells (hepatocellular carcinomas) or of bile-duct cells (cholangiocellular carcinomas). (In the Western world, carcinomas metastatic to the liver from other body sites are more common; these are classified separately.) There is frequently great variation in the appearance of the cells in primary liver-cell cancers, whereas the bile-duct-cell type has a more uniform pattern. The liver-cell type frequently produces bile that may be present in metastases as well as in the primary tumour. Bile secretion is not usually found in the bile-duct carcinomas. Cancers of the liver may occasionally be successfully treated if identified when it is possible to remove all of the tumour surgically.

The pancreas. Adenocarcinoma is the most common type of pancreatic cancer. Many of the cells in tumours of the pancreas are poorly differentiated and difficult to identify. Two-thirds of these tumours arise in the head of the pancreas. The other one-third occur along the body and tail of the organ. They extend by direct invasion of the remaining gland, the duodenum, and the stomach, and by adherence to the adjacent structures. They often obstruct or compress the portal vein to the

liver or the bile duct. The average survival for persons with this form of cancer is between 11 and 16 months.

The colon and rectum. Cancers of the colon and rectum often arise from certain precancerous polyps (protruding growths from mucous membrane). These cancers are usually well-differentiated adenocarcinomas with varying degrees of mucoid degeneration. They arise from the mucosal surface of the intestine, and may grow circumferentially and obstruct the colon. Cancers of both the colon and the rectum may also spread locally and adhere to adjacent organs. These cancers in their initial stages can often be successfully treated with surgery.

The kidney and bladder. Kidney cancers may arise in the interior of the kidneys, the fibrous capsules surrounding these paired organs, or in the kidneys' pelvis regions. (The kidney pelvis is a funnel-shaped cavity that is an extension of a ureter.) Carcinomas in the interior of the kidney may be "clear-cell" carcinomas made up of clear, watery appearing cells, or granular-cell carcinomas made up of cells containing granule-like particles. Some contain both cell types. Papillary tumours, in which the cells form papules, and squamous-cell carcinomas sometimes arise from the epithelium of the renal pelvis. Carcinosarcomas such as Wilms' tumours sometimes occur in children. The probability of five-year arrest of kidney cancer is poor (except in treated Wilms' tumours) because the first symptoms usually occur only after the tumour is already large. (Wilms' tumours probably arise from embryonic tissue; they may contain a variety of tissue in various stages of differentiation.)

Types of kidney cancers

Tumours of the epithelium lining the bladder, which may be benign initially, sometimes become invasive or recur after removal. There are two general types: papillary epitheliomas, which may have fronds growing into the bladder cavity, and invasive squamous-cell epitheliomas. The latter often grow rapidly through the bladder wall and extend into adjoining areas. If cancer is confined to the epithelium when diagnosed, it can often be successfully treated.

The prostate. Prostatic cancers more usually arise on the periphery of the gland adjacent to the rectum. Most often they are slow-growing, small-cell adenocarcinomas; they may also be made up of larger cells. The tumours may rapidly penetrate the capsule of the prostate and metastasize to nearby tissues, including bones. The small-cell variety is not well differentiated, and invades and metastasizes more quickly than the large cell type. When the cancer is confined to the prostate itself, the patient can usually be treated successfully by surgical removal of the gland.

The uterus. More than two-thirds of cancers of the uterus occur in the cervix, or neck of the organ. The remainder develops on the front or back of the corpus, or body, of the uterus. Cancer of the endometrium, the membrane that lines the uterus, usually occurs after menopause. Most uterine cancers are moderately differentiated epidermoid or squamous-cell carcinomas. With early diagnosis, 80 percent of persons with uterine cancer, including cervical cancer, can expect to be successfully treated. The Papanicolaou ("Pap") test for examining cells from the uterine cervix has permitted earlier treatment, and mortality from this form of cancer is falling.

The ovary. Because the developmental patterns of the ovary are poorly understood, there is considerable variation in the classification of ovarian tumours. Cancers of the ovary may develop from a variety of cells, including surface epithelial cells and underlying germ cells, as well as others in various stages of development and with various endocrine functions. Some ovarian tumours produce hormones and may even have a masculinizing effect, while others do not. Most malignant ovarian tumours originate from the surface epithelium and are called serous cystadenocarcinomas. These tumours occur in a variety of cell types and frequently involve both ovaries. Often they have hairlike cilia and lobules or papillary outgrowths. Ovarian cancers ordinarily may be successfully treated surgically if diagnosed at an early stage.

The lymphoid tissue. Lymphomas form a group of cancers of varying malignancy originating in the lymphoid tissues (lymph nodes, spleen, bone marrow, thymus). Lymphomas include lymphosarcomas, which usually arise in lymph nodes or mucosal lymphatic tissue, especially of the gastrointestinal tract; lymphoblastomas (made up of developing lymph cells); lymphocytomas (from mature lymph cells, or lymphocytes); and reticulum-cell sarcomas (see RETICULOENDOTHELIAL SYSTEM, HUMAN). Hodgkin's disease, which is characterized by two kinds of abnormal lymph cells, is also classified as a lymphoma. Lymphomas spread from one lymph area to another, and in advanced stages infiltrate surrounding tissues. In their initial stages, lymphomas, especially Hodgkin's disease, are highly curable with radiation therapy. Chemotherapy may cure some advanced cases.

Types of lymphomas

The blood-forming tissues. Leukemias are a group of cancers of the blood-forming tissues (bone marrow, lymph nodes, or reticuloendothelial system), which usually result in an overproduction of abnormal white blood cells. The most common varieties are myelocytic (granulocytic) leukemia, which results in the production of malignant granulocytes (white blood cells with characteristic granules in their cytoplasm, or extranuclear substance); lymphocytic leukemia, which exhibits malignant lymphocytes; monocytic leukemia, in which malignant monocytes are produced (monocytes are large white blood cells with oval or horseshoe-shaped nuclei); and acute stem-cell leukemia, which results in malignant primitive white cells (stem cell). In some patients, the cells may show a considerable degree of maturation, and the disease progresses slowly (chronic leukemia). In others, the cells may be primitive and poorly differentiated, and the disease progresses rapidly (acute leukemia).

Leukemic cells are disseminated through the bloodstream and lymph system, lodging in other blood-forming tissues, in which they continue their proliferative activity. In more acute forms of leukemia, or in later stages of chronic leukemia, leukemic cells infiltrate many of the body's other tissues. Leukemia leads to anemia and susceptibility to bleeding and infection when normal blood elements are crowded out by cancer cells. In acute leukemia, and to a lesser extent in chronic leukemia, treatment can produce remissions during which symptoms are relieved and the affected person is temporarily restored to health. Prior to the introduction of drug treatment, children with acute leukemia lived only a few weeks, whereas now many survive two to three years, and some even longer.

PREVENTION AND TREATMENT

Prevention. Some, but not all, cancers can be prevented by application of present knowledge. Most lung cancers are very likely to be caused by cigarette smoking, and many skin cancers by frequent overexposure to direct sunlight. These can be prevented by avoidance of their causes. Also, certain cancers caused by occupational factors—for example, bladder cancer among workers in the dye industry—have been prevented by elimination of the causative agents. Other cancers have probably been prevented because chemical substances have not been allowed in foods, drugs, or cosmetics when it was shown that they produced cancers in experimental animals.

Avoidance of the causes of cancer

Diagnosis and detection. Early detection, when the disease is still localized and the affected person has no symptoms, is the best available approach to prevention of cancer death. With the best of modern treatment, about one-third of all cancers can be cured. Some scientists believe that as many as half of all cancers could be successfully treated if identified at an early stage.

There are a variety of medical techniques that allow doctors to detect cancer at an early stage. The most effective early detection method now being used is the Papanicolaou ("Pap") test, which permits physicians to detect early cervical cancer by examination of the microscopic characteristics of cells naturally sloughed off by the uterine cervix. The Pap test allows physicians to detect precancerous conditions, as well as cancers that have not spread beyond their site of origin.

Similar techniques sometimes can be used to verify the presence of suspected lung cancer before the cancers are

large enough to appear on X-rays, and examination of cells shed from the surface of structures in the mouth can aid in detecting early oral cancers.

Cells that are shed by the bladder into the urine sometimes indicate the presence of cancerous papillomas and early bladder cancer. Analysis of such cells is sometimes performed routinely among high-risk groups, such as workers in the aniline-dye industry.

Mammography, a simple, inexpensive X-ray technique used to detect breast cancers that are too small to be palpated, reveals cancers as small as 5 millimetres (0.2 inch) and small calcium deposits that are often indicative of cancer.

Xerography, a method of recording images by means of dust that adheres to electrostatically sensitized plates and sheets of paper, may make it quicker and easier to take and interpret X-rays of the female breast than is now possible, and could significantly improve the likelihood of early diagnosis of breast cancer. A similar process is used to record calcium deposits. Another new experimental technique, thermography, which records heat patterns of the breast, allows physicians to note those patterns characteristic of early cancer.

Treatment. Successful treatment of cancer today requires the complete removal or destruction of all cancerous tissue. With therapy that fails to remove all the cancer cells, the disease recurs. Surgery and radiation are the most effective forms of treatment. Chemotherapy—drug and hormone treatment—is proving helpful in some forms of cancer. The choice of therapy is governed by the type, location, and size of the cancer at the time of diagnosis, and the general condition of the patient.

Surgery. For surgery to be curative, the operative procedure must be performed before the cancer has spread into organs and tissues that cannot be safely removed. During the past century, increasingly radical operations for cancer have become standard. Despite the increasing extent of these procedures, risk has been reduced by improvements in surgical techniques, anesthesiology, and preoperative and postoperative care, especially in the control of infection. Heart-lung pumps, artificial kidneys, and methods of maintaining electrolyte balance and metabolic equilibrium have permitted persons with impaired cardiovascular and kidney functions, or poor general metabolism, to become eligible for cancer surgery. In the future, replacement of bones and blood vessels, and other organ transplantation, may make even more extensive cancer surgery possible.

Major advances have been made in the restoration of structures altered by cancer surgery and in the rehabilitation of persons who have undergone radical surgery.

Rehabilitation

Perfection of the reconstructive techniques performed immediately after cancer removal has markedly shortened the convalescence time for patients with major surgical losses. Persons undergoing certain surgical procedures for cancer of the colon or rectum, for instance, can now be equipped with simple devices for solid waste elimination, and trained in their use. For patients with cancer of the head and neck, the use of new grafting methods and new anatomical sources for tissue flaps make it possible to apply reconstructive techniques at the time the cancer is removed.

Rehabilitation of the patient also plays an important role. Women who have extensive surgery for breast cancer are given treatment for restoration of muscle tone needed for movement of the arms. Great progress has also been made in teaching new mechanisms of speech to persons who have undergone surgical removal of the larynx.

In addition to saving lives by eradicating cancer, surgery also improves the remaining months or years of life for persons whose cancers cannot be eradicated, restoring comfort and a sense of usefulness. When severe pain accompanies cancer, surgery can often bring relief by severing the nerve pathways that carry the painful sensations. In addition, surgery is sometimes necessary to treat abscesses resulting from either the tumour or infection, and to relieve intestinal obstructions, including adhesions occasionally formed as a result of previous surgery. Palliative surgery is also used on occasion to treat tumour-related bone fractures.

Surgery is increasingly more valuable as a preventive measure in controlling cancer. It may be used to eliminate precancerous conditions in the mouth, chronic ulcers that may lead to cancer of the colon, and certain precancerous polyps in the colon and rectum. It may also be used to remove burn scars and other scars that may lead to cancer, precancerous nodules in the thyroid gland, and certain precancerous pigmented moles.

Radiation. Radiation therapy makes use of ionizing radiations—X-rays, particles (electrons, neutrons, and pi-mesons) produced by man-made machines, and gamma rays emanating from radioactive elements—to destroy cells by injuring their capacity to divide. Although some normal cells are also killed during the radiation therapy of cancer, the cells outside the field of radiation are usually able to repair the damage.

Differing sensitivity to radiation

Some cancers do not respond to radiation therapy. The differing sensitivities of various malignant tumours to irradiation are due primarily to the variations in the cells of origin of the tumours. In addition, individual cells within a tumour may have a widely different susceptibility to irradiation. In cancers composed of a variety of cells in different stages of differentiation (epidermoid carcinoma, for instance), even a large dose of radiation may not affect the most differentiated cells. Poor circulation within some tumours decreases their oxygen supply, thus diminishing their sensitivity to radiation.

Development of radiation instruments that produce energy in the multimillion electron-volt range has permitted extensive use of radiation therapy of cancer. Such instruments can deliver a greater radiation dose to deep-seated tumours without the serious skin reactions and discomfort often associated with lower energy X-ray beams. Large areas can be irradiated with more precise definition of the margins and alignment of the beam, less side-scatter, and therefore more protection of adjacent vital structures. The greater versatility of such equipment has made possible the development of treatment techniques involving multiple intersecting radiation beams, rotation of the patient or the radiation source, large fields of radiation shaped to the contours of particular organs, and the pinpointing of beams for cancers of the eye and the larynx. Because of their increased usefulness, these instruments (linear accelerators, betatrons, and radioactive cobalt-60 teletherapy apparatus) have, in some countries, become standard instruments for radiation therapy of deep-seated cancers.

Chemotherapy. Cancer chemotherapy can produce cures in certain forms of cancer. Two cancers frequently cured by drugs are choriocarcinoma, a rare, highly malignant tumour that originates in the placenta; and Burkitt's lymphoma, a cancer common among African children. Treatments with combinations of drugs have produced long-term disease-free remissions in many children with acute leukemia and in persons with advanced stages of Hodgkin's disease. Some of these patients have been in remission more than five years and may, in fact, be cured.

Multiple carcinomas of the superficial layers of the skin have been eradicated after the application of certain cancer-drug ointments to the skin. Wilms' tumour, a form of childhood cancer of the kidney, is often curable when cancer drugs are used in combination with surgery and radiation. Many other forms of cancer are benefitted temporarily or partially by chemotherapy, often giving the patient a more comfortable life, if not a cure. Some cancers are resistant to drugs, however.

Problems encountered with cancer drugs

To date, most cancer drugs are limited in their usefulness. One problem is that only a certain proportion of cells are dividing at any one time, and most current cancer drugs can effectively destroy only that part of the cell population undergoing division. Another problem is that most cancer drugs do some damage to normal as well as cancer cells and tissues. In addition, some cancer cells may eventually become resistant to the drugs. To help overcome these difficulties, combinations of chemotherapeutic agents that act on cells in different ways have been

used in various treatment programs simultaneously or in sequence. This allows cancer cells at different stages of division to be killed, causes less irreparable damage to normal cells, and counteracts the tendency of malignant cells to become resistant to a single drug.

Special supportive and precautionary measures have been developed to protect persons undergoing cancer chemotherapy from the combined effects of the drugs and the disease. Refinements in the transfusion of blood platelets permit multiple transfusions in leukemia patients with critical platelet deficiencies caused either by leukemia or drug toxicity. During periods when a patient's white blood cells are depleted, administration of antibiotics offers protection from many infections. Relatively germ-free environments, such as specially designed hospital rooms, provide sterile atmospheres to protect against fatal infection. Transfusion of large numbers of type-matched human white blood cells has also been of value in protecting persons with nonfunctioning bone marrows against infections.

RESEARCH

Avenues being explored. In leading medical-research centres around the globe, studies focus on developing new cancer drugs, determining the role of viruses in human cancer, developing vaccines or other immunologic defense methods, identifying and eliminating chemical carcinogens, and learning more about the workings of cancer cells.

Cancer drugs. A worldwide search is being conducted to find and develop materials that are effective anticancer agents. Some of the materials tested are naturally occuring ones—botanical specimens, organisms found in soil, sea animals, and plants. Most are developed in chemistry laboratories; in many cases knowledge is utilized of tumour-cell metabolism and existing cancer drugs. Potential drugs initially are screened in laboratory animals for their effects; the drugs with anticancer activity are extensively studied to determine appropriate dose levels and undesirable side effects. If the animal studies are satisfactory, the drugs then undergo careful clinical evaluation, after which they are available for use by practicing physicians if found to be of benefit in human cancer. In the United States alone, about 15,000 preparations are screened annually in animals; four to six reach the stage of clinical evaluation each year.

Role of viruses. A variety of indirect tests are being used in efforts to link viruses with human cancer. Such tests are necessary because those viruses visible with the electron microscope in human tumour specimens are not directly tested in other human beings for ability to cause cancer. Another reason for the indirect tests is that, in animals, it has been found that some tumour viruses are not directly visible because they are incorporated in the genetic material of the cell. Immunofluorescence studies constitute one technique that has been developed for detecting viral antibodies. (Antibodies are proteins made by the body to fight off specific invaders; in this case the antibodies reacting specifically with particular viruses are tagged with a fluorescent dye so that they can be seen under ultraviolet light.) A new approach is a test for a particular enzyme found in all cancer-causing animal viruses tested thus far and essentially absent in many viruses known not to cause cancer. This enzyme, ribonucleic acid (RNA) dependent deoxyribonucleic acid (DNA) polymerase, is also present in white blood cells of some patients with acute leukemia, but not in normal white blood cells tested.

To date, the forms of human cancer most closely linked to viruses are Burkitt's lymphoma and postnasal cancers associated with Epstein-Barr viruses; cancers of the bone, muscle, and other connective tissue; and leukemia, linked to C-type viruses.

Vaccines. If viruses are proven to cause human cancer, one measure for possible control might be immunization. The incidence of cancer in mice and chickens can be greatly reduced by the use of standard virus vaccines. As early as 1959, scientists used mouse leukemia viruses killed with formalin to make vaccines that protect mice against leukemia. In 1964, a vaccine was developed to protect chickens against sarcoma, and, in 1970, a vaccine was developed to protect them against a lymphoma-like illness called Marek's disease. The possibility exists that a vaccine could be developed against the herpes-type Epstein-Barr virus associated with Burkitt's lymphoma if the virus is demonstrated to cause human cancer. Other virus-induced cancers, such as sarcomas induced with C-type viruses, may, however, require different preventive approaches because the complete virus may not be involved, and conventional vaccines might not be effective.

Identification of chemical causes. Many of the known chemical carcinogens have been identified by analysis of their effects on specialized populations, a research technique called epidemiology. Suspected chemicals detected in this and other ways are continually being tested for their ability to cause cancer in laboratory animals. Efforts are being made to develop an even more rapid test for carcinogenicity. One approach is to use human cells grown in flasks (tissue culture) to determine within a day or two whether or not a suspected agent transforms normal cells into cells with characteristics of cancer cells. In conventional screening systems, determination of carcinogenicity in rats or mice requires two years to complete.

Tests for carcinogenicity

In highly industrialized societies, new chemicals are added daily to the environment. Many are considered potentially hazardous. Testing facilities for cancer-causing agents need expanding to evaluate those chemicals that come into widespread use. Also needing expansion are investigations on the ways in which carcinogens work and on ways to block their actions. Research has progressed to a point at which such effort can be effectively expanded.

New prospects. New avenues for possible follow-up are emerging from fundamental research already in process.

Genetic factors. Many scientists are now convinced that damage to the genetic chemicals in human cells, DNA and RNA, may be the key factor in the transformation of normal cells into cancer cells. This conviction is supported by several phenomena. For instance, radiation and some of the cancer-causing chemicals alter DNA, and an abnormally short chromosome, called the Philadelphia chromosome, is found in bone marrow cells and white blood cells from some persons who have chronic myelocytic leukemia. Some scientists have postulated that the genetic material of some viruses is always present in vertebrate cells, is passed along from parent to offspring, and can, under the influence of certain other host genes and cancer-causing agents, evoke malignant transformation.

If it is established that a genetic error is responsible for the growth of cancer, it may be possible to synthesize new genes to replace faulty ones. Initial steps in this direction were made in 1970 when a scientist created the first synthetic gene by duplicating the structure of yeast DNA in the laboratory. Other approaches include modification of the way the genetic code message of the DNA is read by mechanisms controlling the cells' functions.

Immune response. Some scientists believe that even well persons may have cancer cells circulating in their blood at times, but that the normal body's immune responses prevent the cells from invading tissues and forming tumours. It has been shown, furthermore, that in Hodgkin's disease patients' immune capacities decrease as their disease progresses.

Investigations are under way to find a means to bolster the immune responses of persons who have advanced cancer. Animal experiments have shown that immunity to cancer can be developed in some animals and transferred to others. One method of doing this is by exposing the lymphoid cells of nonimmune animals to RNA from an immune animal. Efforts are under way to determine whether immunity can be transferred to cancer patients in this or a similar way.

Transfer of immunity

Vaccines using cellular antigens (substances in and on cells that have been exposed to a virus, to certain chem-

icals, or to radiation) may also be of benefit to cancer patients. Cellular antigens can stimulate antibody production against those agents or against the cancer cells induced by them.

Preliminary studies in a few patients with acute leukemia and melanoma suggest that treatment with an attenuated tuberculosis bacillus called BCG nonspecifically stimulates immune reactions and may be of some benefit. Another substance, a protein called interferon, is produced in animal cells immediately after infection by a virus, and under some conditions partially inhibits cancer induction by these and other viruses without injuring normal cells. Efforts are being made to adapt the use of interferon to treatment of human cancer. Immunotherapy of this type will probably be most useful in combination with other forms of treatment that remove or destroy most of the cancer cells.

Development of new tests. Other research efforts are aimed at developing new tests that will detect cancer at an early stage. Such detection methods might include tests for fetal antigens, substances that are normally present in human embryonic tissues but usually disappear during the last three months before birth. Recent evidence suggests that fetal antigens, when they persist or reappear, may be associated with some forms of human cancer. One of these antigens (known as carcinoembryonic antigen or CEA) has been detected in the blood of persons with cancer of the colon, pancreas, and other areas of the digestive tract. Another, alpha-fetoprotein, is found in the blood of about 75 percent of persons with cancer of the liver. A third is found in association with a variety of other tumours.

International cooperation. Fifty percent of afflicted persons die of forms of cancer that cannot be controlled with even the best of current diagnostic and treatment methods. Only the results of research can save these persons. Because of this, many nations have organized research programs to learn more about the causes and treatment of cancer. In addition, many have joined in international cancer-research organizations to share findings and to cooperate in cancer research on an international scale. Two such organizations are the International Union Against Cancer and the International Agency for Research on Cancer. Participants in the World Health Organization and the Pan American Health Organization also cooperate in cancer research and information dissemination. Through national and international research efforts, knowledge about cancer is accruing at a rapid rate and appears to be ready for accelerated application pointing toward eventual control.

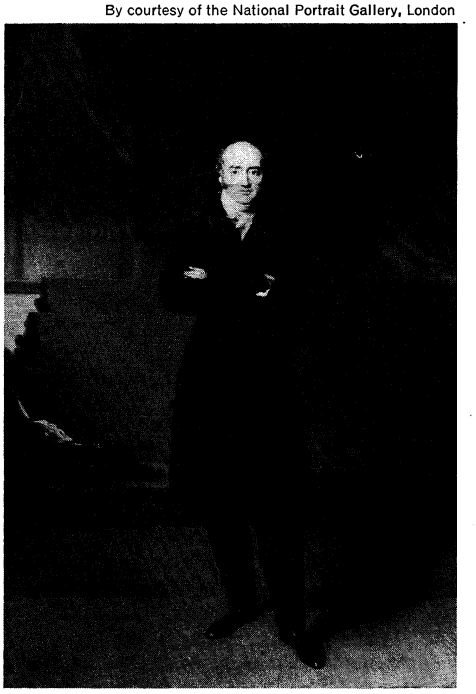
(C.G.B.)

Canning, George

British statesman who was prime minister of Great Britain for a short time during the year 1827, George Canning is chiefly remembered as foreign secretary from 1822 to 1827, when he and William Huskisson, president of the Board of Trade, taught a large portion of the Tory Party to take a more liberal view of many aspects of domestic, colonial, and foreign policy. The ablest and sincerest opponent of parliamentary reform, he nevertheless contributed largely to the creation of that independent and enlightened spirit among the younger members of the House of Commons, without which the great parliamentary Reform Act of 1832 could not have been carried without revolution.

By courtesy of the National Portrait Gallery, London



Canning, painting by Sir Thomas Lawrence and R. Evans, 1st quarter of the 19th century. In the National Portrait Gallery, London.

To some, and especially to his intellectual inferiors, Canning seemed arrogant and contemptuous. His wit and sarcasm were remembered by all who heard or read his speeches. He was the most indefatigable of men, often working from breakfast until late at night without food, and this long-continued irregularity, his friends believed, rendered an irritable temperament still more uncontrollable. The world tended to misjudge his character from his defects and overlooked his energy, patriotism, and outstanding abilities. It was the fashion to say of him that he was no gentleman. The hatred and malignity with which he was assailed by the Tory aristocracy in 1827 showed what mountains of prejudice still existed against a prime minister born outside the governing class. In choosing Canning as prime minister, George IV found that he had to fight over again his father's battles against the pretensions of the great families to deprive the crown of its ancient right to nominate its servants.

Contemporaries said that Canning's ministry was the most popular with the middle classes that had ever been known. As member for Liverpool (1812–22), he came to recognize fully the needs of the rising commercial and industrial interests. He put his country before personal or party interests. None of the party leaders of the time had more generous notions of the obligations that he owed to his supporters. He never thought he could do too much for his friends, but he never used his influence to secure undeserved promotion for them. They, for their part, were drawn to him by bonds of intense personal devotion, and, through his disciples, such as William Huskisson and Lord Palmerston, he wielded an authority that endured beyond the grave.

Family background

Canning was born in London on April 11, 1770. His father, the eldest son of an Irish landowner, was disinherited for his marriage with a beautiful but penniless girl and died in 1771, leaving his wife and year-old son entirely destitute. The widow became an actress and the mistress of an actor, by whom she had five children. In 1783 she married another actor, by whom she had five more children, but this new connection did nothing to rescue her from discredit and misfortune. From this unsatisfactory environment, George Canning was taken away by a wealthy uncle, Stratford Canning, who raised him with his own children, one of whom was the future diplomat, Viscount Stratford de Redcliffe.

Canning was educated at Eton College and at Christ Church, Oxford. After graduating (1791), he soon decided on a political career and, in July 1792, came under the influence of the prime minister, William Pitt, who undertook to find him a seat in Parliament. He was elected for the privately controlled borough of Newtown, Isle of Wight, in July 1793 and quickly became recognized as one of the rising men on the government side of the house. Pitt further procured for him the undersecretaryship of state for foreign affairs in 1796. Though the work was "pretty hard and constant" he found time to contribute to *The Anti-Jacobin* (1797–98), a weekly paper founded to ridicule both English and French men of republican sentiment. In 1799 he left the foreign office and was appointed a commissioner of the Board of Control for the government of India. In May 1800 he was promoted to the office of joint paymaster of the forces and was made a privy councillor. A few weeks later he married an heiress, Joan Scott. By her he had four children, including Charles John, later Earl Canning and a governor general of India.

When Pitt resigned in 1801, Canning, too, left office. Disapproving of Pitt's support of the new prime minister, Henry Addington (later 1st Viscount Sidmouth), he made himself independent in 1802 by giving up the seat of Wendover, which he had represented since 1796, and purchasing election as member of Parliament for the Irish borough of Tralee. In 1803 Pitt began to turn against Addington, and Canning could then go into open opposition without forfeiting Pitt's friendship. On the formation of Pitt's last ministry in May 1804, Canning became treasurer of the navy, but his unpopularity (his biting wit made him many enemies) kept him out of the Cabinet. Much to his disgust, his colleagues resigned after Pitt's death (January 1806) because of the insecurity of their parliamentary position. When, however, in March 1807 the King called upon "the friends of Mr. Pitt" again to form a government, Canning became foreign secretary.

Foreign secretary

Actions in the Napoleonic Wars that occurred during Canning's first tenure of the foreign secretaryship included the seizure of the Danish fleet (his own brilliant planning) and the unfortunate expedition to Walcheren Island off the Scheldt River, in The Netherlands. The Peninsular War, involving British, Spanish, and French resistance to Napoleon on the Iberian Peninsula, was also begun. Holding Viscount Castlereagh, the war secretary, responsible for the disasters that overtook British arms at Corunna in Spain, and at Flushing (Vlissingen) in Holland, Canning, in 1809, insisted on his dismissal. They quarrelled and fought a duel on September 21, in which Canning was wounded in the thigh. Both had already resigned, Canning because of the nonfulfillment by the duke of Portland, William Bentinck, the dying prime minister, of his promise that Castlereagh should be removed from the War Department. Canning offered to form a government, but the King called upon his rival, Spencer Perceval, and Canning remained out of office until 1816.

Lord Liverpool, who succeeded to the premiership in 1812 on Perceval's assassination, tried hard to induce Canning to take office, but Canning refused to allow his old rival Castlereagh (who generously offered to surrender the foreign secretaryship to him and to take the inferior office of chancellor of the exchequer) to retain the leadership of the House of Commons. So Canning lost the chance of being the peacemaker of Europe in 1815, and he had further damaged his reputation in 1814 by accepting what was believed to be a rich sinecure, the post of ambassador to Portugal.

Two years later, he entered the Cabinet as president of the Board of Control. Canning, disapproving of the government's efforts to deprive George IV's queen, Caroline, of her title and position, resigned in December 1820. In the hope of improving his financial position and believing that advancement at home was blocked by the King's hostility to him, he accepted the governor generalship of Bengal in March 1822, with the additional prospect of a peerage on his return; but, before his ship was ready to sail, Castlereagh committed suicide (August 12), and George IV reluctantly acquiesced in Canning's succession to the "whole inheritance"—the foreign secretaryship and the leadership of the House of Commons. He was now the most important member of the government. Afraid of becoming too deeply involved in continental politics and disliking the great despotic sovereigns who were anxious to suppress liberal movements everywhere, he cut England adrift in 1823 from the so-called Holy Alliance engineered by the emperor Alexander I of Russia to preserve the European status quo; prevented European intervention in South America on behalf of Ferdinand VII of Spain; recognized the independence of the rebellious Spanish-American colonies; sent an army to Portugal to meet the threat of attack by Spain; gave diplomatic support to the Greeks in their struggle with the Turks for freedom; and ensured the eventual creation of an independent Greek state.

Lord Liverpool's premiership came to an end in February 1827. He had long since marked out Canning as his successor, but it was far from obvious that Canning would be the King's choice. Although since 1822 he had gained a remarkable ascendancy at Windsor Castle by the success of his foreign policy and by a judicious attention to the royal intimates there, Canning was the leading advocate of Roman Catholic emancipation, and George IV had been persuaded that the cause of the monarchy was linked with that of the Established Church and resistance to the Catholic claims. Robert Peel and the Duke of Wellington, the leading opponents of Catholic relief, knew that no government could be formed without Canning, and Canning refused to serve under another anti-Catholic premier. Finally, on April 10, he was authorized to reconstruct the ministry on the understanding that a Catholic relief bill was not to be forced on the King. Moved partly by personal animosity, partly by dislike of Canning's advocacy of Catholic emancipation, half the Cabinet refused to serve under him, and, in all, more than 40 ministers and political appointees resigned. The Whigs, however, came to his assistance, and most of the independent members of Parliament supported him with their votes. But his ministry lasted only four months; his health broke down under the strain, and he died on August 8, 1827, at Chiswick, near London, in the house of the Duke of Devonshire.

Prime minister

BIBLIOGRAPHY. The most useful biography for the general reader is SIR CHARLES PETRIE, *George Canning*, 2nd ed. (1946). Though not based on much original research, it makes good use of secondary sources. DOROTHY MARSHALL, *The Rise of George Canning* (1938), covers Canning's career to the death of Pitt. It is based on Canning's private papers formerly at Harewood House, Leeds, but now in the Leeds Public Library. However, the quotations contain many inaccuracies.

H.W.V. TEMPERLEY, *The Foreign Policy of Canning, 1822–1827* (1925), is a lengthy and valuable study based on official and private archives but perhaps too detailed for the general reader. For the specialist, there is a short study of Canning's parliamentary friends and supporters in an article by A. ASPINALL, "The Canningite Party," in *Transactions of the Royal Historical Society*, 17:177–226 (1934); and a detailed account of his premiership, based on a large quantity of new material, in A. ASPINALL, *The Formation of Canning's Ministry*, Royal Historical Society, Camden 3rd series, vol. 59 (1937). The specialist will still find useful Canning's *Speeches*, 6 vol. (1828), some corrected by himself.

(A.As.)

Canon Law

Canon law—though in its wider sense it includes precepts of divine law, natural or positive, incorporated in various canonical collections or codes—is in this article defined as that body of rules and regulations (canons) concerning the behaviour and actions of individuals and institutions within certain Christian churches (Roman Catholic, Eastern Orthodox, the independent churches of Eastern Christianity, and the Anglican Communion), which have, through proper ecclesiastical authority, defined, designated, and codified such rules. Though canon law is historically continuous from the early church to the present, it has, as a result of doctrinal and ecclesiastical schisms, developed differing, though often similar, patterns of codification and norms in the various churches that have incorporated it into their ecclesiastical frameworks. The canon law of the Eastern and Western churches was much the same in form until these two groups of churches separated in the Schism of 1054. In Eastern Christianity, however, because of doctrinal and nationalistic disputes during the 5th to 7th centuries, several church groups (especially non-Greek) separated themselves from the nominal head of Eastern Christianity, the patriarch of Constantinople, and developed their own bodies of canon law, often reflecting nationalistic concerns.

Canon law in the Western churches after 1054 developed without interruption until the Reformation of the 16th century. Though other churches of the Reformation rejected the canon law of the Roman Catholic Church, the Church of England retained the concept of canon law and developed its own type, which has acceptance in the churches of the Anglican Communion.

NATURE AND SIGNIFICANCE

A church is defined as a community founded in a unity of faith, a sacramental fellowship of all members with Christ as Lord, and a unity of government. Many scholars assert that a church cannot exist without authority—*i.e.*, binding rules and organizational structures—and that religion and law are mutually inclusive. Thus the calling of a church leader to office is regarded as important in the organizational structure and, like every other fundamental vocation in the churches that accept the validity of canon law, it is also viewed as sacramental and as linked to the priesthood—which, in turn, involves a calling to leadership in liturgy and preaching. According to Roman Catholic belief, the mission of the college of Apostles (the Apostles, presided over by St. Peter in the 1st century AD) is continued in the college of bishops, presided over by the pope. Other churches may accept this view, without at the same time accepting the authority of the pope. The validity of canon law thus rests on an acceptance of this sacramental view and of the transmitted mission of the Apostles through the bishops.

Necessity of authority

Historical and cultural importance of canon law. Canon law has functioned in different historical periods in the organization of the church's liturgy, preaching, works of charity, and other activities through which Christianity was established and spread in the Mediterranean area and beyond. Canon law, moreover, had an essential role in the transmission of ancient Greek and Roman jurisprudence and in the reception of Justinian law (Roman law as codified under the sponsorship of the Byzantine emperor Justinian in the 6th century) in Europe in the Middle Ages. Thus it is that the history of the Middle Ages, to the extent that they were dominated by ecclesiastical concerns, cannot be written without knowledge of the ecclesiastical institutions that were governed according to canon law. Medieval canon law also had a lasting influence on the law of the Protestant churches. Numerous institutions and concepts of canon law have influenced the secular law and jurisprudence in lands influenced by Protestantism: *e.g.*, marriage law; the concepts *jus in re* —*jus ad rem* (law of things); law of obligations; the doctrine of modes of property acquisition; possession; good faith in prescription; representation; wills; legal persons; the concepts of crime and punishment; the law of criminal procedure; and the law concerning proof or evidence. International law owes its very origin to canonists and theologians, and the modern idea of the state goes back to the ideas developed by medieval canonists regarding the constitution of the church. The history of the legal principles of the relation of *sacerdotium* to *imperium*—*i.e.*, of ecclesiastical to secular authority or of church to state—is a central factor in European history.

Problems in the study of canon law and its sources. Because of the discontinuity that has developed between church and state in modern times and the more exclusively spiritual and pastoral function of church organization, scholars in canon law are presently searching for a recovery of vital contact among canon law and theology, biblical exegesis (critical interpretive principles of the Bible), and church history in their contemporary forms. Canon-law scholars are also seeking a link with the empirical social sciences (*e.g.*, sociology, anthropology, and other such disciplines), which is required for insight into and control of the application of canon law. The study of the history of canon law calls not only for juridical and historical training but also for insight into contemporary theological concepts and social relationships. Many sources, such as the documents of councils and popes, are often uncritical and found only in badly organized publications, and much of the material exists only in manuscripts and archives; frequently the legal sources contain dead law (*i.e.*, law no longer held valid) and say nothing about living law. What does and does not come under canon law, what is or is not a source of canon law, which law is universal and which local, and other such questions have to be judged differently for different periods.

The role and function of canon law

The function of canon law in liturgy, preaching, and social activities involves the development and maintenance of those institutions that are considered to be most serviceable for the personal life and faith of members of the church and for their vocation in the world. This function is thus concerned with a continual adaptation of canon law to the circumstances of the time as well as to personal needs.

HISTORY

The formative period: origins to Gratian (c. 1140). The early church was not organized in any centralized structure. Over a long period of time, there developed various patriarchates (churches believed to have been founded by Apostles) and bishoprics, the leaders of which—either as monarchical bishops or as bishops with shared authority (*i.e.*, collegiality)—issued various decrees and regulatory provisions for the clergy and laity within their particular jurisdictions. After the emperor Constantine (died 337) granted tolerance to Christians within the Roman Empire, bishops from various sees (episcopal seats)—especially from the eastern part of the empire—met in councils (*e.g.*, the ecumenical Council of Nicaea, 325). Though these councils are known primarily for their consideration of doctrinal conflicts, they also ruled on practical matters (such as jurisdictional and institutional concerns), which were set down in canons. In the West, there was less imperial interference, and the bishop of Rome (the pope) gradually assumed more jurisdictional authority than his counterpart (the ecumenical patriarch of Constantinople) in the East. Throughout this period there were often conflicting canons, since there were many independently arrived at canonical collections

and no centralized attempt to bring order out of the many collections until the Middle Ages.

Eastern churches. In addition to the New Testament, the writings of the Apostolic Fathers (second generation of Christian writers) and the pseudo-apostolic writings (documents attributed to but not written by the Apostles) contain the oldest descriptions of the customs existing in the East from the 2nd century until the 5th. The sources of all the others are the *Doctrina duodecim Apostolorum* (*Doctrine of the Twelve Apostles*, 2nd century?), the *Didascalia duodecim Apostolorum* (*Teaching of the Apostles*, 3rd century), and the *Traditio apostolica* (*Apostolic Tradition*), attributed to Hippolytus (a 3rd-century bishop of Rome), written in Rome *c.* AD 218 but far more widely distributed in the East. From these documents, the *Constitutiones Apostolicae* (*Apostolic Constitutions*), in which 85 *Canones Apostolicae* (*Apostolic Canons*) were included, were composed *c.* AD 400.

During the period that followed the grant of toleration referred to above, many synods held in the East legislated, among other things, various disciplinary rules, or *canones*. In addition to and in place of the law of custom, written law entered the scene. An ecumenical Council of Chalcedon (AD 451) possessed a chronological collection of the canons of earlier councils of Ancyra (314), Neocaesarea (314–325), Nicaea I (325), Antioch (341), and Gangra (343). This *Syntagma canonum* ("Body of Canons"), or *Corpus canonum orientale* ("Eastern Body of Canons"), was subsequently complemented by the canons attributed to a 4th-century council of Laodicea, Constantinople I (381), Chalcedon (451), Africa (419), Sardica (*c.* 343), Ephesus (431), 85 *Canones Apostolorum*, Constantinople (394), canonical letters of 12 Greek Fathers and of the 3rd-century Latin bishop of Carthage, Cyprian, and the *Constitutiones Apostolicae*. With the exception of the last, the Trullo (supplementary) Council of Quinisextum, or the fifth and sixth councils (692), accepted this complex, along with its own canons, as the official legal code of the Eastern churches. The canons of the second ecumenical Council of Nicaea (787) and of the two councils (861 and 879–880) under Photius, patriarch of Constantinople, were added to that.

Systematic collections and the science of canon law

The systematic collections—and there were many of them—contained either canons of councils or ecclesiastical laws (*nomoi*) of the emperors or both together (nomocanons). The first known Greek collection of canons that is preserved is the *Collectio 50 titulorum* ("Collection of 50 Titles"), after the model of the 50 titles of the work known as the *Pandecta* ("Accepted by All") composed by the patriarch Johannes Scholasticus *c.* 550. He composed from the *Novellae constitutiones* ("Novels," or "New Constitutions") of Justinian the *Collectio 87 capitulorum* ("Collection of 87 Chapters"). The *Collectio tripartita* ("Tripartite Collection"), from the end of the 6th century and composed of the entire Justinian ecclesiastical legislation, was the most widely distributed. The nomocanons were expressions of the fusion of imperial and church authority. The *Nomocanon 50 titulorum* ("Canon Law of 50 Titles") from about 580, composed of the works of Johannes Scholasticus, remained in use until the 12th century. The edition of the *Nomocanon 14 titulorum* ("Canon Law of 14 Titles") was completed in 883 and accepted in 920 as law for the entire Eastern Church.

The science of canon law was pursued together with the study of secular law, especially in the schools in Constantinople and Beirut. The *Scholia* (commentaries) on the *Basilica*, a compilation of all of imperial law from the time of Justinian, promulgated by the Byzantine emperor Leo VI (886–912), influenced the method of commenting on and teaching canon law. The best known commentators in the 12th century were Johannes Zonaras and Theodorus Balsamon. Matthaeus Blastares composed his *Syntagma alphabeticum* ("Alphabetical Arrangement"), an alphabetical manual of all imperial and church law, in 1335 from their works.

Independent churches of Eastern Christianity. The churches of Eastern Christianity that separated from the patriarchal see of Constantinople over a period of several centuries, but primarily during the 5th and 6th centuries, developed bodies of canon law that reflected their isolated and—after the Arab conquests in the 7th century—secondary social position. Among these churches are the Syrian Orthodox Church of Antioch (in Syria), the Ancient Church of the East (the Assyrians), the Armenian Apostolic Church, and the Coptic Church (in Egypt). Another independent church is the Ethiopian Orthodox Church (see also EASTERN CHRISTIANITY; INDEPENDENT CHURCHES).

Though these churches developed an extensive body of canon law throughout their histories, Western knowledge of their canon law has been very scant. In the 20th century, however, over 300 manuscripts dealing with canon law have been discovered in various isolated monasteries and ecclesiastical libraries of the Near East by Arthur Vööbus, an Estonian-American church historian. These manuscripts cover the period from the 3rd century to the 14th and deal with ecclesiastic regulations of the Syrian churches. Included among these manuscripts are the following: "The Canons of the Godly Monastery of St. Mār Mattai" (630), 26 in number, concern the jurisdiction of the metropolitan (an archbishop) over the monastery; the 22 canons of "The Canons of the Blessed Mār Gīwargī, Patriarch of Antioch and Syria, and the Holy Bishops of All Religions with Him" (785) are attempts to regulate church discipline, marriage, and ecclesiastical and social relationships with other religious communities; "The Canons of the Holy Qyriaqos, Which the Patriarch Composed and the Synod of the Saints and Bishops with Him" (794), containing 46 canons, deals with ecclesiastical and moral discipline and with liturgical, cultic, and monastic matters; "The Canons of the Holy Dionysios, the Patriarch of Antioch and Syria and of the Synod Which Was Assembled with Him" (818) contains 12 canons concerned with clergy rebellion, the standard of living of the clergy (which was poor), church property, and marriage; "The Canons Which Were Composed by the Holy Synod Which Assembled in Bēt Mār Šīlā [in the region] of Serūg, and Which Consecrated Mar Dionysios as Patriarch of Antioch, the City of God" (896), which originally contained 40 canons, though only 25 remain, deals with the election and examination of candidates for the hierarchy and clergy, the conduct of priests, marriage, pagan influences, and religious and ecclesiastical duties. These canonical collections come from the West Syrian churches. Other canonical collections of the East Syrian churches were published in the early part of the 20th century.

Western churches. From *c.* 300 until *c.* 550, canon law in Western churches had a certain unity through the acceptance of the Eastern and North African councils and the binding factor of the papal decretal law (answers of popes to questions of bishops in matters of discipline), which did not exist in the East. The African canons, like the Eastern canons at Chalcedon, were read out at the councils of Carthage and, if confirmed, included in the Acts, which contained the newly enacted canons. Thus, at the third Council of Carthage (397), the Compendium of the Council of Hippo (393) was included. The collection of the 17th Council of Carthage (419) was soon accepted in all of the East and West. In Spain the canons of Nicaea I (325) and Chalcedon (451) and also African and south Gallican canons and Roman decretals were taken over, as well as their own canons, but the later *Hispana* (Spanish collection) crowded out all earlier collections. The Council of Elvira (295–314) in Spain was the first that set up a more complete legislation, followed by Gaul in the first Council of Arles in 314. Texts from the East, Spain, and Rome, including the *Quesnelliana* (an early 6th-century canonical collection named for its publisher, the 17th-century Jansenist scholar Pasquier Quesnel), circulated there. Gennadius, a priest from Marseilles (in France), *c.* 480 wrote the *Statuta ecclesiae antiqua* ("Ancient Statutes of the Church"), principally inspired by the *Constitutiones apostolicae*. A tendency toward the unification of canon law revealed itself most clearly in Italy against the disintegrating situation that existed between

Development of canon law in Spain, Gaul, Italy, Germany, and the British Isles

the Eastern and Western churches—*i.e.*, the so-called Acacian Schism (484–518), occasioned by the patriarch Acacius of Constantinople and the emperor Zeno's neglect of the legislation of the Council of Chalcedon—and the breakup of the Western Empire soon after the fall of Rome (476), at the time of the 30-year "Gelasian renaissance," beginning during the reign of Pope Gelasius I. There also existed in Rome translations of Eastern councils: *Vetus Romana, Versio Hispana* ("Ancient Roman, Spanish Version"), *Isidoriana, versio Prisca* ("The Isidorian, Priscan Version"), and *Itala* ("Italian"). By far the most important is that of the *Liber canonum* ("Book of Canons") of the 6th-century Roman theologian Dionysius Exiguus, *c.* 500. The first two versions contain 50 *Canones apostolorum,* Greek canons, and the African canons of the 17th Council of Carthage. Dionysius Exiguus also composed a *Liber decretorum* ("Book of Decretals") from Pope Siricius to Pope Anastasius II. Together, the books form the *Corpus* ("Body") or *Codex canonum* ("Code of Canons"). The *Quesnelliana* and other Italian collections are of less importance.

Until the end of the 7th century a greater decentralization and less mutual contact occurred in the separate German kingdoms. Elements of German law found their way into Roman canon law. The *Collectio Avellana* ("Avellan Collection"), written in Rome, *c.* 555, which was a western nomocanon, the *Collectio Novariensis* ("Novarien Collection"), and the *Epitome Hispanica* ("Spanish Abridgment") entered Italy from Spain. In Africa, the first, albeit primitive, systematic collections appeared: the *Breviatio canonum* ("Abridgment of Canons") of (Fulgentius) Ferrandus, deacon of the Church of Carthage (*c.* 546), and the *Concordia canonum Cresconii* ("Harmony of the Canons of Cresconius," a 6th- or 7th-century author), a systematic compilation of the *Dionysiana,* subsequently found in different manuscripts in Gaul. Here the collections were local ones: every cathedral and monastery had its own *liber canonum.* The church of Arles, the metropolis of southern Gaul, had the *Liber auctoritatum* ("Book of Authorities"; *i.e.*, legal texts), a nomocanon of its privileges. The first systematic Gallic *Collectio Andegavetis* ("Andegavenan Collection"), from the end of the 7th century, was an attempt to unite the ancient law with the native.

In Spain, after the conversion of King Recared in 587, the church of the Visigothic kingdom became a well-knit national church with a classical provincial structure under metropolitan jurisdiction, closely linked to the crown. The national councils of Toledo preserved the unity of law and respect for the ancient law. The *Capitula* ("Chapters") of Martinus, bishop of Braga (*c.* 563), was included completely in the *Hispana* and was also copied outside Spain. The *Collectio Novariensis* was related to the *Epitome Hispanica* ("Spanish Abridgment"), the code of the hierarchy that was temporarily halted at the fourth Council of Toledo (633). The *Hispana* was recognized by popes Alexander III and Innocent III as the authentic *corpus canonum* of the Spanish church. Shortly before the *Hispana,* systematic indices (called *tabula*) were written and were subsequently expanded into *excerpta* ("excerpts") and finally into complete texts, the *Hispana systematica* ("Systematic Spanish [Code]"). After the 10th century, the *Hispana* was also called the *Isidoriana,* attributed to Isidore of Seville, a Spanish encyclopaedist and theologian, who was the author of the *Etymologiae* ("Etymologies"), a universally distributed early medieval book of doctrine.

The most disparate picture is offered by the church in the British Isles. The church there was concentrated around heavily populated monasteries, and discipline outside them was maintained by means of a new penitential practice. In place of ancient canons about public penance, the clergy and monks used *libri poenitentiales* ("penitential books"), which contained detailed catalogs of misdeeds with appropriate penances, and were a counterpart of the *Wehre* (lists of punishments) of the *Leges barbarorum* ("Laws of the Barbarians"). They were private writings without official authority and with very disparate content. From the monasteries founded in Europe by the Irish monk Columbanus and other missionaries of Anglo-Saxon background, the *libri poenitentiales* spread all over the continent, where once again new versions emerged. The *Collectio Hibernensis* ("Hibernian [or Irish] Collection"), *c.* 700, used texts from Scripture, mainly from the Old Testament, for the first time in canonical collections, and texts from the Greek and Latin early Church Fathers in addition to canons. The *Liber ex lege Moysi* ("Book from the Law of Moses"), an Irish work, drew exclusively from the Pentateuch.

The Carolingian reform

The reorganization of the Frankish church began with the Carolingian reform in the middle of the 8th century. The canon law was set down especially in the *Capitularia ecclesiastica* ("Ecclesiastical Articles") of the prince, as well as in the *Capitularia missionum* ("Mission Articles"); *i.e.*, instructions given by the prince to the bishops and abbots who visited in his name. The *Capitularia* ("Short Articles") of Charlemagne, the founder of the Holy Roman Empire, and his son, the emperor Louis the Pious, were collected in 827 by the abbot Ansegisus. Following this model the bishops composed terse *capitula,* the oldest known diocesan statutes, for their clergy. The penance books were condemned and replaced by new ones that were more closely related to tradition. The reception of the *Dionysiana* and the *Hispana* is of importance for the transmission of the text and for the Carolingian cultural renaissance. In 774 Charlemagne received from Pope Adrian I a completed *Dionysiana,* the *Dionysiana-Hadriana,* which was accepted at a national synod in Aachen in 802, but it never was adopted as an official national code. About 800 the *Hadriana* and the *Hispana* were developed into a systematic whole, the *Dacheriana* (canonical collection named for its 17th-century publisher, a French scholar, Jean-Luc d'Achéry)—the principal source of the collections before 850—which was of influence until the Gregorian reform in the 11th century.

After Louis the Pious, the central power of the prince was increasingly divided among counts and barons. German law—which linked the right to govern with land ownership, without distinction between public and private law—expressed itself in the medieval forms of the system of private churches. This northern law looked upon dioceses, churches, and monasteries—with their rights and privileges—as lucrative possessions that deserved to be confiscated, by fraudulent means if necessary.

Such situations became the occasion *c.* 850 for the massive falsifications (*i.e.*, forgeries) of the Pseudo-Isidorian collections: the *Hispana Augustodunensis* ("Spanish Collection of Autun"), the *Capitula Angilramni* ("Chapters of Angilramnus," bishop of Metz), the *Capitularia Benedicti Levitae* ("Frankish Imperial Laws of Benedict the Levite," a fictitious name), and the *Pseudo-Isidorian Decretals.* The central goal of the anonymous Frankish group of authors of these collections was to strengthen the position of the bishops and to rectify the poor condition of ecclesiastical–state affairs. This was accomplished by means of falsified and forged texts that were attributed to the esteemed authority of the old law (*i.e.*, the popes) and the Carolingian princes. They did not have much influence on the real development of canon law, although later collections drew from them abundantly. Only the Magdeburg Centuriators, authors of the *Centuries,* a 16th-century Lutheran church history, denied the genuineness of all the decretals of pseudo-Isidore; the lack of authenticity of the other three works was discovered later.

Before 1000 several collections appeared: about 882 of them in northern Italy in the *Collectio Anselmo dedicata* ("Collection Dedicated to Anselm"), a papally oriented, systematic work; in Germany in the *Libri duo de synodalibus causis et disciplinis ecclesiasticis* ("Two Books Concerning Synodical Causes and Church Discipline") of Regino, abbot of Prüm (906), a manual for the bishops for the judicial interrogation of jurymen during a visitation; and in France in the collection of Abbon, abbot of Fleury (*c.* 996), which defended the legal position of his

monastery against the king and bishop. Intended as a doctrinal book for the young cleric, the Decree of Burchard—bishop of Worms (bishop 1000–25)—became the canon-law manual in the cathedral schools and in the curias (administrative bureaucracies) of bishops and abbots in Germany, France, and Italy. Burchard was a promoter of moderate imperial reform. He did not reject the system of private churches; he only rejected the misuses proceeding from it, such as simony (buying or selling church offices) and the violation of celibacy.

The Gregorian reformation

The slogans of the Gregorian reformation, initiated by Pope Gregory VII, who reigned 1073–85, were *libertas Ecclesiae* ("liberty of the church") and *puritas Ecclesiae* ("purity of the church"): freedom from the system of private churches on all levels; freedom from papal dependence on the Roman nobility and emperor; freedom from dependence of the village priest on his *senior* (the beginning of the fight against investiture); and purity from simony and from the total collapse of celibacy (which was exhibited in the practice of hereditary parishes and bishoprics). Fundamental principles of Gregorian canon law included: only canon law that is given or approved by the pope is valid; papal legates (representatives) stand above the local hierarchies and preside over synods; for possession of every ecclesiastical office, choice and appointment by church authorities is demanded, along with the exclusion of lay investiture; every form of simony makes the appointment invalid; the faithful must boycott the services of married priests. New material was sought, especially for the confirmation of papal primacy, in archives and libraries. The principal new sources were: the *Breviarium* of Cardinal Atto (*c.* 1075), the *Dictatus Papae* ("Dictates of the Pope") of Gregory VII (*c.* 1075), the *Collectio 74 titulorum*, or "Collection of 74 Titles" (1074–76), the collection of Bishop Anselm of Lucca (*c.* 1083) and that of Cardinal Deusdedit (*c.* 1085), the *Liber de vita Christiana* ("Book Concerning the Christian Life") of Bonizo, bishop of Sutri (*c.* 1090).

The investiture battle over the conflicting asserted rights of lay or ecclesiastical officials to invest a church official with the symbols of his spiritual office ended in France, England, and Germany (Concordat of Worms, 1122) in compromises. Gregorian law, which now seems too strict, had to be reconciled with the established traditions. Ivo, bishop of Chartres from 1091 to 1116, contributed to the settlement of the investiture problem by his political activities; his extended correspondence; and his three law collections, *Tripartita* ("Tripartite Collection"), *Decretum* ("Decrees"; *i.e.*, collection of decrees or canons), and *Panormia* (collections of "All the Laws"), the last two practically a fusion of Burchard's Decree with Gregorian law. The famous Prologue, written by Ivo for either the *Decretum* or the *Panormia*, indicated for the first time a method by which the bishop must handle the conflicting strict and liberal texts, with *justitia* ("justice") or *misericordia* ("mercy"). Bernold of Constance, in his little tractates, written between 1070 and 1091, listed several criteria for the reconciliation of conflicting texts: authenticity of the text; identity of the author; difference between law, counsel, and dispensation, between universal and local law, of time and place; different meanings of a word. A Liège (Belgium) canon lawyer, Alger, in his *Liber de misericordia et justitia*, or "Book Concerning Mercy and Justice" (*c.* 1105), applied Ivo's criteria to the problem of the effect of sacraments administered by heretics and persons guilty of simony. The great medieval theologian Abelard developed the method of reconciling texts that are for or against a theological position in his *Sic et non*, or "Yes and No," (1115–17). The same methods were applied by the first writers of glosses (commentaries or interpretations) at the law school in Bologna on the *Pandecta* of Justinian, which was rediscovered *c.* 1070.

The Corpus Juris Canonici (c. 1140–c. 1500). *The "Decree of Gratian."* About 1140 the monk John Gratian completed his *Concordia discordantium canonum* ("Harmony of Contradictory Laws"), later called the *Decretum Gratiani* ("Decree of Gratian"); it became not only the definitive canonical collection of the entire preceding tradition, but also a systematic application of the scholastic method (utilizing reason) to all legal material. The *Concordia* dealt with the sources of the law, ordinations, elections, simony, law of procedure, ecclesiastical property, monks, heretics, schismatics, marriage, penance, and sacraments and sacramentals. Primitive as it was, it provided a foundation for systematic compilation of the legal material by the canonists, and for the expansion of decretal law. It provided a basis for the education in canon law which began in the schools of Bologna, Paris, Orléans, Canterbury, Oxford, Padua, and elsewhere. It was accepted everywhere in the ecclesiastical administration of justice and government.

The Corpus Juris Canonici. From the time that the Gregorian reformation introduced a more centralized ecclesiastical administration, the number of appeals to Rome and the number of papal decisions mounted. New papal laws and decisions, called decretals, first added to Gratian's *Concordia*, were soon gathered into separate collections, of which the best known are the *Quinque compilationes antiquae* ("Five Ancient Compilations"). The first, the *Breviarium extravagantium* ("Compendium of Decretals Circulating Outside"; *i.e.*, not yet collected) of Bernard of Pavia, introduced a system inspired by the codification of Justinian, a division of the material into five books, briefly summarized in the phrase *judex* ("judge"), *judicium* ("trial"), *clerus* ("clergy"), *connubium* ("marriage"), *crimen* ("crime"). Each book was subdivided into titles and these in turn into *capitula*, or canons. This system was taken over by all subsequent collections of decretals. These compilations were the foremost source of the *Liber Extra* ("Book Outside"; *i.e.*, of decretals not in Gratian's Decree) or *Liber decretalium Gregorii IX* ("Book of Decretals of Gregory IX"), composed by Raymond of Peñafort, a Spanish canonist, and promulgated on September 5, 1234, as the exclusive codex for all of canon law after Gratian. On March 3, 1298, Pope Boniface VIII promulgated *Liber Sextus* ("Book Six"), composed of official collections of Innocent IV, Gregory X, and Nicholas III, and private collections and decretals of his own, as the exclusive codex for the canon law since the *Liber Extra*. The *Constitutiones Clementinae* ("Constitutions of Clement") of Pope Clement V, most of which were enacted at the Council of Vienne (1311–12), were promulgated on October 25, 1317, by Pope John XXII, but they were not an exclusive collection. The *Decretum Gratiani*, the *Liber Extra*, *Liber Sextus*, and *Constitutiones Clementinae*, with the addition of two private collections, the *Extravagantes* of John XXII and the *Extravagantes communes* ("Decretals Commonly Circulating"), were printed and published together for the first time in Paris in 1500. This entire collection soon received the name *Corpus Juris Canonici* ("Body of Canon Law").

Collections of decretals

The science of canon law was developed by the writers of glosses, the commentators on the Decree of Gratian (decretists), and the commentators on the collections of decretals (decretalists). Their notations, or glosses, were based on the system used by Gratian: next to the texts of canons parallel texts were noted, then conflicting ones, followed by a *solutio* ("solution"), again with text references. In connection with this the glosses of other canonists were also introduced. In this way the *apparatus glossarum*, continuous commentaries on the entire book, arose. The *glossa ordinaria* ("ordinary explanation") on the different parts of the *Corpus Juris Canonici* was the apparatus that was used universally in the schools. After the classical period of the glossators (12th–14th centuries), terminated by the work of a lay Italian canonist, John Andreae (*c.* 1348), followed that of the postglossators. In the absence of new legislation in the time of the Babylonian Captivity (1309–77)—named after the 6th-century-BC biblical captivity or exile of the Jews to Babylon for 70 years (traditionally)—when the papacy was situated at Avignon, France, and the Great Schism (1378–1417), when there were at least two popes reigning simultaneously, the commentaries on decretals continued, but with a larger production of special tracts; *e.g.*, regarding the laws of benefices and marriage and of *consilia* (advice about concrete legal questions).

From the Council of Trent (1545–63) to the Codex Juris Canonici (1917). *The end of decretal law.* Toward the end of the Middle Ages decretal law ceased to govern. The medieval Christian society (called the *Christianitas*) became politically and ecclesiastically divided, according to the principle of *cuius regio, illius et religio* (*i.e.*, the religion of the prince is the religion of the land). In Protestant areas the former Roman Catholic church buildings and benefices were taken over by other churches; and even in the lands that remained Catholic the churches found themselves in an isolated position as secularization forced the churches to reorganize. With the end of the medieval social system known as feudalism, canon law dealing with benefices, chapters, and monasteries, which were closely bound to the feudal structure, changed. The territorial, material, and economic character of canon law and the decentralization allied with it disappeared. The decision of the reform councils from Pisa (1409) until the fifth Lateran Council (1512–17) affected, in particular, benefices, papal reservations, taxes, and other such ecclesiastical matters. In the same period various concordats (agreements) permitted the princes to intervene in the issue of ecclesiastical benefices and property. Canon law took on a more defensive character with prohibitions regarding books, mixed marriages, participation of Catholics in Protestant worship and vice versa, education of the clergy in seminaries, and other such areas of concern.

At the Catholic reform Council of Trent (1545–63) a new foundation for the further development of canon law was expressed in the *Capita de reformatione* ("Articles Concerning Reform"), which were discussed and accepted in 10 of the 25 sessions. Papal primacy was not only dogmatically affirmed against conciliarism (the view that councils are more authoritative than the pope) but was also juridically strengthened in the conduct and implementation of the council. The central position of the bishops was recovered, over against the decentralization that had been brought about by the privileges and exemptions of chapters, monasteries, fraternities, and other corporate bodies that sprang from Germanic law, as well as caused by the rights granted to patrons. In practically all matters of reform the bishops received authority *ad instar legati S. Sedis* ("like delegates of the Holy See"). Strict demands were made for admission to ordination and offices; measures were taken against luxurious living, nepotism, and the neglect of the residence obligation; training of the clergy in seminaries was prescribed; prescriptions were given about pastoral care, schools for the young, diocesan and provincial synods, confession, and marriage; the right to benefices was purified of misuse; the formalistic law of procedure was simplified.

The council gave the duty of execution of the reform to the pope. On January 26, 1564, Pius IV confirmed the decisions, reserved to himself their interpretation and execution, and on August 2, 1564, established the Congregation of the Council for that purpose. The congregations of cardinals, which proceeded from the former permanent commissions of the *consistorium* (the assembly of the pope with the College of Cardinals), were organized by Pope Sixtus V in 1587. Since then the administrative apparatus of the Curia has consisted of congregations of cardinals together with courts and offices. This apparatus made it possible for the Latin Church to acquire a uniform canon law system that was developed in detail.

The Congregation of Cardinals

Law for the missions. The medieval church knew nothing of "missions." Expansion of the church brought with it expansion of the ordinary hierarchical episcopal structure. This was true also for the new colonies under the right of patronage of the Spanish and Portuguese kings. In the other mission areas and in the areas taken over by the Protestants, where the realization of the episcopal structure and the decretal law adopted by Trent was not possible, the organization of mission activity was taken from missionaries and religious orders and given to the Holy See. The congregation *De Propaganda Fide* ("For the Propagation of the Faith") was established for this purpose in 1622. Missionaries received their mandate from Rome; the administration was given over to apostolic vicars (bishops of territories having no ordinary hierarchy) and prefects (having episcopal powers, but not necessarily bishops) who were directly dependent on the *Propaganda*, from which they received precisely described faculties. A new uniform mission law was created, without noteworthy native influence; this sometimes led to conflict, such as the Chinese rites controversy in the 17th and 18th centuries over the compatibility of rites honouring Confucius and ancestors with Christian rites.

LATE DEVELOPMENTS IN ROMAN CATHOLIC CANON LAW

The first Vatican Council (1869–70) strengthened the central position of the papacy in the constitutional law of the church by means of its dogmatic definition of papal primacy. Disciplinary canons were not enacted at the council; but the desire expressed by many bishops that canon law be codified did have influence on the emergence and content of the code of canon law.

The Codex Juris Canonici (1917). Since the closing off of the *Corpus Juris Canonici* there had been no official or noteworthy private collection of the canon law, except for the constitutions of Benedict XIV (pope 1740–58). The material was spread out in the collections of the *Corpus Juris Canonici* and in the generally very incomplete private publications of the *acta* of popes, of general and local councils, and the various Roman congregations and legal organs, which made canon law into something unmanageable and uncertain. The need for codification was recognized even more because of the fact that since the end of the 18th century, secular law had undergone a period of great codification. Several private attempts to do this had met with little success.

Preparations for reorganization of the Code of Canon Law. On March 19, 1904, Pius X announced his intention to complete the codification, and he named a commission of 16 cardinals, of which he himself was chairman. Bishops and university faculties were asked to cooperate and to make their desires known. The schemas of the five books that were prepared in Rome—universal norms, personal law, law of things, penal law, and procedural law—were proposed in the years 1912–14 to all those who would ordinarily be summoned to an ecumenical council, and with their observations were then reworked in the cardinals' commission. The entire undertaking and all the drafts were under the papal seal of secrecy and, as a matter of fact, were not published. Meanwhile, Pius X introduced various reforms that were to a great degree the results of the commission's work. In July 1916 the preparations for the *Codex Juris Canonici* (Code of Canon Law) were completed. The code was promulgated on Pentecost Sunday, May 27, 1917, and became effective on Pentecost Sunday, May 19, 1918.

The Code of Canon Law. In contrast to all earlier official collections this code was a complete and exclusive codification of all universal church law then binding in the Latin Church. Out of fear of political difficulties, a systematic handling of public church law, especially what concerned the relations between church and state, was omitted. Its main purpose is to offer a codification of the law, and only incidentally adaptation, and so it introduces relatively little that is new legislation. The 2,414 canons are divided into five books that no longer followed the system of the collections of decretals but did follow that of the Perugian canonist Paul Lancelotti's *Institutiones juris canonici* ("Institutions of Canon Law"), Perugia, 1563, which in turn went back to the division of the 2nd-century Roman lawyer Gaius' *Institutiones: personae* ["persons"], *res* ["things"], *actiones* ["actions"], and is based on the fundamental idea of Roman law; *i.e.*, subjective right. Book I, general norms, deals with the area covered by the codex, the relation between old and new law, laws, customs, the way of reckoning time, rescripts, privileges, and dispensations. Book II, about persons, deals with persons in general, corporate bodies, clerics, religious, and laity. Book III, about things, deals with sacraments and sacramentals, consecrated places and times, worship, church teachings, authority, benefices, church property, and foundations. Book IV, on processes, deals

Areas of the Code of Canon Law

with general and special trials, beatification and canonization, and special procedures. Book V, on crimes and punishments, deals with crimes, punishments in general, special punishments, and punishments for extraordinary crimes. In some editions the sources that were used by the editors are indicated at the individual canons. Since the publication of the codex these sources belong to the history of the law. Older general and particular law, in conflict with the codex, has been given up; and, insofar as it is not in conflict with it, serves only as a means for interpreting the code. The old law of custom in conflict with the code and expressly reprobated by it is rendered null; when not reprobated and 100 years old or immemorial it can be allowed by ordinaries for pressing reasons. Acquired rights and concordats in force remain in force. With this change, an independent science of the history of canon law has become necessary, in addition to the dogmatic canonical science of canon law on the basis of the code.

Canon law after the Codex Juris Canonici. In order to ensure the unity of the codification and the law, a commission of cardinals was established on September 15, 1917, for the authentic interpretation of the new code. At the same time it was decided that the cardinals' congregations should no longer make new general decrees, but only instructions for the carrying out of the prescriptions of the code. Should a general decree appear necessary, it was determined, the commission would formulate new canons and insert them into the code. Neither of these decisions was carried out. Only two canons were altered and congregations have promulgated numerous general decrees. New papal legislation has complemented and altered the law of the code. The law on judicial procedure was extended by instructions of the Congregation for the Sacraments to the diocesan courts in cases concerning annulment of ordinations and its attached obligations and of marriages; the Congregation for Religious gave detailed prescriptions for five-year reports of pontifical religious institutes and the papal cloister for religious women; an excommunication *latae sententiae* ("of a sentence already pronounced"; *i.e.*, incurred immediately upon the commission of the offense) was imposed by the Congregation of the Council on violations of the prohibitions against business engagement for clerics and religious, and the Sacred Penitentiary reserved the excommunications of married priests most strictly to the Holy See. The *responsa* of the commission for the interpretation of the code and the documents of the Roman Curia concerning canon law are published in the order of the canons in various private collections. The Sacred Roman Rota (court) developed an extensive jurisprudence regarding marriage law: every year an official publication of the verdicts of the tenth year previous appears. The numerous commentaries on the code are principally concerned with the exegesis (critical interpretation) of the text of the canons; this is prescribed in seminaries and faculties of canon law as the basic text for instruction.

The Eastern churches in union with Rome. The principle for the Catholic Eastern churches (churches in union with the Roman Catholic Church) is that they retain their own traditions in liturgy and church order, insofar as these are not considered to be in conflict with the norms taken by Rome to be divine law. In 1929 Pius XI set up a commission of cardinals for the codification of canon law valid for all uniate churches in the East. In the following year a commission was established for the preparation of the codification and one for the collection of the sources of Eastern law, in which experts of all rites were involved. These collections were published in three series, begun respectively in 1930, 1935, and 1942.

In 1935 the preparatory commission became the Pontifical Commission for the Redaction of the *Codex Juris Canonici Orientalis* ("Body of Oriental Canon Law"). The cooperation of all Eastern ordinaries (bishops, patriarchs, and others having jurisdictions) was requested, and the drafts of the various documents were sent to them. Since then four parts have been published: in 1949, on marriage law; in 1952, on the law for monks and other religious, on ecclesiastical properties, and a title *De Verborum Significatione* ("Concerning the Meaning of Words"), a series of definitions of legal terms used in the canons; and in 1957, on constitutional law, especially of the clergy. The still incomplete codification follows the Latin code with the assimilation of the authentic interpretation and with textual corrections, and also with the insertion of the general law proper to the Eastern churches, including the Orthodox churches, regarding the patriarchs and their synods, marriage law, the law of religious, and other matters. The promulgation was made in Latin, with official translations in Greek, Slavic, Arabic, and Egyptian. The Catholic Eastern churches came under the Congregation for the Eastern Churches that was established on January 6, 1862, by Pius IX as part of the *Propaganda Fide*, and was made independent by Benedict XV on May 1, 1917, and expanded considerably by Pius XI on March 25, 1938. Roman legislation as well as the jurisdiction of a congregation of the Roman Curia was criticized as being incompatible with the traditional autonomy of the Eastern churches in legislation and administration.

VATICAN II AND POSTCONCILIAR CANON LAW

Vatican II. Fundamental to the development of canon law in the Roman Catholic Church is the second Vatican Council's (October 11, 1962–December 8, 1965) vision of the church as the people of God. In this connection the former concept of the church as *societas perfecta* (the "perfect society"), founded by Christ through the mission of the Apostles and their successors, to which one belongs through subjection to the hierarchy, is replaced by a vision of the church as a community in which all possess the sacramental mission to live and proclaim the Gospel, and all have a function in the service of the whole. The legislative and administrative functions remain related to the hierarchy, but this is much more expressly seen as a service for the religious life of the community. The idea of collegiality, resting on the recognition of the vocation received by each one from the Lord, works itself out in the relationship existing among the bishops and with the pope, of the bishops with the clergy, and of the clergy with the laity. Related to this is a tendency to co-responsibility and the democratization of the church structure. Independence has been returned to the Eastern uniate churches, and in regard to their patriarchal synods, greater autonomy is set forth for the bishops in their own dioceses and for the episcopal conferences in their territory, and also an autonomy for the laity to exercise individually and collectively the Christian Mission proper to them; viz., to bring the spirit of Christ also into the secular life of mankind. The right of clergy and laity to a share in the leadership of bishops and pope is recognized. The vision of the people of God as *sacramentum mundi*, a sign of redemption for all mankind, gave a new insight into the relationships with the Protestant churches, the other world religions, and the nonreligious atheistic and humanistic movements. In this view, freedom of religion and philosophy became the most fundamental right of man.

The church and collegiality

Postconciliar legislation. From a schematically chronological survey of the principal conciliar and postconciliar legislation a new era apparently began for canon law—*e.g.*, in 1960, establishment of the Secretariate for Promoting Christian Unity; in 1963, various faculties, previously reserved to Rome, were given to the bishops; in 1964, reorganization of the papal commission for communications media; also in 1964: establishment of the Secretariate for Non-Christians, lifting of the prohibition against cremation, and various faculties, previously reserved to Rome, given to the superiors general of religious institutes. Other legislative changes indicating a new era included several regulations that could not have been proposed with any possibility of their being accepted prior to Vatican II: *e.g.*, in 1965, pre-eminence in the College of Cardinals is given to Eastern patriarchs, after deacon and subdeacon and after the cardinals of the dioceses of the province of Rome; also in 1965, establishment of the Secretariate for Non-Believers, and the Holy Office (formerly the Inquisition) became the

Canon law after 1960

Congregation for the Doctrine of the Faith, with emphasis on the positive fostering of theological research; in 1966, greatly reduced prescriptions for fasting and abstinence were adopted, the Index of prohibited books became a moral guide instead of obligatory law, and in implementation of the conciliar degree on the episcopal office, the principle according to which ordinaries (*e.g.*, bishops) dispense from universal laws only when this is allowed by law or special faculties was replaced by the principle that ordinaries can always dispense unless it is explicitly reserved to Rome—and such reserved dispensations in question are indicated. In addition to these changes, still further canonical regulations were proposed and accepted as follows: in 1966, new regulations for mixed marriages were adopted, and norms were established for the implementation of the conciliar decrees on the office of bishops and priests, religious life, missionary activity, personal and material aid to needy churches, salaries and social insurance for priests and others in the service of the church, introduction of priests' councils and pastoral councils of priests, religious (*i.e.*, monks and nuns), and laity as advisory groups for bishops, international episcopal conferences and their mutual relationships, and other concerns. From 1967 to 1970 more changes were made in canonical regulations—*e.g.*, in 1967, total revision of the norms for indulgences, establishment in the Roman Curia of the council of laymen and the study commission, *Justitia et Pax* ("Justice and Peace"), new dispensation rights for Eastern bishops, directory for ecumenical cooperation with Christian churches, regulation of the office of diaconate, also for married men, reorganization of the Roman Curia; in 1970, a mandate to the secretary of state to discuss with the world episcopacy the question of celibacy and ordination of married men in areas that need priests, and new rules for mixed marriages.

Characteristics of the new law are: a searching for structures to allow all members of the church to have a voice in ecclesiastical decision making; decentralization and autonomy of local churches; regulations from Rome are kept to the general, with ample room for local adaptation; the giving up of the Index and the prohibition of cremation, the minimal fasting regulations and so forth, all point to the emancipation of personal religious life from laws and sanctions. In addition, new regulations are to be enacted only after extensive and open inquiry and test by experience, with possibilities for experimentation. In place of regulations of religious behaviour, canon law may be becoming an ordering of the cooperation of all members of the Roman Catholic Church for the realization of its mission in the world.

Revision of the Code of Canon Law. On January 25, 1959, John XXIII announced the revision of the church's code. On March 28, 1963, he set up a commission of cardinals for that purpose. On April 17, 1964, Paul VI named the first consultants. No publicity has been given to the commission's work, but the first episcopal synod (September 30–October 4, 1967) gave its approval to a document in which several principles for the revision were indicated (*Principia quae codicis juris canonici recognitionem dirigant*, or "Principles Which Guide the Recognition of the Code of Canon Law"): the juridical character of the code ought to be preserved and not, as some wished, be limited to a rule for faith and morals; canon law for the area of each one's personal conscience, should be maintained, but conflicts between law for conscience and public law ought to be avoided, especially in marriage and penal law; as a means to stimulate pastoral work it is recommended that the laws be expressed in a spirit of love, fairness, and humanity; no binding prescriptions are to be given where admonition and counsel suffice; pastoral workers are to be given more discretionary powers and greater freedom is to be given to bishops, especially in mission areas; laws are to be such that ample possibility is given for local adaptation, carrying through the principle of subsidiarity (*i.e.*, that nothing should be committed to higher organs that can be accomplished by individuals or lesser or subordinate bodies), however, with care to retain the unity of law and jurisdiction; regulation of administrative jurisdiction and in principle public jurisdiction; distinction of legislative, administrative, and judicial functions; limitation of punishments; and of punishments incurred immediately upon commission of the offense to very few and very serious crimes. On May 28, 1968, the commission approved the following preliminary division of the new codex:

Division of the new codex

I. Sources of the law (law and custom); the activities of government concerning the legal position of persons (dispensation, privilege, and similar matters)
II. The people of God
  A. Persons in general (duties and rights of all the faithful); legal persons (also right of association)
  B. Persons in particular or various states: clerics, laity, religious, and religious institutes
  C. Hierarchy, or church government
III. Ecclesiastical offices
  A. The teaching office
  B. Priestly office; sacraments and sacramentals, liturgy, consecrated places and times
  C. Pastoral office: administrative organs and the exercise of government in the universal and in the local church
IV. Ecclesiastical property
V. Penal law
VI. Protection of the law
  A. Civil and penal judicial procedure
  B. Administrative procedure

The schema of a *lex ecclesiae fundamentalis* ("fundamental law of the church"), a kind of constitution for the church embracing the fundamental principles of church structure for the Latin and uniate churches in the East, was sent in 1969 to the cardinals of the commission and to the members of the theological commission of the Congregation for the Doctrine of the Faith with the request that observations be submitted before December 31, 1969. A revised text was submitted to the synod of bishops in 1971 but was overwhelmingly rejected and returned to the commission for further revision.

ANGLICAN CANON LAW

The Anglican Communion embraces the Church of England and its daughter churches. Since the submission of the clergy demanded by King Henry VIII in 1534 and the Act of Supremacy in 1534, in which the Parliament recognized him as supreme head of the Church of England and which was renewed by Queen Elizabeth I, the law of the English Church rests on the supremacy of the prince or of the Parliament. It is theoretically accepted that outside the law determined by the English synods in the ancient independent national churches, only the principles of the general canon law—*jus ecclesiasticum commune* ("common ecclesiastical law")—are binding, but other norms, promulgated by popes and councils, are accepted only to the extent that they were accepted by English ecclesiastical or secular courts. For practical purposes the development of church law in the English Church is held by some canonists (usually Roman Catholic) not to be canon law but the ecclesiastical law of the state. The hierarchy has the power to ordain by virtue of the apostolic succession which was preserved—according to the Anglican view—by the consecration of Matthew Parker as archbishop of Canterbury (1559), but it does not possess legislative authority. The ecclesiastical provinces are administered by convocations of Canterbury and York, consisting of an upper house of bishops and a lower house of clergy. In 1919 a Church Assembly was established by the Enabling Act; the assembly consists of three houses (of bishops, members of the convocations, and laity) with the authority to make proposals relating to any matter concerning the Church of England—with the exception of dogmas of faith—and to present these proposals to the ecclesiastical committee of Parliament. If the committee agrees on a positive report, then the Parliament can approve or reject the proposal but not amend it; if both houses accept it, then it acquires the force of law by royal approval. Lambeth Conferences, which have been held approximately every ten years since 1867 at the London palace of the archbishop of Canterbury and which involve all Anglican bishops from all over the world, do not have legislative authority.

Ecclesiastical law of the state

Depending somewhat on Anglican canon law is the Church of South India, a union of Protestant church bodies in South Asia (the Anglican Church of India, Burma, and Ceylon; the Methodist province of South India; the South India United Church—Presbyterian, Congregationalist, and Dutch Reformed), founded in 1947. According to the constitution of the new Church of South India, at the end of an interim period of 30 years canonical reforms of that former mission area are to be anticipated.

Canon law has had a long history of development throughout the Christian era. Not a static body of laws, it reflects social, political, economic, cultural, and ecclesiastical changes that have taken place in the past two millennia. During periods of social and cultural upheaval the church has not remained unaffected by its environment. Thus, canon law may be expected to be involved in the far-reaching changes that have come to be anticipated in the modern world. (P.Hu.)

BIBLIOGRAPHY. The literature on the subject in all its branches is very elaborate, and this is particularly true of the canon law of the Roman Catholic Church. The articles "Law (Christian, Western)" and "Law (Christian, Eastern)" by A. FORTESCUE and "Law (Christian, Anglican)" by A.J. MACLEAN in *Hastings Encyclopedia of Religion and Ethics*, give concise statements of information with references for further study. For an extended study of the history of Western canon law, see A.G. CICOGNANI, *Canon Law*, authorized English version (1934). A fine discussion of legislation in the Roman Catholic Church is contained in R. METZ, *What Is Canon Law?* (1960); brief surveys of the current *Codex Juris Canonici* will be found in T.L. BOUSCAREN and A.C. ELLIS, *Canon Law: A Text and Commentary*, 4th ed. (1966); and in J.A. ABBO and J.D. HANNAN, *The Sacred Canons*, 2nd ed., 2 vol. (1960); while the post-code legislation and interpretation is collected by T.L. BOUSCAREN, *Canon Law Digest*, 4 vol. (1934–58), which is kept up-to-date by annual loose-leaf supplements. The Catholic University of America has published, under the general title of "Canon Law Studies," numerous doctoral theses dealing with particular canons. The sources used in drafting the Latin code have been published by the Vatican Press under the title *Fontes Juris Canonici*; publication of the *Fontes Juris Canonici Orientalis* was begun in 1930. ARTHUR VOOBUS, *Syrische Kanonessammlungen: Ein Beitrag zur Quellenkunde. Westsyrische Originalurkunde 1A-B* (1970–71), discusses the recently discovered canons of the West Syrian churches.

Canova, Antonio

Antonio Canova, an outstanding Neoclassical sculptor, was as important in the development of the Neoclassical style as Jacques-Louis David in painting. Canova's domination of European sculpture at the turn of the 18th century and the beginning of the 19th is reflected in countless adulations in memoirs, poems, and newspapers. "Sublime," "superb," and "marvellous" are adjectives frequently found describing Canova's work in his lifetime. Such was his contemporary fame that Catherine the Great invited him to Russia in 1794, although he declined.

Canova was born on November 1, 1757, in Possagno (Asolo), near Venice, the son of a stonemason. His father died in 1761, and the boy was reared by his grandfather, also a stonemason. Under the protection of a Venetian senator, Canova, at the age of 11, went to work with the sculptor Giuseppe Bernardi (called Torretti), who lived at Pagnano (Asolo). In the same year (1768) Bernardi moved his studio from provincial Pagnano to Venice, and Canova went with him. The boy helped his master, executed a few humble commissions on his own, and, as was customary at the time, studied classical art and drew from the nude.

In 1775 Canova set up his own studio in Venice. In 1779 he sculpted "Daedalus and Icarus," which had been commissioned by Pisani, procurator of the Venetian republic; it was Canova's first important work. Somewhat Rococo in style, the figures were considered so realistic that the sculptor was accused of making plaster casts from life models.

Canova was in Rome in 1779 and 1780, where he met the leading artists of the period, including the Scottish painter-dealer Gavin Hamilton, who directed Canova's studies toward a more profound understanding of the antique. Canova visited Naples and the ancient archaeological sites of Herculaneum, Pompeii, and Paestum. He returned briefly to Venice, but in 1781 he was again in Rome, where he was to spend most of the rest of his life. There he became an active and influential figure in the artistic life of the city and was always willing to help young artists and find them patrons.

Papal commissions

In 1783 Canova received an important commission for the tomb of Pope Clement XIV in the Roman church of Santi Apostoli. When displayed in 1787 crowds flocked to see it. That same year he was commissioned to execute a tomb in St. Peter's to Pope Clement XIII. Completed in 1792, its general treatment shows a more developed understanding of the classical aesthetic of antiquity than his monument to Clement XIV. Subsequent tombs were increasingly Neoclassical and combined restraint with sentiment, in a manner akin to the work of Canova's English contemporary, John Flaxman.

The French invasion of Rome in 1798 sent Canova northward. In Vienna he worked on a funerary monument to Maria Christina (1798–1805) in the Augustiner-

kirche. In 1802, at the pope's instigation, he accepted Napoleon's invitation to go to Paris, where he became court sculptor and considerably influenced French art. He spent part of 1802 in Paris working on a bust of Napoleon, and in 1806 Joseph Bonaparte commissioned an equestrian statue of Napoleon.

About 1807 he finished one of his most famous works in which he shows Napoleon's sister, Pauline Borghese, reclining almost naked on a couch as "Venus Victrix"—a fusion of classical goddess and contemporary portrait. In 1811 he completed two colossal statues of Napoleon (Brera, Milan, and Wellington Museum, London), in which the emperor is shown as a heroic classical nude. In the Napoleonic period he had also begun carving some of his most expressive and ambitious pieces, "Perseus with Medusa's Head" (1801) and the "Pugilists" (1802), both in the Vatican.

Collection of treasures for the papal state

Canova in 1805 was appointed inspector general of fine arts and antiquities of the papal state. In 1810 he was made president of the Accademia di S. Luca in Rome (a position he was to hold for life). After having visited Paris to arrange for the return of Italian art treasures plundered by the French, he went to London (1815) to give his opinion on the Elgin Marbles. The success of his mission in Paris led to the reward of the title of marquis of Ischia by the pope. While in London, the Prince Regent, later George IV, commissioned a life-size group of "Venus and Mars." Other late commissions included the Stuart monument in St. Peter's (1819), the alteration and completion of the equestrian Napoleon into Charles III of Naples (1819), and a monument of George Washing-

ton (1820; destroyed by fire in 1830), idealized in Roman costume, erected at Raleigh, North Carolina, in 1821.

Canova was also a painter. But his paintings (mostly in the Gipsoteca Canoviana at Possagno) constitute a minor part of his works and generally are poor in quality. They include a few portraits and recreations of antique paintings discovered at Herculaneum.

Canova died in Venice on October 13, 1822, and was buried at Possagno in a temple, designed by himself in imitation of the Pantheon in Rome.

MAJOR WORKS

SCULPTURE: "Eurydice" (1773; Museo Civico Correr, Venice); "Orpheus" (1776; Museo Civico Correr, Venice); "Daedalus and Icarus" (1779; Museo Civico Correr, Venice); "Apollo" (1779; Accademia, Venice); "Theseus and the Minotaur" (1781–82; Victoria and Albert Museum, London); tomb of Clement XIV (1783–87; SS. Apostoli, Rome); tomb of Clement XIII (1787–92; St. Peter's, Rome); "Cupid and Psyche" (1792; Louvre, Paris); "Monument to Angelo Emo" (1792–95; Museo Storico Navale, Venice); "Hercules and Lichas" (model 1796, marble, 1815; Galleria Nazionale d'Arte Moderna, Rome); "Perseus with Medusa's Head" (1801; Vatican, Belvedere, Rome); "Pugilists" (1802; Vatican, Belvedere, Rome); "Napoleon As First Consul" (1802; Gipsoteca Canoviana, Possagno); "Monument to Vittorio Alfieri" (1805–10; Sta. Croce, Florence); "Pauline Borghese as Venus Victrix" (1805–07; Borghese Gallery, Rome); "Dancing Girl with Her Hands on Her Hips" (1806–10; Hermitage, Leningrad); "Dancing Girl with Her Finger on Her Chin" (1806–10; Galleria Nazionale d'Arte Antica, Rome); "Venus Italica" (1812; Pitti Palace, Florence); "The Three Graces" (1813–16; Hermitage, Leningrad); "Venus and Mars" (1816–22; Buckingham Palace, London); "Theseus and the Centaur" (1819; Kunsthistorisches Museum, Vienna); "Endymion" (1819–21; Chatworth House, Derbyshire).

BIBLIOGRAPHY. No comprehensive, up-to-date biography in English exists. The best general studies are in Italian; ELENA BASSI, *Canova* (1943); and ANTONIO MUNOZ, *Canova* (1957). ISABELLA ALBRIZZI, *Opere di Canova* (1809, and subsequent editions; Eng. trans., 1824), is still useful. Good specialized studies include: ELENA BASSI, *La Gipsoteca di Possagno: Sculture e Dipinti di Antonio Canova* (1957) and *Il Museo civico di Bassano: I disegni di Antonio Canova* (1959); and HANS OST, *Ein Skizzenbuch Antonio Canovas* (1970).

(D.I.)

Canton

The largest city of southern China, Canton lies at the head of the Chu Chiang (Pearl River) Delta, more than 90 miles inland from the South China Sea. Although the city is commonly known as Canton to Westerners—a name that derives from that of Kwangtung Province, of which it is the capital—the correct name of the city since the 3rd century AD has been Kuang-chou (Guang-zhou in the Pin-yin romanization). Because of its position at the meeting point of inland rivers and the sea, it has long been one of China's main commercial and trading centres. It has served as a doorway for foreign influence since the 3rd century AD and was the first Chinese port to be regularly visited by European traders. The city is also a historic centre of learning and, as the birthplace of the Chinese Nationalist leader Sun Yat-sen, it was the cradle of the Chinese revolution. Its 3,100,000 inhabitants are known as Cantonese and speak their own Chinese dialect. The limits of the municipality have been enlarged since 1949 to incorporate adjoining countries.

Since 1949 Canton has continued to be of great economic importance. Its harbour has been dredged, industry has been introduced, and trade has increased. The city has undergone a vast public works program and is now beautiful as well as busy. (For related articles, see HSI CHIANG [RIVER] and KWANGTUNG.)

History. The earliest known inhabitants of the Canton area were the Pai Yüeh, a Tai, or Shan, people. At the beginning of the Western Chou dynasty (*c.* 1122–771 BC), their chief built a walled town, known as Nan-wu Ch'eng, on Yüeh-hsiu Shan (Yüeh-hsiu Mountain) in the northern section of the present-day city. In 887 BC the town was taken by the mid-Yangtze kingdom of Ch'u and was known as Wu-yang Ch'eng (City of Five Goats).

Non-Chinese origins

Under the Ch'in dynasty (221–206 BC) Canton was made the capital of Nan-hai prefecture. Upon the fall of the Ch'in General Chao T'o (?–137 BC), who had been appointed to a command in 215 BC under Jen Hsiao, with whom he subdued the wild southern tribes), established an autonomous state known as Nan Yüeh, which was, however, annexed in 111 BC by the Han dynasty (206 BC –AD 220). For the next 300 years Chinese assimilation of the Yüeh people proceeded, and integration of the region into the empire took firm root.

During the four centuries from the Three Kingdoms to the founding of the T'ang dynasty (AD 220–618), when North China was overrun by "barbarian" invaders, Canton remained an integral part of the Chinese regimes based in Nanking. During this period the city grew in wealth and population; Buddhist temples were erected, and a flourishing community was maintained by Arab and Hindu traders. Peace and prosperity were further augmented under the T'ang dynasty (618–907). A mosque was built in the 7th century by Muslim traders from the Middle East. Canton's strong identification with this period is attested by the fact that the Cantonese people call themselves "the people of the T'ang" even today. An auxiliary wall and settlement were built on Yü Hill, but the city suffered considerable destruction during the civil strife at the end of the dynasty.

Under the Sung dynasty (960–1126) the increase in Canton's population and the growth of foreign trade made it necessary to enlarge the city. A second auxiliary wall and settlement were constructed on Fan Hill in the late 11th century. With the settlements on the twin hills, the city took on the name Fan-yü (hence the name of the county in which Canton is now located). Under the Southern Sung (1126–1279) Chinese seamen and traders sailed to Southeast Asia, thus opening the way for Chinese emigration abroad in subsequent ages. In the late 13th century and throughout the 14th, many Chinese families from North China moved into the Kwangtung region in the wake of the Mongol conquest. A booming economy resulted as the Yüan rulers (1279–1368) encouraged maritime trade and kept Chinese–Mongol race relations under control.

Period of expansion

Under the Ming dynasty (1368–1644) the city underwent considerable rebuilding and expansion. In 1380 the Fan and Yü hills were razed, and the old town and the two auxiliary districts were combined into one large walled city. In 1535 an outer wall was added to incorporate the new commercial districts on the north bank of the Chu Chiang. Meanwhile, the pattern of foreign trade changed: the supremacy of the Arabs ended with the coming of the Europeans. The Portuguese sent their first embassy to Canton in the early 1500s, followed by the Dutch and the British in the 17th century.

Canton came under the rule of the Ch'ing (Manchu) dynasty from 1644 to 1911. Recognizing the importance of the city, the government made it the capital of the Viceroyalty of Kwangtung and Kwangsi. The British East India Company established a "factory" (foreign traders' residences and business offices) in Canton in 1685, and annual trading operations began in 1699. Throughout the 18th century the French, Dutch, Americans, and other nationals also established trade relations with the city; the "thirteen factories" were located on the waterfront between the city walls and the western suburbs.

Trade moved without undue difficulty until friction began to mount in the 1820s. The foreigners found trade restrictions (through licensed Chinese merchants known as the Co-hong) too irksome, while the Chinese authorities refused to open normal diplomatic relations. The Chinese seized and destroyed large quantities of illegal opium brought in by the British in 1839, and in retaliation the British attacked Chinese positions in the Canton Estuary. The Opium War (1839–42) ended in humiliating defeat for China, and the city saved itself from destruction only by paying a handsome ransom.

Among its other provisions, the Treaty of Nanking (1842) with the United Kingdom opened Canton as a treaty port. In 1844 the French and the Americans ob-

tained similar treaties. Antiforeign sentiment, however, ran high in Canton, and the city refused to open its gates until 1857. The coolie trade and the use of foreign flags to protect pirates caused a succession of crises. Another war broke out between China and Britain and France between 1856 and 1858. Canton was occupied by Anglo-French forces until 1861; and Sha-mien, to the west of the city, was made an Anglo-French concession in 1859.

Amid the woes of foreign imperialism, Canton was deeply shaken by the great antidynastic outbreak of the Taiping Rebellion (1850–64), the leader of which, Hung Hsiu-ch'üan, was born in the northern Canton suburb of Hua-hsien. Many followers of Hung formed secret societies that kept his revolutionary ideals alive even after the failure of the rebellion. For the next 50 years anti-Manchu agitation formed one of the twin forces that gripped Canton; the other was the rise of nationalism.

Canton came under the spell of its most illustrious son, Sun Yat-sen, from 1885 to 1925. Born in Chung-shan Hsien (Chung-shan County) in 1866, Sun made the city the testing ground for his campaign to overthrow the Manchu dynasty and to establish a Chinese republic. The Canton Uprising of 1911 paved the way for the success of the revolution before the end of the year. Then, Canton became the base of operations for action against the warlords between 1916 and 1925 and served as the headquarters of Sun's party, the Kuomintang. Besides completing his San Min Chu-i (Three Principles of the People), Sun reorganized the Kuomintang in 1924 to reactivate the Nationalist revolution. All manner of people flocked to Canton—the right- and left-wing members of the Kuomintang, the members of the newly formed Chinese Communist Party, and Soviet advisers. Chiang Kai-shek, Mao Tse-tung, and Chou En-lai began their careers in Canton under Sun's tutelage.

Headquarters of the Kuomintang

Chiang quickly gained power when he crushed an uprising by the Canton Merchants Volunteer Corps and defeated the disloyal local warlords (1924). With Sun's death in 1925, however, Canton was embroiled in the power struggle between the Communists and the Nationalists. Outmanoeuvring the Communists, Chiang launched the Northern Expedition in 1926, which enabled him to control southeastern China and to set up a conservative Nationalist government in Nanking in opposition to the Communists and the Kuomintang liberals. In 1927 a Communist-led coup attempted to set up a commune (or workers' government) in the city, only to be crushed by Chiang. From 1928 to 1937 Canton was officially under the control of the Nationalist government. It was, however, actually controlled by independent leaders, who levelled criticism at Chiang's dictatorship and threatened secession from Nanking. In 1937, when war against the Japanese broke out, Canton became a prime target of Japanese air raids, and in 1938 it fell to the enemy. Canton remained under Japanese occupation until 1945. The city was left in a state of economic chaos, and it was not until the Communist government took control in 1949 that Canton began a new era of peace and recovery.

The contemporary city. *Physical environment.* Canton lies within the county (*hsien*) of Fan-yü, although the municipality (*shih*) of Kuang-chou embraces the two additional northern counties of Hua and Ts'ung-hua. It is situated on the Chu Chiang, which branches off the Hsi Chiang and forms the northern border of the pear-shaped delta that is 60 miles long and about 25 miles wide. Three major rivers—the Hsi Chiang, which flows across Yunnan and Kwangsi provinces; the Pei Chiang, which forms a link with Hunan and Kiangsi provinces; and the Tung Chiang, which drains the eastern half of Kwangtung Province—converge at the delta.

The Chu Chiang Delta

Canton has three seasons. From April through October, the summer season is wet, hot, and humid; south and southwest winds are often accompanied by typhoons, which are seldom destructive. The July mean temperature is 83° F (28° C). Winter lasts from October through early February and is mild and free of snow; the January mean temperature is 56° F (13° C). The third season, from February through mid-April, is a period of transition that is marked by muggy weather. With an average annual rainfall of 64 inches, most of which falls from May to August, farmers in the surrounding country enjoy a year-round growing season.

Canton stretches along a waterfront (the Chang Ti, or Long Quay), which runs for five miles from east to west along the Chu Chiang. Both the Old City (dating back to the Ming dynasty) and the sections of Hsi-kuan to the west, Nan-kuan to the south, and Tung-kuan to the east are located on the north bank. Sha-mien is a tiny island in the river adjacent to Hsi-kuan. Since the demolition of the city walls in the 1920s, these sections have become one city. The main north–south thoroughfare of Chieh-fang Lu (Liberation Avenue) is intersected about midway by the east–west arterial road of Chung-shan Lu (Sun Yat-sen Avenue). Literally hundreds of smaller streets cut across these avenues at right angles.

On the south bank are the industrial suburbs of Ho-nan to the south and Hua-ti to the southwest and the sports grounds of Er-sha T'ou to the southeast. Another industrial section is located at Hsi-ts'un, a northwestern suburb on the Peking–Canton railroad; and due north are the delightful parks and resorts of Yüeh-hsiu Shan and Pai-yün Shan. The Hai-chu Bridge links the two banks of the river. About nine miles downriver to the east of the bridge is the outer port of Whampoa.

Transportation. Buses, pedicabs (small three-wheeled vehicles propelled by pedalling), and bicycles are the principal means of transportation in the city and its suburbs. The delta is blessed with innumerable canals and creeks; the smaller canals are used by sampans (flat-bottomed boats propelled by oars) and the larger by steamers or motor launches.

Eastfoto

Hai-chu Square in Canton overlooking the waterfront. The buildings bordering the park are exhibition halls used for trade fairs.

The city is a terminus of inland navigation. Large steamers sail regularly between Canton and Wu-chou, Kwangsi Province; and motor launches ply the multitude of rivers in the vast hinterland. Wooden boats navigate farther upstream into interior China.

Canton as transportation hub

Canton is also the focal point of coastal and ocean navigation. Since the completion of dredging and the construction of warehouses and wharf facilities in 1965, it is capable of handling ships of up to 4,000 tons, whereas similar improvements at Whampoa have made it accessible to 10,000-ton vessels.

Canton is served by three railroads—the Peking–Canton railroad, which is a national trunk line; the Canton–Kowloon line, which links the city with Hong Kong; and the Canton–San-shui line, which provides vital transport between the city and the confluence of the Hsi Chiang and the Chu Chiang. Kwangtung is the nation's most advanced province in highway development. Major arterial roads link Canton with Swatow, Mei-hsien, Chanchiang, Hai-an, Hsin-tu (all in Kwangtung), and the Portuguese province of Macau. Canton airport is the largest in South China; it operates regular flights to major cities throughout the nation and maintains international service to North Vietnam, Burma, and Pakistan.

Demography. Canton had an estimated municipal population of 3,100,000 in 1970. With 4,000 persons per square mile, it is one of the most densely inhabited areas in China. The people speak Cantonese, a Chinese dialect with twice as many syllables as Mandarin. Some 300,000 persons lived on sampans and junks on the Chu Chiang until 1960, when they were employed in factories and their squalid homes were removed.

The earliest inhabitants, of Tai or Shan origin, were assimilated by the Chinese long ago. There are, however, small groups of Chinese Muslims (Hui) in the city. A notable demographic feature is the large number of "overseas Chinese," Cantonese who emigrated to Southeast Asia, the United States, Europe, and other parts of the world.

Living conditions. Old Canton was a crowded city of narrow streets and winding alleys. A vigorous modernization program was carried out in the 1920s and 1930s, in which the city walls were demolished, the polluted canals filled in, and the graveyards removed. In their place, wide streets were built, modern sewers introduced, arcades constructed for sidewalk shops, and a pleasant waterfront and numerous parks created. Since 1949 the Communist government has continued the modernization of the city. New housing, modern shops, and handsome government buildings are noticeable everywhere. Most of the new housing consists of buildings of three or four stories, light and well-ventilated, located along wide streets with an abundance of trees and flowers.

Expanded industrial activity

Economic life. Since 1950 there has been substantial expansion of such light industries as the manufacture of textiles, newsprint, refined sugar, processed food, jute, matches, and firecrackers. Heavy industries include the production of machinery, chemicals, iron and steel, cement, trucks, tractors, hydroelectric power, and shipbuilding. Small and medium-sized plants have also been developed for the manufacture of clocks, bicycles, cameras, sewing machines, glassware, and plastic goods. Canton is celebrated for its many handicraft products, including ivory carvings, jade objects, embroideries, sandalwood fans, porcelain ware, paper umbrellas, toys, bamboo and rattan ware, coir (coconut-fibre) matting, palm-leaf fans, and household furniture.

Canton is the centre of the trade of Kwangtung and Kwangsi and the adjacent provinces of South China. Products such as sugar, fruits (especially oranges, bananas, litchi, and pineapples), silk, timber, tea, and herbs are exported, whereas manufactured goods and industrial equipment are transshipped via Canton into the interior. Since 1957 the semi-annual Canton Fair has become an institution of world trade, and in the exhibition halls of the Hai-chu Square an Export Commodities Fair is held every spring and autumn.

Political institutions. The Canton Municipal People's Council, which is elected by the Municipal People's Congress (an elective body that is the organ of government authority in the municipality), is the executive organ of the city's government. It is composed of a mayor, deputy mayors, and some 40 council members. The council formulates policies, issues administrative orders, collects taxes, determines the budget, carries out economic plans, maintains order, and safeguards the rights of the citizens. Serving under its direction are numerous bureaus and commissions in charge of civil affairs, public security, justice, planning, finance, food taxation, industry, commerce, labour, culture, education, public health, physical culture and sports, projects of municipal construction, and public services.

The city is divided into districts (*ch'u*), each of which is administered by a district mayoralty. Under the district, there are police substations and street mayoralties. Neighbourhood associations have various functions, including mediating disputes, conducting literacy campaigns, supervising sanitation and welfare, and "weeding out bourgeois elements."

The driving force behind this governmental system is the Municipal Committee of the Chinese Communist Party. In 1959 it was estimated that the city had 60,000 party members, constituting 3 percent of the total city population and organized into 3,000 basic-level units.

Health and safety. While the people continue to lead a poor and spartan life, their houses are clean and the streets are neat and well maintained. Proper treatment of drinking water and the extermination of rodents, flies, and mosquitoes have put an end to malaria, cholera, dysentery, and bubonic plague. The Bureau of Public Health also conducts energetic campaigns for the public health education of the populace. The city has many hospitals, of which the Kwangtung Provincial People's Hospital, with 600 beds and more than 1,000 staff members, is one of the largest.

Public security is maintained by a large and efficient police department, which has branch departments and substations in all districts. The two major vices of gambling and prostitution have been effectively stamped out. As for fire control and prevention, the Canton fire department is manned by well-trained personnel who use up-to-date equipment.

Education. Canton is one of the nation's most progressive Chinese cities in regard to its educational system. In addition to a large number of kindergartens, primary schools, and middle schools, Canton has numerous institutions of higher learning. These include Sun Yat-sen University, Chinan University, South China Technical University, Canton Chinese Medical College, South China Engineering College, South China Institute of Technology, Canton Institute of Applied Chemistry, and South China Agricultural Institute.

The new educational pattern

Since the Cultural Revolution of the 1960s a new pattern of education has taken shape. The system includes five years in primary schools and four years in middle schools. All students leave middle school at 16 years of age and go directly into factories or communes to engage in physical labour for two years. Entrance to college is gained not by examination but by a "four-step system" of application by the student, selection by the worker and peasant representatives, approval by the factory or the commune, and final approval by the college or university staff. The recruitment of students has become stricter, with a noticeable drop in university enrollment. Intervention in school affairs by the army and workers' teams frequently takes place in order to "end factional strife and establish unity."

Cultural life. Canton has a large number of museums, including the Kuang-chou Museum, with exhibits of the history, industries, and the revolutionary heritage of the region; the Kwangtung Palace of Science for schoolchildren; the Sun Yat-sen Museum; and the Museum of the Peasant Institute, which commemorates Mao Tse-tung's role in the peasant revolution. There are many city and provincial libraries, the largest of which is the Chung-shan Library of Kwangtung Province, with more than 1,000,000 volumes. Equally significant are the Kwangtung Botanical Gardens and Zoological Gardens.

Canton has two daily newspapers—the *Kuang-chou jih-pao* is the official organ of the Canton Municipal Party Committee, and the *Nan-fang jih-pao* is the highest official organ published by the Kwangtung Provincial Party Committee. Influential as these papers are, it is radio broadcasting that truly affects the populace. Canton has five radio stations, three of which broadcast locally, and two of which are provincial. Every corner of the city is equipped with receiver sets, and loudspeakers blare out the day's news and the government's directives.

The vast majority of people in Canton live in austerity, but their modest existence is enlivened by laughter, buoyancy, and vitality. Much of this can be attributed to the expansion of recreational facilities since the 1950s. Public parks, gymnasiums, and sports grounds are found everywhere. Especially noteworthy are the International Sports Centre, the New Gymnasium, Kuang-chou Cultural Park, Yueh-hsiu Shan Park, Pai-yün Shan Park, Huang-hua Kang Park, and Li-chi Wan Park. The parks provide picnic grounds, resort facilities, movie theatres, drama theatres, roller-skating rinks, swimming pools, museums, and exhibition halls.

TREGEAR, *An Economic Geography of China* (1970). Handy references to the history of Canton may be found in W.C. HUNTER, *The "Fan Kwae" at Canton, Before Treaty Days, 1825–1844* (1882; 2nd ed., 1911); T'ANG LEANG-LI, *The Inner History of the Chinese Revolution* (1930); and IMMANUEL C.Y. HSU, *The Rise of Modern China* (1970). EZRA F. VOGEL, *Canton Under Communism* (1969), is a searching study of the changes in the 1950s and 1960s. *China Reconstructs* and *Far Eastern Economic Review* contain articles dealing with current developments.

(P.-c.K.)

Cantor, Georg

The German mathematician Georg Ferdinand Ludwig Philipp Cantor is remembered chiefly for founding set theory, one of the greatest achievements of 19th-century mathematics. By devising original techniques for treating the infinite in mathematics, he contributed substantially to the development of analysis and logic; and, by drawing on ideas of the infinite in the writings of ancient and medieval philosophy, he introduced new modes of thinking concerning the nature of number. His work, moreover, has had a constructive influence on the development of new curricula in basic education in mathematics.

Cantor was born of Danish parents on March 3, 1845, in St. Petersburg (now Leningrad), Russia. His artistic mother, a Roman Catholic, came from a family of musicians, and his father, a Protestant, was a prosperous merchant. When his father became ill in 1856, the family moved to Frankfurt (now in West Germany). Cantor's mathematical talents emerged prior to his fifteenth birthday while studying in private schools and at *gymnasiuma* at Darmstadt first and then at Wiesbaden; eventually, he overcame the objections of his father, who wanted him to become an engineer.

After briefly attending the University of Zürich (Switzerland), Cantor in 1863 transferred to the University of Berlin to specialize in physics, philosophy, and mathematics. There he was taught by the mathematicians Karl Theodor Weierstrass, whose specialization of analysis probably had the greatest influence on him; Ernst Eduard Kummer, in higher arithmetic; and Leopold Kronecker, the specialist on the theory of numbers who later opposed him. Following one semester at the University of Göttingen in 1866, Cantor wrote his doctoral thesis in 1867, *In re mathematica ars propendi pluris facienda est quam solvendi* ("In mathematics the art of asking questions is more valuable than solving problems"), on a question that Carl Friedrich Gauss (*q.v.*) had left unsettled in his *Disquisitiones Arithmeticae* (1801). After a brief teaching assignment in a Berlin girls' school, Cantor joined the faculty at the University of Halle, where he remained for the rest of his life, first as *Privatdozent* (lecturer, paid by fees only) in 1869, then assistant professor in 1872, and full professor in 1879.

Early work

In a series of 10 papers from 1869 to 1873, Cantor dealt first with the theory of numbers; this subject reflected his own fascination with the subject, his studies of Gauss, and the influence of Kronecker. On the suggestion of Heinrich Eduard Heine, a colleague at Halle who recognized his ability, Cantor then turned to the theory of trigonometric series (see ANALYSIS, FOURIER), in which he extended the concept of real numbers. Starting from the work on trigonometric series and on the function of a complex variable done by the German mathematician Bernhard Riemann (*q.v.*) in 1854, Cantor in 1870 showed that such a function can be represented in only one way by a trigonometric series. Consideration of the collection of numbers (points) that would not conflict with such a representation led him, first, in 1872, to define irrational numbers in terms of convergent sequences of rational numbers (quotients of integers) and then to begin his major lifework, the theory of sets and the concept of transfinite numbers.

An important exchange of letters with Richard Dedekind (*q.v.*), mathematician at the Brunswick Technical High School, who was his lifelong friend and colleague, marked the beginning of Cantor's ideas on the theory of sets (see SET THEORY). Both agreed that a set, whether finite or infinite, is a collection of objects (*e.g.*, the integers, $\{0, \pm 1, \pm 2 \ldots\}$) that share a particular property while each object retains its own individuality. But when Cantor applied the device of the one-to-one correspondence (*e.g.*, {a, b, c} to {1, 2, 3}) to study the characteristics of sets, he quickly saw that they differed in the extent of their membership, even among infinite sets. (A set is infinite if one of its parts, or subsets, has as many objects as itself.) His method soon produced surprising results.

Set theory

In 1873 Cantor demonstrated that the rational numbers, though infinite, are countable (or denumerable) because they may be placed in a one-to-one correspondence with the natural numbers (*i.e.*, the integers, as 1, 2, 3, . . .). He showed that the set (or aggregate) of real numbers (composed of irrational and rational numbers) was infinite and uncountable. Even more paradoxically, he proved that the set of all algebraic numbers (the solutions of simple algebraic equations, as, $\sqrt{2}$ and 5) contains as many components as the set of all integers and that transcendental numbers (those that are not algebraic, as π), which are a subset of the irrationals, are uncountable and are therefore more numerous than integers, which must be conceived as infinite.

But Cantor's paper, in which he first put forward these results, was refused for publication in *Crelle's Journal* by one of its referees, Kronecker, who henceforth vehemently opposed his work. On Dedekind's intervention, however, it was published in 1874 as "Über eine Eigenschaft des Inbegriffes aller reellen algebraischen Zahlen" ("On a Characteristic Property of All Real Algebraic Numbers").

While honeymooning the same year with his bride, Vally Guttman, at Interlaken, Switzerland, Cantor met Dedekind, who gave a sympathetic hearing to his new theory. Cantor's salary was low, but the estate of his father, who died in 1863, enabled him to build a house for his wife and five children. Many of his papers were published in Sweden in the new journal *Acta Mathematica*, edited and founded by Gösta Mittag-Leffler, one of the first persons to recognize his ability.

Cantor's theory became a whole new subject of research concerning the mathematics of the infinite (*e.g.*, an endless series, as 1, 2, 3, . . ., and even more complicated sets), and his theory was heavily dependent on the device of the one-to-one correspondence. In thus developing new ways of asking questions concerning continuity and infinity, Cantor quickly became controversial. When he argued that infinite numbers had an actual existence, he drew on ancient and medieval philosophy concerning the "actual" and "potential" infinite and also on the early religious training given him by his parents. In his book on sets, *Grundlagen einer allgemeinen Mannigfaltigkeitslehre* ("Foundations of a General Theory of Aggregates"), Cantor in 1883 allied his theory with Platonic

metaphysics. By contrast, Kronecker, who held that only the integers "exist" ("God made the integers, and all the rest is the work of man"), for many years heatedly rejected his reasoning and effectively blocked his appointment to the faculty at the University of Berlin.

In 1895–97 Cantor fully propounded his view of continuity and the infinite, including infinite ordinals and cardinals, in his best known work, *Beiträge zur Begründung der transfiniten Mengelehre* (published in English under the title *Contributions to the Founding of the Theory of Transfinite Numbers*, 1915). This work contains his conception of transfinite numbers, to which he was led by his demonstration that an infinite set may be placed in a one-to-one correspondence with one of its subsets. By the smallest transfinite cardinal number he meant the cardinal number of any set that can be placed in one-to-one correspondence with the positive integers. This transfinite number he referred to as aleph-null, $\aleph_0$. Larger transfinite cardinal numbers were denoted by aleph-one $\aleph_1$, aleph-two $\aleph_2$, $\cdots$, $\aleph_h$, $\cdots$. He then developed an arithmetic of transfinite numbers that was analogous to finite arithmetic. Thus, he further enriched the concept of infinity. The opposition he faced and the length of time before his ideas were fully assimilated represented in part the difficulties of mathematicians in reassessing the ancient question: "What is a number?" Cantor demonstrated that the set of points on a line possessed a higher cardinal number than $\aleph_0$. This led to the famous problem of the continuum hypothesis, namely, that there are no cardinal numbers between $\aleph_0$ and the cardinal number of the points on a line. This problem has, in the first and second halves of the 20th century, been of great interest to the mathematical world and was studied by many mathematicians, including the Czech-Austrian-American Kurt Gödel and the American Paul J. Cohen.

Transfinite numbers

Although mental illness, beginning about 1884, afflicted the last years of his life, Cantor remained actively at work. In 1897 he helped to convene in Zürich the first international congress of mathematics. Partly because he had been opposed by Kronecker, he often sympathized with young, aspiring mathematicians and sought to find ways to ensure that they would not suffer as he had because of entrenched faculty members who felt threatened by new ideas. At the turn of the century, his work was fully recognized as fundamental to the development of function theory, of analysis, and of topology. Moreover, his work stimulated further development of both the intuitionist and the formalist schools of thought in the logical foundations of mathematics. He died at the University of Halle on January 6, 1918. His work has substantially altered mathematical education in the United States and is often associated with the "new mathematics."

BIBLIOGRAPHY. *Gesammelte Abhandlungen*, ed. by ERNST ZERMELO (1932), contains the collected works of Cantor edited by an authority on set theory. For biographical information, see ERIC T. BELL, *Men of Mathematics* (1937, reprinted 1961), a well-developed history of mathematics with a full chapter on Cantor; DIRK J. STRUIK, *A Concise History of Mathematics* (1948), which discusses the principal mathematicians of the times and their influence on Cantor; and HERBERT MESCHKOWSKI, *Denkweisen grosser Mathematiker* (1961; Eng. trans., *Ways of Thought of Great Mathematicians*, 1964), which devotes a chapter to an elementary account of Cantor's theory of sets.

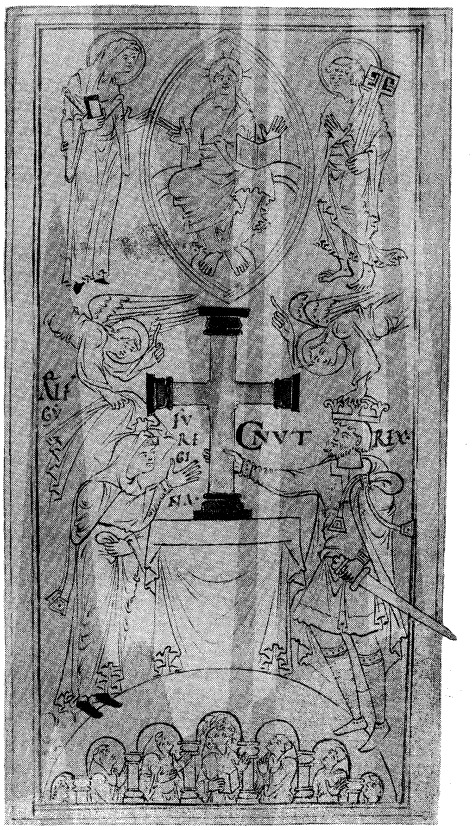
Canute the Great, of Denmark and England

Canute (Knut or Cnut), king of England and Denmark and, after 1028, of Norway, became a power in European politics, respected by emperor and pope. Yet more remarkable than his acquisition of an empire was his development from a typical Viking to an enlightened monarch, to the surprise of contemporaries such as Fulbert, bishop of Chartres, who wrote to him: "We were amazed at your wisdom and equally at your piety." In England he was remembered chiefly as a wise ruler, but



King Canute with Aelfgifu placing a cross on the altar of Newminster Abbey, Morpeth. Angels point to Christ flanked by the Virgin and St. Peter, as the source of royal power. Drawing from the *Newminster Liber Vitae*, c. 1016–20. In the British Museum (Stowe MS. 944).

By courtesy of the trustees of the British Museum

in Scandinavia his minstrels praised his courage and military success, and the sagas his wiliness and diplomatic skill.

Neither the place nor date of Canute's birth is known. As a youth he accompanied his father, Sweyn I Forkbeard, king of Denmark, on his invasion of England in 1013. Canute was left in charge of the fleet at Gainsborough, Lincolnshire, and it was probably then that he met Aelfgifu, daughter of an ealdorman (chief officer) of Northumbria who had been murdered with King Aethelred II's connivance in 1006; she bore him two sons, Sweyn and Harold. Sweyn I Forkbeard was accepted as king of England by the end of 1013 but died in February 1014, and the English invited Aethelred to return. Canute and the men of Lindsey planned a combined expedition, but Canute deserted his allies at Easter and sailed to Denmark, putting his hostages, savagely mutilated, ashore at Sandwich. In 1015 he returned and began a long struggle with Aethelred's son Edmund II Ironside. Earl Uhtred of Northumbria submitted to Canute in 1016 and was murdered in his hall. After Aethelred died in April 1016, the English *witan* (council) elected Canute king at Southampton, but those councillors who were in London, with the citizens, elected Edmund. After several campaigns Canute won a victory at Ashingdon, Essex, on October 18, and the kingdom was then divided; but Edmund died on November 30, and Canute succeeded to the whole.

Elected king

His first actions were ruthless: he gave Englishmen's estates to reward his Danish followers; he engineered the death of Edmund's brother Eadwig; and he had some prominent Englishmen killed or outlawed. Edmund's infant sons, however, eventually reached an asylum in Hungary. Already in 1016, Canute had given the earldom of Northumbria to the Norwegian Viking Eric of Hlathir, and in 1017 he put another famous Viking chief, Thorkell the Tall, over East Anglia. Yet Canute did not

rule like a foreign conqueror for long: by 1018 Englishmen were holding earldoms in Wessex and Mercia. The Danish element in his entourage steadily decreased. Thorkell was outlawed in 1021, and, during the rest of the reign, of his three most influential advisers only one was a Dane. Canute paid off most of his fleet in 1018, and the Danes and the English reached an agreement at Oxford, one authority adding "according to Edgar's law." A draft of the treaty survives, written in the style of Archbishop Wulfstan of York, who later drew up Canute's laws, mainly based on previous legislation. It is likely that it was Wulfstan who aroused in the young Canute an ambition to emulate the best of his English predecessors, especially King Edgar. Canute proved an effective ruler who brought internal peace and prosperity to the land. He became a strong supporter and a generous donor to the church, and his journey to Rome was inspired by religious as well as diplomatic motives.

Foreign relations

He needed English support against external dangers. King Aethelred's sons were in Normandy, and Canute married their mother, Emma, in 1017 to prevent her brother, Duke Richard II, from espousing their cause. English forces helped to secure Canute's position in Scandinavia in 1019, when he went to Denmark to obtain the throne on his brother's death; in 1023, when the outlawed Thorkell was causing trouble; and again in 1026, when his regent in Denmark, Ulf Jarl, the husband of his sister Estrid, joined the king of Norway and the king of Sweden in a coalition against Denmark. Though Canute was defeated at the Battle of the Holy River, Sweden, terms were made. Scandinavian sources attribute to Canute Ulf's death soon afterward. Canute fomented with bribes the unrest of Norwegian landowners against their king, Olaf II Haraldsson, and was able to drive him out in 1028. He put Norway in charge of Haakon, son of Eric of Hlathir, and, after Haakon's death, of his concubine Aelfgifu and their son Sweyn. Olaf attempted to return in 1030 but fell at Stiklestad. Aelfgifu and Sweyn became unpopular and fled to Denmark in 1035 before Canute's death.

In England, peace was broken only by Canute's expedition to Scotland in 1027, by which he secured recognition from three of the Scottish kings. English trade profited by Canute's control of the Baltic trade route. On his pilgrimage to Rome, timed for him to attend the coronation of the emperor Conrad II in 1027, he secured from the latter and other princes whom he met reductions in tolls for English traders and pilgrims. Denmark benefitted from his friendly relations with the Emperor, who surrendered Schleswig and territory north of the Eider River when negotiations were begun before Canute's death for the marriage of the Emperor's son Henry to Canute's daughter Gunhild.

Canute died on November 12, 1035. Neither his illegitimate son Harold, who ruled England until 1040, nor his legitimate son Hardecanute, who succeeded to Denmark in 1035 and to England in 1040, inherited his qualities. The English reverted to their old royal line in 1042, and Denmark passed to Sweyn II, son of Earl Ulf and Estrid.

Canyons, Submarine

For more than a century it has been known that there are valleys cut into the sea floor. Because most land valleys have been interpreted as the result of erosion by rivers, which lose their power to cut when they enter the sea, the origin of these marine valleys represented a puzzle. At first they were interpreted in terms of the submergence of once dry land, but that explanation became less convincing as additional data showed the wide distribution of the sea valleys. Not only did they prove to be abundant on most of the continental slopes that lead from the continental shelf to the deep ocean floor, but more recently it has been shown that they may occur at any depth.

Because the oceans could not have been lowered sufficiently to allow rivers to cut these deep valleys, other explanations were set forth. Of these, the most popular by far has been sea-floor currents. Density currents (*q.v.*) can flow down slopes wherever the ocean water becomes heavier than the surrounding water because of its sediment content; such density currents are called turbidity currents. The sediment content can be generated by water waves (*q.v.*) or by the sliding and slumping of sediments on the continental shelf and slope (*q.v.*). The American geologist Reginald Aldworth Daly suggested in 1936 that these density currents had actually cut the valleys of the sea floor. The idea gained much acceptance in the 1950s after B. Heezen and M. Ewing, of Lamont Geological Observatory, called attention to transatlantic cable breaks off the Grand Banks that accompanied the 1929 earthquake. These breaks occurred in a succession that suggested they were caused by high-speed turbidity currents that roared down the slopes with velocities of up to 60 miles an hour.

This article treats the nature and distribution of submarine canyons and considers the several mechanisms of origin that have been proposed. For additional information on sediment transport, see DENSITY CURRENTS and FLUVIAL PROCESSES. See also CONTINENTAL SHELF AND SLOPE; OCEAN BASINS; and RIVER DELTAS for relevant discussions of the physiographic locale of submarine canyons; and MARINE SEDIMENTS and RIVERS AND RIVER SYSTEMS for treatment of the sediments involved and the relation of submarine to land valleys, respectively.

TYPES OF SUBMARINE VALLEYS

Analogy to terrestrial canyons

The valleys of the sea floor are termed submarine canyons because profiles based on soundings show that many, perhaps most, of the valleys are similar to what are called canyons on land. That is, they have great relief, steep walls, and a V-shaped cross section. Once this name was applied, it was natural to apply the same name to all marine valleys. This is still a common practice, but it is no more reasonable than it would be to call all land valleys canyons. Actually, there are as many types of valleys on the sea floor as there are on land. In addition to true canyons, fault valleys (attributable to deformation of the earth's crust) are found both on the continents and on the sea bottom. Landslide valleys also occur in both environments, and these are quite different from erosion canyons, the difference being catastrophic versus gradual development. The small elongated depressions that cut alluvial fans (*q.v.*) on land can be compared with the valleys that cut the great fans of the sea floor. The U-shaped valleys that result on land from glacial erosion have their counterpart in the similar submarine valleys that cut the continental shelf off glaciated areas.

At least three types of sea-floor valleys are distinct from land types. The shallow, discontinuous valleys that cross or partly cross the continental shelves in a few areas comprise one type. A second occurs near a few large deltas, in the form of a relatively straight-sided trough that crosses the shelf and extends down the slope beyond. Finally, there are low-walled, trough-shaped valleys that wander across the deep-sea floor. None of these valley types would be called a canyon if it were exposed on land.

Because of the diversity of types, submarine valleys may most simply be discussed according to the classification above. Although all the valleys could conceivably have been formed by the same process, such as density currents, their origins were likely more diverse.

PHYSICAL CHARACTERISTICS OF CANYONS OF THE SEA FLOOR

The best known and probably the most common type of ocean-floor valley can properly be called the submarine canyon. These formations have an extraordinary resem-

blance to river-cut land canyons. In addition to their V-shaped cross sections, their floors slope outward as continuously as do land canyons. They have many entering tributaries that form the dendritic (branching) pattern characteristic of land canyons. Their steep walls frequently have rock outcrops, although a sediment cover is more common than in land canyons, and most of the sea canyons have similar winding courses.

Vast dimensions

The vertical dimensions of submarine canyons are surprising. Most of them have walls thousands of feet high, and the highest, in the Bahamas, rises almost three miles from the canyon floor—dwarfing, by comparison, the mile-high walls of the Grand Canyon. Some canyons have been traced for slightly more than 200 miles in length, but most extend less than 30 miles. Usually they can be traced as far as the base of the steep part of the continental slopes, often more than a mile in depth. Their width varies in the same manner as that of land valleys. A narrow gorge off La Jolla, California, is as deep as it is wide, but the more typical canyons have widths of many miles. A three-mile-deep canyon in the Bahamas, for example, is 23 miles wide at its deepest point. By comparison, the Grand Canyon is about 12 miles wide. In both cases, the average slope is small, but photographs show vertical rock walls in the Bahama Canyon, and the Grand Canyon has vertical walls interspersed with terraces and pyramidal buttes (flat-topped and steep-sided hills). The seaward gradients of the canyon floors are generally steeper than those of land canyons. The average floor slope is about 300 feet per mile, but the numerous canyons that closely approach the coastline have high gradients at their heads, sometimes as great as 45°. The gradients almost always decrease in the outer portions.

The appearance of the canyons has been ascertained in recent years both by lowering cameras to the bottom and by observation from deep-diving vehicles. The dives, which have penetrated to depths of over 7,000 feet within a canyon, have been particularly useful in describing physical features. They have indicated that vertical or even overhanging walls are commonplace, and that canyon walls often are grooved or polished as if they had been smoothed by a glacier. The floors, while generally covered with cobbles and other coarse sediment, are locally bare rock. Some have ripple-marked surfaces, which have been shown by remote camera pictures to occur at depths of more than two miles. The floors may vary considerably in gradient, ranging from a gentle slope to a steep drop-off, with the latter often occurring where boulders, fallen from the walls, have allowed sediments to build up above this obstruction.

All of the preceding features suggest that canyons are subject to active marine processes and are by no means mere remnants of long past erosional processes. Further evidence that conditions are far from static comes from repeated soundings taken along the same ranges at the canyon heads. It has been known since the mid-20th century that the profiles sometimes undergo radical changes. Apparently depth increases very suddenly, but shoaling occurs at a more gradual pace. This sudden deepening has broken cables—notably off the Congo, where a canyon extends seaward for 120 miles. Piers and jetties built into submarine canyon heads have collapsed from the sudden removal of sediment on which they were resting.

The nature of the rocks on the canyon walls has been determined by dredging and by observation from deep-diving vehicles. Most of it has proved to be relatively soft and hence rather easily eroded, but there are some canyons that have been cut through very hard rock, even quartzite. Granite walls have been found in several places, and one vertical granite cliff was discovered in a vehicle dive to 4,150 feet off the tip of Baja California. There, both walls of the canyon were granite; in some areas only one of the walls is hard rock, whereas the other wall is relatively soft.

GEOGRAPHIC DISTRIBUTION OF SUBMARINE CANYONS

Submarine canyons are found along most continental slopes, although they have not yet been discovered around Antarctica nor along the slope into the Arctic off northern Europe and Asia, where soundings are spotty because of ice packs. Canyons are cut into the slopes off the Hawaiian Islands and possibly a few other oceanic islands. Soundings on these insular slopes are generally too incomplete to determine whether or not canyons are present. Along some slopes, canyons are as common as on typical mountain fronts, but elsewhere the slopes appear to be free from any canyons for many miles. In general, canyons are scarce wherever the upper continental slopes are very gentle, as south of Cape Hatteras and around Antarctica. A surprising concentration of canyons is found around Ceylon, the tip of Baja California, the east coast of the U.S. north of Cape Hatteras, and along the northwest coast of the Mediterranean. There appears to be little if any relationship between canyons and latitude. The Ceylon canyons and the Congo Canyon are near the Equator, but the longest and largest canyons in the world are in the Bering Sea. The oceanic slopes that are not bordered by either continents or large islands appear to lack submarine canyons, but most of these slopes are not yet sufficiently well explored to make the conclusion certain. Off New England, the oceanic slope with many canyons is separated from the land valley by a shallow bank and a deep gulf inside, but the canyons may have been cut before the inner shelf was deepened by glaciation.

Concentrations of canyons

RELATION OF SUBMARINE CANYONS TO ADJACENT LAND VALLEYS

From a worldwide point of view, it is difficult to generalize about the relationship between sea canyons and the river valleys on adjacent land areas. The canyons, such as those off the east coast of the U.S., head far out from the land and, as most of them lack connecting shelf valleys, it is not known whether they are related to the adjacent land valleys and to the estuaries (*q.v.*) at the valley mouths. When the canyons occur near the coast, it is easier to determine such a relationship. In a study of 57 submarine canyons that come close to the coast, it was determined that 46 (81 percent) were located directly off river valleys, and the remainder had no river valley inside the canyon head. At least one of the latter group, located in northern California, may have been connected with a land canyon before the faulting along the San Andreas Rift shifted the sea floor to the northeast, so that it is now located off a land cliff between canyons. Elsewhere, the shift of a stream mouth after the canyon had been cut may account for the lack of any connection, as at Cap Breton in southwest France, where the Adour River changed its course in the 15th century.

Pleistocene drainage and changes of sea level

The mouths of many streams were drowned by the relatively recent rise of sea level, which accompanied the melting of the great ice sheets of the Pleistocene Epoch (*q.v.*). The relationship of such bays to canyon heads can be compared. In a study of 77 submarine canyons, 13 were found to enter drowned valleys, 25 to lie outside broad embayments that are not clearly drowned valleys, and 39 to occur either off long straight beaches or relatively straight sea cliffs.

Another important consideration is the comparison between the type of land valley with the adjacent canyon on the sea floor. In almost all cases the characteristics of marine canyons are very different from those of land canyons, which usually have much lower gradients, much gentler side slopes, and much broader floors. The closest resemblance of land canyons to adjacent sea canyons is along the west coast of Corsica, but even there, the land valley mouths have low gradients and wide floors compared to the high gradients and narrow floors of the submarine canyon heads.

The drainage pattern of the land valleys also differs from the adjacent submarine canyons. The submarine canyons have a considerable number of tributaries at their heads, which makes them comparable to the land canyons, but in general the land valleys have more tributaries in their lower courses than do submarine canyons. An exception is the large Monterey Submarine Canyon, which has a fine display of tributaries along its entire course.

TRANSPORT OF SEDIMENT THROUGH SUBMARINE CANYONS

Streams carry large quantities of sand to the coast, and wave erosion adds to the supply. Along relatively straight coasts, like those of California, the diagonal approach of water waves (*q.v.*) causes the transport of this sediment along the shore in the direction in which the waves are approaching.

When canyon heads extend across the continental shelf to, or almost to, the coast, they have an enormous effect on sediments being carried along the coast by longshore currents. This sediment, consisting largely of sand, is carried in short jumps, in a process called saltation. Once the sediment has passed the lip of the canyon and falls on the steep sides, there is little chance for the currents, which are induced mostly by waves, to lift it clear. As it piles up on the walls, the sediment becomes unstable and slumps to the canyon floor. Repeated depth measurements across the canyons show that this process would soon fill the heads level with the surrounding shelf if there were no means of carrying the sediment down the canyon. Thus a fill of ten feet in a period of a few months is not uncommon, but ordinarily within about a year the canyon head has somehow been flushed and the sediment must have moved seaward.

Evidence of canyon flushing

The cause of canyon flushing is still somewhat uncertain. Sand flows have been observed in places along the canyon walls where the slopes have become oversteep, but these flows do not take place at slope angles of less than about 30°. There are currents that alternately move up and down the canyon floors with velocities of up to one mile an hour. Such velocity is sufficient to transport sand. The available evidence indicates that the currents moving downcanyon are the strongest. This is supported by ripple markings observed on canyon floors, most of which indicate a downcanyon movement. These ordinary currents, however, are in almost constant operation; so if they were the sole cause of canyon flushing, the long periods of canyon-head filling could not occur. Apparently, some more powerful process operates from time to time to reverse this tendency to fill. Furthermore, cobbles are transported down the canyon floors, and these relatively weak currents are certainly not the cause of their movement. Fairly substantial evidence indicates that large rocks that have fallen from the walls are eventually carried away. Instruments in the head of the canyon near the Scripps Institution of Oceanography have been lost repeatedly. Even an old car body was carried down. On one occasion, a current meter registered three knots of current before it disappeared.

It is thought that the powerful forces at work here are set into operation during large wave periods, but this is not yet confirmed. Some type of density current may be triggered by the sediment thrown into suspension by the large waves. Alternatively, the fill on the canyon floor may be transported by some type of landslide.

Whatever the cause of canyon flushing, there can be little doubt that sediment is somehow carried down the entire canyon length and is the means of building the great fans at the canyon mouths. The thickness of sedi-

ment in some of these fans has been measured, and its total volume far exceeds the volume that would be produced by the cutting of the canyons. This indicates that the fans are largely formed by sediment that is introduced from the land and moves down the canyon.

Presence of "fan-valleys"

One of the interesting features of the submarine fans at canyon mouths is the presence of relatively shallow valleys truncating the upper beds of the fan. These are called "fan-valleys." They differ from submarine canyons because they have relatively low walls, distributaries rather than tributaries (channels that transport water and sediment away from, not toward, the main canyon), and are usually bordered by levees, comparable to the levees on the sides of channels that cross river deltas (*q.v.*). These levees sometimes occur 100 feet or more above the channel floors, and they may rise a score of feet above the general level of the adjacent fan. They apparently result from deposition of the overflow of currents moving down the fan-valley.

Many of the fans are not cut by valleys. However, it is possible that fans can be built upward while valleys cut through them during the process. Recent evidence indicates that the fan-valley outside La Jolla Submarine Canyon has been cut by a change from depositional processes to those of erosion. The fan-valley outside Monterey Canyon has developed a meander comparable to those of rivers flowing in a flood plain.

ORIGIN OF SUBMARINE CANYONS

The discussion of the character of these canyons has provided much of the basis for the discussion of their origin. The resemblance of the canyons on the sea floor to those on land is, of course, an argument favouring a common origin. Also, the location of most known canyons off river valleys adds weight to the argument. If, however, submarine canyons are simply the submerged lower portions of land canyons, there should be a closer relationship between the submerged and the emerged portions. As A.O. Woodford has emphasized, the profiles of the land valleys show a sharp break when they are continued into the sea canyons. A sudden steepening of gradient is found, along with a decided change of character. Nor does it seem reasonable that virtually all continental margins have sunk, submerging the land canyons to extreme depths, although this explanation may account for some submarine canyons, of which those on the west coast of Corsica may well be an example. The discontinuity at the juncture between land and sea canyons could

From F. Shepard, *The Earth Beneath the Sea;* copyright by the John Hopkins University Press

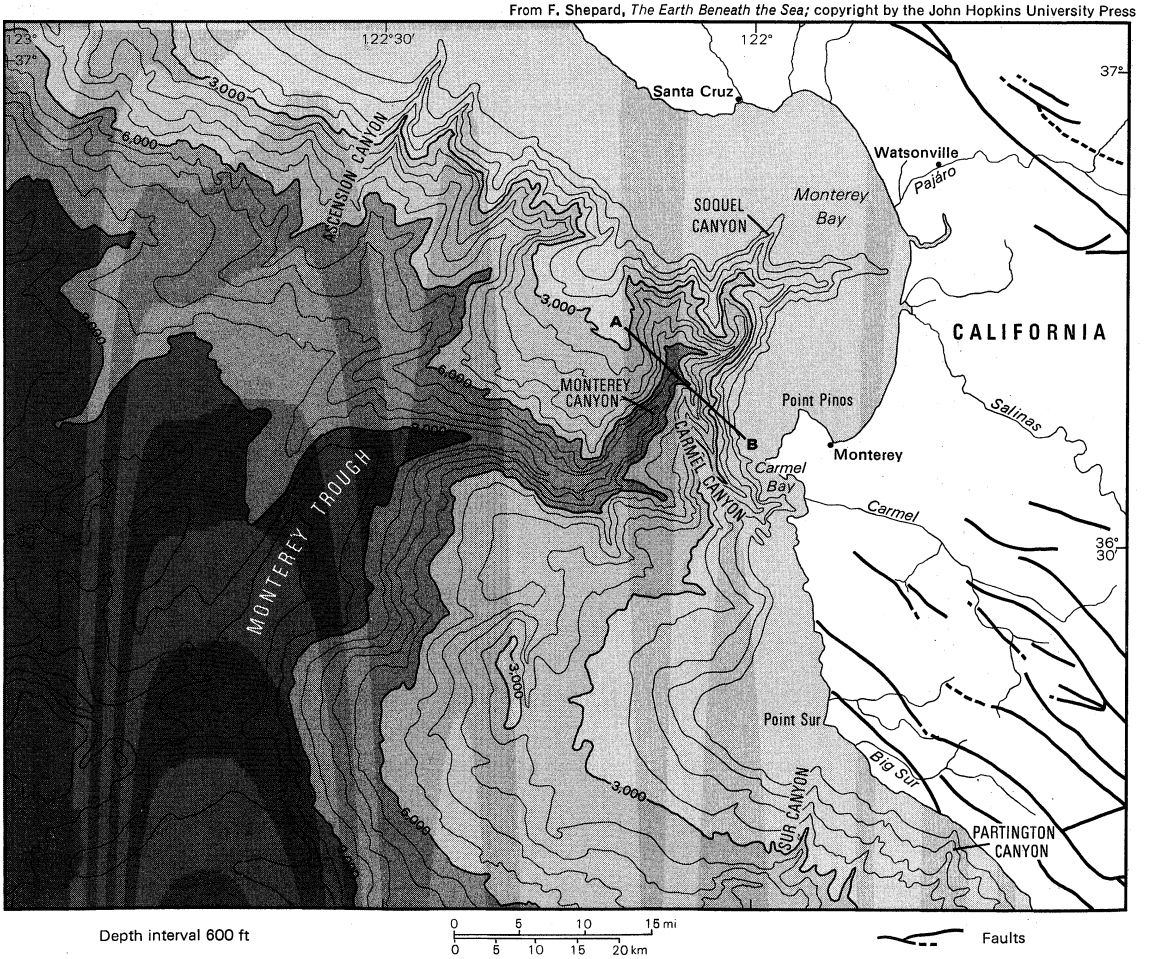

Figure 3: Ocean floor off the coast of Monterey, California. Profile along line A–B is shown in Figure 1.

be due to the delta that is built in the estuary at the mouth of the land canyon.

Importance of marine processes

Accumulating evidence indicating the importance of marine erosion in submarine canyons, and the fact that they are so different in character from the adjacent land valleys, forms convincing evidence that submarine canyons are due primarily to marine processes. In La Jolla Canyon the canyon head is being cut back towards the land at about one foot a year. If currents or other processes are capable of transporting the boulders that fall from the walls to the canyon floor, they should also be capable of eroding the canyon. Finally, the vertical or overhanging walls that occur in the canyons seem to be proof of active erosion. If these walls had been cut long ago, the action of organisms that live on them and the erosive effect of sediments sliding down from the shelf into the canyon should have greatly reduced the declivities. There must be active erosion along the canyon floors and lower walls to maintain the steep slopes.

Creeping action is occurring in the sediment at the head of La Jolla Canyon. A series of stakes driven in a line across the floor of this canyon by Robert Dill, an American marine geologist, show that the stakes in the centre move faster than those on the sides, as in a glacier. Also, an occasional major disturbance carries away all the stakes. Some stakes have been bent downcanyon because the sediment at the surface creeps forward at a faster rate than that beneath. Even in the fan-valley beyond the canyon off La Jolla, the fill shows cracks and steps that suggest a creeping movement.

On the other hand, it does not seem likely that the major transfer of sediment down the canyons, nor their cutting, are due principally to creeping action. Cores taken in the canyon floor have rather well-preserved stratification. If the sediment was creeping continuously down the canyon, this stratification would be much disturbed and would show many drag folds (bending of strata due to the dragging of one bed over and past another) oriented downcanyon. Therefore, it seems likely that the major erosion and transportation of sediments downcanyon is the result of currents which are generally thought to be density currents, even though positive proof is still lacking.

Ages of submarine canyons. Little is known about the age of the existing submarine canyons. Some geologists have thought that they were cut during low sea-level stages of the glacial period, but the huge size of the fans found beyond the canyons means that they probably have been developing for several million years. This would imply an age that antedates the glacial period. Furthermore, geologists have found many features in ancient rocks that appear to represent old submarine canyons subsequently filled with sediments. Lowered sea levels would have helped the movement of sediments onto the continental slopes because of the exposure of the shelves. Canyons certainly are forming, and there is little reason to confine their origin to the short periods when the shelves were laid bare by lowered sea level. These episodes must have been too brief for marine processes to excavate the huge gorges out of granite.

Pre-Pleistocene and present formation

The investigations of a huge canyon in the Bahamas has shown that it was probably in existence in the Pliocene, a period prior to glaciation. It is quite probable that this canyon has been forming for millions of years, while the Bahama limestone banks grew upward, keeping pace with the sinking of the sea floor. Deep wells show that Cretaceous rocks underlie the younger formations in the Bahamas at depths of 6,000 to 7,000 feet. So far as is known, these all were deposited in shallow water, whereas deep-water formations are found along the walls of the submarine canyon.

Submarine fault valleys. Blocks of the earth's crust can drop between upraised masses and can produce valleys in this way. Death Valley in California, the Jordan Valley in the Near East, and the rift valleys of Africa are examples of land valleys in earthquake belts. Most of these valleys have relatively flat floors, straight steep walls, basin depressions, developing lakes, and they lack tributaries. Using the same criteria, fault valleys can be identified on the sea floor. The valley of this type that extends down Sagami Bay in Japan was the locus of the 1923 earthquake that destroyed much of Tokyo and Yokohama. Actually, there are clear signs that this valley, although essentially due to faulting, has been modified by marine processes. Various sea-floor valleys in the earthquake belts south of the Aleutian Islands also

By courtesy of the Geological Society of America

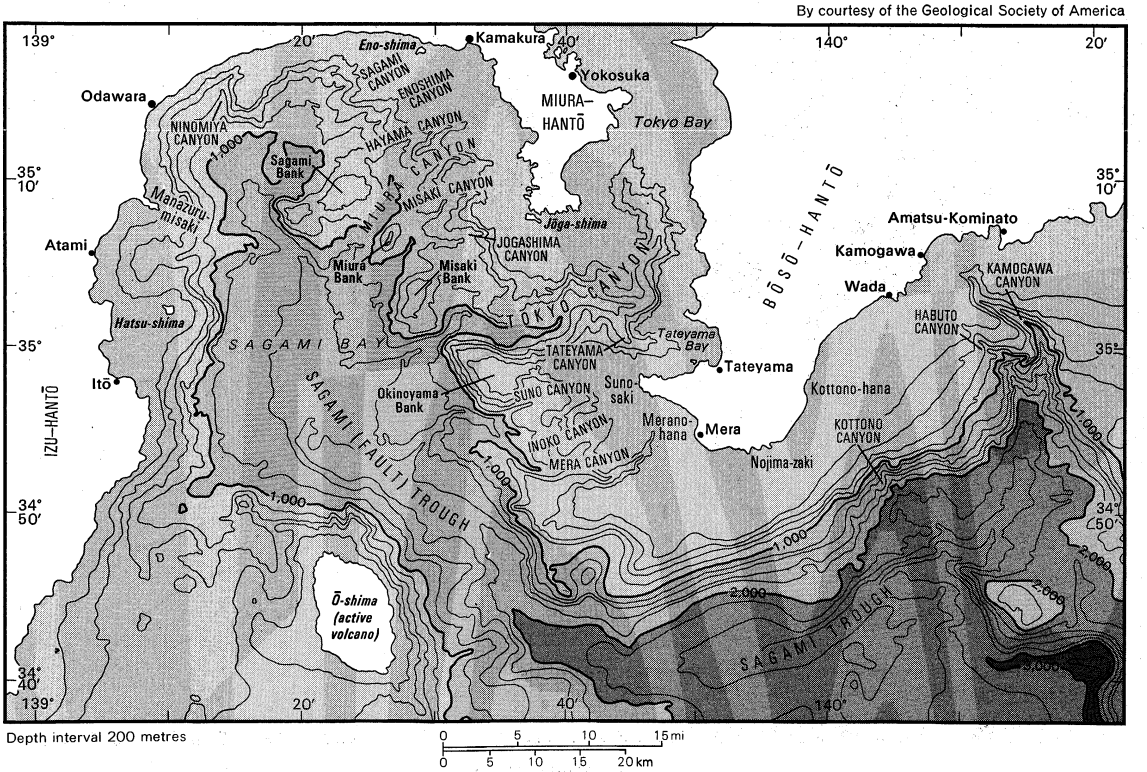

Figure 4: Underwater relief contours off the coast of east central Honshū, Japan.

appear to have the characteristics of fault valleys. Some of them are V-shaped but otherwise suggest fault origin.

Continental shelf valleys. Off New York Harbour, the continental shelf is creased by a shallow valley that can be traced almost to its outer edge. It has walls generally less than 100 feet high, in contrast to those of the submarine canyons, which are thousands of feet high. Its floor does not slope outward continuously, like the canyons, nor are there any entering tributaries. A few other valleys of this sort are found on other continental shelves, but most of them are less continuous. One is found in the English Channel and another in the Sunda Sea between Java and Borneo. These presumably are partly filled remnants of valleys that were cut by rivers during the low stages of sea level of the glacial period.

Relation to glaciated coasts

The other type of shelf valley, termed glacial troughs or glacial channels, is found off most glaciated coasts. These are cut deeper than the river-type of shelf valley and commonly have depths of at least a thousand feet. Their broad floors show deep basin depressions, and they have a considerable number of entering tributaries. Their glacial origin seems certain because many of them are continuations of glacial fjords. Notable examples are the deep Gulf of Maine, the trough in the Gulf of St. Lawrence, and the deep Strait of Juan de Fuca.

Slope gullies. Many submarine slopes have a valley with low walls that are rarely more than 100 feet high. They start and stop on the slope at various depths and have few tributaries. At their outer termini, most have hummocks suggestive of landslide origin. Such slope gullies are found in the front of several great deltas, notably those of the Mississippi, the Rhône, and the Fraser. They change position as the delta builds forward, as shown by comparing old and new surveys. They are the result of slumping of recent sediment.

Delta-front troughs. Out beyond the broad deltas of the Ganges and Indus, broad-floored valleys extend across the shelf and down the adjacent floor. These valleys seem to be related to the delta building. They differ from submarine canyons in their broad trough shape, absence of entering tributaries, and their relatively straight course, in contrast to the winding courses of the canyons. Outside these troughs are great fans cut by fan-valleys, much the same as those outside submarine canyons.

At present, there is not sufficient information to fully understand the origin of the delta-front troughs. Apparently, sediment moves out along them, as along submarine canyons. Off the Mississippi, the head of a delta-front trough has been filled for 30 miles; but a typical trough occurs beyond that distance, and the filled portion of the trough was only discovered by borings and seismic reflection profiling across the shelf.

Role of turbidity currents

Deep-sea channels. The existence of very long channels cutting the deep-sea floor of both the Atlantic and Pacific has been well established. They are cut to depths of as much as several hundred feet below the surrounding sea floor. They have relatively flat floors that are several miles across and, so far as is known, they slope continuously in one direction. Some of them have entering tributaries. Sediments from the channel floors include sand, indicating that strong currents are operating along them. Some of the channels extend out beyond the continental slopes, but others run essentially parallel to the base of the slopes. These channels have been attributed by B. Heezen and others to turbidity currents, but there is no clear evidence. Some valleys may represent shallow fault troughs that have been the locus of turbidity currents coming out from the continental slopes.

BIBLIOGRAPHY. Articles and books on this subject, although by prominent geologists, were written before much was known about the canyons and therefore have become seriously out-of-date. Some of these led to fruitful discussions and introduced important ideas, such as R.A. DALY, "Origin of Submarine Canyons," *Am. J. Sci.*, 31:401–420 (1936), in which the first attempt was made to explain the canyons by turbidity currents. Also, B.C. HEEZEN and M. EWING, "Turbidity Currents and Submarine Slumps, and the 1929 Grand Banks Earthquake," *Am. J. Sci.*, 250:849–873 (1952), gave the first important, although debatable, evidence of highspeed turbidity currents breaking submarine cables. H.W. MENARD, JR., "Deep-sea Channels, Topography, and Sedimentation," *Bull. Am. Ass. Petrol. Geol.* 39:236–255 (1955), gives a complete discussion of some West Coast valleys that cross the fans near the base of the continental slopes, showing their contrast with the canyons that occur higher up the submarine slopes. The only recent attempt to synthesize the rapidly growing information on submarine canyons is found in F.P. SHEPARD and R.F. DILL, *Submarine Canyons, and Other Sea Valleys* (1966).

(F.P.S.)

Cape of Good Hope

Cape of Good Hope, or Cape Province—known as Kaapprovinsie in the Afrikaans language—is situated on the southern extremity of the African continent and is the largest of the four provinces of the Republic of South Africa. The name Cape of Good Hope, while specifically referring to the promontory about 30 miles south of Cape Town, is officially extended to apply to the entire province. Occupying the southern and western region of the republic, the province has an area of 261,826 square miles (678,129 square kilometres), excluding the Transkei Territories (16,554 square miles, or 42,875 square kilometres), which have been separately administered since 1963. It comprises 56 percent of the total area of South Africa. Officially the province still includes an enclave of 374 square miles (969 square kilometres) around Walvis Bay on the coast of South West Africa; this enclave was annexed in 1884 but since 1926 has been administered as part of South West Africa.

The total population at the time of the 1970 census (excluding the Transkei Territories) was about 4,236,000, of which about 1,360,000 are Bantu (Africans speaking a Bantu language), about 1,752,000 are Cape Coloured (of mixed European, Asian, and African descent), and about 1,102,000 are Whites. About 1,097,000 people live in the metropolitan area of Cape Town, the provincial capital and the legislative capital of the republic (see CAPE TOWN; for coverage of historical aspects, see SOUTHERN AFRICA, HISTORY OF; for coverage of associated physical features, see ORANGE RIVER; and VELD).

Dutch settlement

History. The first European settlement in southern Africa was located in what is now Cape Province. This was the victualling station established in 1652 by the Dutch Vereenigde Oostindische Compagnie at Table Bay, 30 miles north of the promontory that the Portuguese navigator Bartolomeu Dias had named Cabo da Boa Esperança ("Cape of Good Hope") in 1488. In 1814 the Cape settlement was ceded to the British and became the Colony of the Cape of Good Hope. In 1910 the colony was constituted a province of the Union of South Africa (since 1961 the Republic of South Africa).

As the early agricultural ventures of the Dutch East India Company proved inadequate to supply the garrison and ships in transit, lands were assigned to independent settlers in 1657 and, to supplement their labour, from 1658 slaves were imported, at first from West Africa and later in larger numbers from Madagascar, Ceylon, and the East Indies. As the amount of livestock obtainable from the nomadic Hottentots to supply ships also proved insufficient, the company itself began to raise stock and later to encourage settlers to do so. At first the paucity of grazing during the summer dry season necessitated the establishment of pastoral outposts in well-watered localities in the immediate hinterland; later, however, colonial pastoralists moved inland seasonally in search of good grazing, as had the Hottentots.

By 1700 grain, wine, and fruit farms were scattered along the eastern foot of Table Mountain (which overlooks Table Bay) as well as along the western foot of the Hottentots-Hollandsberge and Drakenstein ranges 30 to 40 miles to the east, while pastoral farmers ranged as far as 100 miles to the north and east of Table Bay. To this encroachment the Hottentots offered no sustained resistance, withdrawing before the colonists or accepting service with them as shepherds, guides, and interpreters; in the smallpox epidemic of 1713 thousands died. The survivors fled, and by 1730 no tribal remnants remained

within 250 miles of Table Bay. Concurrently, the growing volume of shipping and the consequent demand for livestock provided the economic incentive for the spread of colonial sheep farmers northeastward beyond the Roggeveldberg and Hantamsberg and eastward through the Karroo (a plateau region) until, by 1779, they were in contact and conflict with the Bantu along the Great Fish River.

Stock thefts and reprisals subsequently resulted in a series of frontier wars; the introduction of some 3,500 settlers by the British in 1820 between the Dutch settlers and the African tribes failed to establish an effective buffer settlement, and pacification was achieved only after a series of annexations had by 1894 advanced the frontier to the Mtamvuna River, the southwestern border of the colony of Natal. All the tribal territories east of the Great Kei River were thus reduced to the status of tribal reserves under colonial administration.

The gradual northward diffusion of pastoralists across the Upper Karroo meanwhile had led to the discovery of diamonds in 1867–68 where the trail to Bechuanaland—followed for half a century by traders and missionaries—crossed the Orange River.

The diamond rush

The discovery of diamondiferous intrusions north of the river precipitated a rush of immigrants. It also led to the annexation of Griqualand West by Cape Colony in 1871, despite conflicting claims by the Orange Free State; to the extension (between 1873 and 1884) of the small Cape Town-to-Wellington railway more than 600 miles inland to Kimberley; and to the construction of railways inland from Port Elizabeth and from the port of East London. The fortuitous discovery of diamonds was particularly timely, since the opening of the Suez Canal in 1869 threatened to bankrupt the colony. The era that followed was one of unprecedented population growth and economic activity that attracted capital from overseas. The attention paid to the potential, although then still unknown, mineral wealth of the hinterland gave impetus to expansion. Political manoeuvring culminated in 1885 in the proclamation of a British protectorate over the area extending north to 22° south latitude, and in 1895 the section south of the Molopo River, the present boundary with Botswana, was incorporated within the Cape Colony.

Natural environment. *Physiography.* Most of the province lies at an altitude of between 3,000 and 5,000 feet above sea level, occupying part of the great interior plateau of southern Africa. The edges of the plateau form conspicuous escarpments that trend southward from the Namaqua Highlands in the northwest to the Roggeveldberg in the southwest and from there eastward as the Nuweveldberge, Sneeuberg, and Stromberg mountains until the southern end of the Drakensberg escarpment is reached. These escarpments separate the plateau from a coastal zone with a varied relief in the west and from the broad basins of the Doorn Karroo and the Great Karroo plateaus to the southwest and south. Across the southern part of the province a series of sandstone ranges of equal height enclose the elongated basin of the Little Karroo, running approximately parallel to the south coast. At the western end of these ranges, a complex of similar ranges runs northward from Cape Hangklip, southeast of Cape Town, to the Bokkeveld, about 200 miles to the north. Lowlands, between the mountains and the coast, are narrow and discontinuous, apart from a strip 10 to 50 miles wide between Mossel Bay and Cape Agulhas (the southernmost tip of the African continent) and an area 20 to 60 miles wide between False Bay (immediately south of Cape Town) and St. Helena Bay (about 100 miles to the north).

Climate. Maritime influence upon the climate is restricted to the coastal fringe. Over most of the province the mean annual precipitation is less than 15 inches, and large areas in the northwest receive less than 5 inches.

Droughts

Years of drought are common. Only the southwestern and southern margins receive more than 25 inches of precipitation, mostly in the form of rain resulting from winter cyclones in the southwest, and summer rain resulting from easterly winds beyond Mossel Bay on the south coast. In the interior most of the rain is from summer thunderstorms; the occasional winter rains and the rarer snowfalls are associated with the passage of cyclones. Solar radiation is intense at all seasons, owing to the latitude, to the elevation, and to the usually clear skies; inland mean daily maximum temperatures usually range from 65° F (18° C) in winter to 90° F (32° C) in summer. Frost occurs on more than 60 nights a year; the frostless season lasts for less than 240 days on the southern margin of the Upper Karroo. Snow occasionally mantles all the higher mountain peaks, and only the coastal zone is frost-free.

Vegetation. The vegetation is predominantly xerophytic (adapted for growth under dry conditions). Thornbush savanna (parklike grassland) occurs in the north, while low-growing Karroo bush vegetation, typified by many species of plants adapted to semidesert conditions, occurs south of the Orange River. Desert shrub and succulents (juicy plants) are found in Namaqualand in the northwest. In the southwest region where winter rainfall occurs, the sclerophyll bush (characterized by plants with thickened hardened foliage) is extraordinarily rich in endemic species. Indigenous forest, predominantly evergreen, is found only on the south coast between Mossel Bay and Algoa Bay and on the southern slopes of the Amatole Range, to the northeast of Algoa Bay, where rain occurs at all seasons; farther east it passes into grassland and, in the coastal zone, into xerophytic low forest and bush.

Animal life. Immense herds of springbok and other antelope, wildebeest (gnu), and zebra formerly ranged the interior, while hippopotamuses were found in all the perennial rivers, and elephant and rhinoceroses roamed the coastal zone from Natal in the east to the Olifants River in the west; lion, leopard, and other carnivores were ubiquitous. Though many local place-names recall this rich and varied animal life, today, apart from the smaller species, it has mostly disappeared. Only depleted remnants of it survive in a few scattered game reserves, in some sparsely settled areas where a few springbok still roam, and in some remote mountain areas where the rare leopard preys on the few surviving baboons. Bird life, however, remains numerous and varied. Along the coast, particularly in the west, cormorants and other sea birds abound, while inland each vegetation zone is associated with its own characteristic birds including, in summer, great numbers of migrants from the Northern Hemisphere.

Population. Four ethnic divisions are to be distinguished in the present population, which in 1970 numbered 1,360,000 Bantu (a similar number lived in the Transkeian Territories, which are now separately administered), 1,752,000 Cape Coloured (largely of mixed European, Hottentot, Javanese, and other descent), 1,102,000 Whites (four-fifths of whom lived in urban areas), and 22,000 Asians, most of whom were Indians living in the towns. East of East London, densities of from 75 to 150 persons to the square mile are usual, but west of Port Elizabeth the population only exceeds 10 to the square mile in a 15-to-50-mile-wide coastal zone extending to St. Helena Bay on the west coast. About three-fifths of the total population is urban, and two-fifths of the population lives in the four largest cities —Cape Town (with a population of 1,097,000), Port Elizabeth (469,000), East London (123,000), and Kimberley (104,000).

Afrikaans, English, Xosa, and Sotho

Official languages are Afrikaans and English. In the Transkei Parliament the official language is Xosa, but English, Afrikaans, and Sotho may also be used. Afrikaans, a derivative of Nederlands (the official name of the Dutch language), is the first language of more than half of the Whites and constitutes a powerful cultural bond endowing them with a group consciousness as Afrikaners. It is also the first language of nearly 90 percent of the Coloureds; the remaining Whites and Coloureds are English-speaking. Xosa is the language of 85 percent of the Bantu, Tswana of 9 percent (mainly in the northern interior), and Sotho of nearly 4 percent.

More than half of the Whites and a third of the Col-

oureds belong to the Nederduits Gereformeerde and allied churches (Dutch Reformed churches), 15 to 17 percent of both groups belong to Anglican churches, and about 8 percent are Methodists. The Malays, constituting 6 percent of the Coloureds, are adherents of Islām. Two-thirds of the Bantu are Christian, more than a fifth being Methodists and 16 percent members of independent Bantu churches.

Administration. Legislative and administrative authority is shared between the province and the republic. While most functions are discharged by the national government, an administrator appointed by the state president and a council of 54 members chosen by the provincial white electorate direct the administration of primary and secondary schools and teacher training institutions, as well as of hospital, public health, library and nature conservation services, and the regulation and supervision of municipal councils and other local government bodies. The provincial administration is also responsible for the construction and maintenance of provincial roads and minor public works. Revenue is derived primarily from direct taxation, supplemented by annual grants from the national government.

The area east of the Great Kei River, formerly consisting of tribal territories that were given a considerable degree of local autonomy in 1894, were formed into a semi-autonomous territory within the republic in 1963. This region, the Transkei (one of South Africa's so-called Bantustans), is administered by a legislative assembly of the paramount chiefs, 60 tribal chiefs, and 45 members chosen by the Bantu electorate, with executive authority vested in a cabinet of 6 ministers.

Social conditions. The rate of live births per thousand of the population ranged in 1966 from 24 among Whites to 44 among Coloureds; crude death rates ranged similarly from 9 to 15, the higher Coloured death rates being ascribed to infant mortality, which exceeded 120 per 1,000 live births, as well as to the greater incidence of gastroenteritis, pneumonia, and tuberculosis associated with lower standards of living and hygiene. Life expectancy at birth ranges from 50 years among Coloured males to 72 among White females. Meaningful data for Bantu, among whom registration of births and deaths is not compulsory, are not available.

Free hospital services are provided for lower income groups by the administration and by charitable health services; vaccination against smallpox is compulsory, and free immunization against poliomyelitis is available.

School attendance is compulsory for all White children from 7 to 16 years old, and for most Coloured children from 7 to 14 years old. It is, however, optional for Bantu children, for whom accommodation remains inadequate. Consequently, in 1960 nearly 18 percent of the urban and 47 percent of rural Bantu from 15 to 19 years old had received no formal schooling. Nevertheless, nearly half of the urban and more than a fifth of the rural Bantu over 15 years old were literate in Afrikaans, English, or a Bantu language. Universities have been established for all ethnic groups: for Whites at Cape Town, Grahamstown, Port Elizabeth, and Stellenbosch; for Bantu at Fort Hare near Alice; and for Coloureds at Bellville.

Universities

Economy. Although the economy is fairly diversified, farming remains of paramount importance. Of the economically active population in 1960, one-seventh of the Whites, a quarter of the Coloureds, and nearly three-fifths of the Bantu were employed in agriculture. In a normal year, of South Africa's total farm production, two-thirds of the wheat and wool, 70 percent of the lucerne (alfalfa) hay, most of the mohair, the deciduous fruit, and the grapes, and all of the wine are produced in the Cape. Sheep are raised in the Karroo and cattle in the thornveld north of the Orange River. Lucerne, sultanas, and cotton are grown under irrigation along the Orange River near Upington; lucerne and peanuts (groundnuts) are grown in the Harts Valley. Ostriches still graze in the Little Karroo, but lucerne seed, hay, fruit, tobacco, wool, and mohair have long surpassed ostrich feathers in importance. In the winter rainfall region the lowlands are given over to grain cultivation, sheep raising, and dairy farming, the foothills to vineyards and orchards, and the upland basins to deciduous fruits. These activities support a lively export trade in fresh fruit, table grapes, wine, brandy, and canned goods. In the higher rainfall areas, particularly between Mossel Bay and Humansdorp on the south coast, extensive timber plantations have been established; farther east, citrus fruit is grown under irrigation in the valleys of the Gamtoos, Sundays, Great Fish, and Kat rivers. Chicory and pineapples are produced between Algoa Bay and East London.

Rich fishing grounds lying offshore from the Agulhas Bank to South West Africa are actively exploited by South African and foreign vessels, supplying an important fish meal and canning industry.

Manufacturing industries

By 1968 it was estimated that, out of the economically active population, about 17 percent of the Whites, 16 percent of the Coloureds, and 6 percent of the Bantu were employed in industries, among them food processing and the manufacture of textiles, clothing, footwear, motor vehicles, tires, agricultural fertilizers, pesticides, mining explosives, and pharmaceuticals, as well as marine engineering and ship repairing.

Mineral resources are extensive, but mining employs relatively few people. In Namaqualand copper has been mined for more than a century; rich coastal diamond deposits are worked at Alexander Bay and south of Port Nolloth. Blue asbestos is mined in a zone extending northward from Prieska on the Orange River to beyond Kuruman. Enormous reserves of manganese and high-grade iron ores are mined along the railway northward from Postmasburg to Hotazel to supply South African smelters and overseas markets; shipments overseas through Port Elizabeth exceeded 3,000,000 tons in 1969.

Transport. Harbours and public rail, road, and air transportation services are operated mainly by the South African Railways and Harbours Administration and its subsidiary, South African Airways. Ships drawing up to 40 feet can berth at Cape Town and Port Elizabeth, and up to 35 feet at East London; there are graving docks at Cape Town and East London. Port Elizabeth has ore-loading facilities, and there are grain elevators at Cape Town and East London. There are more than 5,000 miles of three-foot six-inch gauge railway track in the province as well as an extensive road network. More than 3,000 miles of modern highways link the major cities and towns; there are also more than 40,000 miles of provincial roads. South African Airways operates domestic air services linking the port cities and Kimberley to Bloemfontein, Johannesburg, Pretoria, and Windhoek and also international services to Europe, Australia, and Brazil.

Cultural life and institutions. Apart from libraries and archives available in Cape Town (*q.v.*), there are a number of museums, including the South African Museum in Cape Town, the Albany Museum in Grahamstown, and museums at East London, Kimberley, and Port Elizabeth.

Old colonial artifacts

There are also numerous local museums in towns such as Franschhoek, Graaff-Reinet, Paarl, Swellendam, and Tulbagh; these foster interest in old Cape silver, cabinetwork, and other colonial artifacts. The heritage of the colonial era is manifest also in the gracious semi-indigenous Cape Dutch architecture typified in many western Cape Province farmhouses dating from 1780 to 1825 and widely emulated in later buildings throughout South Africa.

A provincial library service circulates books, films, and art reproductions, operating several hundred library centres, and serving rural areas with special buses. In several towns there are art galleries that display works by South African and overseas artists. Theatre and ballet are staged by travelling companies sponsored by Capab (the Cape Performing Arts Board). An amateur Cape Coloured organization, the Eoan Group, is renowned for its standards of operatic production, as are Malay choirs for their repertoire of colonial folk songs. Numerous Afrikaner groups perform *volkspele* (traditional folk dances).

BIBLIOGRAPHY. ROSE, A.P. NEWTON, and E.A. BENIANS (eds.), *Cambridge History of the British Empire*, vol. 8, *South Africa, Rhodesia and the Protectorates* (1936), a comprehensive historical survey, prefaced by chapters on the geographical environment and native populations; A.M. and W.J. TALBOT, *Atlas of the Union of South Africa* (1960), a graphic survey of the climate, vegetation, resources, economic development, and external trade of the Union (1910–50), presented in over 600 maps and charts.

(W.J.T.)

Cape Town

The city of Cape Town, which is the legislative capital of the Republic of South Africa and capital of Cape Province, lies at the northern end of the Cape Peninsula some 30 miles north of the Cape of Good Hope, the traditional landmark for seamen rounding the southern tip of Africa. In one of the world's most beautiful natural settings for urban life, parts of the city and its suburbs wind about the steep slopes of Table Mountain (3,563 feet, or 1,536 metres, high) and neighbouring peaks and rim the shores of Table Bay; other parts lie on the flats below the slopes, or stretch southward across the flats to False Bay. Cape Town—Kaapstad in Afrikaans—is the "mother city" of South Africa. Although today it is essentially a modern city, it was at one time an outpost at the extremity of the known world. (For further historical aspects, see SOUTHERN AFRICA, HISTORY OF.)

History. Table Bay was visited by Portuguese navigators in the 16th century; French, English, and Netherlands ships later stopped at the Cape for fresh water and provisions. Survivors of the Dutch vessel "Haerlem," wrecked in Table Bay in 1647, brought back such glowing reports of the region that the directors of the Netherlands East India Company ordered that a station to supply ships rounding the Cape be established there. In April 1652, the company's representative, Jan van Riebeeck, stepped ashore to select sites for a fort and a vegetable garden. In 1657 men began to be released from the company's employ so that they could become free burghers and farmers. Inland from Table Mountain, a second company farm was established at Newlands, and vines were planted on the slopes of Wynberg ("wine mountain").

Van Riebeeck and his senior officials formed a council of policy and constituted themselves as a court of justice. Free burghers were invited to join the court in cases involving burghers; later burgher-councillors acquired other functions. In 1681 a fire patrol was introduced, and in 1696 a burgher-watch became responsible for fire protection, the maintenance of roads and water supplies, and the preservation of order. The colony began to spread far beyond the Cape Peninsula, and the council of policy came to rely increasingly on the burgher-councillors for fact finding and for advice on town affairs.

The importation of slaves, the introduction of political exiles from the Dutch East Indies and miscegenation with indigenous Hottentots increased the population, but at the beginning of the 18th century the town still consisted of only 200 houses. Its growth was accelerated by rising international tensions and growing appreciation of the strategic importance of the Cape. During the Seven Years' War (1756–63) in which the major European powers were involved, many French and British ships called at the port, which from 1773 onward was referred to by British visitors as "Cape Town." During the American Revolutionary War, which exacerbated tensions between rival European powers, a British fleet sought, in 1781, to occupy the Cape, which directors of the English East India Company described as "the Gibraltar of India." A French fleet, however, reached the Cape first, establishing a garrison there to help the Dutch to defend it. The French presence brought prosperity and gaiety to Cape Town and initiated a surge of building. A visitor in 1791 remarked, "Building here is not only a hobby, it is a passion, a contagious madness, which has infected everybody."

Garrisoned by the French

Burgher representation on the court of justice increased to six, and from 1785 onward a committee of this court, consisting of three burghers and three officials, formally advised the court of policy on urban matters. This committee acquired official status in 1793. During the French Revolutionary Wars a British force occupied the Cape in 1795. The committee, known as the burgher senate, assumed responsibility for the town, which now had 1,000 houses. In 1803 the colony reverted to the Netherlands. The town received its coat of arms embodying an anchor, symbolizing "good hope," and three golden rings from Van Riebeeck's personal coat of arms.

Britain reoccupied the Cape in 1806. The burgher-senate was abolished in 1828, but in 1840 Cape Town, with a population of 20,000, became a municipality divided into 12 districts, each under an elected commissioner. In 1867, the districts were reduced to six, each with three members, and the chairman became mayor. Suburban development, largely inland to the east and down the Cape Peninsula to the south, followed the radial roads and the railway line, construction of which began in 1859. The Alfred Dock opened in 1870. An influx of people followed the discovery inland of diamonds in 1870 and gold in 1886. These developments, as well as the South African War, from 1899 to 1902, between Britain and the combined forces of the Boer Republics brought about a modest industrialization in Cape Town.

From 1881 onward a number of separate municipalities came into being. Improved roads, the introduction of an electric tramway, and a common concern for water supplies and sewerage prompted proposals for amalgamation. It was not until 1913, however, three years after the formation of the Union of South Africa, that the town councils of Cape Town and several adjacent towns combined to form Greater Cape Town, with a total population of about 135,000.

Transformation into a modern city

The city and its environment. The oldest section of Cape Town lies in the area between Table Mountain, its outlying ridges known as Lion's Head, Signal Hill, and Devil's Peak, and the shores of Table Bay. Colourful neighbourhoods include the so-called Malay Quarter, on the lower slopes of Signal Hill, and District Six, above the Castle. The construction of the Duncan Dock between 1938 and 1945 resulted in the reclamation of 480 acres from Table Bay, much of which became available for the extension of the central business district. Present-day residential suburbs stretch round the west side of Signal Hill and the mountain, northward to the adjoining municipality of Milnerton, and southward to False Bay. Industrial development largely followed the railway line eastward to the interior. In this direction lie the municipalities of Goodwood, Parrow, and Bellville. The four magisterial districts of Cape, Wynberg, Bellville, and Simonstown constitute metropolitan Cape Town.

Buildings. In addition to the Castle, the city's oldest monument, built between 1666 and 1677, interesting buildings include the old supreme court, which incorporates part of the structure of a slave lodge built in 1680. The walls of Groot Constantia, the homestead built by governor Simon van der Stel in the nearby Constantia valley, date from about 1685, and the Groote Kerk ("Great Church"; 1836) incorporates a tower built in 1704. Some of the humble flat-roofed homes on the slopes of Signal Hill may date from the 18th-century. One of the finest of several larger buildings remaining from that time, however, is the Koopmans-de Wet House (1701), which has furnishings from the same era; it is an annex of the Cultural History Museum.

Dutch architecture

Much of Cape Town's architecture reflected prototypes from the Netherlands that were modified for the region. Of special interest is the local version of the gable. L.M. Thibault, a French architect who arrived in 1793, designed much that was then new and fashionable in building. Recent architecture reflects European and American trends, and high-rise structures are common. Planning

Cape Peninsula, showing Cape Town (centre) with Table Mountain behind. On the right of Cape Town are Lion's Head and Signal Hill.
Georg Gerster—Rapho Guillumette

of the reclaimed shore led to prolonged discussion and delay in development. A broad boulevard, the Heerengracht, now leads from the harbour to the centre of the city; in this area are situated the provincial opera house (1971) and the municipal centre (1972).

Climate. The climate is Mediterranean in type; it is locally modified by the mass of Table Mountain and by the cold Benguela Current of the South Atlantic. Temperatures average a high of 81° F (27° C) in February, and a low of 45° F (7° C) in July, but it is cooler on the mountain slopes and on the coast. Infrequent freezing occurs. On the average, rain falls on 69 days of the year, over half of it between May and August, the southern winter. The amount of fall varies with proximity to the mountain, those areas close to the slopes receiving as much as twice the precipitation of areas further away. The generally strong winds come from the northwest in winter, and vary from between southeast and southwest in summer. The southerly winds produce a cloud covering of condensed moisture over Table Mountain known as the "table cloth." Referred to as the "Cape doctor," these winds keep air pollution at a low level.

Demography. In 1970 the population of the city of Cape Town was about 722,000. This consisted of about 218,000 whites, 410,000 Coloureds (a legally defined group of mixed racial ancestry), about 10,000 Asians, and 83,000 Bantu. At the same time the population of the metropolitan area was about 1,097,000, consisting of about 379,000 whites, 599,000 Coloureds, 11,000 Asians, and 108,000 Bantu. In the metropolitan area in 1960, English was the home language of about 61 percent of the whites, Afrikaans of about 33 percent, and about 2 percent were equally at home in both languages; about 1 percent spoke German, 1 percent Netherlands, and about 0.33 percent Portuguese. Of the Coloured population, Afrikaans was the home language of 79 percent, English of 18 percent, and both languages 2 percent. The Bantu were predominantly Xosa-speaking. In 1951 about 30 percent of the whites were Anglicans, about 27 percent members of the Nederduits and allied churches, 9 percent of the Roman Catholic church, about 9 percent Methodist, and about 8 percent Jewish.

Housing. Government legislation controls the presence and employment of Bantu outside their reservations. Nearly all Bantu in Cape Town are housed in the townships of Langa, Guguletu, and Nyanga. Public utilities are affected by this policy of segregation; over three-quarters of the rush-hour bus riders are nonwhite—a circumstance which creates problems in maintaining services that are both effective and segregated.

A segregated city

The heavy influx of Coloured work-seekers from the country districts into Cape Town, coupled with the high birth rate, and the removal of Coloured people from areas of the city proclaimed by state legislation to be for white occupation, has presented the municipality with an acute housing problem. By the early 1970s more than 3,000 low-cost housing units had been built for Coloured occupancy, but almost an equal number were still required.

Government. The municipality of Cape Town functions under two main provincial ordinances—those of 1951 and of 1965. The latter brought into effect a system whereby the council delegated much of its authority to an executive committee consisting of a chairman and four members. Each of the four is chairman of a standing committee, which may make recommendations to the full council only through the executive committee. The municipal area is divided into 17 wards, with two councillors representing each ward. From 1972 onward, half the sitting councillors retired biennially. Responsibility for maintaining civil law and order rests with the state, but the municipality has its own traffic police, market constables, and beach and park control officers. There is also a municipal fire brigade.

Economic life. A petroleum refinery and chemical, fertilizer, cement, and automobile-assembly factories are situated in the metropolitan area. In the city the basic industries are connected with ship repair and maintenance, textile and clothing manufacture, food processing, and building. Cape Town is well served by department stores and supermarkets. Numbers of nationwide commercial concerns have their head offices in Cape Town, including a bank, a chain-store, and several insurance companies, one of which was founded in 1845. The re-

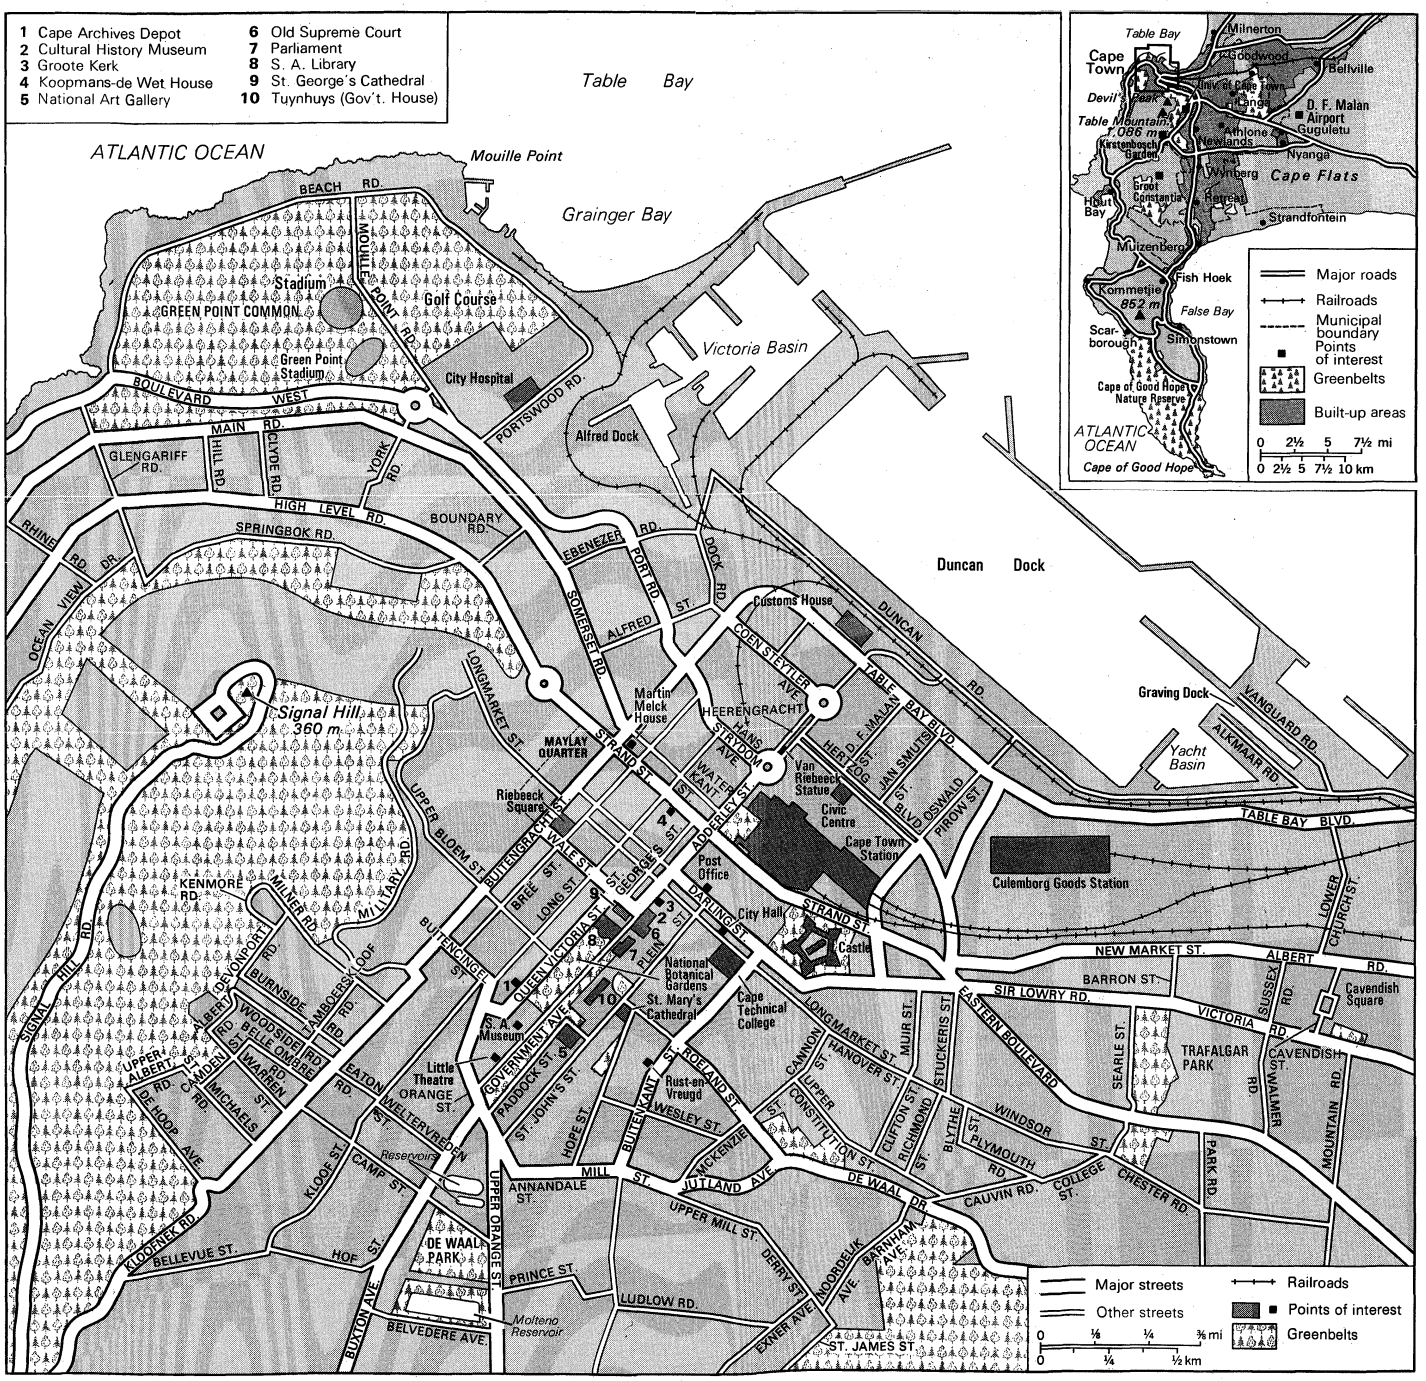
sult of enforced social categorization can be seen in comparative income figures. In 1960 the average income of whites was over five times that of Coloureds, and over three times that of Asiatics.

Transportation and utilities. The port of Cape Town was for long the main gateway to South Africa, handling millions of tons of cargo annually; by the early 1970s, however, most air passengers arrived at Johannesburg, and the port of Durban handled three times as much cargo as Cape Town. The port will not admit ships of more than 40-foot draft at low tide, but its repair facilities and its dry dock are of great importance to interoceanic traffic, especially when the Suez Canal is closed. Extensions to the harbour, and the first of two new basins that are planned, were under construction in the early 1970s. The D.F. Malan Airport acquired international status in 1970, when extensions were begun to accommodate the new large jet aircraft. Cape Town is the terminus of a railway network that extends northward to Rhodesia and beyond. A new railway station was opened in 1968, partly to assist with the heavy suburban passenger traffic. Two private bus companies also serve the area.

Port facilities

In 1958, a major program of freeway construction was launched, backed by the city, the provincial administration, and the central government. Two main radial freeways were developed, both leading southward to False Bay. Supplementing these were two national routes and a beltway circling the central business district.

Cape Town's water is obtained from reservoirs at Wemmershoek, 40 miles east of Cape Town; Steenbras, 30 miles southeast; and Voëlvlei, 40 miles northeast. Electricity is produced by two municipal power stations, at Table Bay and Athlone. The latter carries the major load and in the early 1970s was being expanded. Future supplies are to be purchased in bulk from the national grid of the Electricity Supply Commission, whose first nuclear power station at Melkbosstrand, on the coast 20



Central Cape Town and (inset) its metropolitan area.

miles north of Cape Town, is due to be commissioned in 1978.

Communications. There are three daily newspapers in Cape Town, *Die Burger* in Afrikaans and the *Cape Times* and *The Argus* in English. Radio broadcasting is restricted to the state-controlled South African Broadcasting Corporation, which operates, in addition to its national English, Afrikaans, bilingual commercial, and Bantu programs, the Radio Good Hope—a commercial service that broadcasts music and news in English and Afrikaans.

Television was introduced in 1975.

Health and welfare. The provincial administration is responsible for the main hospital services, which are virtually free to the needy. The best known of the hospitals is the Groote Schuur, where the world's first heart transplant was carried out in 1967. In suburban Bellville are the Karl Bremer and new Tiervlei hospital complexes. The two mental hospitals (Valkenberg and Stikland) are administered by the State Department of Health. The Cape Town municipality is responsible for infectious diseases and chest hospitals, and it maintains many treatment centres and clinics.

Social insurance measures, such as workmen's compensation, unemployment insurance, disability grants, and pensions for war veterans, the aged, and the blind, are administered by the Cape Town offices of the relevant state departments. There are also some 300 voluntary welfare associations that offer services to beneficiaries of all races and religions.

Education. The provincial administration is responsible for the schooling of whites. The South African College, founded in 1829, and Rondebosch Boys' High School are notable among the numerous government schools, and Diocesan College (founded in 1849) among the private. Schooling for Coloureds and Bantu is provided by central government departments. The Cape College for Advanced Technical Education falls under the Central Department of National Education. The University of Cape Town developed from the South African College and came formally into being in 1918. Its main buildings occupy a magnificent site on the Groote Schuur estate of Cecil Rhodes, a major figure in the development of South Africa's mining industry and a prime minister of Cape Colony.

The University of Cape Town

The University College Western Cape, for Coloureds, is situated near Bellville.

Cultural life and recreation. The South African Library, Museum, and National Gallery occupy sites on the former garden of the East India Company. Adjacent is the Cape Archives Depot of the Government Archives Service. The Municipal Botanic Gardens occupy the remains of the garden; the National Botanic Gardens at Kirstenbosch are renowned. The Library of Parliament possesses a notable collection of Africana, and pictures of African interest are exhibited in the Castle and Rusten-Vreugde. The old supreme court building houses the Cultural History Museum.

The municipality supplies a free library service. The Cape Town Symphony Orchestra, the South African College of Music, the Cape Performing Arts Board, and the Little Theatre provide concerts, opera, ballet, and dramatic performances. Public lectures are organized by the department of extramural studies of the university.

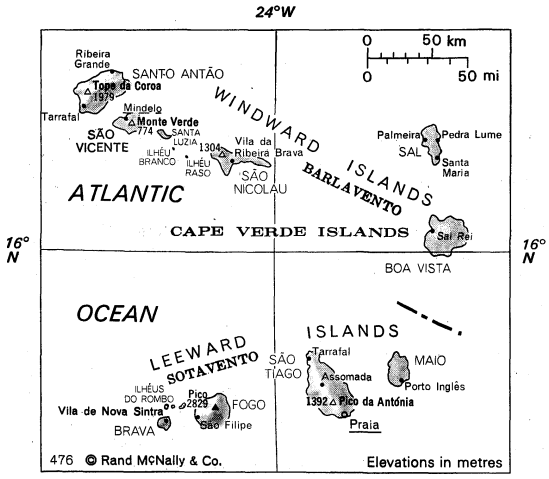
Cape Town has more than 150 formal recreation areas, parks, and playgrounds. Facilities exist for most spectator sports, from horse and motor racing to table tennis. The Green Point Stadium can accommodate 33,000. Separate recreation areas for Coloureds and for Bantu are maintained. The 90 miles (145 kilometres) of peninsula coastline abound in sites for swimming, fishing, and skin diving, and yachting is becoming increasingly popular. There are many scenic drives, and on the mountains are many walks and climbs. A cableway to the summit of Table Mountain provides spectacular views of Cape Town and its environs.

BIBLIOGRAPHY. No academic history of Cape Town has yet been written; the best outline available is that in J.R. SHORTEN, *Cape Town* (1963). P.W. LAIDLER, *The Growth and Government of Cape Town* (1939), is not as comprehensive as the title suggests. The most colourful descriptions of the history may be found in W.J. PICARD, *Gentleman's Walk: The Romantic Story of Cape Town's Oldest Streets, Lanes and Squares* (1968), and *Grand Parade: The Birth of Greater Cape Town 1850–1913* (1969). Commercial development is well treated by R.F.M. IMMELMAN, *Men of Good Hope* (1955), whereas the general background is sketched by A.F. HATTERSLEY in *An Illustrated Social History of South Africa* (1969). Some useful essays appear in A.H. HONIKMAN (ed.), *Cape Town: City of Good Hope* (1966). J.A. MABBUTT (ed.), *The Cape Peninsula* (1952), contains brief but valuable descriptions, whereas the geographical setting was sketched by W.J. TALBOT, "Kapstadt als Weltstadt," in J.H. SCHULTZE (ed.), *Zum Problem der Weltstadt* (1959). Vital statistical information is contained in the CAPE PROVINCIAL ADMINISTRATION, *Greater Cape Town Region, Planning Reports* (mimeographed 1967–68); in the REPUBLIC OF SOUTH AFRICA, BUREAU OF STATISTICS, *Population Census 6th September, 1960*, vol. 2, no. 1, *Report on the Metropolitan Area of Cape Town* (1966); and in DEPARTMENT OF STATISTICS, *Statistical News Release*, Pretoria, May 14, 1971, *Population Census 6 May 1970*, No. 3, Cape District, No. 4, Bellville, No. 5, Simonstown, No. 5, Wynberg. Also valuable are annual reports by various departments of the City of Cape Town, especially that of the medical officer of health, which includes statistics of population. For town planning and traffic, see S.S. MORRIS, "South Africa's Approach to Urban Traffic and Freeways," *Traffic Quarterly*, 18:202–218 (1964); and "Cape Town: Metropolis in the Making," *Town Planning Review*, 40:102–118 (1969).

(E.A.)

Cape Verde Islands

The Cape Verde Islands (Arquipélago de Cabo Verde), making up the Republic of Cape Verde, are located some 385 miles (620 kilometres) off the west coast of Africa between 17°30′ N and 14°30′ N, and 25°30′ W and 22°30′ W. With a total land area of 1,557 square miles (4,033 square kilometres), their population had grown from 272,000 in 1970 to 291,000 (estimated) in 1974. Praia (population 21,500) on São Tiago is the capital.



The islands are named after the westernmost cape of Africa. The archipelago consists of 10 islands and five islets, which are divided into the Windward (Ilhas de Barlavento) and Leeward (Ilhas de Sotavento) groups. The Windward Islands consist of Santo Antão, São Vicente, Santa Luzia, São Nicolau, Boa Vista, and Sal, together with the islets of Raso and Branco. The Leeward Islands include Maio, São Tiago, Fogo, and Brava, and the three islets called the Rombos—Grande, Luís Carneiro, and Cima.

The islands of the archipelago

The largest port in the islands is Mindelo (Porto Grande) on São Vicente. Its deepwater harbour—formed from a volcanic crater with its seaward wall broken—accommodates vessels up to 45,000 tons and is used as a fuelling station, which supplied about 900 vessels a year with imported oil before independence.

The landscape. *Relief.* Volcanic in origin, the islands are mountainous, only three of them—Boa Vista, Maio, and Sal—having much level ground. Fogo (meaning "fire") is an active volcano, which erupted as recently as 1951; its cone rises to 9,281 feet (2,829 metres). The peak of Tope da Coroa on Santo Antão is 6,493 feet (1,979 metres). São Tiago and São Nicolau both have mountains over 4,200 feet (1,300 metres) high. All the islands, but especially the Windwards, have been eroded by sand carried by high winds, so that the outline of the landscape appears jagged. On most of the mountainous islands the cliffs rise sheer from the sea.

Climate. Moderate, stable temperatures and marked aridity characterize the climate. February is the coolest month, with an average temperature of 71° F (22° C), and September the warmest, with an average of 80° F (27° C). Rainfall is almost nil except from August through October, when an average of 0.8 inch (20 millimetres) a month is recorded. The sun, though seldom obscured by rain clouds, is sometimes blocked by a dense mist of fine sand brought by the trade winds from the Sahara.

Vegetation. The distribution of plant life in the archipelago is strongly affected by local variations in the temperature and the rainfall. Springs in the hills, replenished during the rainy season, provide water for irrigation of farms in the valleys below. On the windward slopes of the hills, the lack of rain produces desert conditions, and the sparse shrubs, already overgrazed by goats, almost disappear. The shrubs remaining in these areas are mostly bitter or thorny; some are toxic. A sea mist on the high hills permits some agriculture. Monte Verde, the green mountain of São Vicente, is so called because aloes grow high up, and crops can be raised on a few patches.

Salt areas on Maio and Sal have interesting xerophilous plants.

Animal life. The scarcity of water limits the number of land turtles in the archipelago, but two species of sea turtles land on the sandy shores of the uninhabited islets to lay their eggs. There are no serpents, but there are many geckos, lizards, and several species of skinks. A species of giant skink is protected by law, but it may be extinct. There are 23 known species of butterfly, but none is endemic, and only two species are not of African origin.

Birds

By 1970, 105 species of birds had been recorded, of which only 38 breed regularly, including four petrels and two shearwaters. Among the other bird species are found the greater flamingo, as well as the frigate bird and the buzzard (both nearly exterminated), and the Egyptian vulture, the Cape Verde Islands kite, the red-billed tropic bird, and many smaller birds. An endemic lark is restricted to one of the smallest uninhabited islets. Several other birds are represented by local races, of which the kingfisher, known to early investigators (including Charles Darwin), is among the most conspicuous. The only truly endemic species, however, are the Razo lark and the cane warbler. The remainder of the birds are overseas migrants, one at least from America. A remarkable fact is that gulls and terns do not breed on the islands.

Among mammals, the wild goats found on Fogo are the descendants of domestic goats that were brought to the islands but escaped. The Senegal green monkey, found on São Tiago, was introduced from Africa. Rodents that are found are believed to have originally escaped from ships. A long-eared bat of European origin has been discovered.

People and population. *Ethnic and linguistic groups.* Of the islands' population of nearly 300,000, about 70 percent are Creole (mulatto) and the remainder Negro and European. The population is descended, in part, from African slaves imported by the early Portuguese settlers to work their plantations; others are descended from enslaved Africans who were gathered on the islands to be shipped across the Atlantic and left there when the slave trade was abolished. Most of the principal ethnic types associated with the African continent—Arab, Negro, Hamitic—are in evidence among the population. European strains were introduced not only by the Portuguese but also by visiting sailors. Most of the Europeans on the islands—among whom the Portuguese predominate—live mainly in Praia on São Tiago, or in Mindelo on São Vicente. The islands farther away from the two ports are almost entirely Creole.

Apart from Portuguese, the language of the educated, the inhabitants speak a Cape Verdean Creole dialect called Crioulo; because rough seas separate the different islands, the dialect varies from one island to another. Most of the population is officially Roman Catholic, and a flourishing Protestant mission based in São Tiago has a church and schools in most islands; many animist customs and a belief in voodoo survive, however, in the more remote and pure African villages. There is a Cape Verdean version of the melancholy Portuguese song and dance, the *fada*, known locally as the *morna*.

Demography. Since the 1940s the population has been increasing, despite a steady emigration to Brazil, Africa, Portugal, or the United States. The census taken in 1970 gave 272,000 as the total population. Since the troubles in Angola, many emigrants have returned to the islands,

and others have gone to join their friends and relatives in Canada, the U.S., Venezuela, and Brazil, so that the 1970 census is only approximate. Using that figure, the density overall is 175 persons per square mile (67 persons per square kilometre). Praia and Mindelo are the only towns of any size. The remainder of the population lives in the few fertile valleys or in small fishing hamlets on the coast.

More than 50 percent of the people are under 21; many older inhabitants go overseas, labourers seeking work in the oil fields of Venezuela and professionals in Portuguese-speaking Brazil. These emigrants send money home to their families, and many return on retirement. Some of the professionals are now coming back, believing that the government established in 1975 has a good chance of success.

History. The date of the islands' discovery is disputed; the Venetian captain Alvise Ca' da Mosto (Cadamosto) claimed to have visited them in 1456, but his account is not universally accepted. In 1460 the Portuguese navigators Diogo Gomes and António de Noli discovered Maio and São Tiago. In 1462 the first settlers from Portugal landed on São Tiago, subsequently founding there the most ancient European city in the tropics—Ribeira Grande. With the development of the transatlantic slave trade, the importance and the wealth of the islands increased. In 1532 the first bishop was consecrated, and in 1595 the first governor general was appointed. The prosperity of Ribeira Grande, however, attracted pirates, who attacked the city in 1541. It was later attacked twice—in 1585 and 1592—by the English, the first time under the

command of Sir Francis Drake. After a French attack in 1712, the city was abandoned. To protect the islands against such depredations, the fortress of São Filipe was built.

With the decline of the slave trade (abolished in 1876), and with increasing drought, the prosperity of the islands slowly vanished. In the earlier part of the 19th century, they experienced recurrent drought and famine as well as governmental corruption and maladministration. Conditions improved toward the end of the 19th century, however, as the development of internal trade and communications led to the establishment first of a coaling station at Mindelo, and later, in 1875, of a submarine cable station. After World War I prosperity again declined as fewer ships visited Mindelo. Only after World War II did trade again increase and relative prosperity return. The Portuguese administration was unified under a governor in 1587. The islands' status changed in 1951 from a colony to an overseas province. In 1961 all citizens were given full Portuguese citizenship.

Independence

On July 5, 1975, the Cape Verde Islands became an independent republic. The first president, Aristide Pereira, had been secretary general of the African Party for the Independence of Guinea and Cape Verde (PAIGC) since 1973. The republic is a member of the Organization of African Unity and of the United Nations; a foreign policy of non-alignment has been declared.

The economy. The international airport on Sal gives work to many of that island's 6,000 inhabitants. At Praia the government centre provides work, as does the bunkering trade in Mindelo. In the irrigated valleys there is work for agricultural labourers: bananas and coffee from Santo Antão and Fogo are exported; crops for local consumption include maize (corn), sugarcane, castor beans, broad beans, potatoes, and groundnuts (peanuts). Experimental agricultural stations near Praia have improved the variety of food crops and cattle and poultry as well.

Salt is an important product in Sal, Maio, and Boa Vista. Volcanic rock, a pozzolana used in making cement, is exported. There are few other exports, and the total is not sufficient to pay for necessary imports.

Transportation. There is air service between Espargos, the international airport on Sal, and Lisbon. Within the islands, schooners and a small plane provide local service. On land there are few roads—only 611 miles (984 kilometres); one-third of these are on São Tiago. Most people travel on foot.

Prospects. A great deal depends on water; a team from the UN is currently attempting to find new sources. If additional water is found, either by desalinization (possibly by the utilization of solar energy) or new wells, the development of a small tourist trade may be possible. The volcano on Fogo may be a future source of energy.

Much depends on the stability of the government and aid from other countries. Who will pay for the excellent schools set up by the Portuguese, for the hospitals, for the experimental stations? Who will help in the recurrent periods of drought? The UN and UNESCO are already there, and the island republic became a member of the UN in 1975.

BIBLIOGRAPHY. G.R. CRONE (ed. and trans.), *The Voyages of Cadamosto and Other Documents on Western Africa in the Second Half of the Fifteenth Century* (1937), is an account by Alvise Ca' da Mosto (Cadamosto), a Venetian explorer and trader who appears to have been the first European to land on the Cape Verdes; whether he, as he claimed, or the Portuguese were the first also to discover the archipelago is discussed in the introduction to this volume. WILLIAM DAMPIER, *A New Voyage Round the World*, 3 vol. (1698–1703), contains one of the earliest descriptions of the islands. DAVID A. and W.M. BANNERMAN, *A History of the Birds of the Cape Verde Islands* (1968), includes a useful general bibliography and an account of the islands' history, explorers, vegetation, birds, and butterflies. See also CAPE VERDE ISLANDS, *25 Anos de Actividade* (1951), a review of social and economic progress from 1926. For economic and demographic information prior to independence, see *Anuário Estatístico*, vol. 2, *Províncias Ultramarinas*, of the government of Portugal.

(W.M.B.)

Capital and Interest

Capital in economics is a word of many meanings. They all imply that capital is a "stock" by contrast with income, which is a "flow." In its broadest possible sense, capital includes the human population; nonmaterial elements such as skills, abilities, and education; land, buildings, machines, equipment of all kinds; and all stocks of goods —finished or unfinished—in the hands of both firms and households.

In the business world the word capital usually refers to an item in the balance sheet representing that part of the net worth of an enterprise that has not been produced through the operations of the enterprise. In economics the word capital is generally confined to "real" as opposed to merely "financial" assets. Different as the two concepts may seem, they are not unrelated. If all balance sheets were consolidated in a closed economic system, all debts would be cancelled out because every debt is an asset in one balance sheet and a liability in another. What is left in the consolidated balance sheet, therefore, is a value of all the real assets of a society on one side and its total net worth on the other. This is the economist's concept of capital.

Kinds of capital

A distinction may be made between goods in the hands of firms and goods in the hands of households, and attempts have been made to confine the term capital to the former. There is also a distinction between goods that have been produced and goods that are gifts of nature; attempts have been made to confine the term capital to the former, though the distinction is hard to maintain in practice. Another important distinction is between the stock of human beings (and their abilities) and the stock of nonhuman elements. In a slave society human beings are counted as capital in the same way as livestock or machines. In a free society each man is his own slave—the value of his body and mind is not, therefore, an article of commerce and does not get into the accounting system. In strict logic persons should continue to be regarded as part of the capital of a society; but in practice the distinction between the part of the total stock that enters into the accounting system, and the part that does not, is so important that it is not surprising that many writers have excluded persons from the capital stock.

Another distinction that has some historical importance is that between circulating and fixed capital. Fixed capital is usually defined as that which does not change its form in the course of the process of production, such as land, buildings, and machines. Circulating capital consists of goods in process, raw materials, and stocks of finished goods waiting to be sold; these goods must either be transformed, as when wheat is ground into flour, or they must change ownership, as when a stock of goods is sold. This distinction, like many others, is not always easy to maintain. Nevertheless, it represents a rough approach to an important problem of the relative structure of capital; that is, of the proportions in which goods of various kinds are found. The stock of real capital exhibits strong complementarities. A machine is of no use without a skilled operator and without raw materials for it to work on.

THE DEVELOPMENT OF CAPITAL THEORY

The classical school. Although ancient and medieval writers were interested in the ethics of interest and usury, the concept of capital as such did not rise to prominence in economic thought before the classical economists (Adam Smith, David Ricardo, Nassau Senior, and John Stuart Mill).

The ideas of economists about capital

Smith laid great stress on the role played by the accumulation of a stock of capital in facilitating the division of labour and in increasing the productivity of labour in general. He recognized clearly that accumulation proceeds from an excess of production over consumption. He distinguished between productive labour, which creates objects of capital, and unproductive labour (services), the fruits of which are enjoyed immediately. His thought was strongly coloured by observation of the an-

nual agricultural cycle. End of the harvest saw society with a given stock of grain. This stock was in the possession of the capitalists. A certain portion of it they reserved for their own consumption and for the consumption of their menial servants, the rest was used to feed "productive labourers" during the ensuing year. As a result, by the end of the next harvest the barns were full again and the stock had replaced itself, perhaps with something left over. The stock that the capitalists did not reserve for their own use was the "wages fund"—the more grain there was in the barn in October the sharper the competition of capitalists for workers, and the higher real wages would be in the year to come. The picture is a crude one, of course, and does not indicate the complexity of the relationship between stocks and flows in an industrial society. The last of the classical economists, John Stuart Mill, was forced to abandon the wages-fund theory. Nevertheless, the wages fund is a crude representation of some real but complex relationships, and the theory reappears in a more sophisticated form in later writers.

The classical economists distinguished three categories of income—wages, profit, and rent—and identified these with three factors of production—labour, capital, and land. Ricardo especially made a sharp distinction between capital as "produced means of production," and land as the "original and indestructible powers of the soil." In modern economics this distinction has become blurred.

The Austrian school. About 1870 a new school developed, sometimes called the Austrian school from the fact that many of its principal members taught in Vienna, but better perhaps called the Marginalist school. The movement itself was thoroughly international, and included such figures as William Stanley Jevons in England and León Walras in France. The so-called Austrian theory of capital is mainly based on the work of Eugen Böhm-Bawerk. His *Positive Theory of Capital* (1889) set off a controversy that has not yet subsided. In the Austrian view the economic process consisted of the embodiment of "original factors of production" in capital goods of greater or lesser length of life that then yielded value or utility as they were consumed. Between the original embodiment of the factor and the final fruition in consumption lay an interval of time known as the period of production. In an equilibrium population it can easily be shown that the total population (capital stock) equals the annual number of births or deaths (income) multiplied by the average length of life (period of production). The longer the period of production, therefore, the more capital goods there will be per unit of income. If the period of production is constant, income depends directly on the amount of capital previously accumulated. Here is the wages fund in a new form. Unfortunately, the usefulness of Böhm-Bawerk's theory is much impaired by the fact that it is confined to equilibrium states. The great problems of capital theory are dynamic in character, and comparative statics throws only a dim light on them.

Later thinking. The Marginalist school culminated in the work of three men—P.H. Wicksteed in England, Knut Wicksell in Sweden, and Irving Fisher in the United States. The last two especially gave the Austrian theory clear mathematical expression. Perhaps the greatest contribution of the Austrian theory was its recognition of the importance of the valuation problem in the relation of capital to interest. From the mere fact that physical capital produces an income stream, there is no explanation of the phenomenon of interest, for the question is why the value of a piece of physical capital should be less than the total of future values that are expected to accrue from it. The theory also makes a contribution to the problem of rational choice in situations involving waiting or maturing. The best example is that of slowly maturing goods such as wines or timber. There is a problem here of the best time to draw wine or to cut down a tree. According to the marginal theory this is at the time when the rate of net value growth of the item is just equal to the rate of interest, or the rate of return in alternative investments. Thus, if a tree or a wine is increasing in value at the rate of 7 percent per annum when the rate of interest is 6 percent it still pays to be patient and let it grow or mature. The longer it grows, however, the less the rate of value growth, and when the rate of value growth has fallen to the rate of interest, then is the time to reap the fruits of patience.

The contributions of John Maynard (Lord) Keynes to capital theory are incidental rather than fundamental. Nevertheless, the "Keynesian revolution" had an impact on this area of economic thought as on most others. It overthrew the traditional assumption of most economists that savings were automatically invested. The great contribution of Keynes, then, is the recognition that the attempt to save does not automatically result in the accumulation of capital. A decision to restrict consumption is only a decision to accumulate capital if the volume of production is constant. If abstention from consumption itself results in a diminution of production, then accumulation (production minus consumption) is correspondingly reduced.

CONTINUING PROBLEMS

Important theoretical questions

The theory of capital was not a matter of primary concern to economists in the mid-20th century, though some revival of interest occurred in the late 1950s. Nevertheless, certain problems remain of perennial interest. They may be grouped as follows.

Heterogeneous goods. First are the problems involved in measuring aggregates of goods. Real capital includes everything from screwdrivers to continuous strip-rolling mills. A single measure of total real capital can be achieved only if each item can be expressed in a common denominator such as a given monetary unit (*e.g.*, dollars, sterling, francs, etc.). The problem is particularly complicated in periods of rapid technical change when there is change not only in the relative values of items but in the nature of the list itself. Only approximate solutions can be found to this problem and no completely satisfactory measure is possible.

A related problem that has aroused considerable interest among accountants is how to value capital assets that have no fixed price. In the conventional balance sheet the value of some items is based on their cost at an earlier period than that of others. When the general level of prices is changing this means that different items are valued in monetary units of different purchasing power. The problem is particularly acute in the valuation of inventory. Under the more conventional "FIFO" (First In, First Out) system, inventory is valued at the cost (purchase price) of the latest purchases. This leads to an inflation of inventory values, and therefore of accounting profits, in time of rising prices (and a corresponding deflation under falling prices), which may be an exaggeration of the long-run position of the firm. This may be partially avoided by a competing system of valuation known as LIFO (Last In, First Out), in which inventory is valued at the purchase price of the earliest purchases. This avoids the fluctuations caused by short-run price-level changes, but it fails to record changes in real long-run values. There seems to be no completely satisfactory solution to this problem, and it is wise to recognize the fact that any single figure of capital value that purports to represent a complex, many-dimensional reality will need careful interpretation.

The accumulation process. A second problem concerns the factors that determine the rate of accumulation of capital; that is, the rate of investment. It has been seen that investment in real terms is the difference between production and consumption. The classical economist laid great stress on frugality as the principal source of capital accumulation. If production is constant it is true that the only way to increase accumulation is by the reduction of consumption. Keynes shifted the emphasis from the reduction of consumption to the increase of production, and regarded the decision to produce investment goods as the principal factor determining the rate of

growth of capital. In modern theories of economic development great stress is laid on the problem of the structure of production—the relative proportions of different kinds of activity. The advocates of "balanced growth" emphasize the need for a developing country to invest in a wide range of related and cooperative enterprises, public as well as private. There is no point in building factories and machines, they say, if the educational system does not provide a labour force capable of using them. There is also, however, a case to be made for "unbalanced growth," in the sense that growth in one part of the economy frequently stimulates growth in other parts. A big investment in mining or in hydroelectric power, for example, creates strains on the whole society, which result in growth responses in the complementary sectors. The relation of inflation to economic growth and investment is an important though difficult problem. There seems to be little doubt that deflation, mainly because it shifts the distribution of income away from the profit maker toward the *rentier* and bondholder, has a deleterious effect on investment and the growth of capital. In 1932, for instance, real investment had practically ceased in the United States. It is less clear at what point inflation becomes harmful to investment. In countries where there has been long continuing inflation there seems to be some evidence that the structure of investment is distorted. Too much goes into apartment houses and factories and not enough into schools and communications.

Capital and time. A third problem in capital theory is that of the period of production and the time structure of the economic process. This cannot be solved by the simple formulas of the Austrian school. Nevertheless, the problem is a real one and there is still a need for more useful theoretical formulations of it. Decisions taken today have results extending far into the future. Similarly, the data of today's decisions are the result of decisions taken long in the past. The existing capital structure is the embodiment of past decisions and the raw material of present decisions. The incompatibility of decisions is frequently not discovered at the time they are made because of the lapse of time between the decision and its consequences. It is tempting to regard the cyclical structure of human history, whether the business cycle or the war cycle, as a process by which the consequences of bad decisions accumulate until some kind of crisis point is reached. The crisis (war or depression) redistributes power in the society and so leads to a new period of accumulating, but hidden, stress. In this process, distortion in the capital structure is of great importance.

Capital and income. A fourth problem is the relationship between the stocks and the flows of a society, or in a narrower sense the relation between capital and income. Income, like capital, is a concept capable of many definitions; a useful approach to the concept of income is to regard it as the gross addition to capital in a given period. For any economic unit, whether a firm or an individual, income may be measured by that hypothetical amount of consumption that would leave capital intact. In real terms this is practically identical with the concept of production. The total flow of income is closely related to both the quantity and structure of capital; the total real income of a society depends on the size and skills of its population, and on the nature and extent of the equipment with which they have to work. The most important single measure of economic well-being is real income per person; this is closely related to the productivity of labour, and this in turn is closely related to capital per person, especially if the results of investment in human resources, skills, and education are included in the capital stock.

INTEREST

The nature of interest

Historically, the concept of capital has been so closely bound to the concept of interest that it seems wise to take these two topics together, even though in the modern view it is capital and income rather than capital and interest that are the related concepts.

Interest as a form of income may be defined as income received as a result of the possession of contractual obligations for payment on the part of another. Interest, in other words, is income received as a result of the ownership of a bond, a promissory note, or some other instrument that represents a promise on the part of some other party to pay sums in the future. The obligations may take many forms. In the case of the perpetuity, the undertaking is to pay a certain sum each year or other interval of time for the indefinite future. A bond with a date of maturity usually involves a promise to pay a certain sum each year for a given number of years, and then a larger sum on the terminal date. A promissory note frequently consists of a promise to pay a single sum at a date some time in the future.

If $a_1, a_2, \ldots a_n$ are the sums received by the bondholder in years $1, 2 \ldots n$, and if P_o is the present value in year O, or the sum for which the bond is purchased, the rate of interest r in the whole transaction is given by the equation

$$P_o = a_1(1 + r)^{-1} + a_2(1 + r)^{-2} + \cdots + a_n(1 + r)^{-n}.$$

There is no general solution for this equation, though in practice it can be solved easily by successive approximation, and in special cases the equation reduces to much simpler forms. In the case of a promissory note, for instance, the equation reduces to the form

$$P_o = a_n(1 + r)^{-n}, \text{ or } \log (1 + r) = \frac{\log a_n - \log P_o}{n}$$

where a_n is the single promised payment. In the case of a perpetuity with an annual payment of a, the formula reduces to

$$P_o = a[(1 + r)^{-1} + (1 + r)^{-2} + \cdots \text{ to inf.}] = \frac{a}{r}$$

whence $r = \frac{a}{P_o}$.

Thus if one had to pay $200 to purchase a perpetual annuity of $5 per annum, the rate of interest would be 2½ percent.

It should be observed that the dimensions of the rate of interest are those of a rate of growth. The rate of interest is not a price or ratio of exchange; it is not itself determined in the market. What is determined in the market is the price of contractual obligations or "bonds." The higher the price of a given contractual obligation, the lower the rate of interest on it. Suppose, for instance, that one has a promissory note that is a promise to pay one $100 in one year's time. If I buy this for $100 now, the rate of interest is zero; if I buy it for $95 now the rate of interest is a little over 5%; if I buy it for $90 now, the rate of interest is about 11%. The rate of interest may be defined as the gross rate of growth of capital in a contractual obligation.

A distinction is usually made between interest and profit as forms of income. In ordinary speech, profit usually refers to income derived from the ownership of aggregates or assets of all kinds organized in an enterprise. This aggregate is described by a balance sheet. In the course of the operations of the enterprise, the net worth grows, and profit is the gross growth of net worth. Stocks, as opposed to bonds, usually imply a claim on the profits of some enterprise.

THE DEVELOPMENT OF INTEREST THEORY

Interest theory since Aristotle

In ancient and medieval times the main focus of inquiry into the theory of interest was ethical, and the principal question was the moral justification of interest. On the whole, the taking of interest was regarded unfavourably by both classical and medieval writers. Aristotle regarded money as "barren" and the medieval schoolmen were hostile to usury. Nevertheless, where interest fulfilled a useful social function elaborate rationalizations were developed for it. Among the classical economists, the focus of attention shifted away from ethical justification toward the problem of mechanical equilibrium. The question then became this: Is there any equilibrium rate of interest or rate of profit in the sense that where actual rates are above or below this, forces are brought into

play, tending to change them toward the equilibrium? The classical economists did not provide any clear solution for this problem. They believed that the rate of interest simply followed the rate of profit, for people would not borrow or incur contractual obligations unless they could earn something more than the cost of the borrowing by investing the proceeds in enterprises or aggregates of real capital. They believed that the growth of capital itself would tend to reduce the rate of profit because of the competition of the capitalists. This doctrine is important in the Marxian dynamics in which the struggle of capital to avoid a falling rate of profit is seen as a critical factor leading, for instance, to unemployment, foreign investment, and imperialism.

Senior and Marx. In the framework of classical economics, the work of Nassau Senior deserves mention. He raised the question whether profit or interest were "paid for" anything; that is, whether there was any identifiable contribution to the general product of society that would not be forthcoming if this form of income were not paid. He identified such a function and called it abstinence. Karl Marx denied the existence of any such function and argued that the social product must be attributed entirely to acts of labour, capital being merely the embodied labour of the past. On this view, profit and interest are the result of pure exploitation in the sense that they consist of an income derived from the power position of the capitalist and not from the performance of any service. Non-Marxist economists have generally followed Senior in finding some function in society that corresponds to these forms of income.

The Marginalists. The Marginalists generally held that profit and interest were related to the marginal productivity of the extension of the period of production. Böhm-Bawerk assumed that "roundabout" processes of production would generally be more productive than processes with shorter periods of production; he thought there was a productivity of "waiting" (to use the term of Alfred Marshall) and saw the rate of interest as an inducement to the capitalist to extend the period of production.

A low rate of interest leads to concentration on longer, more roundabout processes, and a high rate of interest on shorter, less roundabout processes. There is a limit, however, on the period of production imposed by the existing stock of accumulated capital. If one embarks on a long process with insufficient capital, he will find that he has exhausted his resources before the end of the process and before the fruits can be gathered. It is the business of the rate of interest to prevent this, and to adjust the roundaboutness of the processes used to the capital resources available. The Marginalists' theory of interest reached its clearest expression in the work of Irving Fisher. He saw an equilibrium rate of interest as determined by the interaction of two sets of forces: the impatience of consumers on the one hand, and the returns from extending the period of production on the other.

Keynes. John Maynard Keynes brought a new approach. His liquidity preference theory of interest is a short-run theory of the price of contractual obligations ("bonds"), and it is essentially an application of the general theory of market price. If people as a whole decide that they want to hold a larger proportion of their assets in the form of money, and if new money is not created to satisfy this desire, there will be a net desire to sell securities and the price of securities will fall. This is the same thing as a rise in the rate of interest. Conversely, if people want to get rid of money the price of securities will rise and the rate of interest will fall. This, then, is the theory of the "market" rate of interest, by contrast with the Marginalists' theory, which concerns itself with whether or not there is a long-run equilibrium rate of interest. The controversy, therefore, between the liquidity preference theory—which regards interest as a "bribe" to prevent people holding money rather than bonds—and the time preference theory—which regards interest as a bribe to persuade people to postpone enjoyments to the future—can be resolved by placing the former in the short run and the latter in the long run.

CONTEMPORARY QUESTIONS

The middle of the 20th century saw a considerable shift in the focus of concern relating to the theory of interest. Economists seemed to lose interest in the equilibrium theory, and their main concern was with the effect of rates of interest as a part of monetary policy in the control of inflation. It was recognized that the monetary authority could control the rate of interest in the short run. The controversy lay mainly between the advocates of "monetary policy" and the advocates of "fiscal policy." If inflation is regarded as a symptom of a desire on the part of a society to consume and invest more in total than its resources permit, it is clear that the problem can be attacked either by diminishing investment or by diminishing consumption. On the whole, the attack of the advocates of monetary policy is on the side of diminishing investment, through raising rates of interest and making it harder to obtain loans, though the possibility that high rates of interest may restrict consumption is not overlooked. The alternative would seem to restrict consumption by raising taxes. This has the disadvantage of being politically unpopular. The mounting concern with economic growth, however, has raised considerable doubts about the use of high rates of interest as an instrument to control inflation. There is some doubt whether high interest rates in fact restrict investment; if they do not, they are ineffective, and if they do, they may be harmful to economic growth. This is a serious dilemma for the advocates of monetary policy. On the other hand, it must be admitted that the type of fiscal policy that might be most desirable theoretically has achieved very limited public support.

Interest rates and inflation

The problem of the ethics of interest is still unresolved after many centuries of discussion; as long as the institution of private property is accepted, the usefulness of borrowing and lending can hardly be denied. In the long historic process of inheritance, widowhood, gain and loss, by which the distribution of the ownership of capital is determined, there is no reason to suppose that the actual ownership of capital falls into the hands of those best able to administer it. Much of the capital of an advanced society, in fact, tends to be owned by elderly widows, simply because of the greater longevity of the female. Society, therefore, needs some machinery for separating the control of capital from its ownership. Financial instruments and financial markets are the principal agency for performing this function. If all securities took the form of stocks or equities, it might be argued that contractual obligations (bonds), and therefore interest as a form of income, would not be necessary. The case for bonds and interest, however, is the case for specialization. There is a demand for many different degrees of ownership and responsibility, and interest-bearing obligations tap a market that would be hard to reach with equity securities; they are also peculiarly well adapted to the obligations of governments. The principal justification for interest and interest-bearing securities is that they provide an easy and convenient way for skilled administrators to control capital that they do not own, and for the owners of capital to relinquish its control. The price society pays for this arrangement is interest.

The ethics of interest

There remains the problem of the socially optimum rate of interest. It could be argued that there is no point in paying any higher price than one needs to, and that the rate of interest should be as low as is consistent with the performance of the function of the financial markets. This position, of course, would place all the burden of control of economic fluctuations on the fiscal system, and it is questionable whether this would be acceptable politically.

The ancient problem of "usury," in the form of the exploitation of the ignorant poor by moneylenders, is still important in many parts of the world. The remedy is the development of adequate financial institutions for the needs of all classes of people rather than the attempt to prohibit or even to limit the taking of interest. The complex structure of lending institutions in a developed society—banks, building societies, land banks, cooperative

banks, credit unions, and so on—testifies to the reality of the service that the lender provides and that interest pays for. The democratization of credit—that is, the extension of the power of borrowing to all classes in society—is one of the important social movements of the 20th century.

BIBLIOGRAPHY. A standard history of interest theory up to the end of the 19th century is EUGEN VON BOHM-BAWERK, *Kapital und Kapitalzins*, 3 vol. (1884–1912; Eng. trans., *Capital and Interest*, 3 vol., 1959, reprinted 1970); for the medieval approach to interest, see GEORGE O'BRIEN, *An Essay on Mediaeval Economic Teaching* (1920, reprinted 1968). The most important writings of the classical economists are ADAM SMITH, *An Inquiry into the Nature and Causes of the Wealth of Nations* (1776); DAVID RICARDO, *Principles of Political Economy and Taxation* (1817); NASSAU W. SENIOR, *An Outline of the Science of Political Economy* (1836); and JOHN STUART MILL, *Principles of Political Economy*, 2 vol. (1848). For the Marginalist school, the great work is EUGEN VON BOHM-BAWERK, *Positive Theory of Capital* (1889), vol. 2 of *Capital and Interest*. Others include FRIEDRICH VON WIESER, *Theorie der Gesellschaftlichen Wirtschaft* (1914; Eng. trans., *Social Economics*, 1927); W.S. JEVONS, *The Theory of Political Economy*, 4th ed. (1924); LEON WALRAS, *Éléments d'économie politique pure*, 2nd ed. rev. (1889; Eng. trans., *Elements of Pure Economics*, 1954); J.B. CLARK, *The Distribution of Wealth* (1899); KNUT WICKSELL, *Über Wert, Kapital und Kente* (1893; Eng. trans., *Value, Capital and Rent*, 1954), and *Geldzins und Güterpreise* (1898; Eng. trans., *Interest and Prices*, 1936); P.H. WICKSTEED, *The Common Sense of Political Economy* (1910); IRVING FISHER, *The Nature of Capital and Income* (1906), and *The Theory of Interest As Determined by Impatience to Spend Income and Opportunity to Invest It* (1930). For Marxist theory, the beginning student should probably read the abridged Marx; that is, KARL MARX, *Capital and Other Writings*, trans. by S. TRASK (1932); a somewhat unorthodox Marxist treatment is JOAN ROBINSON, *The Accumulation of Capital* (1956); and the standard modern work is ERNEST MANDEL, *Traité d'économie marxiste*, 2 vol. (1962; Eng. trans., *Marxist Economic Theory*, 2 vol., 1968). For the Keynesian contribution, the basic texts are JOHN MAYNARD KEYNES, *Treatise on Money* (1930), and *The General Theory of Employment, Interest, and Money* (1936). A good simplified exposition of the system is L.R. KLEIN, *The Keynesian Revolution*, 2nd ed. (1966). Other works somewhat in the Marginalist tradition are F.H. KNIGHT, *Risk, Uncertainty, and Profit* (1921); F.A. HAYEK, *The Pure Theory of Capital* (1941); J.R. HICKS, *Value and Capital*, 2nd ed. (1946); GUSTAV CASSEL, *The Nature and Necessity of Interest* (1903); F.A. and V.C. LUTZ, *The Theory of Investment of the Firm* (1951); B.S. KEIRSTEAD, *Capital, Interest, and Profits* (1959); ROBERT M. SOLOW, *Capital Theory and the Rate of Return* (1963); and L.M. LACHMANN, *Capital and Its Structure* (1956). General works that may be useful are K.E. BOULDING, *Economic Analysis*, 4th ed., 2 vol. (1966); R. DORFMAN, P.A. SAMUELSON, and R.M. SOLOW, *Linear Programming and Economic Analysis*, ch. 11–12 (1958); and NICHOLAS KALDOR, *Essays on Value and Distribution*, ch. 9–10 (1960).

(K.E.Bo.)

Capparales

Capparales, the caper order of flowering plants, consists of eight families, 367 genera, and 4,000 species. The type family, Capparaceae, derives its name and importance from *kapparis*, the Greek name used by Dioscorides for *Capparis spinosa*, which is the source of capers of commerce. The genus *Capparis* is often confined to arid regions of the tropics and subtropics and includes diverse growth forms such as trees, shrubs, and stragglers. In addition to this dominant genus, the order has several other genera, which provide food and flowers to mankind. The cabbage, cauliflower, knol kohl (all three are varieties of *Brassica oleracea*), turnip (*B. rapa*), and radish (*Raphanus sativus*) are important vegetables, rich in sulfur compounds and vitamin C. The edible mustard oil is from the seeds of *Brassica juncea* and *B. campestris*. The well-known horseradish tree (*Moringa oleifera*) is cultivated for its edible roots and fruits and for ben oil, used as a lubricant for watches. The mignonette (*Reseda odorata*), stock (*Matthiola incana*), wallflower (*Cheiranthus cheiri*), and candytuft (*Iberis* species) are garden plants widely cultivated for their flowers.

The two so-called crucifixion thorns (*Koeberlinia spinosa* and *Canotia holacantha*) together constitute an interesting growth form characterized by leafless, thorny thickets found only in the southwestern deserts of North America.

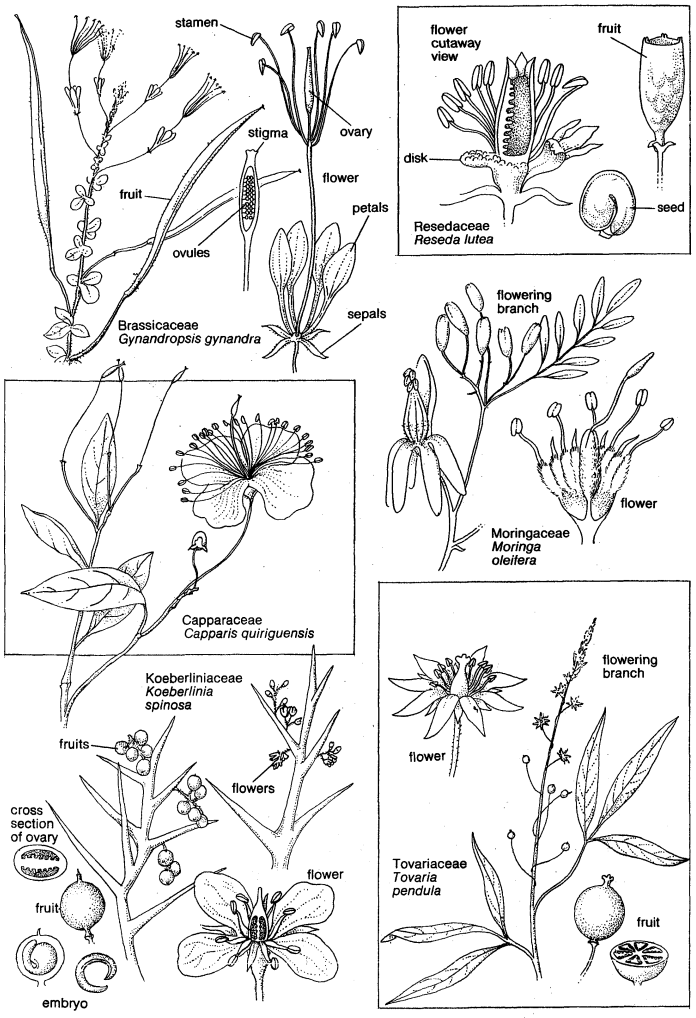
GENERAL FEATURES

Diversity of habit. The members of the order exhibit diverse growth features. Some, such as *Crataeva nurvala* and *Moringa oleifera*, are small, deciduous trees, cultivated in the tropics and subtropics. Many others are armed or unarmed (*i.e.*, thorny or not) shrubs. The arms are the paired, stipular (located at the base of leafstalks), recurved thorns, as in *Capparis spinosa* (capers), *C. micrantha*, and *Apophyllum anomalum*, which are distributed in the Mediterranean region, Africa, and Australia, respectively. The arms may also consist of the tips of the branches in *Zilla myagroides* of the Nubian Desert of Africa and *Koeberlinia spinosa* and *Canotia holacantha* (crucifixion thorns) of the southwestern deserts of North America. The leaves are short-lived in many of these species. The order is also rich in stragglers (sprawling, vinelike forms), such as *Capparis sepiaria* of India, *C. cucurbitina* and *C. scortechinii* of Malaysia, and woody lianas, such as *Maerua arenaria* of India, *Roydsia parviflora* and *R. scortechinii* of Malaysia, and *Ritchiea frangrans* of tropical Africa. The Australian *Emblingia calceoliflora* is a prostrate undershrub with a hispidulous (hairy) stem. *Cleome* (bee plant) and allied genera are mostly glandular, annual (short-lived) herbs; *Isomeris arborea* (burro fat), a close ally, is a shrub in the Mexican desert. The herbaceous annuals are also represented widely by *Capsella bursa-pastoris* (shepherd's purse), the herbaceous perennials (plants that continue to grow season after season) by *Cheiranthus cheiri* (wallflower) and *Cochlearia officinalis* (scurvy grass), and the woody perennials by *Alyssum spinosum* and *Vella spinosa*, all of the above belonging to the north temperate zone. The common aquatic forms are *Rorippa palustris* (marsh cress), *Cardamine pratensis* (cuckooflower), *C. rotundifolia* (mountain watercress), *Nasturtium officinale* (watercress), and *Subularia aquatica*, which are all found in temperate regions and on tropical mountains. *Nasturtium officinale* has spreading stems that root at the nodes ("joints" of a stem) and pinnate leaves (*i.e.*, leaves with either veins or separate leaflets arranged along either side of a central axis). *Subularia aquatica* has long, narrow, centric (shieldlike) leaves; its flowers either project above water or remain submerged and then rely on self-fertilization, because they remain closed. There are tufted xerophytes (plants adapted to dry habitats) such as *Erophila verna* and *Anastatica hierochuntica* (rose of Jericho) of Europe and the Mediterranean region, which have hairy or fleshy leaves and grow on sand dunes. Saline (salty-habitat) succulents, such as *Cakile maritima* (sea rocket) and *Crambe maritima* (sea kale), are found along the Atlantic and Baltic shores and in the Mediterranean region.

Thorns

Economic importance. *Examples from the family Capparaceae.* The pickled flower buds of *Capparis spinosa* are the commercial European capers. The root bark is bitter and may be used to treat rheumatism, paralysis, toothache, and disorders of the liver and spleen. The fruits and flower buds of *C. decidua* are edible and are often preserved in salt vinegar. The flower buds are used as potherbs. The fruit is astringent and has been used to treat heart disorders. The hard, heavy wood is used to make tool handles and boat knees (a bent piece of wood used as a brace in boat construction) because it is resistant to termite attack. *C. sepiaria*, the Indian caper, is planted as a hedge. It has been used to decrease fevers and to treat skin diseases. *C. zeylanica* fruits are edible and used in curries. The root bark has been used as a sedative and is effective against cholera. *C. mitchellii* fruits are edible and are consumed in Australia and Tasmania, where they occur. *C. corymbifera* flower buds are preserved in salt vinegar and eaten. The pounded leaves and twigs of *Cadaba farinosa* are made into cakes, puddings, and cereals; as food, it is called forsa or balambe in the

Edible and useful products



Representative plants from six of the eight families of the order Capparales.
Drawing by M. Pahl

Arabian Peninsula and tropical Africa. The leaves and seeds of *Cleome icosandra* are useful as external applications for wounds and ulcers. The seeds are also used in curries. *C. spinosa* (spiderflower) is grown as an ornamental. The ashes from the stems and leaves of *Courbonia virgate* are used as a source of salt in parts of The Sudan and Arabia.

Examples from the family Brassicaceae. *Alliaria officinalis* (garlic mustard) is used to treat gangrenous infections. *Armoracia lapathifolia* is the well-known horseradish, whose roots are used for flavouring food products. *Barbarea verna* (Belle Isle cress) is used as a vegetable. *Brassica campestris* variety *sarson* (yellow sarson, or Indian colza) provides seed oil, which is used for cooking, and oil cake, which is used as cattle feed; the tender leaves and shoots are eaten as a vegetable. *B. campestris* variety *toria* (Indian rape) has similar uses. The tender leaves and shoots of *B. hirta* (white mustard) are used as a vegetable; the seeds yield a fatty oil. *B. juncea* (Indian mustard) seed oil is used for cooking. *B. napus* (rape) leaves are used as vegetables. The seeds of *B. nigra* (black mustard) are used as a spice and condiment. *B. oleracea* variety *acephala* is the vegetable borecole, or kale. *B. oleracea* variety *botrytis* is cauliflower or broccoli, which are grown all over the world for their edible inflorescences (flower clusters). *B. oleracea* variety *capitata* is cabbage, a common vegetable. *B. oleracea* variety *gemmifera* is Brussels sprouts, a bud-bearing cabbage, the young shoots, buds, and leaves of which are edible. *B. oleracea* variety *gongylodes* is kohlrabi, or knol kohl, the short, swollen stem of which is edible. *B. pekinensis* is Chinese cabbage. *B. rapa* is the turnip. *Raphanus sativus* is the well-known radish.

Plants related to cabbage

NATURAL HISTORY

Adaptations for pollination. The perpetuation and spread of this order is facilitated by the efficient adaptation of its flowers, fruits, and seeds for pollination and dispersal. In the family Capparaceae, the pollination is by insects, which are attracted by nectar secretion, dense aggregation of the flowers, and the bright colours of the petals. Dichogamy, the maturing of the male and female organs of the same flower at different times, favours cross-pollination in many cases, as does, in *Cleome spinosa* (spiderflowers), the production of male flowers alternating with female and bisexual flowers in succession. In the family Brassicaceae, both cross- and self-pollination of the flowers occur. The twisting of stamens (male pollen-producing structures) to one side may favour cross-pollination. In such instances, however, the slightest irregularity in the movement of the visiting insect may cause self-pollination because of the close proximity of the anthers (pollen sacs) to the stigma (sticky, pollen-receiving surface of the female structure). In *Cardamine chenopodifolia* and *Subularia aquatica*, the flower remains submerged and closed (the cleistogamous condition) when the water is high. *Pringlea antiscorbutica* (Kerguelen Island cabbage) is wind-pollinated in the absence of insects suitable for its pollination. The flowers are without petals but have exerted (long, extended past the end of the flower) anthers and long, filiform (thread-like), stigmatic pollen-catching structures. In *Cardamine pratensis* (lady's smock), self-sterility favours cross-pollination. In mignonette (*Reseda odorata*) of the family Resedaceae, different parts of the flower play different functions in the process of pollination. Nectar is secreted by the large, posteriorly projected petal-like disk. The white, fringed edges of the petals, the red anthers, and the strong odour attract the insect visitors. The pistil (female structure consisting of stigma, style, and ovary), with terminal, papillose (nipple-like) stigmas, projects from the centre, and the stigmas receive the pollen carried by insect visitors. If the insects fail to visit the flowers, the stigmas, which lie directly below the anthers, eventually receive pollen from them and achieve self-pollination.

Adaptations for dispersal. The dispersal of fruits and seeds in the Capparales order is caused by a variety of agents. The wind is the chief agent of dissemination in the desert. In North African deserts, fruits and seeds are either winged or are light or hairy; a pair of wings usually surrounds the fruit in *Zilla macroptera*, and the seeds are velvety in *Cleome arabica*. In *Morettia phileana* of the Nubian Desert and *Sisymbrium altissium* (tumbling mustard) of Europe and North America, the withered plants and their inflorescences (flower clusters) are blown about, scattering the fruits and seeds. In *Anastatica hierochuntica* (rose of Jericho), of the deserts of Asia Minor and North Africa, the plants curve into balls, or "roses," in drought and are blown along by the wind until they reach a wet spot; there the balls unfold along with the valves of the fruit, dispersing the seeds. In *Biscutella californica* the fruits are edged with hairs. In *Cochlearia*, the four- to six-seeded locules (ovary chambers) are dispersed by the valves acting as wings. In *Draba verna* (whitlow grass) the thin septum of the dried fruit sends the small, light seeds away like tennis balls from a racket. The fruits of *Crataeva nurvala* and *C. macrocarpa* in Malaysia, Burma, and Indochina and the seeds of *Mathiola incana* (stock) and *Nasturtium officinale* (watercress) are dispersed by river waters. The seeds of *Cakile maritima* and *Crambe maritima* and the fruits of *Raphanus maritimus* are disseminated by sea tides. In *Nasturtium lacustre* and *Cardamine pratensis* (cuckooflower) the leaves with bulbils or adventitious buds float and develop into new plants elsewhere. Animals act as agents for the dispersal of seeds in the order Capparales through their excreta. Seeds of *Sisymbrium sophia* and *Capsella bursa-pastoris*, for example, are distributed through the excreta of cattle; fruits of *Draba alpina* and seeds of *Cardamine bellidifolia* and *Cochlearia arctica*, are dispersed in the excreta of birds; and fruits of *Draba verna* are carried in the excreta of earthworms. The seeds of Capparales

Wind-blown tumbling plants

may also be dispersed by simple adhesion to the feet of man, cattle, and the wheels of carts. The mucilaginous seeds of *Capsella bursa-pastoris* stick to the feet of gulls and those of *Cardamine* (white top), *Senebiera heleniana*, and *Lepidium perfoliatum* (peppergrass) to seashore birds.

Adaptation to environment. The propagation of plants by seeds is strongly handicapped in saline and arid conditions because of incomplete seed ripening in mother plants at times; low soil moisture; hard, nonabsorbing soil crusts; high concentrations of soluble salts; or destruction of seedlings due to various factors such as irregular rainfall, animals, wind erosion, and deposition of mud. Large seeds with large food supplies may be advantageous in establishing seedlings in spite of competition for light and moisture, eating by animals, wind erosion, and other factors. The large seeds of *Crambe maritima*, for example, send down an extensive root at an early stage of development, enabling the species to colonize adverse habitats in the early phase.

Delayed germination. Many of the desert seeds possess germination-inhibiting substances. The seeds of *Eruca boveana* and *Carrichtera annua* of the dry Mediterranean, Arabian, and Persian regions contain inhibiting factors; as much as ten to 20 centimetres (four to eight inches) of rain wash away these factors, thereby considerably improving the percentage of germination of such seeds. The fruit valves of *Sinapis alba* contain a blastokoline substance that suppresses the germination of the seeds. Some desert annuals from Arizona sprout only after a long period of ripening. *Lepidium lasiocarpum* is ready to germinate after one year and *Streptanthus arizonicus* after 26 months. The presence of inhibitors and the habit of germinating only after a long period of ripening are believed to be adaptations to the scattering of germination in time, enabling the seeds to get established at times when favourable external conditions exist. Many annuals seem to counterbalance the danger of extermination in dry habitats by profuse seed production. Even the tiniest ephemeral, such as *Erophila verna* of the Mediterranean region, sets numerous fruits and ripens large numbers of seeds.

Significance of delayed germination

Sexual versus vegetative propagation. The natural propagation of plants by seeds is observed mainly in crop plants. In ornamentals, however, the propagation is both by seeds and vegetative means.

In an environment that is favourable for growth and flowering, such as the damp woodlands of the British Isles, profuse vegetative propagation takes place as an alternative to low seed production. In *Cardamine pratensis* (lady's smock), although the plants flower profusely, because of scanty seed production, 70 percent of them reproduce vegetatively by means of buds developed at the base of the terminal leaflets. In *Dentaria bulbifera* (coralroot) the reproduction is exclusively or mainly by means of bulbils that replace the lower flowers on the inflorescence. The upper flowers rarely produce fertile seeds. The bulbils, about one millimetre in length and three in thickness, normally develop near the parent plant. Vegetative spreading is also by rhizomes, horizontal, rootlike stems. The species is restricted to certain woods in Great Britain, although many other woodlands appear to be suited for its growth. Similarly, *Nasturtium sylvestre* (wood cress) also rarely produces fertile seeds in spite of free flowering. It spreads profusely by means of prostrate stems that root at the nodes.

Ecology. Members of this order grow in varied ecological conditions. Trees, shrubs, and climbers of *Crataeva*, *Maerua*, and *Capparis* grow in tropical rain forests. In tropical deserts the undershrubs and shrubs such as *Farsetia aegyptiaca*, *Zilla myagroides*, *Capparis spinosa*, *C. decidua*, *Apophyllum anomalum*, *Koeberlinia spinosa*, and *Canotia holacantha* grow on clefts of rocks and sandy hillocks.

Plants such as *Crambe maritima*, *Cakile maritima*, and *Cochlearia anglica* grow along the seashore, enduring low concentrations of salts and the consequent physiological dryness. *Draba alpina*, *Cochlearia nudicaulis*, and *Cardamine bellidifolia* grow in Arctic regions, withstanding continuous light during summer and low temperatures and dry winds in winter. *Cochlearia fenestrata*, along with its flowers and fruits, resists low temperature without protection.

FORM AND FUNCTION

Morphological features. The order consists of herbs, shrubs, small trees, and lianas. The leaves are alternate or opposite, simple or palmately compound, and they have stipules. In *Capparis*, *Apophyllum*, *Koeberlinia*, and *Canotia*, the leafless shrubs form dense thickets either by recurved stipular spines or thorny-tipped branches.

The flowers have petals, are bisexual, and are hypogynous (*i.e.*, the sepals, petals, and stamens arise at the base of the ovary) or perigynous (sepals, petals, and stamen partly enclose the ovary), with numerous to few stamens and an ovary of two or more fused carpels. The fruit may be a fleshy berry or drupe or a dry silique, silicle, or capsule—fruits that open by one or more sutures, or lines of weakness. The seeds are curved or straight, winged or nonwinged.

Physiological features. In desert species such as *Capparis decidua* and the crucifixion thorns, spiny, leafless, green stems form thickets, and there are strongly developed taproots. *Apophyllum anomalum* of Australia is also leafless but is covered with a thick coat of plant hairs. In *Zilla spinosa* and *Ochradenus baccatus* the leaves of the rainy season are replaced by smaller, summer leaves. The seaside *Cakile maritima* and the dune-inhabiting *Cochlearia officinalis* are succulents; by storing water in their stems and leaves, the former resists high salt concentrations and the latter drought.

Dry habitat adaptations

The Arctic and Alpine *Draba alpina*, *Cochlearia nudicaulis*, *C. fenestrata*, and *Cardamine bellidifolia* have thick, small, cushion-like stems and short, leathery leaves with concealed stomata (pores).

EVOLUTION AND CLASSIFICATION

The families Capparaceae and Brassicaceae form the core of the order Capparales. They have many common vegetative and floral features and cells. Other shared features suggest that the family Capparaceae is ancestral to the Brassicaceae.

The orders Capparales and Violales are regarded by somes authorities as parallel offshoots of the order Theales. Others, however, consider the Capparales to have originated from the most primitive members of the order Violales, similar to the family Flacourtiaceae of that order.

Annotated classification.

ORDER CAPPARALES

Herbs, shrubs, small trees, and lianas; leaves alternate or opposite, simple, pinnately or palmately compound, with stipules; flowers with petals, bisexual, hypogynous or perigynous, regular or irregular; stamens numerous to few; ovary of 2 or more fused carpels with parietal placentation; fruits fleshy berries or drupes or dry dehiscent siliques, silicles, or capsules; seeds reniform (kidney-shaped) or not, or winged or nonwinged; embryo conduplicate (folded) or curved; endosperm scanty. Distribution mainly topics.

Family Capparaceae

Herbs, shrubs, climbers, and trees; leaves alternate, simple or pinnate; stipulate or not; flowers regular (radially symmetrical) and bisexual; sepals 4, overlapping; petals 4, overlapping; stamens 6 to numerous; disk annual or missing; ovary on a gynophore (a stalk), 1-celled; ovules campylotropous (turned at right angles to their stalks), with parietal placentation (*i.e.*, ovules are attached to ovary walls); stigma capitate, sessile; fruit a capsule, berry, or drupe; seeds angular or reniform (kidney-shaped); endosperm (starchy, nutrient tissue) scanty; embryo curved and folded. The family includes 42 genera and 925 species distributed in warm temperate and tropical regions of the world.

Family Brassicaceae (Cruciferae; mustard family)

Annual or perennial herbs with pungent juice; leaves alternate, without stipules; flowers bisexual, regular, sepals 4, 2 saccate (bag-shaped), imbricate (overlapping); petals 4, imbricate; stamens 6, tetradynamous (4 long and 2 short stamens); ovary 2-celled with a central partition; ovules many, in 2 series on 2 parietal placentae, or 1 or 2 erect; stigma fused or 2-lobed; fruit a silique or silicle (short or long, respectively, podlike fruits); seeds small; endosperm none;

cotyledons (seed leaves) plano-convex. There are about 373 genera and 3,200 species, cosmopolitan in distribution but centred chiefly around the Mediterranean.

Family Moringaceae

Trees; leaves deciduous, alternate, pinnate; lacking stipules; flowers bilaterally symmetrical, bisexual in panicles (many-branched clusters); sepals 5-cleft, petaloid, imbricate; petals 5; disk-lining calyx tube; stamens 5 perfect alternating with 5 to 7 sterile, antherless ones; anthers 1-locular (chambered); ovary 1-locular, parietal placentation; style (upper part of ovary) tubular; stigma truncate; fruit a capsule; seeds many, winged; endosperm none; cotyledons plano-convex; radicle (root end of embryo) short; plumule (aerial end of embryo) many-leaved. One genus with 12 species distributed from Africa to India.

Family Resedaceae

Annual and perennial herbs; leaves alternate; stipules gland-like; flowers bilaterally symmetrical, bisexual; sepals 2- to 8-lobed, imbricate; petals 6 to 8, valvate; stamens 3 to 45 on an androgynophore (a stalk supporting both male and female structures); disk strongly developed posteriorly; ovary of 2 to 7 fused carpels, 1-locular, gaping at the tip; parietal placentation; stigma sessile (*i.e.*, perched directly on the ovary —there is no style); fruit a capsule; seeds numerous, reniform; embryo curved or folded; cotyledons incumbent (*i.e.*, they lie face to face in the seed with the back of one against the hypocotyl of the embryo); endosperm absent. Six genera with 70 species distributed from Europe to Central Asia and India and in South Africa and California.

Family Koeberliniaceae

Shrubs; branches spine-tipped; leaves alternate, scalelike, deciduous; without stipules; flowers in racemes, bisexual; sepals 4 or 5, imbricate; petals 4 or 5, imbricate; stamens 5 to 10; ovary 5- to 2-locular with axile placentation; style persistent; fruit a few-seeded capsule or a berry; embryo straight or curved; endosperm scanty. Two genera with 1 species each, distributed in southwestern United States and Mexico.

Family Tovariaceae

Annuals; leaves alternate, trifoliate (of 3 leaflets); flowers bisexual, regular; sepals 8, imbricate; petals 8, imbricate; stamens 8, positioned opposite the lobes of the petals; ovary 6- to 8-locular, axile placentation; stigma sessile, 8-rayed; fruit a berry; seeds numerous, small; embryo curved; endosperm scanty. One genus with 2 species distributed in Mexico, Jamaica, and the tropical Andes.

Family Emblingiaceae

Undershrubs; leaves opposite; flowers solitary in the axils of leaves; sepals 5, the portion next to the flower axis dimidate (halved—having the appearance that ½ is missing); petals 2, connate, slipper-like, stamens 8 or 9, on an androgynophore, the 4 located away from the main flower axis fertile, the 4 or 5 next to the flower axis sterile; ovary 1, with 1 basal ovule; stigma sessile; fruit dry and indehiscent; seed flattened; embryo linear, folded together lengthwise; endosperm scanty. One genus with a single species distributed in Australia.

Family Pentadiplandraceae

Shrubs and climbers; leaves alternate; without stipules; flowers polygamous (both unisexual and bisexual flowers found on the same plant); sepals 5, valvate; petals 5, connivent (in contact) at base, imbricate; stamens 9 to 13, present in male and bisexual flowers; rudimentary ovary present in male flowers; female flowers with 10 long, slender sterile stamens; ovary superior on a short stalk, 5- to 4-locular with axile placentation; fruit a berry. One genus with 2 species in Africa.

Critical appraisal. There are many taxonomic problems in this order.

The Cleomoideae, a subfamily of the Capparaceae, closely resemble the family Brassicaceae in their herbaceous habit and capsular fruit with central partitions. Some authorities raise the Cleomoideae to the rank of family, called Cleomaceae, which is considered to be closely related and basic to the family Brassicaceae. This treatment needs support from other enquiries such as floral anatomy, embryology, and pollen morphology, however.

The resemblance and position of the family Tovariaceae with respect to the family Capparaceae could be better understood if the vascular anatomy of the axile placentation and eight-parted flower were better known.

The systematic position of the family Emblingiaceae is disputed. It shows resemblance with the families Capparaceae, Goodeniaceae, Scrophulariaceae, and Verbenaceae and Polygalaceae. More information on the floral and vegetative anatomy, embryology, and others is necessary to know the exact relationship of this group.

(H.S.N.)

Caprimulgiformes

The order Caprimulgiformes includes about 100 species of soft-plumaged birds, the major groups of which are called nightjars, nighthawks, potoos, frogmouths, and owlet frogmouths. The order also includes the aberrant oilbird of South America. Most are twilight or night-flying birds. Many produce sounds that are startling, strange, or weirdly beautiful and are surrounded by an aura of mystery richly endowed to elicit interest and sometimes fear from man. The name of the type genus *Caprimulgus*, "goatsucker," derives from an ancient belief that the birds seen flitting about the goats at dusk, actually preying on the insects disturbed or attracted by the goats, were taking milk from the goats' udders, a misconception no doubt fortified by the birds' uncommonly large mouths. There is now a tendency to replace the name goatsucker with the more appropriate term nightjar, derived from the birds' voices.

The caprimulgiform birds are sparrow- to raven-sized (14–55 centimetres) birds with enormous gapes, cryptically coloured and patterned plumage, short legs and, for the most part, long wings.

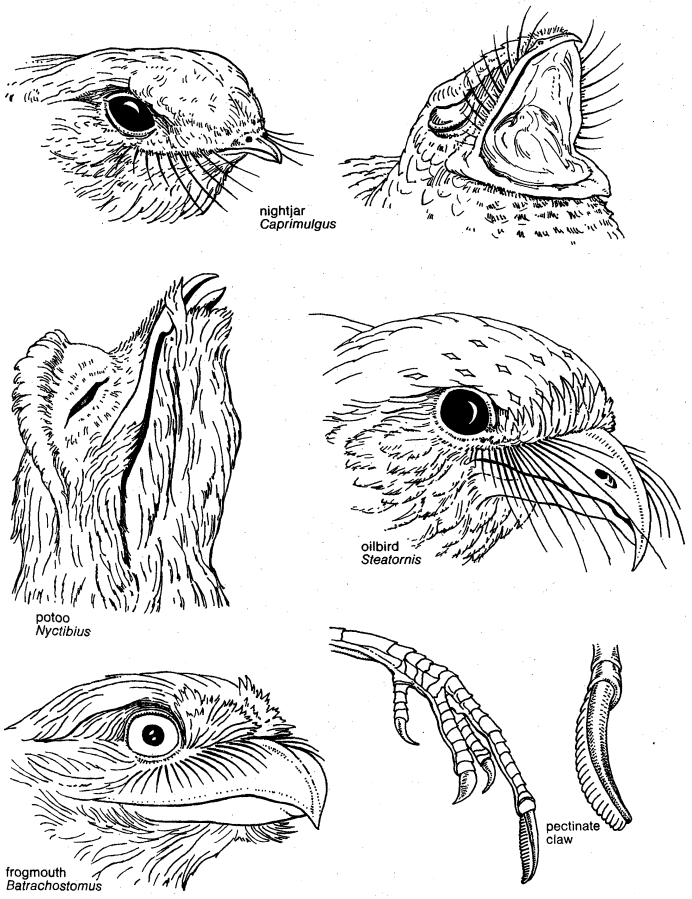
Comparison with owls

All caprimulgiform birds are rather similar in general appearance, but each family has certain peculiar characteristics both in form and in habits. Their closest relatives are the owls (Strigiformes) which they resemble in many ways, but there are numerous differences between them. Many of these are internal, but among those externally apparent are the bill and feet, which are not raptorial; the flatter head with eyes placed laterally rather than in a frontal facial disk; the relatively shorter tarsi and longer tails. Closer inspection reveals differences in the number of primary feathers in the wing and usually of secondaries and tail feathers as well. The nightjars also share some features with the swifts (Apodiformes), but these seem to be more superficial and coincidental than indicative of close phylogenetic relationship.

Although the true nightjars (Caprimulgidae) are amply distributed throughout the world, the other families are more restricted. The order is absent from New Zealand and some oceanic islands.

NATURAL HISTORY

The caprimulgiform birds are primarily crepuscular, their activity being largely limited to the periods of dawn and dusk, although they are also nocturnal when there is



Beak and claw structure of representative Caprimulgiformes.
Drawing by E.J. Pfiffner

sufficient illumination, especially by moonlight. Some species may become active on dark, cloudy days, and a few are somewhat diurnal. Oilbirds possess a system of echolocation that permits them to fly freely in total darkness, an adaptation related to their roosting and nesting in caves, and are thus implicitly well equipped for nocturnal life. They leave their caves at dusk and return at dawn and are highly gregarious in their foraging behaviour as well as in roosting and nesting. The other members of the order are more or less solitary. Some nightjars that are migratory behave gregariously during migration and to some extent while in their "wintering" regions.

Although aerial feeders, most of the true nightjars roost on the ground, rocks, or fallen trunks, but some prefer horizontal branches of trees, in which case they usually perch lengthwise along the branch. Some ground roosters, however, will seek higher perches as singing posts or from which to forage; these are often slender branches or vines and the birds sit on them crosswise. Some species may even roost so perched. Unlike the nightjars, the frogmouths, potoos, and owlet frogmouths are arboreal. The last normally sit crosswise on a branch and fairly upright, both when active and at rest, resembling small, long-tailed owls. Potoos and frogmouths frequently sit crosswise and upright when actively foraging and also appear very owllike, although at rest they may perch quite differently. The potoos are noted for a peculiar stance, perching usually at the top of a stump, broken branch, or at a knob on an upwardly inclined limb. When alarmed in daylight they slowly flatten their plumage and stretch their bills upward in a stiff posture with the eyes nearly closed and the bill slightly open. Frogmouths adopt a similar broken-branch alarm posture.

During the day, the oilbird perches horizontally on ledges inside caves, usually on its nest. Ledges are limited and mostly occupied by nests. On its forays outside it has been observed to perch on the bare parts of tree branches. Its mien is rather hawklike, but its crouching stance, unique in some ways, is more like that of a nightjar.

Habitat. The caprimulgiform birds exploit ample food sources that are almost uniquely theirs. There are no other primarily frugivorous nocturnal birds to compete with the oilbird, its distribution being limited by the availability of suitable caves in regions providing the proper fruit for food.

Competition between species

The nightjars, by far the largest and most successful group, have no effective avian competitors for the great numbers of night-flying insects except among themselves; and the different nightjars have come to occupy almost all habitats, from semidesert to very humid regions and from sea level to 4,000 metres' altitude, with further advantage by preferring the more open areas: savannas, grasslands, and forest clearings. When woodland dwellers, they live in the more open forests or brushwood growths, and many use the woodlands only for diurnal concealment or nesting, doing most of their feeding at the edge or in clearings.

Competition between the nightjars and potoos is reduced because the latter hunt mostly from higher perches in open country or exploit the space above the great forests, a vast niche occupied by practically no other nocturnal bird.

Frogmouths and owlet frogmouths inhabit forested savannas, forest edge, second growth, and the more open forests. Thus their chief competitors are the insectivorous owls. As with the nightjars, differences in food preferences and methods of hunting minimize this competition. The hole-nesting owlet frogmouths, however, have to contend not only with owls but also many diurnal species for suitable nesting sites, and this may explain why they are apparently the least successful family in the order, as suggested by their limited distribution and paucity of numbers.

Food habits. Except for the oilbird, caprimulgiform birds are insectivorous, with some of the larger species occasionally carnivorous. Many of the nightjars and nighthawks feed in continuous hawking flight, which may be rather erratic as they pursue their prey. Others of the order make short sallies from arboreal or terrestrial perches in the manner of flycatchers, frequently taking advantage of the increased visibility afforded by roads. Many nightjars take crawling insects by swooping from arboreal perches or by running along the ground, being far more agile on their feet than is generally believed. Almost all insects are taken, but beetles predominate in the food of many species. Also important are moths, the winged forms of termites and ants, and mosquitos; even small birds are taken. There seems to be little difference between the general kinds of food items taken by the New and Old World nightjars (subfamily Caprimulginae), but the Old World species rely more on foraging in continuous flight than do most in the New World, where aerial foraging is largely limited to the nighthawks (Chordeilinae).

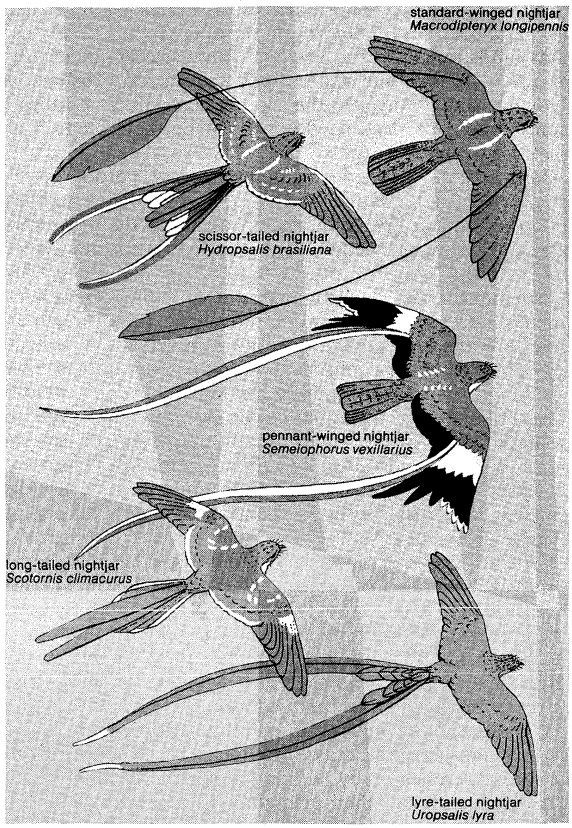
Potoos sally from exposed arboreal perches, sometimes fairly close to the ground, to feed on essentially the same types of insects as the nightjars. The prey items of frogmouths are mostly terrestrial. In short sallies from elevated perches, frogmouths capture large, crawling arthropods on the ground or on branches. Snails, frogs, mice, small birds, and occasionally fruit also are taken. Owlet frogmouths feed mostly on terrestrial prey, much in the manner of the frogmouths, but also sally from a perch to take flying insects.

Aberrant in so many ways, oilbirds are the only nocturnal, exclusively frugivorous birds. The fruits eaten are primarily of various trees of the palm, laurel, and bursera families and have large hard seeds. The firm, fleshy pericarp of the fruit is exceedingly rich in protein and oily fats. The fruits are swallowed whole and the seeds later regurgitated. D.W. Snow has found that oilbirds apparently possess an efficient olfactory sense, suggesting that they employ scent in locating certain of the fruit-bearing trees. The fruits of palms, however, are not aromatic and are no doubt located by sight. The actual col-

lection of the fruit seems to depend on sight. In feeding, the birds reach out with their bills and pluck the individual fruits while hovering. When feeding on large compact bunches of fruit they sometimes cling briefly with their feet.

Males of most, if not all, nightjars have patches of white feathers that serve as signals in mating. These patches are concealed when the bird is at rest but flashed in courtship displays. Males of several species in Africa and South America develop elongated wing or tail feathers that function in courtship and are lost following the breeding season.

Drawing by E.J. Pfiffner



Specialized feathers in male Caprimulgiformes.

Vocalizations. The primary signals for mating and territorial purposes in most caprimulgiforms, however, are vocal and mechanical sounds. The voice is usually well developed, often having such distinctive patterns that the birds are named onomatopoeically (whippoorwill, chuck-will's-widow, etc.). The almost human lament of the common potoo (*Nyctibius griseus*) in South America has in some places earned this species the name "poor-me-one," and both it and the grotesque bawl of the great potoo (*N. grandis*) have been the source of many superstitious beliefs and legends. Frogmouths sing with various nasal booming, hooting, or croaking sounds, and the little known owlet frogmouths are reported to give owllike whistles, churring calls, and a loud hissing note. Among the true nightjars, some species produce slowly or rapidly repeated churring sounds, in some cases rather toadlike, while others produce a warbled or whistled song, not at all disagreeable. Whistled phrases may be repeated hundreds of times without a break. Many different types of calls are used in different contexts, but the primary song, different for each species, appears to be the most important mechanism for species recognition. Besides vocal sounds, many species produce mechanical sounds in displays, such as claps and whirrs of the wings. In some species the vocalizations are given primarily in flight, in others primarily when perched; still others have different calls or songs when flying than when perched.

Oilbirds produce a variety of sounds, from clucking calls, apparently used to maintain contact, to harsh snarls and screams, when excited. They seem to have no primary song, which may be superfluous to their gregarious and specialized mode of life. Of greatest interest are the rapidly pulsated clicks which are emitted in shorter or longer bursts and which D.R. Griffin has found are used by the oilbird for navigation in total darkness on the principle of echolocation. These clicks are in the range of 7,000 cycles per second and thus audible to humans, in contrast to the ultrasonic pulsations used by bats in their system of echolocation. So far as is known, the only other birds to employ echolocation are some of the cave-swiftlets (*Collocalia* species). To what extent oilbirds use echolocation outside the caves is not known. As do their relatives in the order, they have large, sensitive eyes and probably navigate visually outside their caves.

Echolocation by the oilbird

Reproduction. There is considerable diversity in nesting habits among caprimulgiform families. Nightjars make no nest, depositing their eggs directly on the ground or on the leaf-covered floor of woodland. Occasionally they use a slight natural depression or scratch out a place among the debris. Populations of a few species (notably the North American nighthawks) have adapted to urban life and nest on flat gravel-covered rooftops. The one or two slightly glossy eggs may be cryptically coloured (profusely marbled with pink, buff, brown, or gray) or be quite in contrast with their surroundings (white to buffy, usually with slight lines or blotches of colour). Incubation lasts about 19 days and may be by both adults or only by the female, there being considerable variation in this behaviour even within some species.

In contrast to the simplified nesting of nightjars, frogmouths construct nests on the horizontal forks of trees. In the genus *Podargus* the nest is of twigs and other plant matter and the two or three eggs are white; in *Batrachostomus* the nest is a pad of the birds' own down, bound and camouflaged externally with cobwebs and lichens, one white egg being laid. Both sexes are believed to incubate, the period being about 30 days. Owlet frogmouths nest mostly in hollow trees but also in tunnels in banks. They lay three or four white eggs, usually on a mat of leaves or fur. The incubation period is as yet unknown. The potoos are the most highly restricted nesters, for they must find a branch or stub with a suitable depression or crevice of just the right size to accommodate the single egg they lay. The egg is flat white, marked with brown and gray, and is incubated by both parents for 30 to 35 days.

On ledges in the caves they inhabit, the oilbirds build up a shallow nest rim of viscous, regurgitated fruit matter, which sets to a firm structure. As the accumulation of seeds raises the level inside the nest, the rim is constantly added to, so as to maintain a slight depression. The nests are used year after year and gradually grow to low mounds. Inevitably some seeds and the feces of very young nestlings contribute to the fabric of the rim. Two to four eggs are laid (white, subelliptical, slightly rough surface); both sexes incubate, the period being about 33 days.

Behaviour of the nestling

The chicks of nightjars are semiprecocial: they are down covered (buffy to brownish, plain or mottled, highly cryptic), fed by both parents, capable of opening their eyes on the first day (normally keeping them closed for several days), capable of walking on first day, and able to hop or run very well by third or fourth day. They usually run with wings raised, resembling young ducklings in gait. From the beginning chicks may solicit feeding by walking to the front of the adult, reaching up, and pecking at its bill. During the first days they are fed a regurgitated whitish viscous substance but later only partially digested insects. As early as the second day, although sometimes not until a week later, the chicks are led to different resting sites, at first only a metre or so at a time, but gradually much greater distances. Some of this moving may result from the chicks' own wanderings, for they are often restless and leave the covering adult.

In many cases both parents brood the chicks, in others

only the female does so, and rarely the male assumes the primary role. By about two weeks the young are well feathered and too large for successful brooding; they rest at first near a parent but later quite alone.

Undisturbed young birds fly voluntarily at from 22 to 28 days; disturbed young may fly much earlier. About the time they are able to fly they begin a certain amount of feeding on their own but are still largely dependent up to 40 to 50 days. When two young hatch, one of them frequently develops more slowly and most often disappears during the second week. If it survives, however, it may require up to 40 days to reach the state of voluntary flight.

The nestlings of frogmouths, potoos, and owlet frogmouths are semidependent, covered with whitish down, fed by both parents, and remain in the nest until fledged. A.F. Skutch found that a young common potoo began wandering over the boughs of the nest tree at about four weeks. This same nestling first made trial flights at 47 days and finally left the nest tree when 50 days old. Other reports indicate the nestling period of potoos to be of 40–45 days, that of frogmouth to be about 30 days. The young are brooded only during the first half of this period, by which time young potoos have attained the juvenile plumage (whitish mottled with brownish) and are already accomplished in assuming the "broken branch" posture of adults.

On the whole, the caprimulgiform birds, like most birds, breed solely or mostly at the time of maximum abundance of food supply. Oilbirds may nest to some extent throughout the year, but the maximum nesting takes place during that time of year when the greatest number of appropriate trees are fruiting. Baby oilbirds are helpless (altricial), hatched blind and virtually naked, with only a little sparse down. They have an exceedingly slow rate of development. A thicker coat of down replaces the initial one after three weeks, and the adult plumage begins to appear at five weeks, there being no special juvenile plumage. The nestlings are apparently fed semidigested fruit pulp during the first days. At about two weeks there is a gradual change to whole fruits, regurgitated by the adults into the mouths of the young. As a result of the oil-rich fruit diet, young oilbirds build up extraordinary deposits of fat, which has led to economic exploitation. The fat can be boiled down to a high quality, durable oil, suitable for cooking and lighting. For this reason oilbirds were once subject to heavy predation by their human neighbours, a practice that continues even today, on a much reduced scale because of a general trend toward protection. The fat buildup reaches its maximum at about 70 days, at which time a young oilbird may weigh half again as much as an adult. By this time the plumage is well developed but not fully grown. The weight decreases as the feathers grow, until at an age of 100–120 days the young leave the nest, flying well and looking like adults. Both parents participate in feeding and brooding, the latter ceasing after about four weeks.

Migration. A number of tropical caprimulgiforms are sedentary, but the widespread cosmopolitan nightjars exhibit all degrees of migration. These migrations may be short, even local, or quite long. Some populations of the common nighthawk (*Chordeiles minor*) of North America and the European nightjar (*Caprimulgus europaeus*) migrate south to Argentina and South Africa, respectively. Actually, transequatorial migrations in both directions occur, as birds take advantage of the general alternation of seasons, and hence of food supply, on opposite sides of the Equator.

Lowering of body temperature in torpor

Hibernation. Some nightjars are able to cope with temporary food shortages by entering into periods of torpidity, a faculty they share with some swifts, hummingbirds, and a few others. The only known instances of apparently regular, prolonged annual hibernation in these birds, however, are reported for the poorwill *Phalaenoptilus nuttallii*, a nightjar. A banded individual was found by E.C. Jaeger to hibernate in the same small hollow in a rock during several successive winters. The bird was inert, with respiration and heart rates reduced to almost immeasurable levels and body temperature about 22° C below normal. Subsequent laboratory experiments have shown that several species of nightjar have the ability to relax into a torpid state under abnormal conditions. Such an efficient means of conserving energy may be more generally possessed than is presently realized throughout a family whose habits largely limit the birds to two brief periods of feeding a day, causing them to be especially vulnerable to involuntary fasting if inclement weather should prevent feeding during those periods.

FORM AND FUNCTION

Members of this order are easily recognized by their extremely wide mouths, large eyes, short legs and small, weak feet, and, except in the oilbird, soft plumage, in which browns and grays predominate.

The size of the gape is astonishing. When the bird opens its mouth, the opening seems to span the entire head, which is nearly the case. The beak, always somewhat hooked, is large and horny in the oilbird and frogmouths but reduced to a small projection in the remaining families. In body proportions, caprimulgiforms often appear chunky on account of the fluffiness of their plumage, but their actual bodies are proportionately no stouter than most songbirds. The tail is of medium length, except in males of those species with ornamental tail features. The wings are medium to long, and rounded in most species, pointed in a few, especially the nighthawks.

The plumage of all forms presents unexcelled examples of natural camouflage. Coloured in rufescent to ochreous browns, grays, white, and black, the species are variously patterned in greatest accord with their normal surroundings during daytime rest. Those nightjars that roost inside woodlands are streaked and spotted in a way resembling fallen leaves and other detritus on the forest floor. Those that dwell on gravelly terrain are speckled or otherwise patterned. The latter often contrast rather than blend with the soil, appearing like one of the many stones scattered about. The owlet frogmouths appear as clusters of dead leaves. Potoos and frogmouths are streaked and mottled like bark so that in the daytime alarm posture they appear most effectively as dead stubs.

Red and gray colour phases

Caprimulgiform species are frequently dichromatic, having grayish and reddish phases. These appear to be randomly distributed in some cases and sex-linked in others, there being several species of nightjars in which males are more grayish, females more reddish.

Except for possible freaks, the iris colour is brown in nearly all members of the order. Yellow occurs in the irises of some potoos, and yellow, orange, and ruby in frogmouths. Contrary to some reports, oilbirds do not have blue irises nor are any nightjars known to have yellow eyes.

CLASSIFICATION

Distinguishing taxonomic characters. The most important characters used to define the caprimulgiform birds are the type of plumage, structure of the feet and legs, form and structure of the bill, palatal structure, arrangement of the pelvic muscles and flexor tendons, shape of dorsal vertebrae, meristic characters such as the number of primary and secondary feathers and rectrices, presence or absence of intestinal ceca and of an oil gland, location of syrinx, presence and type of rictal bristles, powder down patches, carotid artery relationships, and a few other anatomical details. Variations in some of these same features characterize the different subgroups.

Annotated classification. The arrangement presented is the same as that proposed by A. Wetmore (1918) in a modification of R. Ridgway (1914). The group was then considered a suborder Nycticoraciae of the order Coraciiformes. The subsequent shift to ordinal level with the name Caprimulgiformes has long been accepted.

ORDER CAPRIMULGIFORMES

Soft plumaged (except Steatornithes), cryptically patterned birds with relatively weak anisodactyle feet and very short tarsi; deeply cleft gape (except Steatornithes); pelvic muscle formula AXY (XY in Steatornithes); flexor tendons fused

(synpelmous); 10 primaries; 11–13 secondaries; 10 rectrices; aftershaft small but present; 2 carotid arteries and oil gland present (except in *Podargus* and *Nyctibius*).

Suborder Steatornithes

Dorsal vertebrae opisthocoelous (concave behind); gape not exceptionally deeply cleft; rostrum movably articulated with skull; plumage firm.

Family Steatornithidae (oilbird)

No fossil record. Locally distributed in Guyana, Venezuela, Colombia, Ecuador, Peru, and Trinidad. Desmognathous palate (maxillopalatine bones fused), palatines narrow and not expanded posteriorly; large, strong bill with hard rhamphoteca (horny covering) and subterminal tooth, surrounded by long vibrissae; bronchial syrinx; 15 cervical vertebrae. One species, length 40 centimetres.

Suborder Caprimulgi

Dorsal vertebrae heterocoelous (saddle-shaped); deeply cleft gape; rostrum fixed; plumage soft.

Family Podargidae (frogmouths)

No fossil record. Confined to Australasian (except New Zealand) and southern Oriental regions (including extreme southern India). Desmognathous palate; palatines broad throughout, slightly expanded posteriorly; wide, strong bill with hard rhamphotheca; bronchial syrinx; 13 cervical vertebrae; well-developed powder down tufts on either side of rump; oil gland absent in *Podargus*, very small in *Batrachostomus;* one carotid artery (left). Twelve species, length 20–40 centimetres.

Family Nyctibiidae (potoos)

Upper Pleistocene to present. Neotropical region. Schizognathous palate (small vomers and separate maxillopalatines); palatines narrow anteriorly, greatly expanded posteriorly; small, weak bill but with prominent horny angular projection on maxillary tomium midway between tip and rictus and tomium very broad, horny, and strongly convex from that point to rictus; extremely short tarsi; toes unusually wide basally, forming a broad flattened sole; tracheobronchial syrinx; 14 cervical vertebrae; large powder down patches on sides and breast; no oil gland; one carotid artery (left). Five to 7 species, length 20–55 centimetres.

Family Aegothelidae (owlet frogmouths)

No fossil record. Australasian region (except New Zealand). Desmognathous palate; bill similar to Podargidae but shorter, weaker, and largely hidden by forehead feathering; bronchial syrinx; unique in the order in lacking ceca. Eight species; length 16–25 centimetres.

Family Caprimulgidae (nighthawks, nightjars)

Earliest probable fossil Oligocene, earliest modern fossil *Caprimulgus* in Pliocene (Europe). Worldwide in tropical and temperate zones; absent from northernmost Eurasia and America, southernmost South America, New Zealand, and some oceanic islands; subfamily Chordeilinae (nighthawks) restricted to New World. Schizognathous palate (except *Chordeiles* and perhaps other Chordeilinae); palatines narrow anteriorly, greatly expanded posteriorly; small, weak bill; well-developed rictal bristles (except *Eurostopodus* and Chordeilinae); small, weak feet; lateral toes much shorter than middle toe, fourth toe with only four phalanges (segments; five is normal for this order), middle claw with inner edge pectinated; hallux very short and directed inward; tracheobronchial syrinx; 14 cervical vertebrae. Seventy to 80 species; 14–40 centimetres (without ornamental feathers).

Critical appraisal. The major divisions of the caprimulgiform birds are clearly defined and their composition remarkably homogeneous so that there are no apparent taxonomic problems above the level of genus. The rather aberrant oilbird has some characters similar to owls, but the weight of evidence places it in this order. Studies of the egg-white proteins by C.G. Sibley show that it is clearly caprimulgiform. These investigations indicate a close relationship between the nightjars and the owls but do not support one to the swifts. Within the order the main taxonomic problems relate to re-evaluation at the generic level and clarification of species limits. These are likely to be settled only with the aid of field studies utilizing bioacoustical methods in combination with other disciplines.

BIBLIOGRAPHY. The natural history of North American nightjars is extensively discussed by A.C. BENT, "Life Histories of North American Cuckoos, Goatsuckers, Hummingbirds and Their Allies," *Bull. U.S. Natn. Mus. 176* (1940); that of European nightjars in D.A. BANNERMAN and G.E. LODGE, *The Birds of the British Isles*, vol. 4 (1955). F. HAVERSCHMIDT, *The Birds of Surinam* (1968), includes much information on the South American caprimulgiforms. J.P. CHAPIN, "Birds of the Belgian Congo, Part II," *Bull. Am. Mus. Nat. Hist.*, vol. 75 (1939), contains readable accounts of the natural history of several tropical nightjars. D.W. SNOW, "The Natural History of the Oilbird, *Steatornis caripensis*, in Trinidad, W.I." *Zoologica*, vol. 46, pp. 27–48 (1961) and vol. 47, pp. 199–222 (1962), provides an excellent and readable account of the natural history of that species. The information on nightjar hibernation is scattered among a number of short journal articles, but the reader will find interesting summaries in E.C. JAEGER, "Further Observations on the Hibernation of the Poorwill," *Condor*, vol. 51, no. 3, pp. 105–109 (1949); and J.T. MARSHALL, JR., "Hibernation in Captive Goatsuckers," *Condor*, vol. 57, no. 3, pp. 129–134 (1955). A review of the more recent work in this field is presented by G.T. AUSTIN and W.G. BRADLEY, "Additional Responses of the Poorwill to Low Temperatures," *Auk*, vol. 86, no. 4, pp. 717–725 (1969).

(P.A.S.)

Caracalla

Emperor of Rome from 211 to 217, Caracalla has often been regarded as one of the most bloodthirsty tyrants in Roman history, whose reign contributed to the decay of the Empire. His best known achievements are the Constitutio Antoniniana de Civitate, of 212, which gave Roman citizenship to almost all inhabitants of the empire and the construction in Rome of the *Thermae Antonin-ianae*, or Baths of Caracalla.

By courtesy of The Art Museum, Princeton University

Caracalla, marble bust, 3rd century. In the Art Museum, Princeton University.

Born at Lugdunum (Lyons), in Gaul, on April 4, 188, he was the elder son of the future emperor Lucius Septimius Severus, a North African, and Julia Domna, a Syrian. He was originally named Bassianus, after his maternal grandfather, who had been high priest of the Syrian sun-god Elagabalus. On receiving the title Caesar in 196, he assumed the name Marcus Aurelius Antoninus, because his father wanted to connect his family with the famous dynasty of the Antonines. In 198 he was given the title of Augustus, which nominally meant he had equal rank with his father. The nickname Caracalla was based on his alleged designing of a new cloak of that name. Another of his nicknames, Tarautas, was that of an ugly, insolent, and bloodthirsty gladiator whom he was thought to resemble.

The ancient sources concerning his life and character are by no means reliable. One of them, for example, recounts that as a boy he was amiable, generous, and sensitive and only later became insufferable; but the same source reports in another context that he was fierce by nature. Modern treatments emphasize Caracalla's Syrian heritage as one of the most important elements in his character, although here, too, due caution must be applied, since Eastern origin was in no way incompatible

with a high degree of Romanization. Julia herself was well acquainted with Greco-Roman culture and hired excellent teachers to give her son the best education available. It is reported that he studied the Greek orators and tragedians and was able to quote long passages from the Greek playwright Euripides but also that he strongly despised education and educated people. This may have been the result of his passion for military life, which probably developed when he accompanied his father on his many military expeditions.

At the age of 14 he was married to Fulvia Plautilla, the daughter of the influential and ambitious commander of the imperial guard, Fulvius Plautianus; he is said to have hated Plautianus and played an important role in having him executed on the charge of a conspiracy against the imperial dynasty. He also exiled his own wife to an island and later killed her.

Enmity between Caracalla and Geta

A significant development was the growing rivalry between Caracalla and his younger brother Geta, a rivalry that was aggravated when Severus died during a campaign in Britain (211), and Caracalla, nearing his 23rd birthday, passed from the second to the first position in the empire. All attempts by their mother to bring about a reconciliation were in vain, and Caracalla finally killed Geta, in the arms of Julia herself, it is said. There can be no doubt about the savage brutality of Caracalla's act, but a solution that would have been at once moral and practicable was not in sight.

Caracalla next showed considerable cruelty in ordering many of Geta's friends and associates put to death. Probably in order to regain goodwill, he granted an amnesty to exiles, a move denounced as hypocritical in ancient sources, which also slander Caracalla's most famous measure, the so-called Constitutio Antoniniana de Civitate, as a device designed solely to collect more taxes.

His expeditions against the German tribes in 212/213, when he senselessly massacred an allied German force, and against the Parthians in 216–217 are ascribed by ancient sources to his love of military glory. Just before the Parthian campaign, he is said to have perpetrated a "massacre" among the population of Alexandria, probably in response to a disturbance there.

Caracalla's unpredictable behaviour is said to have prompted Macrinus, the commander of the imperial guard and his successor on the throne, to plot against him: Caracalla was assassinated at Carrhae, in Mesopotamia, at the beginning of a second campaign against the Parthians on April 8, 217.

Character

Important for the understanding of his character and behaviour is his identification with Alexander the Great. Admiration of the great Macedonian was not unusual among Roman emperors, but, in the case of Caracalla, Alexander became an obsession that proved to be ludicrous and grotesque. He adopted clothing, weapons, behaviour, travel routes, portraits, perhaps even an alleged plan to conquer the Parthian empire, all in imitation of Alexander. He assumed the surname Magnus, the Great, organized a Macedonian phalanx and an elephant division, and had himself represented as godlike on coins.

Another important trait was Caracalla's deeply rooted superstition; he followed magical practices and carefully observed all ritual obligations. He was tolerant of the Jewish and Christian faiths, but his favourite deity was the Egyptian god Sarapis, whose son or brother he pretended to be. He adopted the Egyptian practice of identifying the ruler with god and is the only Roman emperor who is portrayed as a pharaoh in a statue.

In the many portraits of him, Caracalla's head is usually shown inclined to the right, facing left—like Alexander—his look fierce, his forehead distorted by sharp wrinkles, his chin split into two halves, with curly hair, a short-cut beard and moustache, and a rather flat and blunt nose. Modern authors suggest that his features are typically North African, inherited from his father. In any event, the expression of vehemence and cruelty is obvious, and some sources say that he intentionally reinforced this impression, perhaps because it flattered his vanity to spread fear and terror. It is also said, contradictorily, that he was of small size but excelled in bodily exercises, that he shared the toils of the rank and file but also weakened his virility by a dissolute life and was not even able to bear the weight of a cuirass.

A similar inconsistency characterizes the judgments about his mental state. He was said to be mad but also sharp minded and ready witted. His predilection for gods of health, as documented by numerous dedicatory inscriptions, may support the theory of mental illness.

If Caracalla was a madman or a tyrant, the fact had no great consequences for his administration of the empire, which may or may not have been vitally influenced by Julia Domna and the great jurists who surrounded him. He was venerated by his soldiers, who forced the Senate to deify him after his death, and there is no indication that he was especially disliked among the general population. In any case, the Roman Empire at that time was still strong enough to bear a ruler who certainly lacked the qualities of an outstanding emperor.

BIBLIOGRAPHY. English translations of the ancient sources in the "Loeb Classical Library": CASSIUS DIO, *Dio's Roman History*, trans. by E. CARY, bk. 77–79; *Herodian*, trans. by C.R. WHITTAKER, bk. 3 and 4; *Scriptores Historiae Augustae*, vol. 2, trans. by D. MAGIE. The most reliable of these sources is Cassius Dio. The most detailed treatment of Caracalla's life and reign is the dissertation of D.C. MACKENZIE, *The Reign of Caracalla* (1949).

(F.P.K.)

Caracas

Caracas, capital of the Republic of Venezuela and of its federal district, is one of the most highly developed Latin American cities. From a modest city at the beginning of the 20th century, it had become the country's metropolis, with a population early in the 1970s of nearly 2,200,000 in its metropolitan area. With its new avenues, bridges, streets, and multi-storied buildings, it is a cosmopolitan business and residential centre. The city, which lies 3,025 feet (922 metres) above sea level in a valley surrounded by mountains of the central highlands, offers a series of impressive views from its numerous hilltops, to which modern construction has spread. Almost all of the valley's inhabitable area has been covered by urban growth, and the once green and peaceful valley is now an urban area, crisscrossed by automotive traffic, in which the pace of life is becoming increasingly feverish. The area of the city is 29.7 square miles, of the metropolitan area is 139 square miles, and of the federal district is 745.1 square miles.

History. A ranch was established in the valley in 1555 by Francisco Fajardo, the son of a Spanish captain and an Indian chief's daughter, and in 1561 Juan Rodríguez Suárez founded a town on the site of the ranch; but the town was soon destroyed by Indian attacks. The conquest and resettlement of the region began in 1566, and Diego de Losada is credited with the actual founding of the city in 1567. He named it Santiago de León de Caracas in honour of the apostle James, who is the patron saint of Spain; of don Pedro Ponce de León, who was the provincial governor; and of the Caracas Indians, who inhabited the region. The valley was fertile and the climate pleasant and healthy.

The colonial city

In 1578 the city was a quadrilateral formed of 24 squares centred on a plaza. The streets were straight and cobbled, and down them came rivulets of water from the hills. Three houses were made of brick, each of two floors, with straw roofs; most houses had walls of *bajareque* (cane and earth), packed earth, or adobe and roofs of straw or tile. The average house was large, with tree-filled patios and arcades and separate slave quarters and stable.

The urban area at that time was limited by the Catuche and Caroata ravines in the east and west, respectively; the Cerro El Avila on the north; and the Río Guaire on the south. Initial growth in the area was along the road to the north and then toward the south. Later, development progressed to the west and east, making necessary the construction of bridges across the ravines, and then, at the beginning of the 20th century, became more pronounced in the east. Caracas now has two urban centres:

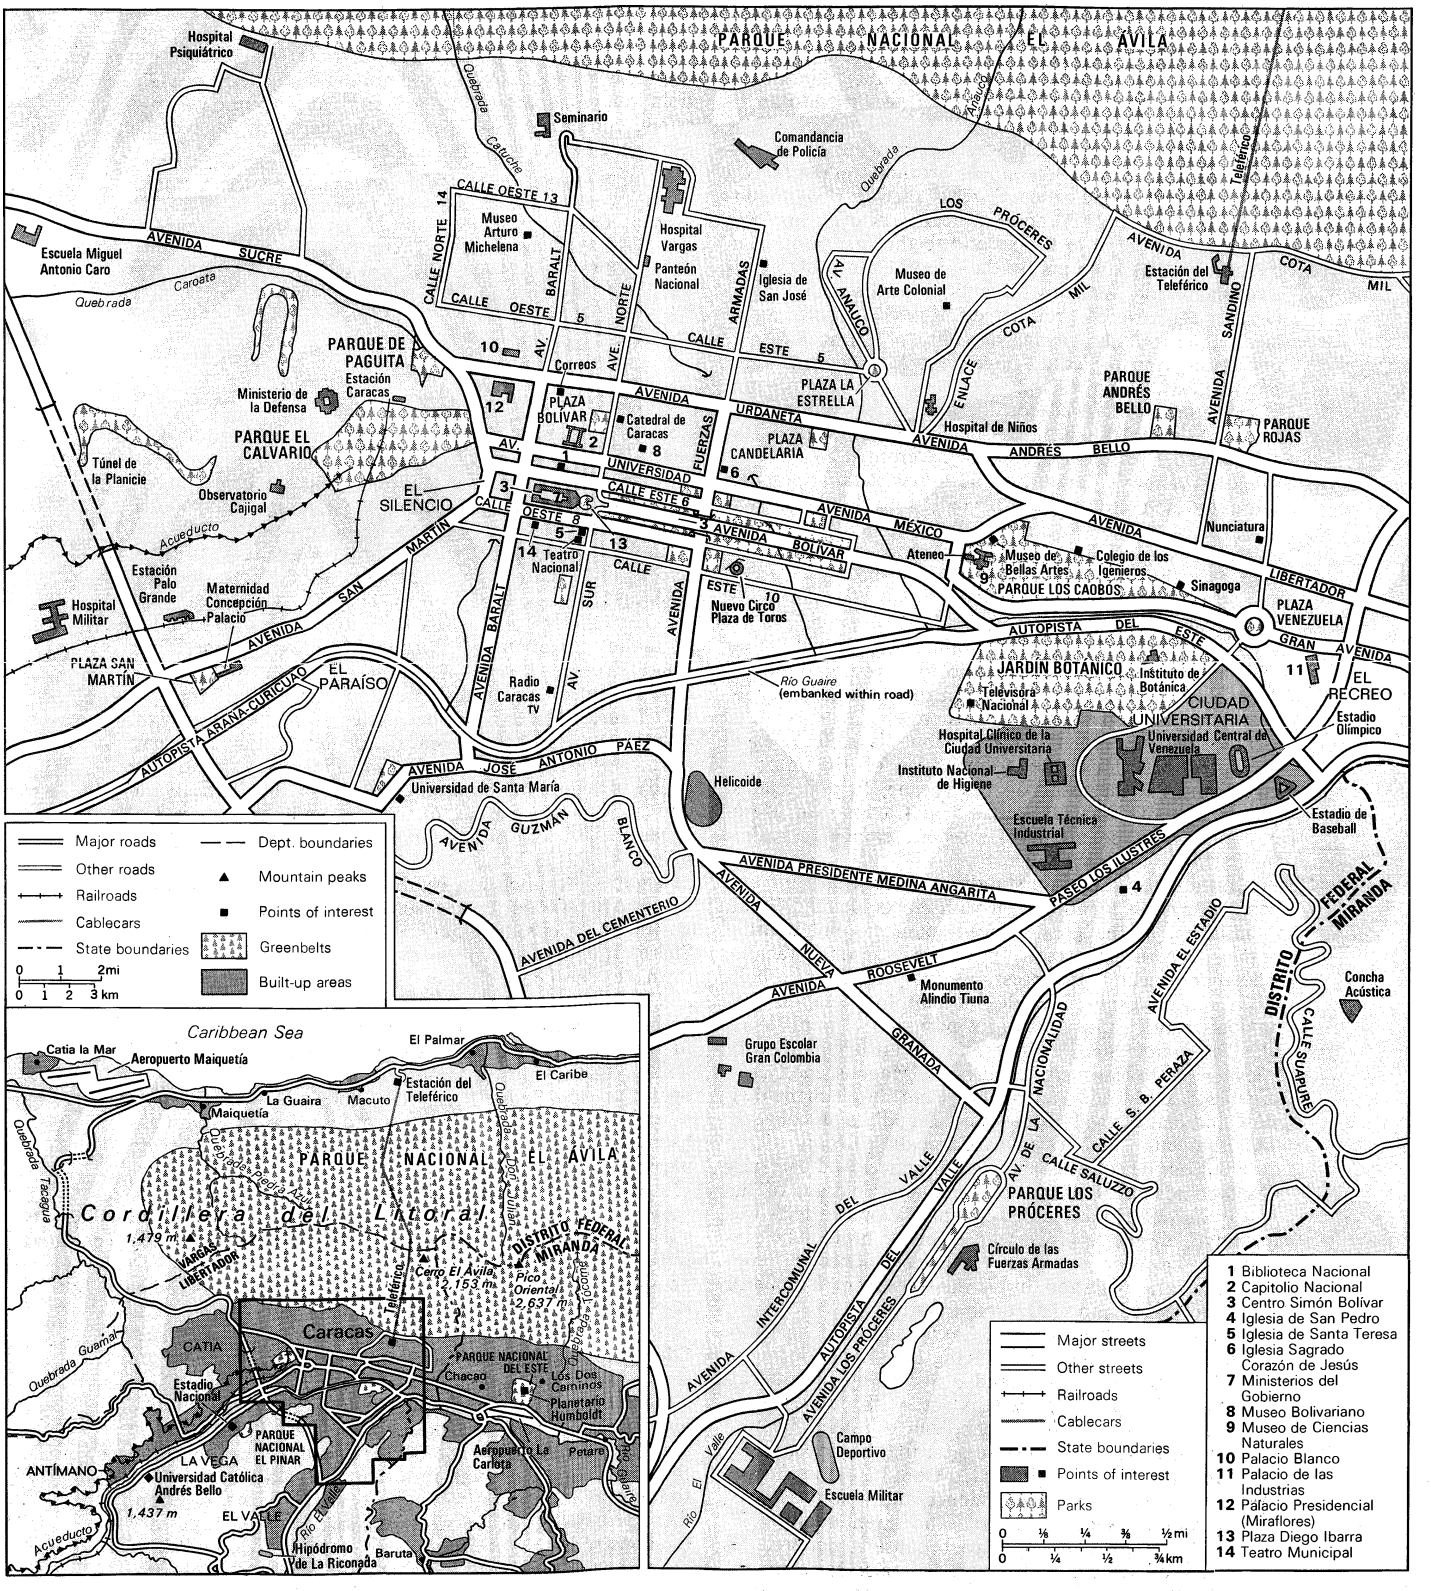
the Old City around the main plaza (named Plaza Bolívar in 1865) and the El Recreo commercial centre located between the old city and Chacao, the area of greatest growth toward the east, where the city has expanded into the state of Miranda.

The city was sacked by English buccaneers in 1595. Its buildings were almost totally destroyed by two great earthquakes in 1755 and 1812, and, in the war of independence, it was repeatedly subjected to slaughter and pillage by both sides. In 1577 Caracas acquired its status as a provincial capital. Later, it successively became the residence of the captain general of Venezuela and, upon independence, the capital of the republic.

The contemporary city. *The city site and layout.* The site of the city is a high rift valley seven miles inland from the Caribbean Sea, to the north.

Valley topography

Caracas is sheltered between two mountain systems that enclose it at all cardinal points. The Cordillera del Litoral a very high mountain range, protects the north from east to west; and toward the south and east are the hills of the Serranía del Interior, the slopes of which reach as far as the valley's centre, interrupting the gentle inclines of the



Central Caracas and (inset) its metropolitan area.

terrain that comes down from the Cordillera del Litoral. The greater part of the valley consists of hills and lowlands with occasional brief flatlands. Hill and valley interweave forming the principal valley and secondary valleys that make up the metropolitan area.

The municipal area (*i.e.*, city) extends 5.7 miles from north to south and 3.1 miles from east to west. The metropolitan area includes the municipal area, the four surrounding parishes, and five towns in the state of Miranda. It extends 9.3 miles from north to south and 17.6 miles from east to west.

Climate and environment. The decisive climatic factor is the valley's altitude. Temperatures range from 45° to 91° F (7.2° to 32.8° C), the annual mean being about 68° F (20° C). During the rainy season (May–November) the humidity is high, but during the dry season (December–April) the weather is delightful.

At the end of the 19th century and the beginning of the 20th, Caracas still retained the red roofs and blue hills evoked by its poet J.A. Pérez Bonalde. Almost all of these have now disappeared from the city. The stone streets no longer exist, and the ample houses surrounded by trees and ancient haciendas and plantations once outside the city have been replaced by rows of houses and apartment buildings.

Caracas' principal river is the Guaire, once large and important but now reduced to very small volume. Its principal affluent in the metropolitan area is the Río El Valle, and other affluents include the Quebrada Baruta and the Quebrada Anauco. These water sources are not suitable for human consumption, and the rainwater received by the catchment basin is insufficient for the population's needs.

Rich plant and animal life

Throughout the valley, on the numerous mountain spurs and their slopes, the abundant vegetation remains green throughout the year, irrigated by the streams and brooks flowing from the mountain ranges. This rich Caracan flora contains great variety including orchids and other tropical plants and flowers and many fruit trees and other species. The metropolitan area has 97 species of birds in its parks and gardens and is visited by migrating species from October to April, and there are many multicoloured butterfly species throughout the area all year. The valley contains fauna that abound in native species including marsupials, 30 species of bat, armadillo, sloth, mountain deer, fox, skunk, puma, and many others.

Pattern of growth. In 1870, the urban transformation of Caracas began under Pres. Guzmán Blanco. Under the influence of the French architectural taste of the period, many buildings in the Spanish colonial style disappeared or were modified. Bridges and avenues were built, and some streets were widened to encourage the city's growth. At the beginning of the 20th century, the first urban real-estate development, designed for the upper class, was built outside the old city and called El Paraíso. A short time later, Nueva Caracas, an urban real-estate development for the middle class, was begun in Catia, to the west.

Beginning in 1936, after the death of Gen. Juan Vicente Gómez, who had been dictator for 27 years, the country experienced a new era of prosperity. Caracas grew in population and extended its construction as far as was geographically possible. In the downtown area of the city, the El Silencio district was transformed into a middle-income complex of apartment buildings: this development was programmed in 1939, together with a Regulating Plan for Caracas. It was built between 1941 and 1945 and consisted of six blocks containing 750 residential apartments and 200 commercial locations; the first work of such magnitude in the country, the development marked the beginning of the city's modern architectural tendency.

Rapid urban development

These years marked the beginning of the city's construction fever and its urban development. The change in the appearance of Caracas was an abrupt and overwhelming one. The old city began to disappear, and the great rows of trees on the nearby haciendas gave way to modern residential developments. Numerous suburbs went up overnight on the spurs of the hills, and villas and commercial buildings were built at a feverish pace in the valley plains. In addition, there was an over-reached boom, at all levels, in the large-scale building and sale of cooperative apartment houses. Also, there progressively appeared publicly built urban housing developments controlled by the Workers' Bank.

Transportation. Caracas is linked directly by highway to several neighbouring towns and connected by a large network of heavily trafficked roads to more distant communities. La Carlota Airport links Caracas to the most important cities within Venezuela, and Maiquetía Airport, located 12 miles from Caracas on the coast, provides international connections. La Guaira and Puerto Cabello are Caracas' natural ports, through which most merchandise is imported. An aerial cablecar rises from sea level to 6,904 feet on the Cerro el Avila between La Guaira and Caracas; another goes from the city itself to

Karl Weidmann—Pix

Santa Teresa Church (lower left) and Centro Simón Bolívar in downtown Caracas.

the Avila summit. A modern highway including two long tunnels through the mountains leads to the beaches and tourist areas of the coast. Within the city a great number of buses, private automobiles, taxis, and jitneys contribute to increasing traffic congestion during rush hours. The public transportation system is deficient, but plans have been made for the construction of a subway. The city has modern avenues and several large expressways.

Demography. There were about 18,500 inhabitants in the city in 1771. The figure was 40,000 in 1800. Growth came to a halt during the war for independence between 1810 and 1830 and began to revive only toward the end of the century. The slight increase was intensified during the first decades of the 20th century. After 1930, encouraged by the country's exploitation of oil, rapid population growth began. Metropolitan Caracas' population reached the 1,000,000 mark in 1955, and the 1971 census figure approached 2,200,000. Statistics reveal that since 1936 the population of Caracas proper has increased nearly nine-fold while the city has grown six times in area, and the demand for transportation has increased eight and a half times.

Population growth

The racial elements of the Caracan population, like that of Venezuela as a whole, include the white, Indian, and black races, with white and mestizo (mixed white and Indian) predominating. The dominant religion is Roman Catholicism, but other religions are permitted, including Protestantism and Judaism. Domestic migration, intense in recent years, has created the problem of marginal slums, known as the poverty belt, surrounding Caracas. Foreign immigration is appreciable.

Housing. There were about 260,000 housing units in Caracas at the time of the 1961 census, distributed as follows: 90,000 houses and villas; 90,000 apartments; 26,000 individual rooms in rooming houses, country homes, apartments, and tenements; and 54,000 *ranchos* (poverty housing constructed with scrap materials). By 1971 there were 400,000 housing units and the number of *ranchos* had declined substantially. Since the early 1960s large blocks of uniform dwellings have gradually replaced old homes in the Spanish colonial style, of which few now remain.

Economic life. The city's growing industry includes the production of sugar, processed foods, beverages, tobacco (cigarettes), clothing, wood, paper and cardboard, graphic arts, marblework, jewelry and silversmithing, butter and vegetable oils, rubber, glass, chemical and pharmaceutical products, plastics, leather and hides, and metallurgy and naval and automotive construction. The construction industry has become the foremost urban activity, creating a parallel growth in auxiliary industries such as cement and construction materials. Caracas is the centre of both domestic and foreign commerce and supplies the domestic market with most of its industrial production. As a result of its position as the centre of private and foreign capital and of state finances, it is the principal centre of petroleum-related activities and the seat of the country's major banking houses and industrial and commercial enterprises.

Government. Caracas is the permanent site of the national government's executive, legislative, and judicial branches. Caracas itself is governed through the Liberator department of the federal district, composed of ten urban parishes and four parishes outside the urban area. Five towns in the state of Miranda (Petare, Chacao, Leoncio Martínez [Los Dos Caminos], Baruta, and El Hatillo) form an integral part of the metropolitan area. Caracas has been the seat of an archbishopric since 1804, of a bishopric since 1535.

Public utilities. The city is supplied with water by aqueducts under the control of the National Institute of Sanitary Works. The main aqueduct is the Butterfly Dam, which collects the waters of the Tuy rivers from the nearby Tuy valleys at Lagartijo.

Caracas has had electric power since 1897. There are now several thermoelectric plants in the valley, in addition to others using hydroelectric power. Gas is supplied by pipelines from two systems in the interior, Las Mercedes in Guárico and Anaco in Anzoátegui.

Health. Caracas is endowed with clinics, sanatoriums, hospitals, and rest homes for the health care of the capital's population. The principal health centre is the Clinic Hospital of University City.

Like all great cities, Caracas has a pollution problem as a result of excessive emissions from automobiles, factories, and chimneys, as well as from other contaminants produced by industrial activity and the burning of waste and rubbish collected in the city. A great deal of contaminated water collects in the lower part of the Río Guaire, complicating the problem still further. Noise, a fourth form of environmental pollution, has intensified, especially as a result of the greater number of automobiles.

Education. There are five sectors of education both public and private: primary, secondary, normal, arts and trades, and university. There are, in addition, numerous kindergartens for those under six years. The most important centre of higher education is the Central University of Venezuela (also known as the University of Caracas), established 1721. With a capacity of 30,000 students, its buildings and installations form a modern university city enclave in the centre of the valley. Other universities are Simón Bolívar, which is public and oriented toward technology, and the private universities Andrés Bello Catholic, Metropolitan, and Santa Maria. Other educational centres include the National Institute of Hygiene, the Technical Industrial School, the Gran Colombia Normal School (for girls), the Miguel Antonio Caro Normal School, and the Military Academy. Located on the highway leading to the nearby town of Los Teques is a centre of advanced scientific research. There is also a specialized institute devoted to the technical preparation of workers at all levels.

Higher education

Cultural life. Numerous cultural activities in the city include theatre, exhibitions of painting and sculpture, concerts, lectures, dance, and film. The principal cultural institutions are the academy of the language, the academies of history, medicine, political and social sciences, physical sciences and mathematics, and fine arts, as well as Writer's House, the Athenaeum of Caracas, and the Venezuelan Association of Journalists. Also in Caracas are the national library and the fine arts and the natural science museums, as well as art galleries, which have proliferated in recent years. Theatrical activity is concentrated in the municipal and national theatres, and numerous outlying theatres provide opportunities for small acting groups. The Institute of Culture and Fine Arts has developed an intense cultural program in the metropolitan area.

The media. Caracas has wide press service. The most important dailies are *El Nacional*, *El Universal*, *Ultimas Noticias*, *La Religión*, and *La Verdad*, appearing in the afternoon, and the evening papers, *El Mundo*, *Meridiano*, *El Globo*, and *Extra*. There is also an English daily, *The Daily Journal*. There are several weekly magazines, literary and cultural journals, and scientific publications. There are also four commercial television stations and one government station, as well as 28 radio stations.

Recreation. Numerous athletic stadiums are available for baseball, football, tennis, and other sports; there are also swimming pools, golf courses, a bullfighting ring, and a racetrack. The mountains and the beaches are nearby. There are public gardens and plazas, a zoo, monuments, museums, and historic buildings, churches, and avenues. The most popular parks are the Avila National Park, a forest preserve on the Cerro El Avila, Los Caobos Park, once the forest of a coffee plantation, the Central University Botanical Garden, and the Parque del Este, in La Floresta. A program for the creation of "pocket parks" out of uncultivated land in the metropolitan area has already resulted in the creation of a modern park from the old El Paraíso race track. This policy is helping in part to solve the problem of insufficient green zones within the populated area.

Caravaggio

Michelangelo Merisi, called Caravaggio after his birthplace, was an early Baroque painter who was probably the most revolutionary artist of his time. Abandoning the Platonic ideal of representing human and religious experience through idealized types that had guided a century of art before him, he kept his eye firmly on man, discovering that life is always a drama and that all experience, even mystical, seems to take its first steps within the concreteness and sensuality of physical phenomena. Possessed of an intensely emotional and rebellious personality and with a thorough understanding of the significance of real events in a physical world, he became in his work a master of the dramatic moment; his paintings reveal dramatic tension drawn to the snapping point. His view of man remains unique in his period of art, however, and, although he was widely admired and his remarkable techniques imitated, he was a solitary figure in his own time.

Anderson—Alinari

"The Calling of St. Matthew," oil on canvas by Caravaggio, c. 1597–98. In the Contarelli Chapel, S. Luigi dei Francesci, Rome. 3.39 × 3.49 m.

Caravaggio was born September 28, 1573, in Caravaggio, a town near Milan in northern Lombardy. He was the son of Fermo Merisi, steward and architect of the Marquis of Caravaggio. Orphaned at 11, Caravaggio was apprenticed in the same year to Simone Peterzano of Milan, a painter and teacher of drawing who sometimes styled himself "the pupil of Titian" but whose painting bore little relation to that of the Venetian master. Peterzano promised to keep the boy four years and train him to work on his own. Caravaggio may have stayed on at Peterzano's studio after the four years were over, or he may have begun independent work, travelling to the art centres of Venice or Bologna.

At some time between 1588 and 1592, Caravaggio went to Rome. He was already in possession of the fundamental technical skills of painting and had acquired, with characteristic eagerness, a thorough understanding of the approach of the Lombard and Venetian painters, who opposed to idealized Florentine painting had developed a style that was nearer to representing nature and events. Travelling from Milan to Rome, the young painter must certainly have stopped at Parma, Bologna, Florence, and Assisi and seen the works of the Carracci, contemporary innovators from Bologna, and the earlier masterpieces of Masaccio and Giotto. These encounters probably influenced Caravaggio to temper with a firmer line his Milanese technique, vibrant with chromatic and atmospheric transparency, and to discipline in formal composition the passionate, almost instinctive adherence to reality that appears in his plainest and most humble subjects.

Early influences

First years in Rome. Caravaggio arrived in Rome at the beginning of the last decade of a century that had been dominated artistically by the presence of Michelangelo, held to be without equal, and dominated intellectually by the Council of Trent, which launched the energetic and exuberant period of the Counter-Reformation. Rome was a city in ferment, overflowing with visitors, among whom were artists from all over the world, like Caravaggio moved by ambition and necessity, seeking glory and fortune. Caravaggio settled into the cosmopolitan society of the Campo Marzio. This decaying neighbourhood of inns, eating houses, temporary shelter, and little picture shops in which Caravaggio came to live suited his circumstances and his temperament. He was virtually without means, and his inclinations were always toward anarchy and against tradition. In these surroundings Caravaggio began the first phase of his career in Rome.

These first five years were an anguishing period of instability and humiliation. According to his biographers, Caravaggio was "needy and stripped of everything" and moved from one unsatisfactory employment to another, working as an assistant to painters of much smaller talent. He earned his living for the most part with hackwork and never stayed more than a few months at any studio. Finally, probably in 1595, he determined to set out on his own and began to sell his pictures through a dealer, a certain Maestro Valentino, who brought Caravaggio's work to the attention of Cardinal Francesco del Monte, a prelate of great influence in the papal court. Caravaggio soon came under the protection of del Monte and was invited to receive board, lodging, and a pension in the house of the Cardinal. This patronage made possible the beginning of Caravaggio's first experience of security and prestige.

Patronage of Cardinal del Monte

Despite spiritual and material deprivations, Caravaggio had painted up to the beginning of del Monte's patronage not less than some 40 works, many of them ambitious compositions: "The Musicians," "Lute Player," "Ecstasy of St. Francis," "The Young Bacchus," "The Fortune-teller," "Rest on the Flight into Egypt," "Narcissus at the Fountain," "The Magdalene," "The Sacrifice of Isaac," and "Basket of Fruit" are the most outstanding of these early works. They form a series of astonishing pictorial inventions, which show great taste and delicacy in their craftsmanship and a sureness and felicity of expression that is in sharp contrast to the daily quality of Caravaggio's disorderly and dissipated life. These were works for private collectors. In each composition there is proof of Caravaggio's professional attitude toward painting. In particular, these early paintings proclaim his conviction that "it takes as much hard work to do flowers as a human figure" and that "the painter who is worth something can execute natural things well." In "Basket of Fruit" the fruits, painted with brilliance and vivid realism, are handsomely disposed in a straw basket, and they form a striking composition in their visual apposition.

Major Roman commissions. With these works reality won its battle with manner, but it is in the cycle of the life of St. Matthew in the Contarelli Chapel that Caravaggio's realistic naturalism first fully appears. Probably through the agency of del Monte, Caravaggio ob-

St. Matthew cycle

tained, in 1597, the commission for the decoration of the Contarelli Chapel in the church of S. Luigi dei Francesci in Rome. This commission established him, at the age of 24, as a *pictor celeberrimus*, a "renowned painter," with important protectors and clients. The task was an imposing one. The scheme called for three large paintings of scenes from the saint's life, "St. Matthew and the Angel," showing the Evangelist writing his Gospel with the assistance of an angel; "The Calling of St. Matthew," showing the moment when Christ chose Matthew as a disciple; and "The Martyrdom of St. Matthew." The execution of all three works, in which Caravaggio substituted a dramatic realism imbued with disquieting social attitudes for the illustrative formulas of the hagiographic tradition, provoked public astonishment. Perhaps Caravaggio was waiting for this test, on public view at last, to reveal the whole range of his diversity and novelty. His novelty in these works is not only one of the surface appearance of structure and subject, but it involves the artistry itself, the sense of time and the light. The first version of the canvas that was to go over the altar, "St. Matthew and the Angel," was so offensive to the canons of S. Luigi dei Francesci, who had never seen such a representation of a saint, that it had to be redone. The Evangelist has the physical features of a plowman or a common labourer. His big feet seem to stick out of the picture, brutally thrown in the face of the faithful, and his posture, legs crossed, is awkward almost to the point of vulgarity. The angel does not stand graciously by but forcefully pushes Matthew's hand over the page of a heavy book, as if he were guiding an illiterate. What the canons did not understand was that Caravaggio, in elevating this humble figure, was copying Christ, who had himself raised Matthew from the street.

The other two scenes of the St. Matthew cycle are no less disconcerting in the realism of their drama. "The Calling of St. Matthew" shows the moment at which two men and two worlds confront each other: Christ, in a burst of light, entering the room of the toll collector, and Matthew, intent on counting coins in the midst of a group of gaily dressed idlers with swords at their sides. In the glance between the two men, Matthew's world is dissolved. In "The Martyrdom of St. Matthew" the event is captured just at the moment when the executioner is forcing his victim to the ground. The scene is a public street, and, as Matthew's acolyte flies in terror, passersby glance at the act with idle unconcern. The most intriguing aspect of these narratives is that they seem to be reconstructions of visual testimony, in a scenic fiction as close as possible to the truth, as if they were being performed in thick darkness when a sudden illumination revealed them and fixed them in memory at the instant of their most intense drama.

Caravaggio's use of light

Light is the instrument of Caravaggio's pictorial revolution: it is as active and determining of the structure of the work as line and colour. A 20th-century art critic, Robert Longhi, compared the importance of Caravaggio's use of light to that of the Renaissance discovery of perspective. His light is not that of nature; it is a magical light that falls solidly from above, almost always from a point at the onlooker's shoulder, a stage light that modifies the colour scheme so that it loses affected subtleties like the iridescence of skin and becomes terse, emphatically dark in tone. The 17th-century painter Francesco Albani, said Caravaggio "ground flesh" instead of colours.

The decoration of the Contarelli Chapel was completed by 1602. Caravaggio, though not yet 30, overshadowed all his contemporaries. There was a swarm of orders for pictures, private and ecclesiastical. "The Crucifixion of St. Peter" and "The Conversion of St. Paul," "The Deposition of Christ," the "Madonna dei Palafrenieri" ("Madonna of the Serpent"), and the "Death of the Virgin" all belong to this period. Some of these paintings, done at the high point of Caravaggio's artistic maturity, provoked violent reaction. The "Madonna with Pilgrims," or "Madonna di Loreto," for the church of S. Agostino, was a scandal because of the "dirty feet and torn, filthy cap" of the two old people kneeling in the foreground. The "Death of the Virgin" was refused by the Carmelites because of the indignity of the Virgin's plebeian features, bared legs, and swollen belly like that of a drowned woman. At the advice of Rubens, the picture was bought by the Duke of Mantua in April 1607 and displayed to the community of painters at Rome for one week before removal to Mantua.

Reactions to Caravaggio's style

Culmination of mature style. Artists, men of learning, and enlightened prelates were fascinated by the subtle magic implicit in the robust and bewildering art of Caravaggio, but the negative reaction of church officials reflected the self-protective irritation of academic painters and the instinctive resistance of the more conservative clergy and much of the populace. The more brutal aspects of Caravaggio's paintings were condemned without recognition of the riddling and disquieting message Caravaggio had linked to them. It is true that Caravaggio's common people bear no relation to the graceful suppliants popular in much of Counter-Reformation art. They are plain working men, muscular, stubborn, tenacious of the only good they have: a hard life that will pass away in martyrdom, death, and poverty. The 20th-century art historian Maurizio Calvesi sees in Caravaggio's iconography an inclination away from orthodoxy. In the "Madonna of the Serpent," the Virgin is small in relation to the figure of Jesus, and while she steps on the serpent's head, it is the force of his foot pressing down on hers that crushes it. The act belongs to Jesus and not to the Virgin, immaculate symbol of the church, as tradition would have the scene. Calvesi suggests that the reason God the Father does not appear in "The Conversion of St. Paul," where he is traditionally present, is that Caravaggio's lighting is based on a principle close to the teachings of the heretic Giordano Bruno of immanent divinity, which holds that the divine participates and is inherent in nature and man.

Criticism did not cloud Caravaggio's success. His reputation and income increased, and he began to be envied. The despairing bohemian of the early Roman years had disappeared, but, although he moved in the society of cardinals and princes, the spirit was the same, still given to wrath and riot. Karel van Mander, a Dutch painter, who met him in Rome during Caravaggio's happiest period in 1602–03, wrote:

> In Italy there is a Michelangelo da Caravaggio who does wonderful things . . . He holds the works of other masters of no account . . . A mixture of grain and chaff will not stay at his work, but after two weeks will give himself over to play for a month or two, a sword at his side, a servant behind, spinning from one game to another, inclined to duels and scuffles, a hard man for company.

The details of the first Roman years are unknown, but after the time of the Contarelli project Caravaggio had many encounters with the law. In 1600 he was accused of blows by a fellow painter, and the following year he wounded a soldier. In 1603 he was imprisoned on the complaint of another painter and released only through the intercession of the French ambassador. In April 1604 he was accused of throwing a plate of artichokes in the face of a waiter, and in October he was arrested for throwing stones at the Roman Guards. In May 1605 he was seized for misuse of arms, and on July 29 he had to flee Rome for a time because he had wounded a man in defense of his mistress. Within a year, on May 29, 1606, again in Rome, during a furious brawl over a disputed score in a game of tennis, Caravaggio killed one Ranuccio Tomassoni.

Problems with the law

Flight from Rome. In terror of the consequences of his act, Caravaggio, himself wounded and feverish, fled the city and sought refuge on the nearby estate of a relative of the Marquis of Caravaggio. He then moved on to other places of hiding and eventually reached Naples, probably in early 1607. He remained at Naples for a time, painting a "Madonna of the Rosary" for the Flemish painter Louis Finson and one of his late masterpieces, "The Seven Works of Mercy," for the chapel of Monte della Misericordia. It is impossible to ignore the connection between the dark and urgent nature of this

painting and what must have been his desperate state of mind. It is also the first indication of a shift in his painting style.

At the end of 1607 or the beginning of 1608, Caravaggio travelled to Malta, where he was received as a celebrated artist. He worked hard, completing several works, the most important of which was "The Beheading of St. John the Baptist" for the cathedral. In this scene of martyrdom, shadow, which in earlier paintings stood thick about the figures, is here drawn back, and the infinite space that had been evoked by the huge empty areas of the earlier compositions is replaced by a high, overhanging wall. This high wall, which reappears in later works, can be linked to a consciousness in Caravaggio's mind of condemnation to a limited space, the space between the narrow boundaries of flight and prison. On July 14, 1608, Caravaggio was received into the Order of Malta as a "Knight of Justice"; soon afterward, however, either because word of his crime had reached Malta or because of new misdeeds, he was expelled from the order and imprisoned. He escaped, however.

Flight to Sicily

Caravaggio took refuge in Sicily, landing at Syracuse in October 1608, restless and fearful of pursuit. Yet his fame accompanied him; at Syracuse he painted his late, tragic masterpiece, "The Burial of St. Lucy," for the church of Sta. Lucia. In early 1609 he fled to Messina, where he painted "The Resurrection of Lazarus" and "The Adoration of the Shepherds"; then to Palermo where he did the "Adoration with St. Francis and St. Lawrence" for the Oratorio di S. Lorenzo. The works of Caravaggio's flight, painted under the most adverse of circumstances, include some of the greatest compositions of his career. Although the structural designs are more grandly impressive than ever before, these works show a subdued tone and a delicacy of the expression of emotion that renders feeling even more intense than do the overt dramatics of his earlier paintings. The unfailing excellence of these calm, intense works is remarkable in view of the distractions that must have beset him.

His desperate flight could be ended only with the Pope's pardon, and Caravaggio may have known that there were intercessions on his behalf in Rome when he again moved north to Naples in October 1609. Bad luck pursued him, however; at the door of an inn he was attacked and wounded so badly that rumours reached Rome that the *pittore celebre* was dead. After a long convalescence he sailed in July 1610 to Port' Ercole, a Spanish possession within the Papal States. He was arrested by mistake and detained two days in prison. On his release, he discovered that the boat that was to take him to Rome had sailed, taking his belongings. Misfortune, exhaustion, and a revival of fever were at last too much for him. He collapsed on the beach in sight of the departing boat and died a few days later, on July 18, 1610, not yet 37.

MAJOR WORKS

"The Young Bacchus" (1593; Uffizi, Florence); "Boy Bitten by a Lizard" (1593; Louvre, Paris); "Boy with a Basket of Fruit" (1593; Borghese Gallery, Rome); "The Fortune-teller" ("La Zingara"; 1594; Louvre, Paris); "Rest on the Flight into Egypt" (*c.* 1590; Galleria Doria-Pamphili, Rome); "The Sacrifice of Isaac" (1594–96; Uffizi, Florence); "Lute Player" (Hermitage, Leningrad); "The Magdalene" (Galleria Doria-Pamphili, Rome); "Basket of Fruit" (1596; Pinacoteca Ambrosiana, Milan); "The Supper at Emmaus" (1596–98; National Gallery, London); "The Calling of St. Matthew" (S. Luigi dei Francesci, Rome); "St. Matthew and the Angel" (S. Luigi dei Francesci, Rome); "The Marytyrdom of St. Matthew" (1598–1601; S. Luigi dei Francesci, Rome); "The Conversion of St. Paul" (Sta. Maria del Popolo, Rome); "The Crucifixion of St. Peter" (1601; Sta. Maria del Popolo, Rome); "The Deposition of Christ" (1602–04; Vatican Museum, Rome); "Madonna with Pilgrims" ("Madonna di Loreto"; 1603–06; S. Agostino, Rome); "Madonna dei Palafrenieri" ("Madonna of the Serpent"; Borghese Gallery, Rome); "Death of the Virgin" (1605–06; Louvre, Paris); "St. Jerome" (Borghese Gallery, Rome); "Ecce Homo" (Galleria di Palazzo Rosso, Genoa); "The Supper at Emmaus" (Brera, Milan); "Madonna of the Rosary" (Kunsthistoriches Museum, Vienna); "The Seven Works of Mercy" (1607; Monte della Misericordia, Naples); "The Beheading of St. John the Baptist" (1608; Catherdral, Valletta, Malta); "Portrait of Alof de Wignacourt" (1608; Louvre, Paris); "Sleeping Cupid" (Pitti Palace, Florence); "St. John the Baptist" (Borghese Gallery, Rome); "Salome Receives the Head of St. John the Baptist" (National Gallery, London); "The Burial of St. Lucy" (1608; Sta. Lucia, Syracuse); "The Resurrection of Lazarus" (1609; Museo Nazionale, Messina); "The Adoration of the Shepherds" (1609; Museo Nazionale, Messina); "Adoration with St. Francis and St. Lawrence" (1609; Oratorio di S. Lorenzo, Palermo).

BIBLIOGRAPHY. R. LONGHI, the introduction to the catalog of the exhibition *Il Caravaggio e dei Caravaggeschi* (1951); and *Il Caravaggio* (1952), in French and Italian (with complete bibliography to date of publication), are fundamental for understanding both the man and the artist. Other important studies are: L. VENTURI, *Il Caravaggio* (1951); B. BERENSON, *Del Caravaggio, delle sue incongruenze e della sua fama* (1951; Eng. trans., *Caravaggio: His Incongruity and His Fame*, 1953); W.F. FRIEDLAENDER, *Caravaggio Studies* (1955); H. WAGNER, *Michelangelo da Caravaggio* (1958); A. BERNJOFFROY, *Le Dossier Caravage* (1959); R. JULLIAN, *Caravage* (1961), perhaps the best monograph (well documented); R.P. HINKS, *Michelangelo Merisi du Caravaggio: His Life, His Legend, and His Works* (1953); F.E. BAUMGART, *Caravaggio: Kunst und Wirklichkeit* (1955); and G. DELOGU, *Caravaggio* (1962). Important contributions concerning the problems of the Caravaggeschi may be found in the essays of D. MAHON that appeared in *Burlington Magazine* (1951, 1953, 1956) and *Art Bulletin* (1953). Among the popular monographs are: C. BARONI, *Tutta la pittura del Caravaggio*, 4th ed. (1956); S. BOTTARI, *Caravaggio* (1966); R. CAUSA, *Caravaggio*, 2 vol. (1966); and A. OTTINO DELLA CHIESA (with an introduction by R. GUTTUSO), *L'opera completa del Caravaggio* (1967), which contains the most ample iconography of the works attributed to Caravaggio by a variety of sources. S. SAMEK LUDOVICI, *Vita del Caravaggio* (1966), condenses all material on Caravaggio by the authors in his own time.

(L.Ca.)

Carbanions

Carbanions are negatively charged particles (anions or, when the sign of the charge is not specified, simply ions), in which the charge is located predominantly on carbon atoms. They are formally derived from neutral organic (carbon-containing) molecules by removal of positively charged atoms or groups of atoms, and they are important chiefly as chemical intermediates—that is, as substances used in the preparation of other substances. Important industrial products, including useful plastics, are made using carbanions.

The simplest carbanion, the methide ion (CH_3^-), is derived from the organic compound methane (CH_4) by a loss of a proton (hydrogen ion, H^+) as shown in the following chemical equation:

$$CH_4 \rightleftharpoons CH_3^- + H^+$$

methane methide ion proton

in which the symbols C and H represent, respectively, carbon and hydrogen atoms; the subscripts indicate the numbers of atoms of each kind included in the molecules; the superscript plus and minus signs indicate, respectively, positive and negative charges; and the double arrows indicate that the reaction shown can proceed in either the forward or the reverse direction, a condition known as reversibility.

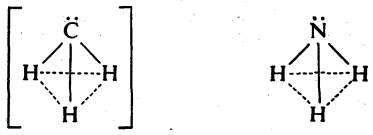
Carbanions as bases

This equation also serves to demonstrate another definition of carbanions as the conjugate (paired) bases of carbon acids. The definition is based on the fact that the reaction shown is, in fact, an acid–base equilibrium, and that an equivalent equation can be written for the formation of every carbanion known. In addition, the definition of carbanions as bases is useful because it makes it possible to express the stability of carbanions in terms of simple acid-dissociation-equilibrium constants—numerical figures that indicate the extent to which the reaction of the type shown proceeds to the right at equilibrium. Expression of carbanion stabilities in numerical terms permits more exact comparisons than would otherwise be possible.

Molecular structures. In discussing the structures of carbanions it is necessary to distinguish between localized and delocalized ions. In the former, the negative charge

is confined largely to one carbon atom, whereas, in the latter, it is distributed over several atoms.

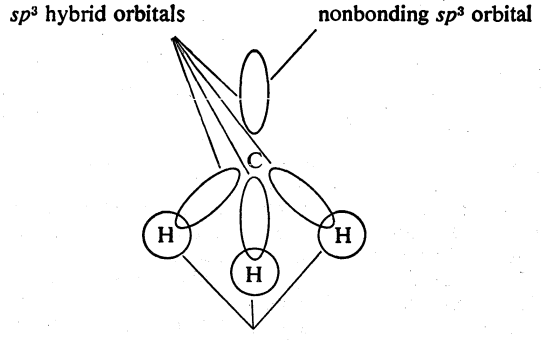
Localized ions. The simplest localized carbanion is the above mentioned methide ion (CH_3^-). It is isoelectronic (it has identical electron configuration) with the neutral molecule ammonia (formula NH_3, N being the chemical symbol for the nitrogen atom). Although, for reasons to be outlined below, it is difficult to determine the exact structure of isolated carbanions, the geometry of the methide ion is best represented by a pyramid with the carbon atom at the apex, a structure similar to that of the ammonia molecule. Both structures are shown below:



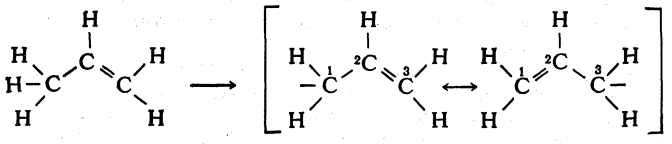
methide ion ammonia molecule

in which the solid lines represent bonds between atoms and the dotted lines merely indicate the bases of the pyramids.

In terms of molecular orbitals—molecular orbitals being the regions that electrons occupy as they make up the bonds between atoms—this corresponds to three so-called sigma bonds (bonds symmetrical about the axis between the atoms) generated from carbon sp^3 hybrid orbitals and three hydrogen *s* orbitals, whereas the fourth sp^3 orbital is occupied by two electrons and is nonbonding—*s* and *p* orbitals being particular electron pathways associated with individual atoms, and hybridized orbitals being special combinations of the separate orbitals. A drawing of the methide ion with the various orbitals is shown below:



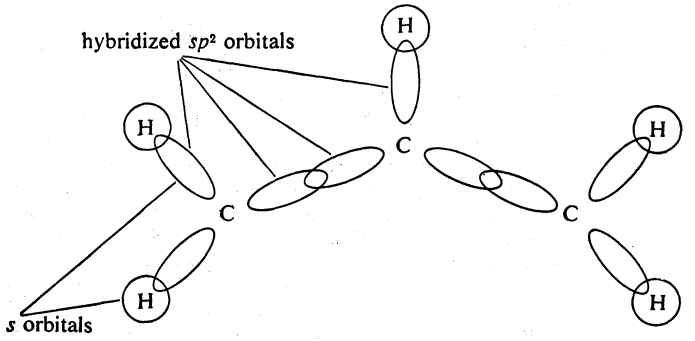
Delocalized ions. The allyl carbanion (formula, $C_3H_5^-$), a somewhat more elaborate unit than the methide ion, serves as the prototype for the structures of delocalized carbanions. It is derived from the substance propene by loss of a proton, as shown in the equation below, and its structure is best characterized by the "resonance" relationship expressed by the two formulas enclosed within square brackets:



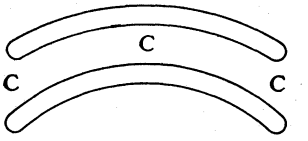
propene resonance forms of the allyl carbanion

A substance (like the allyl carbanion), whose structural formula is expressed in terms of separate resonance forms, is considered to have a hybrid structure similar to all the resonance forms but truly expressed by none of them alone.

In molecular orbital terms, the allyl carbanion is described as a planar structure in which all three carbon atoms are sp^2 hybridized (a different form from that above) forming a sigma-bonded system, along with a pi-bonded system (pi bonds being above and below the axis of the bond) that contains four electrons in two pi orbitals, one of which is bonding and the other nonbonding. The sigma-bond and pi-bond systems of the allyl carbanion are shown below:



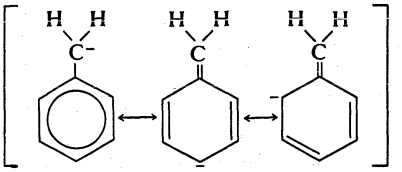
sigma-bond system of allyl carbanion



pi-bond system of allyl carbanion

Formally, the negative charge is contained in the pi system and is mainly associated with carbon atoms 1 and 3 (numbered as shown) as indicated by the resonance formalism.

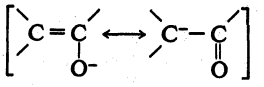
An additional example of this kind of carbanion is the benzylic anion (shown below), in which the negative charge can be distributed over a much more extended pi-bond system, which includes an aromatic ring (a circle of carbon atoms joined by sigma and pi bonds). A resonance formulation of this anion is given below:



resonance forms of benzylic anion

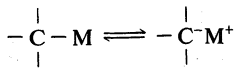
Enolate anions

Closely related to the allyl carbanion are the enolate anions, in which one of the carbon atoms is replaced by an oxygen atom. Enolate ions are derivatives of ketones and aldehydes (compounds containing a double bond between carbon and oxygen atoms), from which they can be generated by abstraction of a proton from the carbon atom located next to the carbon of the carbonyl group. The resonance forms of an enolate ion are as shown below:



Because of the greater attraction for electrons (electronegativity) of oxygen as compared to carbon, the resonance structure with negative charge on oxygen contributes more than half to the true representation of the compound. In a typical enolate ion, in other words, the oxygen atom bears more of the negative charge than the carbon atom. As a generalization about the geometry of carbanions, it may be stated that localized carbanions are thought to have nonplanar structures, whereas delocalized ions with the negative charge residing in the pi system are most likely planar.

Ion pairs. To preserve electrical neutrality, it is mandatory that in a solution containing carbanions there must exist a corresponding cation (positive ion) for each carbanion. If the two ions of opposite charge are in close contact with each other, a covalent (nonionic) bond may form. This reaction is represented by the equilibrium that follows.

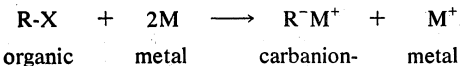


compound with covalent bond — ion pair

in which M in most cases is a metal atom. Because for a given carbanion, the reaction of ionization is favoured by a low electron affinity of the cation, the largest carbanion character of such a compound is exhibited when the atom M is an alkali metal—lithium, sodium, potassium, cesium, and rubidium. Even in cases in which the tendency to form covalent bonds is negligible, however, the properties of free carbanions cannot always be observed. This situation arises from the fact that there is a strong electrostatic attraction (the kind of attraction that exists between positive and negative charges) between the cation and the anion, leading to the pairing of these ions of opposite charge. The resulting "tight" ion pairs can be broken up only if the interactions of the individual ions with the solvent are large enough to overcome the attraction between the ions. Therefore, only in solvents that strongly solvate at least one type of the ions can free carbanions be observed. Examples of solvents with strong tendencies to solvate the cations are ethers and dimethyl sulfoxide. In general, the energy needed to separate ion pairs is larger when the charge on the anion is localized than when it is delocalized. In fact, if the carbanion is derived from a simple alkane (compound of carbon and hydrogen, as for example the methide ion (above), no common solvent exists that provides enough solvation energy to separate the ion pairs and that is, at the same time, inert to chemical reaction with the anion. Therefore, alkyl alkali-metal compounds do not dissociate to free ions, and their properties are characteristic of the ion pairs only. Often ion pairs themselves preferentially form polymeric aggregates or ion clusters.

Preparation. Since the carbanion character is most pronounced when the associated cation is an alkali-metal ion, any preparation of organic-alkali-metal compounds is a source of carbanions. The reaction of organic halides (organic compounds containing atoms of chlorine, bromine, or iodine) with alkali metals is one of the most often used methods. This reaction can be expressed:

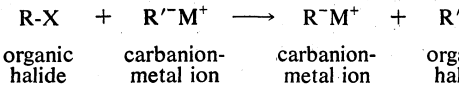
Reaction with alkali metals



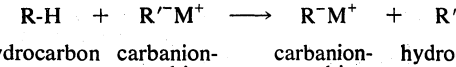
organic halide — metal atoms — carbanion-metal ion pair — metal ion-halide ion pair

in which R is an organic group; X is an atom of chlorine, bromine, or iodine; and M is an atom of an alkali metal.

The conversion of one carbanion into another is frequently useful and can be accomplished with either hydrocarbons or organic halides, as shown by the equations below:



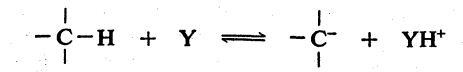
organic halide — carbanion-metal ion pair — carbanion-metal ion pair — organic halide



hydrocarbon — carbanion-metal ion pair — carbanion-metal ion pair — hydrocarbon

in which R is any hydrocarbon group. Examples are the preparation of phenylsodium from chlorobenzene and sodium metal as in the first equation, and of phenyllithium from iodobenzene and butyllithium—as in the second equation—and the reaction of methyllithium with acetylene to give lithium acetylide—as in the third equation.

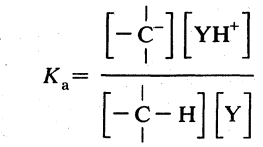
Reactions. Perhaps the most common reaction of carbanions is related to their action as carbon bases—as shown in the first equation in this article. For practical purposes, it is useful to redefine this acid–base equilibrium by the equation:



hydrocarbon — base — carbanion — conjugate acid

in which Y is a proton acceptor (base).

Consideration of carbanion formation in terms of such an equilibrium makes it possible to express the relative stability of the carbanion with regard to the corresponding hydrocarbon in quantitative terms—that is, to assign a numerical value to the basicity (proton-attracting power) of the carbanion. This is done, first of all, by determining an equilibrium constant for the equilibrium reaction above; the equilibrium constant is defined as the ratio of the concentrations (relative amounts) of the reaction products to the reactants or in mathematical terms



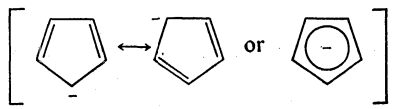
in which K_a is the acid equilibrium constant, and the terms in square brackets are the concentrations of the enclosed entities. For convenience equilibrium constants are frequently converted to another quantity, the acidity exponent, which is almost invariably referred to by its symbolic representation, pK_a. The pK_a is the negative logarithm of the equilibrium constant, or mathematically, $pK_a = -\log K_a$.

Equilibrium constant and acidity exponent

For a given base (Y), increasing basicity of a carbanion is reflected in a decreasing equilibrium constant (K_a) and an increasing pK_a. It is customary to express the basicity of carbanions in pK_a units defined as above for the special case in which the base (Y) is water, although for the vast majority of cases the equilibrium cannot be measured directly in aqueous solution because it is displaced too far to the left side.

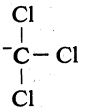
The pK_a's of most carbon acids range from approximately 15 to above 40, indicating that carbanions are much stronger bases than water (which has a pK_a of 15.7). The large variation in pK_a among the different carbon acids reflects the varying degree of internal stabilization in the corresponding carbanions. Generally, three different mechanisms of stabilizing carbanions have been recognized. The first is the already mentioned stabilization by resonance. Examples of resonance-stabilized carbanions are the allyl and benzyl carbanions, each of which has a pK_a of about 35. Particularly large resonance stabilization is encountered in the cyclopentadienyl anion (pK_a about 15), which has an aromatic pi electron system not present in the corresponding hydrocarbon, as shown below:

Stabilizing factors



cyclopentadienyl anion

A second factor lending stability to carbanions is the inductive (electron-withdrawing) effect of neighbouring electronegative atoms. An example is provided by the comparison of the pK_a's of methane (formula, CH_4), pK_a about 40, and chloroform ($CHCl_3$), pK_a less than 25. The greater stability of the trichloromethide ion,



trichloromethide ion

which results from removal of a proton from chloroform, can be understood in terms of the inductive effect of the chlorine atoms, which reduces the free charge on carbon and distributes it to the chlorine atoms.

The third effect is based on a change in electronegativity of the carbon atom carrying the negative charge. An example of this effect is the sequence of decreasing pK_a's from ethane through ethylene to acetylene (the respective pK_a's being 42, 36, and 25). In the corresponding carbanions, shown below, the negative charge resides on carbon atoms that are, respectively, sp^3, sp^2, and sp hybridized.

$$CH_3CH_2^-, \quad H_2C{=}CH^-, \quad HC{\equiv}C^-$$

ethide carbanion | ethenide carbanion | acetylide carbanion

Since the electronegativity of the carbon increases with increasing *s*-character of the bonding (that is, in the order sp^3, sp^2, and sp) the carbanion stability follows the same trend.

Thus, it can be seen that simple alkyl carbanions have none of the effects known to stabilize carbanions, and, therefore, they should be the most basic of all carbanions. Such is indeed the case, and the pK_a's of all simple alkyl carbanions range above 40.

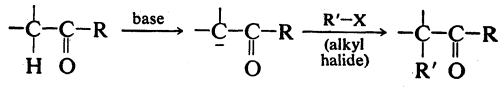
A type of reaction that makes carbanions valuable synthetic intermediates is their ability to function as nucleophiles (positive-charge seeking groups) in displacement reactions. Methylsodium, for example, reacts with methyl bromide to give ethane, as follows:

Carbanions in nucleophilic displacement reactions

$$CH_3^-Na^+ + CH_3Br \longrightarrow CH_3CH_3 + NaBr.$$

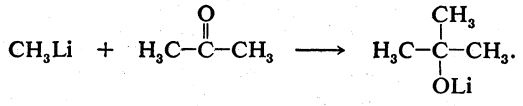
methylsodium | methyl bromide | ethane | sodium bromide

This reaction type is extensively used for the alkylation of ketones. In the process, the ketones are first converted into their enolate ions and then alkylated with a suitable alkyl halide, as in the example below:



ketone | enolate ion | alkylation product

Another synthetically useful reaction is the addition of carbanions to carbonyl groups; for example, methyllithium adds to acetone to give lithium *tert*-butoxide, as shown



methyllithium | acetone | lithium *tert*-butoxide

Carbenes

Carbenes are highly reactive molecules containing divalent carbon atoms—that is, carbon atoms that utilize only two of the four bonds they are capable of forming with other atoms. Occurring usually as transient intermediates during chemical reactions, they are important chiefly for what they reveal about chemical reactions and molecular structure. In addition, some chemical compounds, particularly those in which the molecules contain carbon atoms arranged in small rings, can best be prepared by the use of carbenes.

Carbenes must be clearly distinguished from compounds with multiple bonds. The simplest carbene, methylene, for example, is composed chemically of one carbon atom (indicated by the symbol C) joined to two hydrogen atoms (H) in a structure represented schematically as H — C — H. In the compound hydrogen cyanide, the carbon atom also is joined to only two atoms—in this case a hydrogen atom and a nitrogen (N) atom—and the structure of this compound is represented as H — C ≡ N. Hydrogen cyanide is not classed as a carbene, because, although the carbon atom is joined only to two other atoms, it is not divalent; all four valences of carbon are utilized in the single bond to the hydrogen atom and in the triple bond to the nitrogen atom (as represented by the three lines in the diagram between C and N). Hydrogen cyanide is, therefore, a multiply bonded compound, not a carbene.

General considerations. According to the electronic theory of bonding, bonds between atoms are formed by a sharing of electrons. In terms of this theory, then, carbenes are compounds in which only two of the four valence, or bonding, electrons of the carbon atoms are actually engaged in bonding with other atoms. By contrast, in multiply bonded compounds, such as hydrogen cyanide, all four of the valence electrons of the atoms are involved in bonds with other atoms. Because there is no excess or deficiency of electrons in the molecules of carbenes, they are substances that are electrically neutral (nonionic).

Carbenes as a class also are referred to as divalent carbon compounds or, with reference to methylene, the simplest member of the series, as methylenes. Carbenes generally are named as derivatives of carbene or methylene. For example, the substance containing a carbon atom and two chlorine (Cl) atoms, Cl–C–Cl, is known as dichlorocarbene or, less commonly, as dichloromethylene.

Because of the great reactivity of carbenes, they normally have very short lifetimes, and it is not surprising, therefore, that unambiguous and direct experimental evidence of their existence has been obtained only recently. Divalent carbon compounds had been postulated, however, as long ago as 1876, when it was proposed that dichlorocarbene, Cl–C–Cl, was an intermediate in the base-catalyzed hydrolysis (decomposition brought about by water) of chloroform, (formula, $HCCl_3$). Toward the end of the 19th century, an extensive theory had been developed that postulated divalent carbon compounds as intermediates in many reactions. Later work, however, disproved many of these postulates, and, as a result, methylene was no longer put forward as a hypothetical reaction intermediate. A strong revival of carbene chemistry occurred in the 1950s after unambiguous evidence had demonstrated their existence and studies by several methods had yielded detailed information about their structures. At the same time, it became apparent that the high reactivity of carbenes was an asset to the synthetic chemist, who put them to use in the construction of molecules difficult to prepare by other means.

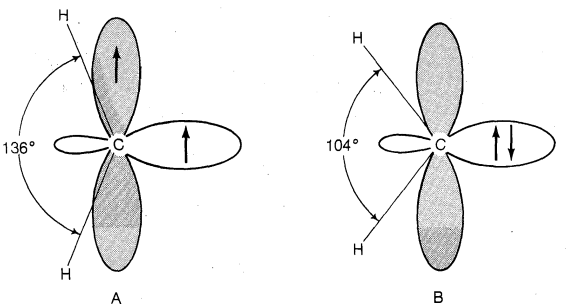
Early investigations of carbenes

Electronic configuration and molecular structure. Carbenes are of interest to the theoretical chemist because the theory of chemical bonding predicts two fundamentally different electron configurations for these substances, either one of which may correspond to the ground state of the molecules (state of lower energy content) depending only on the nature of the atoms and groups attached to the divalent carbon atom. This duality arises from the fact that the two bonds of the carbene utilize only two of the four valence orbitals on carbon—orbitals being the regions occupied by the various electrons in an atom. The two valence orbitals of the carbon atom not used in bonding are available to accept the two nonbonding electrons. In general, each orbital can accommodate two electrons if their spins are paired—that is, if the angular momenta are of opposite sign. There are thus two possible distributions of the nonbonding electrons: they may be in the same orbital and have paired (opposite) spins, or they may be divided between the two available orbitals and have parallel spins. Substances with electrons having parallel (or unpaired) spins show a magnetic effect (moment). In a magnetic field this moment may be parallel, perpendicular, or antiparallel (parallel but proceeding in the reverse direction) to the direction of the field; these three possible alignments correspond to three forms of slightly different energy, and, as a result, substances with unpaired electrons can exist in all three forms and are said to be in a triplet state. By contrast, substances with all electrons paired show no net magnetic moment and are referred to as singlet states. In principle, carbenes can exist in either the singlet or triplet state (depending upon whether the electrons are in the same or different orbitals, respectively).

Singlet and triplet states

In most organic compounds (compounds of carbon), the singlet state is more stable than the triplet state, and the normal or ground state of the molecule is of this form. In these compounds triplets occur only as excited or high-energy states. In carbenes, on the other hand, because of the two nonbonding electrons and the two vacant orbitals, it is expected on theoretical grounds that the triplet state should be of comparable stability to the singlet state and may, in fact, be the ground state.

Theoretical considerations also suggest that the carbene carbon atom and the two atoms joined to it are arranged in a "V" rather than in a linear fashion—that is, the bonds from the carbon atom to the two substituent atoms are situated at an angle that is less than 180°—in both the triplet and the singlet states. The bond angle for the singlet state, however, is predicted to be larger than that for the triplet state. These predictions are fully supported by experiments. The simplest carbene, methylene, has been shown by a technique called electron magnetic resonance spectroscopy to have a triplet ground state, in which the angle between the carbon–hydrogen bonds equals 136°. The singlet state of methylene, which can be obtained in special circumstances, has been studied by another technique, optical spectroscopy, and its bond angle has been determined to be 104°. The structures and the configurations of the nonbonding electrons of the triplet and singlet states of methylene are shown as A and B in the accompanying drawing; the loops represent



Nonbonding orbitals in the triplet (A) and singlet (B) state of methylene; the axis of the shaded orbital is perpendicular to the plane defined by the carbon atom (C), the hydrogen atoms (H), and the unshaded orbital (see text).

the orbitals not used in bonding, and the pairing and nonpairing of electron spins are indicated by antiparallel and parallel arrows, respectively. This schematic orbital representation shows both nonbonding orbitals occupied in A (the triplet state) and an empty orbital in B (singlet).

The structural features that determine whether a singlet or a triplet state corresponds to the lower energy form of the carbene molecule may be summarized by the rule that, with few exceptions, carbenes having only carbon or hydrogen atoms attached to the divalent (carbene) carbon atom have triplet ground states, whereas those with nitrogen, oxygen, and halogen substituents have singlet ground states. Examples of triplet carbenes are methylene (H–C–H), phenylmethylene (C_6H_5–C–H), diphenylmethylene (C_6H_5–C–C_6H_5) and propargylene

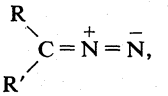
$$(HC \equiv C - C - H).$$

Carbenes with known singlet ground states are methoxymethylene (CH_3O–C–H), chloromethylene

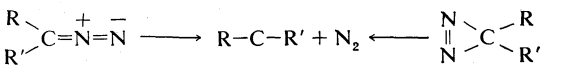
$$(Cl - C - H),$$

and phenylchloromethylene (C_6H_5–C–Cl).

Formation. Because carbenes are molecules with high energy content, they must be made from high-energy precursors, or extra energy must be provided from external sources. Chemical transformations induced by light, so-called photochemical reactions, often are used to prepare carbenes, because the energy of the absorbed light is taken into the high-energy structures. Organic compounds containing a diazo group (two nitrogen atoms joined to one another and to a carbon atom by a double bond) are the most frequently used precursors of carbenes. The molecular structure of diazo compounds is represented by the generalized formula



in which R and R′ represent two organic groups, which may be the same or different. On either photolysis or pyrolysis (treatment with light or heat, respectively), diazo compounds cleave to yield the corresponding carbene and a free molecule of nitrogen gas. The great stability of the nitrogen molecule constitutes the driving force of the reaction. Diazirins, which are ring, or cyclic, compounds, with a structure similar to that of the diazo compounds, undergo the same cleavage reaction and are frequently used as precursors of carbenes. The production of a carbene from either a diazo compound or a diazirin occurs as shown below:

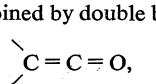


diazo compound — carbene — nitrogen — diazirin

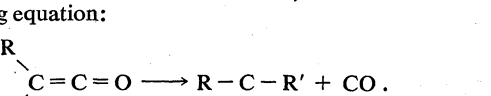
In these formulas R and R′ represent organic groups (either the same or different). The alternate precursors of the carbene are here represented by the formulas on the extreme left and right; in the centre are the products—that is, the carbene and nitrogen. The arrows indicate the direction in which the chemical conversion occurs. When the photolysis of diazo compounds or diazirins is carried out at very low temperature in an unreactive solid medium, it is often possible to prevent the resulting carbene from undergoing further reaction. Measurable amounts of the carbene may persist, therefore, in the solid medium, or matrix, for a long time. For example, methylene, the most reactive carbene of all, has been generated by photolysis of diazirin in a crystalline matrix of the inert gas xenon (cooled to the boiling point of helium) in which it persisted long enough to be studied. Many other carbenes have been produced by similar matrix isolation techniques.

Isolation of carbenes

The photolytic decomposition of certain ketenes, substances the molecules of which contain two carbon atoms and an oxygen atom joined by double bonds,

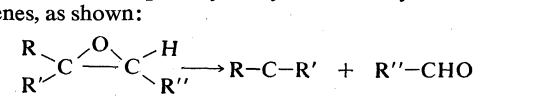


gives carbon monoxide and carbenes, as shown in the following equation:



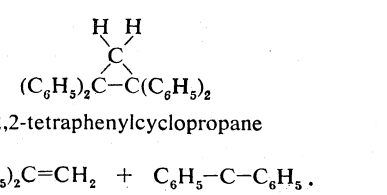
ketene — carbene — carbon monoxide

In some cases epoxides, compounds the molecules of which include three-membered oxygen-containing rings, can be cleaved photolytically into aldehydes and carbenes, as shown:



epoxide — carbene — aldehyde

Under certain circumstances, even cyclopropanes, the molecules of which contain three-membered carbon rings, can serve as carbene precursors in photochemical reactions. For example, 1,1,2,2,-tetraphenylcyclopropane is converted to diphenylcarbene, by the reaction given below:



1,1,2,2-tetraphenylcyclopropane

1,1-diphenylethylene — diphenylcarbene

The formation of carbenes by way of electrically charged, or ionic, intermediates is exemplified by the reaction of chloroform with a strong base, potassium *tert*-butoxide.

In the first step of this reaction, a proton or hydrogen ion (H^+) is removed from the chloroform molecule in a normal acid–base reaction. The resulting potassium trichloromethide then loses potassium chloride to give dichlorocarbene, as shown:

$$Cl_3CH + KOC(CH_3)_3 \longrightarrow \overset{+}{K}\overset{-}{C}Cl_3 + HOC(CH_3)_3$$

chloroform; potassium *tert*-butoxide; potassium trichloromethide; *t*-butyl alcohol

$$\overset{+}{K}\overset{-}{C}Cl_3 \longrightarrow Cl-C-Cl + KCl$$

potassium trichloromethide; dichlorocarbene; potassium chloride

Other haloforms, compounds conforming to the formula HCX_3, in which X equals an atom of chlorine, bromine, or iodine, react in an equivalent way to form the corresponding dihalocarbenes.

Organometallic compounds also can serve as precursors of carbenes. The decomposition of tribromomethylphenyl mercury to phenylmercuric bromide and dibromocarbene is an example of this reaction type.

$$C_6H_5-Hg-CBr_3 \longrightarrow C_6H_5-Hg-Br + Br-C-Br$$

tribromomethylphenyl mercury; phenylmercuric bromide; dibromocarbene

Reactions. Because of their unsaturated valences, carbenes are very reactive molecules. Methylene, for example, is one of the most reactive molecules known in organic chemistry, and there are few organic compounds able to resist attack by this substance. The reactivity of carbenes is somewhat reduced when stabilization results from the phenomenon known as resonance, which is said to occur when alternate electronic structures (called resonance forms) can be written for a single molecular type. The actual state of the molecule is then thought to include characteristics of all the forms and to be more stable than any of them individually. Difluorocarbene and methoxycarbene, for example, are much less reactive than methylene, presumably because the resonance forms shown in the formulas below contribute to internal stabilization.

Resonance forms

$$F-C-F \longleftrightarrow \overset{+}{F}=\overset{-}{C}-F \longleftrightarrow F-\overset{-}{C}=\overset{+}{F}$$

resonance forms of difluorocarbene

$$CH_3O-C-H \longleftrightarrow CH_3\overset{+}{O}=\overset{-}{C}-H$$

resonance forms of methoxycarbene

In these representations, the various resonance forms of a single hybrid structure are connected by double-headed arrows, and the plus and minus signs indicate positive and negative charges, respectively, produced by shifts of electrons.

The various chemical reactions that carbenes undergo can be classified as either intramolecular or intermolecular reactions. Intramolecular reactions, or rearrangements, involve only the carbene itself and include no other outside substances; if structurally possible, they lead to stable molecules in which the carbon atom is in its normal, or tetravalent, state. An example of an intramolecular reaction is the rearrangement of methylcarbene to ethylene, in which a hydrogen atom undergoes a shift from one carbon atom to the next:

$$CH_3-C-H \longrightarrow H_2C=CH_2.$$

methylcarbene; ethylene

Such an intramolecular rearrangement, of course, is not possible for carbenes comprised of only three atoms, such as methylene itself or the halomethylenes.

Intermolecular reactions are those involving two or more separate molecules. Three important classes of intermolecular reaction of carbenes are known: dimerization, addition, and insertion reactions. Dimerization of carbenes—that is, combination of two molecules of the carbene—gives olefins, the molecular formulas of which are exactly twice that of the carbene. An example is the formation of tetramethoxyethylene from dimethoxycarbene.

Intermolecular reactions

$$2CH_3O-C-OCH_3 \longrightarrow (CH_3O)_2C=C(OCH_3)_2$$

dimethoxycarbene; tetramethoxyethylene

The addition of carbenes to olefins and acetylenes is a very useful reaction because it constitutes a simple way to synthesize cyclopropanes and cyclopropenes having a great variety of structures. Two examples are shown below; in one case the carbene is generated from chloroform, and in the other it is produced by photolysis of a diazo compound.

1. $Cl_3CH + KOC(CH_3)_3 \longrightarrow Cl-C-Cl + HOC(CH_3)_3 + KCl$

chloroform; potassium *tert*-butoxide; dichlorocarbene; *tert*-butyl alcohol; potassium chloride

$$Cl-C-Cl + (CH_3)_2C=C(CH_3)_2 \longrightarrow \begin{matrix} Cl & Cl \\ \diagdown & \diagup \\ & C \\ \diagup & \diagdown \\ (CH_3)_2C & -C(CH_3)_2 \end{matrix}$$

dichlorocarbene; tetramethylethylene; 1.1-dichloro-2,2,3,3-tetramethylcyclopropane

2. $H-\underset{\displaystyle COOCH_3}{\underset{|}{C}}=N_2 \longrightarrow H-C-COOCH_3 + N_2$

methyldiazoacetate; carboxymethylcarbene; nitrogen

$$H-C-COOCH_3 + C_6H_5-C\equiv C-C_6H_5 \longrightarrow \begin{matrix} H & COOCH_3 \\ \diagdown & \diagup \\ & C \\ & \| \\ C_6H_5-C & -C-C_6H_5 \end{matrix}$$

carboxymethylcarbene; diphenylacetylene; 3-carboxymethyl-1,2-diphenylcyclopropene

Intramolecular versions of this type of addition reaction are also possible, as shown by the cyclization of allylcarbene generated from the corresponding diazo compound. The resulting bicyclobutane—an unusual compound, which contains a ring system with considerable strain resulting from abnormal angles between bonds—demonstrates the value of carbene reactions for the synthesis compounds difficult to obtain by other methods.

$$CH_2=CH-CH_2-\underset{\displaystyle H}{\underset{|}{C}} \longrightarrow CH_2 \begin{matrix} \diagup \\ \diagdown \end{matrix} \underset{\displaystyle H}{\underset{|}{C}} \begin{matrix} \diagup \\ \diagdown \end{matrix} CH_2$$

allylcarbene; bicyclobutane

The insertion reaction takes place only with the more reactive carbenes; it is defined as the insertion of a carbene into the bond between a carbon atom and an attached hydrogen atom. Methylene itself undergoes this reaction with all known types of carbon–hydrogen bonds. An example is the formation of toluene from benzene and methylene, as shown:

$$C_6H_6 + H-C-H \longrightarrow C_6H_5CH_3.$$

benzene; methylene; toluene

The less reactive carbenes; *e.g.*, difluorocarbene and methoxycarbene, do not take part in insertion reactions.

There is a substantial difference in reactivity between carbenes in the singlet and triplet states. Although both singlet and triplet carbenes undergo the same three reaction types, the triplet state is usually much less reactive. There are also differences in the mechanisms by which singlet and triplet carbenes undergo addition and insertion reactions.

Reactivity differences between triplet and singlet states

Analytical and physical study. Because carbenes occur chiefly as intermediates in the course of chemical reactions, much of their study is conducted by kinetic methods, as the general field of investigation of rates of reaction and the factors that influence them is known. Much of the available information about the structures of carbenes has been obtained by optical spectroscopic methods —that is, by the study of light absorption patterns— which have revealed, for example, the bond lengths and angles in the various carbenes. Electron-spin resonance spectroscopy, the physical method that gives information about the angular momenta of electrons, has been especially useful in differentiating triplet from singlet states. Both optical and electron-spin resonance spectroscopy must be used in the detection of carbenes, because, generally, these substances are too reactive for analytical methods of ordinary types.

Carbohydrate

The term carbohydrate, which means watered carbon, represents a class of naturally occurring compounds and derivatives formed from them. In the early part of the 19th century, substances such as wood, starch, and linen were found to be composed mainly of molecules containing atoms of carbon (C), hydrogen (H), and oxygen (O), and to have the general formula $C_6H_{12}O_6$; other organic molecules with similar formulas were found to have a similar ratio of hydrogen to oxygen. The general formula $C_x(H_2O)_x$ is commonly used to represent many carbohydrates.

Carbohydrates are probably the most abundant and widespread organic substances in nature. Essential constituents of all living things, carbohydrates are formed by green plants from carbon dioxide and water during the process of photosynthesis. Carbohydrates serve organisms as energy sources and as essential structural components; in addition, part of the structure of nucleic acids, which contain genetic information, consists of carbohydrate.

GENERAL FEATURES

Classification and nomenclature. Although a number of classification schemes have been devised for carbohydrates, the division into four major groups—monosaccharides, disaccharides, oligosaccharides, and polysaccharides—used here is among the most common. Most monosaccharides, or simple sugars, are found in grapes, other fruits, and honey. Although they can contain from three to nine carbon atoms, the most common representatives consist of five or six joined together to form a chainlike molecule. Three of the most important simple sugars, glucose—also known as dextrose, grape sugar, and corn sugar—fructose (fruit sugar), and galactose, have the same molecular formula, ($C_6H_{12}O_6$), but, because their atoms have different structural arrangements, the sugars have different characteristics; *i.e.*, they are isomers. Slight changes in structural arrangements are detectable by living things and influence the biological significance of isomeric compounds. It is known, for example, that the degree of sweetness of various sugars differs according to the arrangement of the hydroxyl groups (— OH) comprising part of the molecular structure; a direct correlation between taste and any specific structural arrangement, however, has not yet been established—that is, it is not yet possible to predict the taste of a sugar by knowing its specific structural arrangement. The energy in the chemical bonds of glucose indirectly supplies most living things with a major part of the energy necessary for them to carry on their activities. Galactose, rarely found as a simple sugar, is usually combined with other simple sugars to form larger molecules.

Basic molecular structures

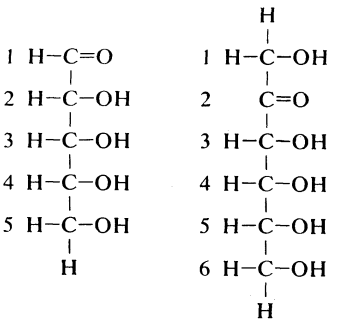
Two molecules of a simple sugar linked to each other form a disaccharide, or double sugar. The disaccharide sucrose, or table sugar, consists of one molecule of glucose and one molecule of fructose; sources of sucrose include sugar beets and cane sugar. Milk sugar, or lactose, and maltose are also disaccharides. Before the energy in disaccharides can be utilized by living things, the molecules must be broken down into their respective monosaccharides.

Oligosaccharides, which consist of three to six monosaccharide units, are rather infrequently found in natural sources, although a few plant derivatives have been identified.

Polysaccharides (the term means many sugars) represent most of the structural and energy-reserve carbohydrates found in nature. Large molecules that may consist of as many as 10,000 monosaccharide units linked together, polysaccharides vary considerably in size, in structural complexity, and in sugar content; several hundred distinct types have thus far been identified. Cellulose, the principal structural component of plants, is a complex polysaccharide comprised of many glucose units linked together; it is the most common polysaccharide. The starch found in plants and the glycogen found in animals also are complex glucose polysaccharides. Starch (from the old English word *stercan* meaning "to stiffen") is found mostly in seeds, roots, and stems, where it is stored as an available energy source for plants. Plant starch may be processed into such foods for man as bread, or it may be consumed directly—as are potatoes. Glycogen, which consists of branching chains of glucose molecules, is formed in the liver and muscles of higher animals and is stored as an energy source.

Names for monosaccharides

The generic nomenclature ending for the monosaccharides is -ose; thus, the term pentose (pent = five) is used for monosaccharides containing five carbon atoms, and hexose (hex = six) is used for those containing six. In addition, because the monosaccharides contain a chemically reactive group that is either an aldehydo group  or a keto group  , they are frequently referred to as aldopentoses or ketopentoses or aldohexoses or ketohexoses; in the examples below, the aldehydo group is at position 1 of the aldopentose, the keto group is at position 2 of the ketohexose. Glucose is an aldohexose—*i.e.*, it contains six carbon atoms, and the chemically reactive group is an aldehydo group.



aldopentose ketohexose

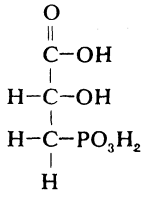
Importance. The importance of carbohydrates to living things can hardly be overemphasized. The energy stores of most animals and plants are both carbohydrate and fat (lipid) in nature; carbohydrates are generally available as an immediate energy source, whereas fats act as a long-term energy resource and tend to be utilized at a slower rate. Glucose, the prevalent uncombined, or free, sugar circulating in the blood of higher animals, is essential to cell function. The proper regulation of glucose metabolism is of paramount importance to survival.

The ability of ruminants, such as cattle, sheep, and goats, to convert the polysaccharides present in grass and similar feeds into protein provides a major source of protein for man. A number of medically important antibiotics, such as streptomycin, are carbohydrate derivatives. The cellulose in plants is used to manufacture paper, wood for construction, and fabrics.

Role in the biosphere. The essential process in the biosphere, the portion of the earth in which life can occur, that has permitted the evolution of life as it now exists is the conversion by green plants of carbon dioxide from the atmosphere into carbohydrates, using light energy from the sun. This process, called photosynthesis, results in both the release of oxygen gas into the atmosphere and the transformation of light energy into the chemical energy of carbohydrates. The energy stored by plants during the formation of carbohydrates is used by animals to carry out mechanical work and to perform biosynthetic activities.

Photosynthesis

All green plants apparently photosynthesize in the same way, yielding as an immediate product the compound 3-phosphoglyceric acid; the formula, in which P represents phosphorus, is illustrated below.



3-phosphoglyceric acid

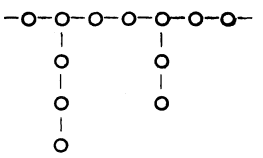
This compound then is transformed into cell-wall components such as cellulose, varying amounts of sucrose, and starch—depending on the plant type—and a wide variety of polysaccharides, other than cellulose and starch, that function as essential structural components. For a detailed discussion of the process of photosynthesis, see PHOTOSYNTHESIS.

Role in human nutrition. The total caloric, or energy, requirement for an individual depends on age, occupation, and other factors but generally ranges between 2,000 and 4,000 calories per 24-hour period (one calorie is the amount of heat necessary to raise the temperature of 1,000 grams of water from 15° to 16° C [59° to 61° F]). Carbohydrate that can be utilized by man produces four calories per gram as opposed to nine calories per gram of fat and four per gram of protein. In areas of the world where nutrition is marginal, a high proportion (approximately one to two pounds) of an individual's daily energy requirement may be supplied by carbohydrate, with most of the remainder coming from a variety of fat sources.

Although carbohydrates may comprise as much as 80 percent of the total caloric intake in the human diet, for a given diet, the proportion of starch to total carbohydrate is quite variable, depending upon the prevailing customs. In the Far East and in areas of Africa, for example, where rice or tubers such as manioc provide a major food source, starch may account for as much as 80 percent of the total carbohydrate intake. In a typical Western diet, 33 to 50 percent of the caloric intake is in the form of carbohydrate. Approximately half (*i.e.*, 17 to 25 percent) is represented by starch; another third by table sugar (sucrose) and milk sugar (lactose); and smaller percentages by monosaccharides such as glucose and fructose, which are common in fruits, honey, syrups, and certain vegetables such as artichokes, onions, and sugar beets. The small remainder consists of bulk, or indigestible carbohydrate, primarily the cellulosic outer covering of seeds and the stalks and leaves of vegetables.

Role in energy storage. Starches, the major plant-energy-reserve polysaccharides utilized by man, are stored in plants in the form of nearly spherical granules that vary in diameter from about three to 100 microns (about .0001 to .004 inches). Most plant starches consist of a mixture of two components, amylose and amylopectin (see diagrams following). As the diagrams show, the glucose molecules comprising amylose have a straight-chain, or linear, structure; amylopectin has a branched-chain structure and is a somewhat more compact molecule. Several thousand glucose units may be present in a single starch molecule (each –O– represents one glucose molecule).

amylose



amylopectin

In addition to granules, many plants have large numbers of specialized cells, called parenchymatous cells, the principal function of which is the storage of starch; examples of plants with these cells include root vegetables and tubers. The starch content of plants varies considerably; the highest concentrations are found in seeds and in cereal grains, which contain up to 80 percent of their total carbohydrate as starch. The amylose and amylopectin components of starch occur in variable proportions; most plant species store approximately 25 percent of their starch as amylose and 75 percent as amylopectin. This proportion can be altered, however, by selective-breeding techniques, and some varieties of corn have been developed that produce up to 70 percent of their starch as amylose, which is more easily digested by man than is amylopectin.

Starch content of plants

In addition to the starches, some plants (*e.g.*, the Jerusalem artichoke and the leaves of certain grasses, particularly rye grass) form storage polysaccharides composed of fructose units rather than glucose. Although the fructose polysaccharides can be broken down and utilized to prepare syrups, they cannot be digested by higher animals.

Starches are not formed by animals; instead, they form a closely related polysaccharide, glycogen. Virtually all vertebrate and invertebrate animal cells, as well as those of numerous fungi and protozoans, contain some glycogen; particularly high concentrations are found in the liver and muscle cells of higher animals. The overall structure of glycogen, which is a highly branched molecule consisting of glucose units, has a superficial resemblance to that of the amylopectin component of starch, although the structural details of glycogen are significantly different. Under conditions of stress or muscular activity in animals, glycogen is rapidly broken down to glucose, which is subsequently utilized as an energy source. In this manner, glycogen acts as an immediate carbohydrate reserve. Furthermore, the amount of glycogen present at any given time, especially in the liver, directly reflects an animal's nutritional state; *i.e.*, when adequate food supplies are available, both glycogen and fat reserves increase, but when food supplies decrease or when the food intake falls below the minimum energy requirements, the glycogen reserves are depleted quite rapidly, while those of fat are used at a slower rate.

Role in plant and animal structure. Whereas starches and glycogen represent the major reserve polysaccharides of living things, most of the carbohydrate found in nature occurs as structural components in the cell walls of plants. Carbohydrates in plant cell walls generally consist of several distinct layers, one of which contains a higher concentration of cellulose than the others. The physical and chemical properties of cellulose are strikingly different from those of the amylose component of starch.

In most plants, the cell wall is about 0.5 microns thick (one micron = 10^{-3} millimetre) and contains a mixture of cellulose, pentose-containing polysaccharides (pentosans), and an inert (chemically unreactive) plastic-like material called lignin. The amounts of cellulose and pentosan may vary; most plants contain between 40 and 60 percent cellulose, although higher amounts are present in the cotton fibre.

Polysaccharides also function as major structural components in animals. Chitin, which is similar to cellulose, is found in insects and other arthropods. Other complex

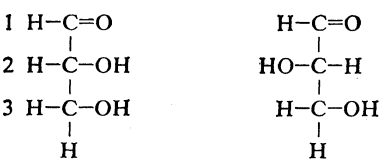
polysaccharides predominate in the structural tissues of higher animals.

THE STRUCTURAL FEATURES OF CARBOHYDRATES

Stereoisomerism. Late 19th-century studies by the German chemist Emil Fischer showed that carbohydrates, such as fructose and glucose, with the same molecular formulas but different structural arrangements and properties (*i.e.*, isomers) can be formed by relatively simple variations of their spatial, or geometric, arrangements. This type of isomerism, called stereoisomerism, exists in all biological systems; and, among carbohydrates, the simplest example is provided by the three-carbon aldose sugar glyceraldehyde. There is no way by which the structures of the two isomers of glyceraldehyde (see the formulas, which are the so-called Fischer projection formulas commonly used to distinguish between such isomers) can be made identical, excluding breaking and reforming the linkages, or bonds, of the hydrogen (— H) and hydroxyl (— OH) groups attached to the carbon at position 2. The isomers are, in fact, mirror images akin to right and left hands; the term enantiomorphism is frequently employed for such isomerism. The chemical and physical properties of enantiomers are identical except for the property of optical rotation.

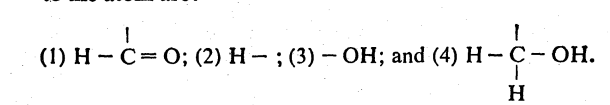
Isomers of glyceraldehyde

Optical rotation is the rotation of the plane of polarized light. Polarized light is light that has been separated into two beams that vibrate at right angles to each other; solutions of substances that rotate the plane of polarization are said to be optically active, and the degree of rotation is called the optical rotation of the solution. In the case of the isomers of glyceraldehyde, the magnitudes of the optical rotation are the same, but the direction in which the light is rotated—generally designated as plus, or *d* for dextrorotatory (to the right), or as minus, or *l* for levorotatory (to the left)—is opposite; *i.e.*, a solution of D-(*d*)-glyceraldehyde causes the plane of polarized light to rotate to the right, and a solution of L-(*l*)-glyceraldehyde rotates the plane of polarized light to the left. Fischer projection formulas for the two isomers of glyceraldehyde are given below (see *Configuration*, below, for explanation of D and L).



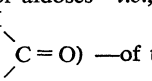
D-(*d*)-glyceraldehyde L-(*l*)-glyceraldehyde

Configuration. Molecules, such as the isomers of glyceraldehyde—the atoms of which can have different structural arrangements—are known as asymmetrical molecules. The number of possible structural arrangements for an asymmetrical molecule depends on the number of centres of asymmetry; *i.e.*, for n (any given number of) centres of asymmetry, 2^n different isomers of a molecule are possible. An asymmetrical centre in the case of carbon is defined as a carbon atom to which four different groups are attached. In the three-carbon aldose sugar, glyceraldehyde, the asymmetrical centre is located at the central carbon atom. The four different groups attached to the atom are:



The position of the hydroxyl group (— OH) attached to the central carbon atom—*i.e.*, whether — OH projects from the left or the right—determines whether the molecule rotates the plane of polarized light to the left or to the right. Since glyceraldehyde has one asymmetrical centre, n is one in the relationship 2^n, and there thus are two possible isomers. Sugars containing four carbon atoms have two asymmetrical centres; hence, there are four possible isomers (2^2). Similarly, sugars with five carbon atoms have three asymmetrical centres, and thus have eight isomers (2^3). Keto sugars have one less asymmetrical centre for a given number of carbon atoms than do aldehydo sugars.

A convention of nomenclature, devised in 1906 and based on the arrangement of the hydroxyl groups at the asymmetrical carbon atom in glyceraldehyde, states that the form of glyceraldehyde whose asymmetrical carbon atom has a hydroxyl group projecting to the right (see Fischer projection formulas) is designated as of the D-configuration; that form, whose asymmetrical carbon atom has a hydroxyl group projecting to the left is designated as L. All sugars that can be derived from D-glyceraldehyde—*i.e.*, hydroxyl group attached to the asymmetrical carbon atom most remote from the aldehydo or keto end of the molecule projects to the right—are said to be of the D-configuration; those sugars derived from L-glyceraldehyde are said to be of the L-configuration. See Table 1 for aldoses—*i.e.*, sugars containing an



aldehydo group (—of the D-configuration.

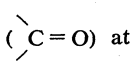
The configurational notation D or L is independent of the sign of the optical rotation of a sugar in solution. It is common, therefore, to designate both, as for example, D-(*l*)-fructose or D-(*d*)-glucose; *i.e.*, both have a D-configuration at the centre of asymmetry most remote from the aldehydo end (in glucose) or keto end (in fructose) of the molecule, but fructose rotates the plane of polarized light to the left, and glucose is dextrorotatory—hence the latter's alternative name dextrose. Although the initial assignments of configuration for the glyceraldehydes were made on purely arbitrary grounds, studies carried out nearly half a century later established them as correct in an absolute spatial sense. In biological systems, only the D or L form may be utilized.

DL pairs

It should be noted that when more than one asymmetrical centre is present in a molecule, as is the case with sugars containing four or more carbon atoms, a series of DL pairs exists, and they are functionally, physically, and chemically distinct; thus, although D-xylose and D-lyxose (see Table 1) both contain five carbon atoms and are of the D-configuration, the spatial arrangement of the asymmetrical centres (at carbon atoms 2, 3, and 4) is such that they are not mirror images.

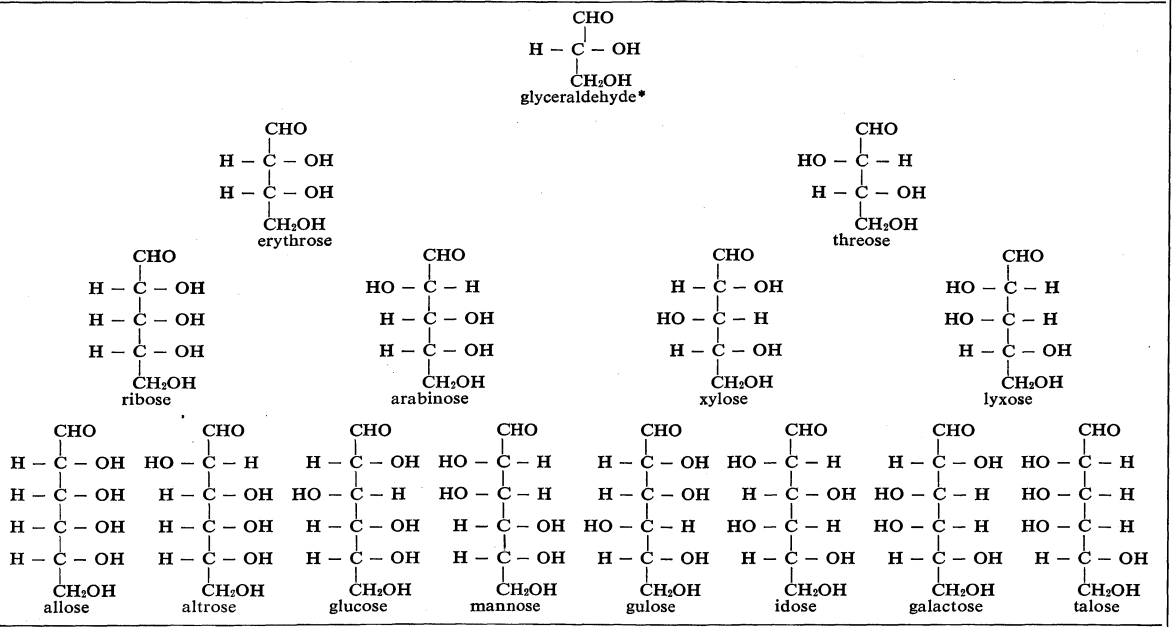
Hemiacetal and hemiketal forms. Although optical rotation has been one of the most frequently determined characteristics of carbohydrates since its recognition in the late 19th century, the rotational behaviour of freshly prepared solutions of many sugars differs from that of solutions that have been allowed to stand. This phenomenon, termed mutarotation, is demonstrable even with apparently identical sugars and is caused by a type of stereoisomerism involving formation of an asymmetrical centre at the first carbon atom (aldehydo carbon) in aldoses and the second one (keto carbon) in ketoses.

Most pentose and hexose sugars, therefore, do not exist as linear, or open-chain, structures in solution, as indicated for the aldoses in Table 1, but instead form cyclic, or ring, structures termed hemiacetal or hemiketal forms, respectively. As illustrated for glucose and fructose, the cyclic structures are formed by the addition of the hydroxyl group (— OH) from either the fourth, fifth, or sixth carbon atom (in the diagram, the numbers 1 through 6 represent the positions of the carbon atoms) to

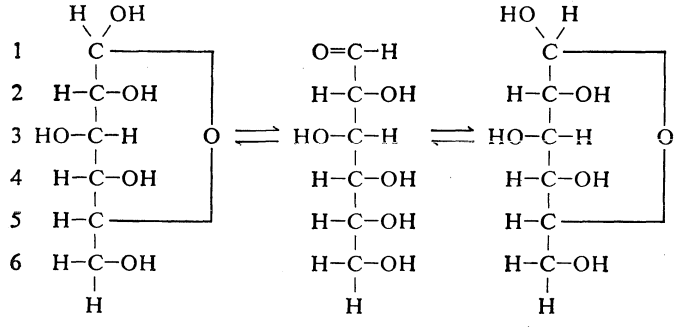


the carbonyl group (at position 1 in glucose or 2 in fructose. A five-membered ring is illustrated for the ketohexose, fructose; a six-membered ring is illustrated for the aldohexose, glucose. In either case, the cyclic forms are in equilibrium with (*i.e.*, the rate of conversion from one form to another is stable) the open-chain structure—a free aldehyde if the solution contains glucose, a free ketone if the solution contains fructose; each form has a different optical rotation value. Since the various forms are in equilibrium with each other, a constant value of optical rotation is measurable; the two cyclic forms represent more than 99.9 percent of the sugar in the case of a glucose solution.

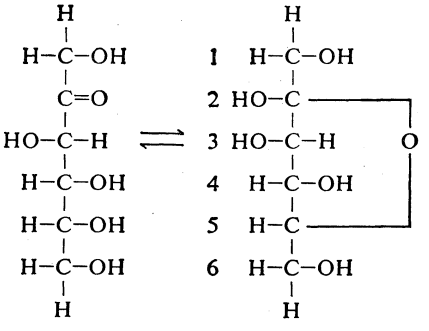
Table 1: Aldoses, up to Aldohexoses, of the D-Series



*Aldehydo carbon (—CHO) is carbon atom 1; the remaining carbon atoms are numbered in succession. The hydroxyl groups only are shown for the asymmetrical carbon atoms. The D-configuration is derived from the asymmetrical carbon atom most remote from the aldehydo end of the molecule; *i.e.*, the hydroxyl group at carbon 3 in 4 carbon sugars; 4 in pentoses, and 5 in hexoses projects to the right. The L-series are corresponding mirror images; *i.e.*, the hydroxyl group projects to the left.



α-D-glucose (hemiacetal form) | D-glucose (linear, open-chain, or free form) | β-D-glucose (hemiacetal form)



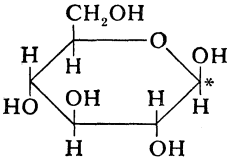
D-fructose (linear, open-chain, or free form) | α-D-fructose (hemiketal form)

Anomeric carbon atom

By definition, the carbon atom containing the aldehydo  or keto group  is termed the anomeric carbon atom; similarly, carbohydrate stereoisomers that differ in configuration only at this carbon atom are called anomers. When a cyclic hemiacetal or hemiketal structure forms, the structure with the new hydroxyl group projecting on the same side as that of the oxygen involved in forming the ring is termed the alpha anomer (see hemiacetal forms for glucose and diagram); that with the hydroxyl group projecting on the opposite side from that of the oxygen ring is termed the beta anomer (see diagram).

alpha isomer | beta isomer

The spatial arrangements of the atoms in these cyclic structures are better shown (glucose is used as an example) in the representation devised by the British organic chemist Walter Norman (later Sir Norman) Haworth about 1930; they are still in widespread use. In the formulation the asterisk indicates the position of the anomeric carbon atom; the carbon atoms, except at position 6, usually are not labelled.



Haworth formulation of β-D-glucose

The large number of asymmetrical carbon atoms and the consequent number of possible isomers considerably complicates the structural chemistry of carbohydrates.

CLASSES OF CARBOHYDRATES

Monosaccharides. *Sources.* The most common naturally occurring monosaccharides are D-glucose, D-mannose, D-fructose, and D-galactose among the hexoses, and D-xylose and L-arabinose among the pentoses. In a special sense, D-ribose and 2-deoxy-D-ribose are ubiquitous because they form the carbohydrate component of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA), respectively; these sugars are present in all cells as components of nucleic acids. Sources of some of the naturally occurring monosaccharides are listed in Table 2.

D-xylose, found in most plants in the form of a polysac-

Table 2: Some Naturally Occurring Monosaccharides

sugar	sources
L-arabinose	mesquite gum; wheat bran
D-ribose	all living cells as component of ribonucleic acid
D-xylose	corncobs; seed hulls; straw
D-ribulose	one derivative, is an intermediate in photosynthesis
2-deoxy-D-ribose	as constituent of deoxyribonucleic acid
D-galactose	lactose; agar; gum arabic; brain glycolipids
D-glucose	sucrose; cellulose; starch; glycogen
D-mannose	seeds; ivory nut
D-fructose	sucrose; artichokes; honey
L-fucose	marine algae; seaweed
L-rhamnose	poison-ivy blossom; oak bark
D-mannoheptulose	avocado
D-altroheptulose	numerous plants

charide called xylan, is prepared from corncobs, cottonseed hulls, or straw by chemical breakdown of xylan. D-galactose, a common constituent of both oligosaccharides and polysaccharides, also occurs in carbohydrate-containing lipids, called glycolipids, which are found in the brain and other nervous tissues of most animals. Galactose is generally prepared by acid hydrolysis (breakdown involving water) of lactose, which is composed of galactose and glucose. Since the biosynthesis of galactose in animals occurs through intermediate compounds derived directly from glucose, animals do not require galactose in the diet. In fact, high dietary concentrations of galactose may lead to cataract formation in the lens of the eye because galactose is readily reduced to a metabolically inactive and relatively insoluble alcohol (galactitol).

D-glucose (from the Greek word *glykys*, meaning "sweet"), the naturally occurring form, is found in fruits, honey, blood, and, under abnormal conditions, in urine. It is also a constituent of the two most common naturally found disaccharides, sucrose and lactose, as well as the exclusive structural unit of the polysaccharides cellulose, starch, and glycogen. Generally, D-glucose is prepared from either potato starch or cornstarch.

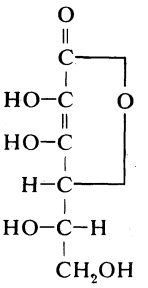
D-fructose, a ketohexose, is one of the constituents of the disaccharide sucrose and is also found in uncombined form in honey, apples, and tomatoes. Fructose, generally considered the sweetest monosaccharide, is prepared by sucrose hydrolysis and is metabolized by man.

Chemical reactions. The reactions of the monosaccharides can be conveniently subdivided into those associated with the aldehydo or keto group and those associated with the hydroxyl groups.

Reactions involving the aldehydo or keto group

The relative ease with which sugars containing a free or potentially free aldehydo or keto group can be oxidized to form products has been known for a considerable time and once was the basis for the detection of these so-called reducing sugars in a variety of sources. For many years, analyses of blood glucose and urinary glucose were carried out by a procedure involving the use of an alkaline copper compound. Because the reaction has undesirable features—extensive destruction of carbohydrate structure occurs, and the reaction is not very specific (*i.e.*, sugars other than glucose give similar results) and does not result in the formation of readily identifiable products—blood and urinary glucose now are analyzed by using the enzyme glucose oxidase, which catalyzes the oxidation of glucose to products that include hydrogen peroxide. The hydrogen peroxide then is used to oxidize a dye present in the reaction mixture; the intensity of the colour is directly proportional to the amount of glucose initially present. The enzyme, glucose oxidase, is highly specific for β-D-glucose.

In another reaction, the aldehydo group of glucose  reacts with alkaline iodine to form a class of compounds called aldonic acids. One important aldonic acid is ascorbic acid (vitamin C, see structure), an essential dietary component for man and guinea pigs.



ascorbic acid,
vitamin C
(L-gulonolactone-
2, 3-enediol)

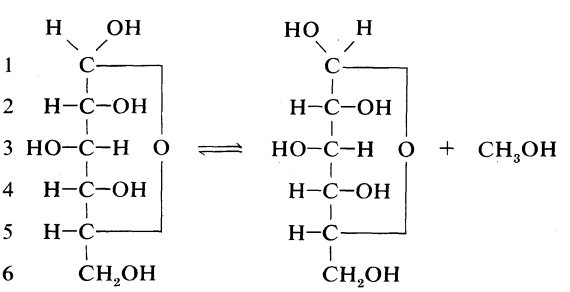
The formation of similar acid derivatives does not occur with the keto sugars.

Either the aldehydo or the keto group of a sugar may be reduced (*i.e.*, hydrogen added) to form an alcohol; compounds formed in this way are called alditols, or sugar alcohols. The product formed as a result of the reduction of the aldehydo carbon of D-glucose is called sorbitol (D-glucitol). D-glucitol also is formed when L-sorbose is reduced. The reduction of mannose results in mannitol, that of galactose in dulcitol.

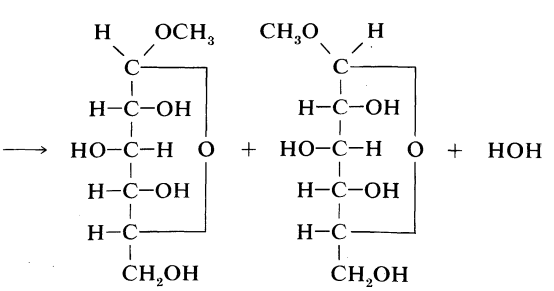
Sugar alcohols of commercial importance are sorbitol (D-glucitol), commonly used as a sweetening agent, and D-mannitol, also used as a sweetener, particularly in chewing gums, because it has a limited water solubility and remains powdery and granular on long storage.

Formation of glycosides

The hydroxyl group attached to the anomeric carbon atom (*i.e.*, the carbon containing the aldehydo or keto group) of carbohydrates in solution has unusual reactivity, and derivatives, called glycosides, can be formed; glycosides formed from glucose are called glucosides. Equilibration between the α- and β-anomers of a glycoside in solution (*i.e.*, mutarotation) cannot occur. The reaction by which a glycoside is formed (see below) involves the hydroxyl group (— OH) of the anomeric carbon atom (numbered 1) of both α and β forms of D-glucose—α and β forms of D-glucose are shown in equilibrium in the reaction sequence—and the hydroxyl group of an alcohol (methyl alcohol in the reaction sequence); methyl α-D-glucosides and β-D-glucosides are formed as products, as is water.



α-D-glucose (in equilibrium in solution) β-D-glucose methyl alcohol

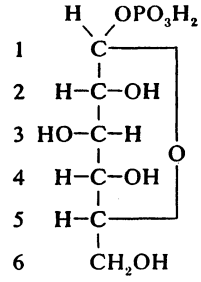


methyl-α-D-glucoside methyl-β-D-glucoside water

Among the wide variety of naturally occurring glycosides are a number of plant pigments, particularly those red, violet, and blue in colour; these pigments are found in flowers and consist of a pigment molecule attached to a sugar molecule, frequently glucose. Plant indican (from *Indigofera* species), composed of glucose and the pigment indoxyl, was important in the preparation of indigo dye before synthetic dyes became prevalent. Of a number of heart-muscle stimulants that occur as glycosides, digitalis is still used. Other naturally occurring glycosides include vanillin, which is found in the vanilla bean, and amygdalin (oil of bitter almonds); a variety of glycosides found in mustard have a sulfur atom at position 1 rather than oxygen.

A number of important antibiotics are glycosides; the best known are streptomycin and erythromycin. Glucosides—*i.e.*, glycosides formed from glucose—in which the anomeric carbon atom (at position 1) has phosphoric acid linked to it are extremely important biological compounds.

For example, α-D-glucose-1-phosphate (see formula), is an intermediate product in the biosynthesis of cellulose, starch, and glycogen; similar glycosidic phosphate derivatives of other monosaccharides participate in the formation of naturally occurring glycosides and polysaccharides.



α-D-glucose-1-phosphate

The hydroxyl groups other than the one at the anomeric carbon atom can undergo a variety of reactions, several of which deserve mention. Esterification, which consists of reacting the hydroxyl groups with an appropriate acidic compound, results in the formation of a class of compounds called sugar esters. Among the common ones are the sugar acetates, in which the acid is acetic acid. Esters of phosphoric acid and sulfuric acid are important biological compounds; glucose-6-phosphate, for example, plays a central role in the energy metabolism of most living cells, and D-ribulose 1,5-diphosphate is important in photosynthesis.

Formation of methyl ethers

Treatment of a carbohydrate with methyl iodide or similar agents under appropriate conditions results in the formation of compounds in which the hydroxyl groups are converted to methyl groups (— CH_3). Called methyl ethers, these compounds are employed in structural studies of oligosaccharides and polysaccharides because their formation does not break the bonds, called glycosidic bonds, that link adjacent monosaccharide units. In the reaction sequence shown, a segment of a starch molecule, consisting of three glucose units, is indicated; the Haworth formulation used to represent one of the glucose units shows the locations of the glycosidic bonds and the — OH groups. When complete etherification of the starch molecule is carried out, using methyl iodide, methyl groups become attached to the glucose molecules at the three positions shown in the methylated segment of the starch molecule; note that the glycosidic bonds have not been broken by the reaction with methyl iodide. When the methylated starch molecule then is broken down (hydrolyzed), hydroxyl groups are located at the positions in the molecule previously involved in linking one sugar molecule to another, and a methylated glucose, in this case named 2,3,6 tri-*O*-methyl-D-glucose, forms. The linkage positions (in the example, at carbon atoms 1 and 4; the carbon atoms are numbered in the structure of the methylated glucose), which are not methylated, in a complex carbohydrate can be established by analyzing the locations (in the example, at carbon atoms 2, 3, and 6) of the methyl groups in the monosaccharides. This technique is useful in determining the structural details of polysaccharides, particularly since the various methylated sugars are easily separated by techniques involving gas chromatography, in which a moving gas stream carries a mixture through a column of a stationary liquid or solid, the components thus being resolved.

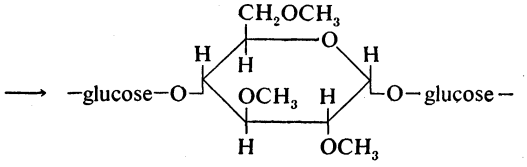
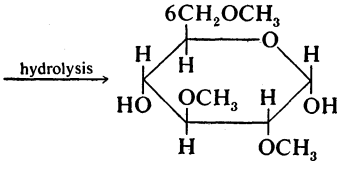
methyl iodide



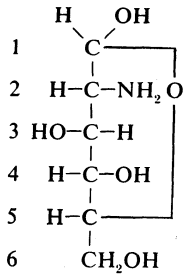
methylated segment of starch molecule



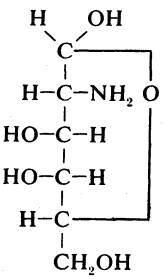
methylated glucose

When the terminal group (CH_2OH) of a monosaccharide is oxidized chemically or biologically, a product called a uronic acid is formed. Glycosides that are derived from D-glucuronic acid (the uronic acid formed from D-glucose) and fatty substances called steroids appear in the urine of animals as normal metabolic products; in addition, foreign toxic substances are frequently converted in the liver to glucuronides before excretion in the urine. D-glucuronic acid also is a major component of connective tissue polysaccharides, and D-galacturonic acid and D-mannuronic acid, formed from D-galactose and D-mannose, respectively, are found in several plant sources.

Other compounds formed from monosaccharides include those in which one hydroxyl group, usually at the carbon at position 2 (see formulas for D-glucosamine and D-galactosamine) is replaced by an amino group (— NH_2); these compounds, called amino sugars, are widely distributed in nature. The two most important ones are glucosamine (2-amino-2-deoxy-D-glucose) and galactosamine (2-amino-2-deoxy-D-galactose).



D-glucosamine

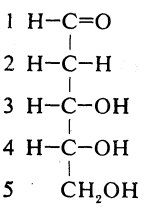


D-galactosamine

Neither amino sugar is found in the uncombined form. Both occur in animals as components of glycolipids or polysaccharides; *e.g.*, the primary structural polysaccharide (chitin) of insect outer skeletons and various blood-group substances.

In a number of naturally occurring sugars, known as

deoxy sugars, the hydroxyl group at a particular position is replaced by a hydrogen atom. By far the most important representative is 2-deoxy-D-ribose (see formula), and pentose sugar found in deoxyribonucleic acid (DNA); the hydroxyl group at the carbon atom at position 2 has been replaced by a hydrogen atom.

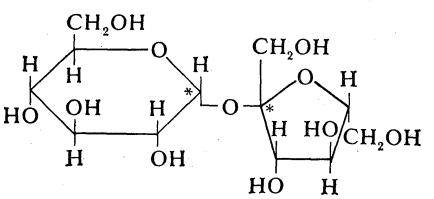


2-deoxy-D-ribose

Other naturally occurring deoxy sugars are hexoses, of which L-rhamnose (6-deoxy-L-mannose) and L-fucose (6-deoxy-L-galactose) are the most common; the latter, for example, is present in the carbohydrate portion of blood-group substances and in red-blood-cell membranes.

Disaccharides and oligosaccharides. Disaccharides are a specialized type of glycoside in which the anomeric hydroxyl group of one sugar has combined with the hydroxyl group of a second sugar with the elimination of the elements of water. Although an enormous number of disaccharide structures are possible, only a limited number are of commercial or biological significance.

Sucrose and trehalose. Sucrose, or common table sugar, has a world production amounting to well over 10,000,000 tons annually. The unusual type of linkage between the two anomeric hydroxyl groups of glucose and fructose (see formula, in which the asterisk indicates anomeric carbon atom), means that neither a free aldehydo group (on the glucose moiety) nor a free keto group (on the fructose moiety) is available to react unless the linkage between the monosaccharides is destroyed; for this reason, sucrose is known as a nonreducing sugar.



sucrose

Invert sugar

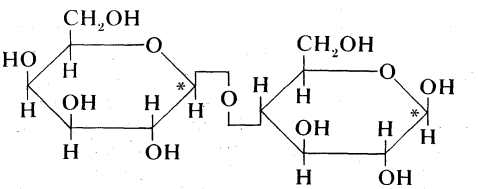
Sucrose solutions do not exhibit mutarotation, which involves formation of an asymmetrical centre at the aldehydo or keto group. If the linkage between the monosaccharides comprising sucrose is broken, the optical rotation value of sucrose changes from positive to negative; the new value reflects the composite rotation values for D-glucose, which is dextrorotatory (+ 52°), and D-fructose, which is levorotatory (− 92°). The change in the sign of optical rotation from positive to negative is the reason sucrose is sometimes called invert sugar.

The commercial preparation of sucrose takes advantage of the alkaline stability of the sugar, and a variety of impurities are removed from crude sugarcane extracts by treatment with alkali. After this step, syrup preparations are crystallized to form table sugar. Successive "crops" of sucrose crystals are "harvested," and the later ones are known as brown sugar. The residual syrupy material is called either cane final molasses or blackstrap molasses; both are used in the preparation of antibiotics, as sweetening agents, and in the production of alcohol by yeast fermentation.

Biologically, sucrose is formed following photosynthesis in plants by a reaction in which sucrose phosphate first is formed.

The disaccharide trehalose is similar in many respects to sucrose but is much less widely distributed. It is composed of two molecules of α-D-glucose and is also a nonreducing sugar. Trehalose is present in young mushrooms and in the resurrection plant (*Selaginella*); it is of considerable biological interest because it is also found in the circulating fluid (hemolymph) of many insects. Since trehalose can be converted to a glucose phosphate compound by an enzyme-catalyzed reaction that does not require energy, its function in hemolymph may be to provide an immediate energy source, a role similar to that of the carbohydrate storage forms (*i.e.*, glycogen) found in higher animals.

Lactose and maltose. Lactose is one of the sugars (sucrose is another) found most commonly in human diets throughout the world; it comprises about 5 percent or more of the milk of all mammals. Lactose consists of two aldohexoses—β-D-galactose and glucose—linked so that the aldehydo group at the anomeric carbon of glucose is free to react (see structural formula, in which the asterisk indicates position of anomeric carbon atoms); *i.e.*, lactose is a reducing sugar.



β-lactose

A variety of metabolic disorders related to lactose may occur in infants; in some cases, they are the result of a failure to metabolize properly the galactose portion of the molecule.

Importance of maltose

Although not found in uncombined form in nature, the disaccharide maltose is biologically important because it is a product of the enzymatic breakdown of starches during digestion. Maltose consists of α-D-glucose linked to a second glucose unit in such a way that maltose is a reducing sugar. Maltose, which is readily hydrolyzed to glucose and can be metabolized by animals, is employed as a sweetening agent and as a food for infants whose tolerance for lactose is limited. Table 3 lists the component sugars of, the linkage between, and the occurrence of a number of disaccharides and oligosaccharides.

Table 3: Representative Disaccharides and Oligosaccharides

common name	component sugars	linkages	sources
Cellobiose	glucose, glucose	β 1 → 4†	hydrolysis of cellulose
Gentiobiose	glucose, glucose	β 1 → 6	plant glycosides, amygdalin
Isomaltose	glucose, glucose	α 1 → 6	hydrolysis of glycogen, amylopectin
Raffinose*	galactose, glucose, fructose	α 1 → 6, α 1 → 2	sugarcane, beets, seeds
Stachyose*	galactose, galactose, glucose, fructose	α 1 → 6, α 1 → 6, α 1 → 2	soybeans, jasmine, twigs, lentils

*Note that raffinose and stachyose are galactosyl sucroses. †The linkage joins carbon atom 1 (in the β configuration) of one glucose molecule and carbon atom 4 of the second glucose molecule; the linkage may also be abbreviated β-1, 4.

Polysaccharides. Polysaccharides, or glycans, may be classified in a number of ways; the following scheme is frequently used. Homopolysaccharides are defined as polysaccharides formed from only one type of monosaccharide. Homopolysaccharides may be further subdivided into straight-chain and branched-chain representatives, depending upon the arrangement of the monosaccharide units. Heteropolysaccharides are defined as polysaccharides containing two or more different types of monosaccharides; they may also occur in both straight-chain and branched-chain forms. In general, extensive variation of linkage types (see Table 4) does not occur within a polysaccharide structure, nor are there many polysaccharides composed of more than three or four different monosaccharides; most contain one or two.

Homopolysaccharides. In general, homopolysaccharides have a well-defined chemical structure, although the molecular weight of an individual amylose or xylan molecule may vary within a particular range, depending

Table 4: Representative Homopolysaccharides

homopolysaccharide	sugar component	linkage	function	sources
Cellulose	glucose	β, 1 → 4	structural	throughout plant kingdom
Amylose	glucose	α, 1 → 4	food storage	starches, especially corn, potatoes, rice
Chitin	N-acetylglucosamine	β, 1 → 4	structural	insect and crustacean skeleton
Inulin	fructose	β, 2 → 1	food storage	artichokes, chicory
Xylan	xylose	β, 1 → 4	structural	all land plants
Glycogen	glucose	α, 1 → 4, 6 ← 1, α	food storage	liver and muscle cells of all animals
Amylopectin	glucose	α, 1 → 4, 6 ← 1, α	food storage	starches, especially corn, potatoes, rice
Dextran	glucose	α, 1 → 6, 4 ← 1, α	unknown	primarily bacterial
Agar*	galactose	α, 1 → 3	structural	seaweeds

*May contain sulfate groups.

on the source; molecules from a single source also may vary in size, because most polysaccharides are formed biologically by an enzyme-catalyzed process lacking genetic information regarding size. Several naturally occurring homopolysaccharides are listed in Table 4.

Cellulose and xylans

The basic structural component of most plants, cellulose, is widely distributed in nature. It has been estimated that nearly 10,000,000,000 tons of cellulose are synthesized yearly as a result of photosynthesis by higher plants. The proportion of cellulose to total carbohydrate found in plants may vary in various types of woods from 30 to 40 percent, and to more than 98 percent in the seed hair of the cotton plant. Cellulose, a large, linear molecule composed of 3,000 or more β-D-glucose molecules, is insoluble in water.

The chains of glucose units comprising cellulose molecules are frequently aligned within the cell-wall structure of a plant to form fibre-like or crystalline arrangements. This alignment permits very tight packing of the chains and promotes their structural stability but also makes structural analysis difficult. The relationships between cellulose and other polysaccharides present in the cell wall are not well established; in addition, the presence of unusual chemical linkages or nonglucose units within the cellulose structure has not yet been established with certainty.

During the preparation of cellulose, raw plant material is treated with hot alkali; this treatment removes most of the lignin, the hemicelluloses, and the mucilaginous components. The cellulose then is processed to produce papers and fibres. The high resistance of cellulose to chemical or enzymatic breakdown is important in the manufacture of paper and cloth. Cellulose also is modified chemically for other purposes; *e.g.*, compounds such as cellulose acetate are used in the plastics industry, in the production of photographic film, and in the rayon-fibre industry. Viscose rayon is produced from an ester of cellulose, and cellulose nitrate is employed in the lacquer and explosives industries.

The noteworthy biological stability of cellulose is dramatically illustrated by trees, the life-span of which may be several thousand years. Enzymes capable of breaking down cellulose are generally found only among several species of bacteria and molds. The apparent ability of termites to utilize cellulose as an energy source depends on the presence in their intestinal tracts of protozoans that can break it down. Similarly, the single-celled organisms present in the rumina of sheep and cattle are responsible for the ability of these animals to utilize the cellulose present in typical grasses and other feeds.

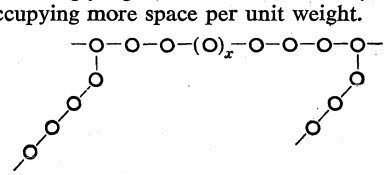
Xylans are almost as ubiquitous as cellulose in plant-cell walls and contain predominantly β-D-xylose units linked as in cellulose (see Table 4). Some xylans contain other sugars, such as L-arabinose, but they form branches and are not part of the main chain. Xylans are of little commercial importance.

Starch

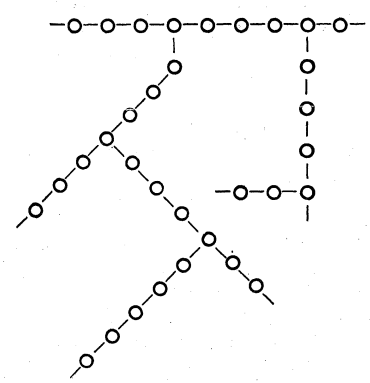
The term starch refers to a group of plant reserve polysaccharides consisting almost exclusively of a linear component (amylose) and a branched component (amylopectin). Man's utilization of starch as an energy source depends on his ability to convert it completely to individual glucose units; the process is initiated by the action of enzymes called amylases, synthesized by the salivary glands in the mouth, and continues in the intestinal tract. The primary product of amylase action is maltose, which is hydrolyzed to two component glucose units as it is absorbed through the walls of the intestine.

A characteristic reaction of the amylose component of starch is the formation with iodine of a complex compound with a characteristic blue colour. About one iodine molecule is bound for each seven or eight glucose units, and at least five times that many glucose units are needed in an amylose chain to permit the effective development of the colour.

The amylopectin component of starch is structurally similar to glycogen in that both are composed of glucose units linked together in the same way, but the distance between branch points (see schematic diagrams, in which —O— represents one glucose unit) is greater in amylopectin than in glycogen, and the former may be thought of as occupying more space per unit weight.



schematic amylopectin structure



schematic glycogen structure

The applications of starches other than as foods are limited, although they are employed in adhesive manufacture; in addition, starch nitrate has some utility as an explosive.

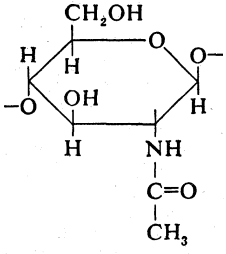
Glycogen

Glycogen, which is found in all animal tissues, is the primary animal storage form of carbohydrate and, indirectly, of rapidly available energy. The distance between branch points in a glycogen molecule is only five or six units (see schematic diagram above), which results in a compact treelike structure. The ability of higher animals to form and break down this extensively branched structure is essential to their well-being; in conditions known as glycogen storage diseases, these activities are abnormal, and the asymmetrical glycogen molecules that are formed have severe, often fatal, consequences. Glycogen synthesis and breakdown are controlled by substances called hormones.

Large molecules—*e.g.*, pectins and agars—composed of galactose or its uronic-acid derivative (galacturonic acid) are important because they can form gels. Pectins, which are predominantly galacturonans, are produced from citrus fruit rinds; they are used commercially in the preparation of jellies and jams. Agar is widely employed in biological laboratories as a solidifying agent for growth media for micro-organisms and in the bakery industry as a gelling agent; it forms a part of the diet of people in several areas of the Far East.

Dextrans, a group of polysaccharides composed of glucose, are secreted by certain strains of bacteria as slimes. The structure of an individual dextran varies with the strain of micro-organism. Dextrans can be used as plasma expanders (substitutes for whole blood) in cases of severe shock. In addition, a dextran derivative compound is employed medically as an anticoagulant for blood.

Chitin is structurally similar to cellulose, but the repeating sugar is 2-deoxy-2-acetamido-D-glucose (*N*-acetyl-D-glucosamine, see structural formula) rather than glucose.



N-acetyl-D-glucosamine

Sometimes referred to as animal cellulose, chitin is the major component of the outer skeletons of insects, crustaceans, and other arthropods, as well as annelid and nematode worms, mollusks, and coelenterates. The cell walls of most fungi also are predominantly chitin, which comprises nearly 50 percent of the dry weight of some species. Since chitin is nearly as chemically inactive as cellulose and easily obtained, numerous attempts, none of which has thus far been successful, have been made to develop it commercially. The nitrogen content of the biosphere, however, is stabilized by the ability of soil micro-organisms to degrade nitrogen-containing compounds such as those found in insect skeletons; these micro-organisms convert the nitrogen in complex molecules to a form usable by plants. If such micro-organisms did not exist, much of the organic nitrogen present in natural materials would be unavailable to plants.

Heteropolysaccharides. In general, heteropolysaccharides (heteroglycans) contain two or more different monosaccharide units. Although a few representatives contain three or more different monosaccharides, most naturally occurring heteroglycans contain only two different ones and are closely associated with lipid or protein. The complex nature of these substances has made detailed structural studies extremely difficult. The major heteropolysaccharides include the connective-tissue polysaccharides, the blood-group substances, glycoproteins (combinations of carbohydrates and proteins) such as gamma globulin, and glycolipids (combinations of carbohydrates and lipids), particularly those found in the central nervous system of animals and in a wide variety of plant gums (see Table 5).

Connective tissue heteropolysaccharides

The most important heteropolysaccharides are found in the connective tissues of all animals and include a group of large molecules that vary in size, shape, and interaction with other body substances. They have a structural role, and the structures of individual connective-tissue polysaccharides are related to specific animal functions; hyaluronic acid, for example, the major component of joint fluid in animals, functions as a lubricating agent and shock absorber when stress or weight is put on a joint surface.

The connective-tissue heteropolysaccharides contain acidic groups (uronic acids or sulfate groups) and can bind both water and inorganic metal ions. They can also play a role in other physiological functions; *e.g.*, in the accumulation of calcium before bone formation. Ion-binding ability also appears to be related to the anticoagulant activity of the heteropolysaccharide heparin (see Table 5).

The size of the carbohydrate portion of glycoproteins such as gamma globulin or hen-egg albumin is usually between five and ten monosaccharide units; several such units occur in some glycoprotein molecules. The function of the carbohydrate component has not yet been established except for glycoproteins associated with cell surfaces; in this case, they appear to act as antigenic determinants—*i.e.*, they are capable of inducing the formation of specific antibodies.

PREPARATION AND ANALYSIS

In general, monosaccharides are prepared by breakdown with acids of the polysaccharides in which they occur. Because sugars usually are difficult to obtain in crystalline form, the crystallization process usually is begun by "seeding" a concentrated solution of the sugar with crystals. The techniques employed for separation of monosaccharides depend to some extent on their physical and chemical properties; chromatographic procedures are frequently used.

Oligosaccharides and polysaccharides are prepared from natural sources by techniques that take advantage of size, alkaline stability, or some combination of these and other properties of the molecule of interest. It should be noted that preparation of an oligosaccharide or polysaccharide usually results in a range of molecular sizes of the desired molecule. The purity of a carbohydrate preparation, which is frequently based on an analysis of its composition, is more easily established for monsaccharides and disaccharides than for large, insoluble molecules such as cellulose.

Optical rotation

A variety of organic chemical analytical techniques are generally applicable to studies involving carbohydrates. Optical rotation, for example, once was frequently used to characterize carbohydrates. The ability to measure the rotation of the plane of polarized light transmitted through a solution containing a carbohydrate depends on finding a suitable solvent; water usually is used, with light at a wavelength of 589 mμ (millimicrons). Optical rota-

Table 5: Representative Heteropolysaccharides

heteropolysaccharide	component sugars	functions	distribution
Hyaluronic acid	D-glucuronic acid and *N*-acetyl-D-glucosamine	lubricant, shock absorber, water binding	connective tissue, skin
Chondroitin-4-sulfate*	D-glucuronic acid and *N*-acetyl-D-galactosamine-4-*O*-sulfate	calcium accumulation, cartilage and bone formation	cartilage
Heparin*	D-glucuronic acid, *L*-iduronic acid, *N*-sulfo-D-glucosamine	anticoagulant	mast cells, blood
Gamma globulin*	*N*-acetyl-hexosamine, D-mannose, D-galactose	antibody	blood
Blood group substance*	D-glucosamine, D-galactosamine, *L*-fucose, D-galactose	blood group specificity	cell surfaces, especially red-blood cells

*Covalently linked to protein; the proportion of protein to carbohydrate in such complex molecules varies from about 10% protein in the case of chondroitin-4-sulfate to better than 95% for gamma globulin.

tion is no longer widely used to characterize monosaccharides. The magnitude and sign of the optical rotation of glycosides, however, is useful in assigning configuration (α or β) to the hydroxyl group at the anomeric centre; glycosides of the α-configuration generally have rotations of higher magnitude than do the same glycosides of the β-configuration. Optical rotation is not a completely additive property; a trisaccharide composed of three glucose residues, for example, does not have a rotation three times that of one glucose molecule. Sugar alcohols and sugar acids cannot form ring structures; their rotation values are extremely small, suggesting a relationship between ring structure and the ability of a carbohydrate to rotate the plane of polarized light. Certain types of reactions (*e.g.*, glycoside hydrolysis) can be monitored by measuring the change in optical rotation as a function of time. This technique is frequently used to examine the breakdown of disaccharides or oligosaccharides to monosaccharide units, especially if a large change in the net optical rotation may be expected, as occurs in the hydrolysis of sucrose.

A number of other optical techniques used in chemistry have been applied to the analysis of carbohydrates. Infrared spectroscopy, which is used to measure vibrational and rotational excitation of molecules, and nuclear magnetic-resonance spectroscopy, which measures the excitation of certain components of molecules in a magnetic field induced by radio-frequency radiation, are valuable, although the similarity of the functional groups (*i.e.*, the hydroxyl groups) limits use of the former technique for most sugars. Proton magnetic-resonance spectroscopy, nuclear magnetic resonance applied only to protons (H atoms), is widely employed to identify the relative spatial arrangements of individual hydrogen atoms in a molecule. When they are precisely placed, the corresponding positions of the hydroxyl groups attached to the same carbon atom can be deduced. An extension of this technique utilizes the resonance spectroscopy of carbon-13, a nonradioactive isotope of carbon, so that ring structures can be established with considerable accuracy. Both the proton and carbon magnetic resonance methods are best applied to monosaccharides; they are less valuable in studying polysaccharides because an individual hydrogen atom in a large molecule is too small for accurate detection.

The study of polysaccharide structure usually focusses on the chemical composition, the linkage between the monosaccharide units, and the size and shape of the molecule. The last two properties can be ascertained by techniques usually applied to large molecules; *e.g.*, the most accurate molecular weight method measures the sedimentation properties of the molecule in an applied gravitational field (*e.g.*, the rate at which a solid material is deposited from a state of suspension or solution in a liquid). Indications of the shape of polysaccharide molecules in solution are obtained from viscosity measurements, in which the resistance of the molecules to flow (viscosity) is equated with the end-to-end length of the molecule; the viscosity of hyaluronic acid, for example, shows a marked dependence on both concentration of the acid and the salt content of the solution, and, under conditions approximating those found in biological systems, the molecule may be thought of as occupying a great deal of space. Alternatively, the compact nature of a glycogen molecule of equal molecular weight results in its accommodation to a much smaller space.

The identification of sugars in a mixture resulting from the hydrolytic breakdown of a heteropolysaccharide is most often carried out by chromatography of the mixture on paper, silica gel, or cellulose. Ready separations can be achieved between pentoses, hexoses and, for example, deoxy sugars; closely related compounds such as D-glucose and D-galactose also can be separated using chromatographic techniques. The linkage positions in polysaccharides are usually determined using the methylation procedure described previously. The various monosaccharide methyl ethers are separated by gas–liquid chromatography.

Detailed statements about polysaccharide structure and function are limited by the statistical nature of some measurements (*e.g.*, branching frequency), the biological variability of parameters such as size and molecular weight, and incomplete information about associative interactions in living things.

(E.A.D.)

Carbonate Minerals

Carbonate minerals are naturally occurring substances that contain the carbonate ion CO_3^{2-} as a major structural and compositional unit. As a group, the carbonates are rather soft minerals with hardnesses between 1 and 5 on the Mohs scale (which ranges to 10 for diamond); and, with the exception of the uranyl and the alkali carbonates, they tend to be relatively insoluble in water. Because the carbonate ion reacts with the hydronium (hydrogen) ion to liberate carbon dioxide gas, the carbonates are characterized by their solubility, often with effervescence, in acids. The crystal structures of many carbonate minerals reflect the trigonal (three–fold) symmetry of the carbonate ion, which consists of a carbon atom centrally located in an equilateral triangle of oxygen atoms. The planar structure of the carbonate ion also results frequently in highly anisotropic physical properties in the carbonates, such as the high birefringence (difference between the transmission of light in different crystal directions) characteristic of many carbonate minerals.

Uses of carbonate minerals

Two common carbonates, calcite and dolomite, are among the most abundant and widely distributed minerals found on the surface of the Earth. As the principal constituents of limestones, dolostones, and marbles, these minerals have a wide variety of commercial uses and account for approximately 70 percent of all rock quarried in the United States. These materials are extensively used for building and ornamental stone, for concrete and road stone, for the production of natural and portland cements, in agriculture, and as fluxes in steel-smelting processes. In addition, calcite crystals are vital components in the manufacture of optical polarizing prisms; certain limestones are used in lithography; and natural and precipitated calcite is used in the production of candy, chewing gum, food fillers, glass, glue, pharmaceutical products (antacids, antibiotics, etc.), rubber, shoe polish, soap, toothpaste, whitewash, and many other commodities. Calcite also is used as an ore of metallic calcium and as a raw material in the manufacture of other chemical compounds of calcium. Dolomite and magnesite are used as ores, as chemical sources of magnesium, and as major sources of refractory compounds (heat–resistant substances used as furnace linings).

Other carbonate minerals are used as ores and as chemical sources of iron, manganese, zinc, lead, copper, barium, strontium, sodium, uranium, and rare-earth elements. Aragonite (pearl), malachite, rhodochrosite, smithsonite, and calcite (coral, onyx, marble) are used as gems or for other ornamental purposes (see GEMSTONES).

CLASSIFICATION

The generally accepted system of classification of minerals (*q.v.*) is based upon the principal anion (negatively charged ion) present. Subclassification within the carbonate minerals is based upon the nature of the anionic unit or upon the presence and identity of other anionic species. The subclasses within the carbonate minerals include (1) anhydrous normal carbonates, which are those minerals that contain only carbonate as an anion and no structural water; (2) hydrated normal carbonates, which are those minerals that contain only carbonate anions that do have structural water of hydration; (3) acid carbonates, which are minerals that contain the acid carbonate (bicarbonate) anion, HCO_3^-; (4) minerals containing hydroxide (OH^-) or halide (F^-, Cl^-) ions in addition to carbonate; and (5) compound carbonates or minerals that contain other anions, such as sulfate (SO_4^{2-}) or phosphate (PO_4^{3-}), in addition to carbonate. There are also some minerals that properly belong in other major classes, such as silicate or sulfate minerals. These may contain the carbonate ion as a minor anionic unit. The subclasses may further be divided into compositional types, depending upon whether single or multiple cationic (positively charged) species are present, and into isostructural groups (minerals with similar crystal structures).

The most important carbonate minerals, whether from the economic or the geologic point of view, belong to three major structural groups (calcite, dolomite, and aragonite) within the anhydrous normal carbonate class (class 1). Alkali carbonates and bicarbonates such as nahcolite, trona, thermonatrite, and natron (predominantly in classes 2 and 3), are relatively rare, and are of geologic interest because of their unusual mode of occurrence, as later described. Certain other carbonates, although geologically rare, may locally be concentrated in sufficient quantities to be economically important as minor ore minerals. Such minerals include malachite and azurite (which because of their aesthetic appeal are highly prized by mineral collectors) in class 4, lanthanite (class 2), bastnaesite and related rare-earth carbonates, and hydrozincite (all in class 4), and various uranium and uranyl carbonates such as rutherfordine (class 1), andersonite, swartzite, bayleyite, and liebigite (all in class 2). For species in each class see RELATED ENTRIES under CARBONATE MINERALS in the *Ready Reference and Index*.

CRYSTALLOGRAPHY AND CHEMICAL PROPERTIES

Calcite group. As previously noted, calcite is one of the most common and most widely distributed minerals known. It occurs in a wide variety of geological settings and frequently forms large, well-defined crystals. Calcite displays the widest variety of crystal habits of any known substance; more than 600 different crystal forms have been reported. Despite this diversity of possible forms, only a few are commonly observed. Several of the more common forms are illustrated in Figure 1. Calcite exhibits essentially perfect rhombohedral cleavage corresponding to the form r of Figure 1. Because all calcite crystals will preferentially break along these planes, virtually all crystal fragments of calcite will possess this habit.

Double refraction of calcite

The abundance and variety of large, essentially perfect crystals and the marked anisotropy (directional variation) of many of its physical properties have resulted in extensive studies of calcite throughout the history of crystallography. The phenomenon of double refraction was first observed in cleavage rhombs of calcite from Iceland and was described in detail in 1678. Further study of this phenomenon led to the discovery of polarization of light in 1808. René-Just Haüy's studies of calcite in 1781–1801 led to a theory of crystal structure and to the development of geometrical crystallography. The observed variation dependent on composition of the crystallographic and other physical properties of calcite and other members of the calcite group led to the theory of isomorphism in 1820. The crystal structure of calcite was one of the first to be determined by X-ray diffraction, being described by Sir Lawrence Bragg in 1914. Subsequently, calcite was used as a standard for X-ray wavelengths. The phenomenon of twin gliding (reorientation of a single crystal to produce twins) in crystals was not only first recognized, but was also first experimentally produced in calcite.

The crystal structure of calcite is shown in Figure 2; it is hexagonal-rhombohedral. The structure can most easily be visualized as consisting of alternating planes of calcium ions and carbonate ions, arranged with hexagonal symmetry within each plane. It is often convenient to refer to the unit cell illustrated because it corresponds to a distorted sodium chloride-type structure. This cell is referred to as the "morphological" unit cell, representing the cleavage rhombohedron (rhombohedral angle = 101° 55′) of calcite; it is not, however, a true unit cell. The directional configuration of the carbonate "triangles" alternates in successive carbonate planes, requiring a doubled c-axis component for the true unit cell.

The parallel planar arrangement of the carbonate ions accounts for the extreme anisotropy in many physical properties of calcite. The high birefringence (double refraction) of calcite arises from the fact that light vibrating parallel to the carbonate planes is propagated much more slowly than that vibrating perpendicular to the planes. This results in widely different indices and angles of refraction for light vibrating in the different directions.

Consequently, unpolarized light will be resolved into two plane-polarized components, refracted at different angles by the calcite crystal. This separation of totally plane-polarized light rays is utilized in the construction of optical polarizing prisms. Other anisotropic properties related to the planar carbonate configuration include thermal expansion and linear compressibility. With increasing temperature, calcite expands in a direction perpendicular to the carbonate planes but contracts in the parallel directions. This leads to a decrease in the rhombohedral angle with increasing temperature. Conversely, increasing hydrostatic pressure causes a contraction perpendicular to the carbonate planes but expansion within the planes.

Chemical composition and variability

Chemically, most natural calcite is relatively pure. Divalent (doubly charged) cations may substitute for calcium but only to a very limited extent. Small amounts of Mg^{2+}, Fe^{2+}, or Mn^{2+} commonly may replace Ca^{2+}; less commonly, Zn^{2+}, Ni^{2+}, Cu^{2+}, Co^{2+}, Sr^{2+}, Ba^{2+}, or Pb^{2+} may be found. The presence of even such small amounts of the transition metal ions Mn^{2+}, Fe^{2+}, Co^{2+}, Cu^{2+}, or Ni^{2+} may be sufficient to impart pale colours to calcite; however, strong coloration of calcite is usually caused by the presence of other finely disseminated minerals that become included during growth of the calcite crystals.

The anhydrous normal carbonates of all divalent cations smaller than calcium also crystallize with the calcite structure, forming an isostructural series. As such, the crystallographic and related physical properties of these minerals are similar to those of calcite. The variation of crystallographic parameters is given in Table 1.

Table 1: Crystallographic Parameters of Minerals of the Calcite Group

	formula	radius of cation*	crystal axes* true unit cell		rhombohedral angle—true unit cell
			a_o	c_o	
Calcite	$CaCO_3$	1.00	4.99	17.06	46° 4′
Otavite	$CdCO_3$	0.95	4.92	16.30	47° 19′
Rhodochrosite	$MnCO_3$	0.83	4.78	15.66	47° 43′
Siderite	$FeCO_3$	0.78	4.69	15.37	47° 43′
Magnesite	$MgCO_3$	0.72	4.63	15.02	48° 11′
Smithsonite	$ZnCO_3$	0.75	4.65	15.03	48° 20′
Cobaltocalcite	$CoCO_3$	0.74	4.66	14.96	48° 33′
Gaspeite	$NiCO_3$	0.69	4.60	14.72	48° 40′

* Dimensions in angstrom units.

Of these minerals, otavite, gaspeite, and cobaltocalcite have extremely limited occurrences. Smithsonite, although not widely distributed, occasionally occurs in sufficient quantity to be mined as an ore of zinc. Magnesite, siderite, and, to a lesser extent, rhodochrosite occur in sufficient abundance and distribution to be of interest both geologically and economically. These three minerals form complete solid solution series (complete atomic substitution is possible) with one another, and minerals of intermediate composition within these series have properties proportionately intermediate between those of the pure end members. Solid solution between these minerals and calcite is limited, perhaps by the differences in ionic size between Ca^{2+} and Mg^{2+}, Fe^{2+}, or Mn^{2+}. Instead, in-

termediate compounds are found, forming the isostructural group dolomite, ankerite, and kutnahorite.

Dolomite group. Of all carbonate minerals, dolomite is second only to calcite in abundance, distribution, and geologic and economic importance. Compositionally, dolomite may be described as calcite with exactly half the calcium ions replaced by magnesium. Structurally, this is accomplished by the replacement of alternate planes of calcium ions in the calcite structure with planes of magnesium ions. This lowers the symmetry and more reflections appear in the X-ray diffraction pattern.

Distinction of dolomite from calcite

Dolomite commonly occurs as a massive mineral and is only rarely observed to form well-defined crystals. The forms displayed are the more common forms of calcite; the rhombohedron r of Figure 1 being most frequently encountered. Typically this form is found to possess curved faces, which, in extreme cases, result in saddle-shaped crystals, illustrated in Figure 1. When treated with cold, dilute acid, calcite effervesces briskly, whereas dolomite reacts very slowly.

As in the simple carbonates, Fe^{2+} and Mn^{2+} can substitute freely for Mg^{2+} in the dolomite structure, resulting in solid solution series. Although intermediate members are uncommon, it is likely that a complete series exists between dolomite and kutnahorite. The pure cation-ordered compound $CaFe(CO_3)_2$ never has been observed in natural or in synthetic systems; though a wide range of compositions corresponding to ferroan dolomites and ankerites may be found in natural materials. Because this solid solution series is continuous, the distinction between ankerite and ferroan dolomite is arbitrary. The name ankerite is commonly applied to those species in which at least 20 percent of the magnesium positions of dolomite are occupied by iron. The system is usually complicated by the presence of manganese and often by excess calcium. The ranges of naturally occurring compositions in the system $CaCO_3$–$MgCO_3$–$FeCO_3$ are shown in Figure 4.

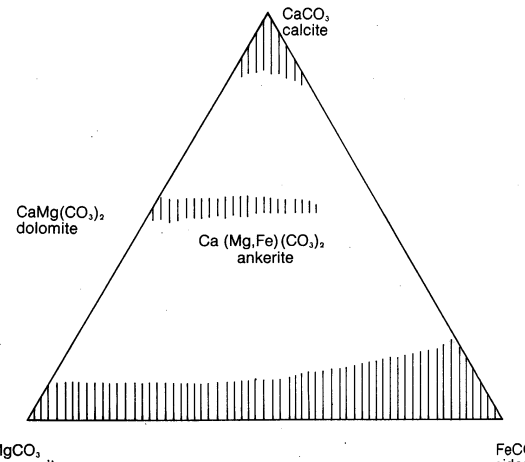

Figure 4: Naturally occurring compositions in the system $CaCO_3$–$MgCO_3$–$FeCO_3$. Shaded areas indicate the approximate compositional ranges that occur in nature.

Kutnahorite commonly contains some iron and is frequently deficient in calcium, indicating that the manganese ion is large enough to substitute in part for calcium in the dolomite structure. Dolomite and ankerite, however, are almost never deficient in calcium but frequently contain a small excess, indicating that magnesium and iron do not enter the calcium positions in dolomite, but that calcium may substitute in part for magnesium.

Crystallographic data for these minerals are given in Table 2. For purposes of comparison, calculated data for hypothetical ideal solid solutions are included. The structural change produced by cation ordering is apparent in the data for dolomite but does not cause significant change in the parameters of ankerite or kutnahorite.

Aragonite group. The third major structural group of the anhydrous normal carbonates includes aragonite, the high-pressure polymorph of $CaCO_3$ (discussed later), and the carbonates of all divalent ions larger than calcium. Aragonite, although a reasonably common mineral in modern sedimentary environments, is thermodynamically unstable with respect to calcite and, given time, it should invert to the more stable calcite structure. Accordingly, aragonite is unknown in ancient geological deposits; however, aragonitic fossil shell material as old as 450,000,000 years (Ordovician Period) has been described.

Table 2: Crystallographic Parameters of Minerals of the Dolomite Group

	formula	crystal axes*		rhombohedral angle
		a_o	c_o	
Dolomite	$CaMg(CO_3)_2$	4.81	16.01	47° 7′
Hypothetical solution†	$CaMg(CO_3)_2$	4.81	16.04	47° 4′
Ankerite	$Ca(Mg_{0.67}Fe_{0.33})(CO_3)_2$	4.82	16.10	47° 0′
Hypothetical solution†	$CaFe(CO_3)_2$	4.84	16.22	46° 52′
Kutnahorite	$CaMn(CO_3)_2$	4.88	16.36	46° 52′
Hypothetical solution†	$CaMn(CO_3)_2$	4.88	16.36	46° 52′

*Dimensions in angstrom units. †Hypothetical ideal solid solutions of the composition indicated.

Although the structure of aragonite is orthorhombic, it is related to that of calcite. The aragonite structure may also be visualized as consisting of alternating layers of calcium and of carbonate ions; however, the calcium ions form a distorted hexagonal close-packed arrangement in aragonite rather than a cubic close-packed type of array as in calcite, and each layer of carbonate ions consists of two closely spaced parallel planes containing carbonate "triangles" of opposite directional configuration. The c-axis of the orthorhombic cell is perpendicular to the calcium and the carbonate layers. The hexagonal arrangement of calcium ions within each plane results in a pseudohexagonal symmetry for the structure, which is reflected in the morphology of many twinned crystals. The variation of crystallographic parameters within the aragonite group is given in Table 3.

Structure of aragonite

Table 3: Crystallographic Parameters of Minerals of the Aragonite Group

	formula	cation radius*	crystal axes*		
			a_o	b_o	c_o
Aragonite	$CaCO_3$	1.18	4.95	7.95	5.73
Strontianite	$SrCO_3$	1.29	5.13	8.42	6.09
Cerussite	$PbCO_3$	1.33	5.17	8.48	6.13
Witherite	$BaCO_3$	1.47	5.26	8.84	6.56

*Dimensions in angstrom units.

The orthorhombic symmetry of the aragonite structure requires an optically biaxial character. The preservation of the parallel planar arrangement of the carbonate ions, however, results in a marked difference between the index of refraction perpendicular to the planes (1.530 for aragonite) and the indices parallel to the planes (1.680 and 1.685 for aragonite), thus preserving the high birefringence characteristic of the rhombohedral carbonates.

Compositional variations within the aragonite group are not systematic. A complete solid solution series appears to exist between witherite and strontianite. Compositional variations in cerussite are largely unknown; however, only limited substitution of calcium and strontium for lead is observed in natural materials. Appreciable solid solution exists between strontianite and aragonite, but the system is complicated by the metastable nature of the aragonitic materials. Substitution of Ca^{2+} in witherite is severely limited, and the intermediate compounds barytocalcite and alstonite are found. These intermediates, unlike those in the rhombohedral carbonates, bear no simple structural relationship to the isostructural end members. Substitution of cations smaller than calcium is extremely limited in all the members of the aragonite

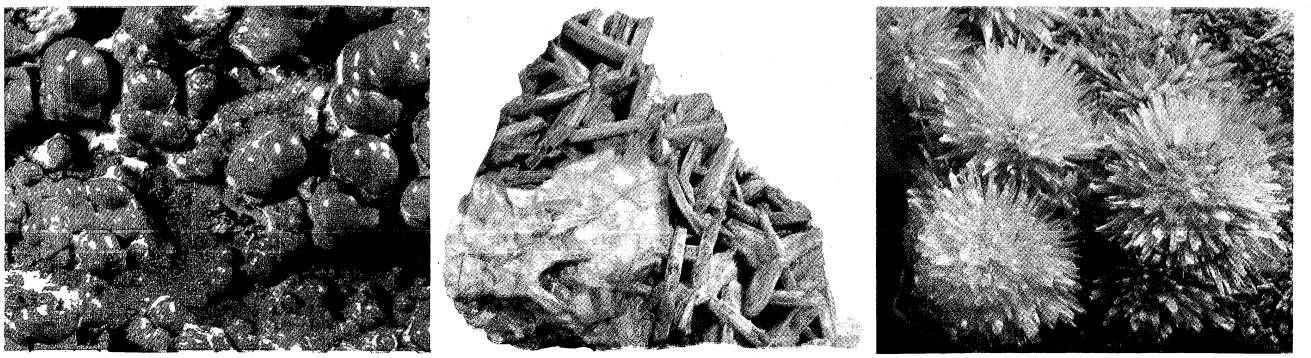

Figure 5: (Left) Azurite (blue) and reniform masses of malachite from Zacatecas, Mexico. (Centre) Flat rhombohedral crystals of calcite from Anthony's Nose, Hudson River, N.Y. (Right) Divergent needlelike aragonite crystals from Huttenberg, Austria.

group. The recently discovered minerals norsethite, benstonite, and burbankite apparently are structurally related to calcite.

Other carbonate minerals. No other carbonate minerals have been investigated as extensively as those of the calcite, dolomite, and aragonite groups. Other isomorphous groups and compositional series are composed of minerals that are only of academic interest. Most other minerals of economic importance are those that have potential use as ores. Of these, the most abundant are malachite and azurite, which are among the more common minerals containing copper. The beauty of crystallized specimens of these minerals (see Figure 5) has always attracted collectors, and polished malachite has often been used as an ornamental material.

Carbonates as a source of rare-earth elements

Bastnaesite and related minerals in class 4 are among the more important sources of rare-earth elements. The chemical formulas for these minerals typically indicate only one rare-earth element, usually cerium, lanthanum, or yttrium; however, most rare-earth elements are present in solid solution. The series parisite–roentgenite–synchisite is interesting in that these minerals are intermediate, both compositionally and structurally, between bastnaesite and vaterite, a third polymorph of $CaCO_3$ that has no known stability field (conditions that govern stable occurrence).

The extremely rare uranium and uranyl carbonates rutherfordine (class 1); andersonite, swartzite, bayleyite, liebigite (all class 2); rabbittite (class 4); and schroeckingerite (class 5) have been identified as secondary minerals, forming on exposed surfaces of uranium-bearing rocks used as ores. Since most of these minerals are soluble in water, they are found only in arid regions. These minerals are characterized by bright yellow-green colour and intense fluorescence under ultraviolet radiation.

Another group of genetically related minerals are the alkali carbonates and bicarbonates, most commonly thermonatrite, natron, pirssonite, gaylussite (all class 2); trona, nahcolite (class 3); and northupite (class 4). These minerals also are characterized by relatively high solubilities in water, and typically are found in saline evaporite deposits. Such deposits occasionally are sufficiently large to permit the use of trona as an ore of sodium.

OCCURRENCE OF THE CARBONATE MINERALS

Effect of temperature, pressure, humidity, and acidity

Stability considerations. The formation of carbonate minerals in natural environments is severely limited by their breakdown, especially at elevated temperatures. Several of the hydrated carbonates are stable only in high humidity environments and readily decompose to lower hydrates or to anhydrous compounds at lower humidities. Practically all hydrated carbonates, all acid carbonates, and most carbonates containing hydroxide or halide ions decompose to anhydrous carbonates or to oxides at relatively low temperatures (less than 300° C). Accordingly, these minerals, which constitute the vast majority of species of carbonate minerals, are found only in surface or near-surface environments. The thermal stability of hydrates and hydroxycarbonates is increased somewhat by elevated water pressures; consequently, such minerals may form in low-temperature hydrothermal or metasomatic (mineral–replacement) deposits.

The anhydrous normal carbonates are the most refractory of all the carbonates, but even these minerals decompose at elevated temperatures. The stability relations are also affected by the presence of water; calcite has been found to begin melting at approximately 750° C in the presence of water at a pressure of one kilobar.

Considerations of the relative abundances of the various elements in the Earth's crust and the thermal stabilities of the various carbonates explains the ubiquitous nature of the calcium and magnesium carbonates, the relatively common occurrence of iron and manganese carbonates, and the relative rarity of all other carbonate minerals.

Because the majority of carbonate minerals are deposited from aqueous solutions, their formation is controlled by solubility relations. The solution chemistry of the carbonates is in turn controlled by the complex behaviour of the carbonate ion in solution. Dissolution of a simple carbonate can be represented by the dissociation reaction:

$$MCO_3\,(\text{solid}) = M^{2+} + CO^{2-}_3\,(\text{aqueous});$$

however, in aqueous solution the carbonate ion immediately hydrolyzes:

$$CO^{2-}_3 + H_2O = HCO^-_3 + OH^-.$$

Thus, an increase in the pH of an equilibrated solution will result in precipitation of the solid carbonate while acidification will cause further dissolution of the solid. This situation is further complicated by the presence of dissolved carbon dioxide in most natural water, yielding carbonic acid:

$$CO_2\,(\text{gas}) + H_2O = H^+ + HCO^-_3.$$

Because the solubility of CO_2, forming acidic solutions, is increased by high pressures and low temperatures, these factors also increase the solubility of the solid carbonate minerals in CO_2–saturated solutions. Conversely, an increase in temperature or a decrease in pressure will cause a saturated solution to precipitate solid carbonates.

Carbonates in igneous and metamorphic rocks. Occurrences of carbonate minerals in igneous rocks are for the most part limited to the most refractory compounds: calcite, dolomite, and magnesite. Calcite frequently is found filling the cavities in amygdular basalts and occasionally is found filling huge cavities in basalt. The large, optically perfect cleavage fragments from Iceland, with which the discoveries of double refraction and of polarization of light were made, occur in this manner. In reference to the type locality, all cleavage rhombs of transparent, colourless calcite are referred to as the variety Iceland spar. Calcite and dolomite occur as primary igneous minerals in the rare but geologically important rocks kimberlite and carbonatite. Carbonatites also may

include ankerite, siderite, and small amounts of the bastnaesite group of rare-earth carbonates. Certain recent carbonatite flows have crystallized carbonates containing sodium and potassium as well as calcium. Magnesite occurs as an igneous mineral in the rock-type sagvandite and has been found in some basic lava flows.

Similarly, occurrences of carbonates in metamorphic rocks (*q.v.*) consist predominantly of the refractory calcium and magnesium carbonates. Magnesite most commonly forms as an alteration product of magnesium-rich peridotites and serpentinites. Metamorphism of carbonate sediments typically results in recrystallization to form calcite or dolomite marbles, often in massive deposits such as those of the Dolomite Alps in the South Tyrol. Metamorphism of impure carbonate sediments may result in the formation of complex minerals such as spurrite and tilleyite (class 6). Increasing amounts of other minerals (especially silica or silicates) and increasing temperatures cause breakdown of the carbonates, either by chemical reaction or by simple thermal decomposition; and mineral associations with calcite and dolomite are used as indicators of the degree of metamorphism.

Sediments and rocks of marine origin

Carbonates in sedimentary rocks. The principal occurrences of carbonates are in sediments and sedimentary rocks (*q.v.*). Many modern marine sediments (*q.v.*) are composed largely or entirely of carbonate minerals, primarily calcite, metastable magnesian calcite, and aragonite. The vast majority of these materials are formed by the action of marine organisms. Large deposits of carbonate muds consist of the discarded exoskeletons of microscopic organisms such as Foraminifera, pteropoda, and coccolithophorida. Ancient deposits of this sort are represented by chalk, such as that forming the White Cliffs of Dover. Other carbonate accumulations of biological origin include coral reefs, such as those still active in the mid-Pacific atolls and the Great Barrier Reef of Australia, and sediments consisting of shell material from a variety of invertebrates. The mineral composition of these materials is interesting, because the highly magnesian calcites (characteristic of lower orders of organisms, particularly algae) and aragonites (typically formed by higher organisms) represent metastable forms. Most organisms secrete only one mineral (either aragonite or a calcite) that is characteristic of the species; however, the shells of certain mollusks consist of alternating layers of calcite and aragonite, and some cephalopods deposit different minerals in different parts of the skeleton (see also LIMESTONES AND DOLOMITES; ELEMENTS, PHYSIOLOGICAL CONCENTRATION OF).

These carbonate sediments tend to become compacted and consolidated, forming limestones. Such postdepositional changes, generally referred to as diagenesis, may involve simple cementation of shell material by further deposition of $CaCO_3$ or may involve a complete recrystallization by essentially simultaneous dissolution and redeposition, a process that may obliterate the shell outlines. Such limestones are abundant and widespread, often forming extensive deposits, and are frequently known to be precursors of extensive metamorphic deposits.

Dolomite also occurs in abundant, extensive deposits, frequently containing fossil shell material of the same sort found in limestones. These deposits constitute one of the major problems of carbonate geochemistry, for such deposits are unquestionably of sedimentary origin. Yet nowhere on Earth are similar deposits being formed today, and experimental studies have consistently failed to synthesize ordered dolomite under conditions available in natural sedimentary environments. It is generally thought that these formations were originally deposited as calcium carbonate sediments and were diagenetically converted into dolomite, perhaps by the action of magnesium-rich solutions. Such dolomitization, however, must either invoke conditions during past geologic ages that no longer exist or it must proceed so slowly that it is unobservable in modern sediments.

Dolomite in the process of formation recently has been discovered in a number of restricted localities, all characterized by the presence of hypersaline solutions. These are typically evaporite-type deposits (see EVAPORITES), which also may produce the much rarer soluble alkali carbonates and bicarbonates. The relationship between these modern dolomites and the widespread older dolomites is uncertain. It may be that the shallow epicontinental seas that are considered to have been prevalent in the past developed higher temperatures, higher salinities, and higher Mg^{++}/Ca^{++} ratios in solution than are now available in the deep oceans. These are all factors that increase the rate of dolomitization.

Carbonate in fresh water and in caves

Extensive non-marine carbonate deposits that are collectively referred to as travertine are formed from springs, rivers, lakes, and in caves. Many lake deposits result from the action of calcareous algae; but much travertine is considered to be of inorganic origin, typically precipitated from carbonate-saturated subsurface or spring water. As subsurface water, acidified by dissolved carbon dioxide, seeps through preexisting limestone strata, it dissolves calcium carbonate, often creating caverns. Occasionally vast networks of underground passages are formed, such as those of Mammoth Cave in Kentucky and the Carlsbad Caverns in New Mexico. In all probability, many other systems exist that have no surface entrances but may be revealed by sinkholes at the surface, caused by the collapse of underground chambers. During the initial stages of cave formation, the process of dissolution predominates; during later stages deposition frequently occurs as the carbonate-saturated water slowly evaporates or loses carbon dioxide (CO_2) as it enters the cavern. Such cave deposits (speleothems) include stalactites and stalagmites, flowstone, and rock-milk and are usually composed of calcite or aragonite, rarely of dolomite (see also CAVES AND CAVE SYSTEMS).

Frequently, carbonate-saturated groundwater (*q.v.*) reaches the surface, forming springs and spring-fed streams and lakes (see SPRINGS AND WELLS). As the water loses CO_2, solid carbonates are precipitated, forming travertine. These deposits may be porous and spongy or may be compact varieties, often banded due to inclusion of impurities along the "growing" surface (alabaster, Mexican onyx).

Other types of occurrence. In arid regions, such groundwater may evaporate at the surface, depositing dissolved carbonate materials as a duricrust (a hardened crust) known as calcrete. In semiarid climates, as the groundwater rises toward the surface, calcium carbonate precipitates between soil particles, cementing them together to form a deposit known as caliche. If the soil material is calcareous, the material formed by such recrystallization and cementation is called nari.

These various modes of occurrence account for the bulk of the common carbonates but not for the majority of carbonate mineral species. A number of the carbonate minerals are of exotic origin; fairchildite and buetschliite, for example, are known only from clinkers formed by fusion of wood ash in lightning-struck trees. Most carbonates are formed either by deposition from hydrothermal fluids or by metasomatic alteration of other minerals. Thus, the calcite-group minerals (calcite, magnesite, siderite, rhodochrosite, and cobaltocalcite) typically occur in relatively low-temperature hydrothermal veins; whereas smithsonite, otavite, and gaspeite occur predominantly as replacement minerals. Other carbonates occurring as primary hydrothermal minerals include witherite, strontianite, hydromagnesite, and dawsonite. The remaining carbonates, including many economically important species, usually are considered to be secondary minerals, formed either by the action of carbonated water upon metallic elements such as the sulfide minerals (*q.v.*) or by reaction between metal-bearing solutions and other carbonate deposits. Secondary carbonate minerals that typically occur in the oxidized zone of ore deposits (*q.v.*) include cerussite, malachite, azurite, bismutite, beyerite, lanthanite, zaratite, phosgenite, hydrozincite, and aurichalcite. Most sedimentary dolomite and siderite is considered to be of secondary origin, replacing original calcite or aragonite.

Carbonates in ore deposits

EXPERIMENTAL STUDIES

As new mineral species are discovered, their physical and chemical properties must be studied in sufficient detail to distinguish them from established species. Typically, such studies include the determination of the chemical composition, variations in composition, crystallographic parameters, optical characteristics, and various other physical properties such as specific gravity, hardness, colour, streak, etc. Further studies may include synthesis of the compound and the determination of the crystal structure. Virtually all of the carbonate minerals have been studied to this extent but a few (*e.g.*, kutnahorite, alstonite, huntite, shortite) have resisted attempts at synthesis, and several do not form crystals of sufficient size or perfection to allow structural analysis.

The calcium and magnesium carbonates and the other members of their isostructural groups have been the subjects of extensive investigation. The most important of these studies have been the experimental determinations of phase relations including the decomposition relations already mentioned, polymorphism, solubility studies, and phase relations among the several members of the groups. Of these studies, the most interesting and perhaps the most important are those dealing with the polymorphism of calcium carbonate and with the equilibrium phase relations in the system $CaCO_3$–$MgCO_3$.

Stability fields and their significance

Polymorphism of calcium carbonate. Calcite II is believed to have a structure similar to that of calcite, but the carbonate triangles are randomly rotated. It rapidly inverts to calcite I (normal calcite) and therefore is never observed under earth-surface conditions. Aragonite is shown to be stable only at very high pressures. Its structure is sufficiently different from that of calcite, however, so that once formed, aragonite may persist for long periods in the calcite stability field without inverting. Another polymorph, calcite III, exists at even higher pressures (above 17 kilobars at 25° C) but, like calcite II, immediately inverts to calcite I at lower pressures. Vaterite, which is known as a mineral and frequently occurs as a transient phase during laboratory precipitation of calcium carbonate, is not a stable phase in the range of pressures and temperatures thus far investigated and may be an example of a substance with no true stability field.

The equilibrium relations indicate that aragonite is stable with respect to calcite only under conditions that are rarely encountered on earth. The high pressures required for aragonite stability are met at greater depths within the earth's crust; however at these depths the temperature is considered to be sufficiently high that the stable phase must be either calcite I or calcite II. The conditions of high pressure at moderate temperatures necessary for the stable formation of aragonite occasionally may be met during metamorphism, but certainly the biogenic and inorganic sedimentary aragonites must be forming metastably, and recent experimental results indicate that some metamorphic aragonite also may form metastably within the calcite stability field.

Calcite-dolomite-magnesite equilibria. Figure 6 shows the equilibrium relationships between calcite, dolomite, and magnesite. At low temperatures, solid solution in magnesite and in dolomite is negligible and is small in calcite. The order-disorder (degree of ordering) relationship between high-temperature magnesian calcites and dolomite is not known with certainty; the dashed line separating the two fields in the diagram represents the limiting conditions under which ordering reflections appear in the X-ray patterns of dolomite. The most interesting aspect of the diagram is the implication that at lower temperatures, namely those encountered in sedimentary environments, the stable assemblages of intermediate compositions consist of mixtures of the essentially pure compounds. Thus, the magnesian calcites (often containing more than 10 mole percent magnesium) formed by many organisms are, like the aragonite formed by others, unstable under the conditions of formation. Furthermore, additional studies have shown that dolomite is the only solid carbonate that is thermodynamically stable in contact with solutions of the approximate composition of sea water, which contains more magnesium than calcium. Even pure calcite is metastable when precipitated in sea water; and dolomite, the only stable phase, is almost never observed. In those instances in which dolomite is observed to be forming in hypersaline environments, it typically is calcium-rich and therefore stable only at high temperatures.

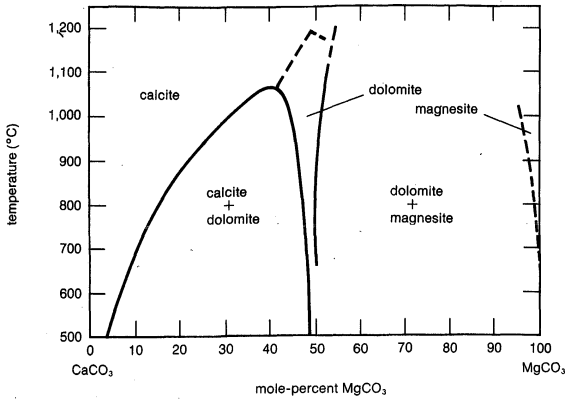

Figure 6: Phase diagram of the system $CaCO_3$–$MGCO_3$, showing the mineral species that are in equilibrium at a particular composition and temperature.
From J. Goldsmith and H. Heard, *Journal of Geology*, vol. 69 (1961); University of Chicago Press

Thus the most interesting and puzzling aspects of the carbonate minerals are the frequent occurrences of metastable phases. Similar occurrences are known in other mineral groups, and the formation and persistence of metastable phases may prove to be a much more common phenomenon than is now realized.

Carbon Group Elements and Their Compounds

The carbon group of five chemical elements consists of carbon (symbol C, atomic number 6), silicon (symbol Si, atomic number 14), germanium (symbol Ge, atomic number 32), tin (symbol Sn, atomic number 50), and lead (symbol Pb, atomic number 82); they comprise Group IVa in the arrangement of elements known as the periodic table (see PERIODIC LAW). Except for germanium, all of these elements are familiar in daily life either as the pure element or in the form of compounds, although, except for silicon, none is particularly plentiful in the Earth's crust. Carbon forms an almost infinite variety of compounds, in both the plant and animal kingdoms. Silicon and silicate minerals are fundamental components of the Earth's crust; silica (silicon dioxide) is sand. Tin and lead, with abundances in the crust lower than those of some so-called rare elements, are nevertheless com-

mon in everyday life. They occur in highly concentrated mineral deposits, can be obtained easily in the metallic state from those minerals, and are useful as metals and as alloys in many applications. Germanium, on the other hand, forms few characteristic minerals and is most commonly found only in small concentrations in association with the mineral zinc blende and in coals. Although germanium is indeed one of the rarer elements, it assumed importance upon recognition of its properties as a semiconductor (*i.e.*, limited ability to conduct electricity).

Carbon as an element was discovered by the first man to handle charcoal from his fire; thus, together with sulfur, iron, tin, lead, copper, mercury, silver, and gold, carbon was one of the small group of elements well known in the ancient world. Modern carbon chemistry dates from the development of coals, petroleum, and natural gas as fuels and from the elucidation of synthetic organic chemistry, both of these branches having been substantially developed since the 1800s.

Amorphous elemental silicon was first obtained in a state of purity in 1824 by the Swedish chemist Jöns Jacob Berzelius; impure silicon had already been obtained in 1811. Crystalline elemental silicon was not prepared until 1854, when it was obtained as a product of electrolysis. In the form of rock crystal, however, silicon was familiar to the predynastic Egyptians, who used it for beads and small vases; to the early Chinese; and probably to many others of the ancients. The manufacture of glass containing silica was carried out both by the Egyptians—at least as early as 1500 BC—and by the Phoenicians. Certainly, many of the naturally occurring compounds called silicates were used in various kinds of mortar for construction of dwellings by the earliest men.

Mendeleyev's prediction

Germanium is one of three elements the existence of which was predicted in 1871 by the Russian chemist Dmitry Ivanovich Mendeleyev when he first devised his periodic table. Not until 1886, however, was germanium identified as one of the elements in a newly found mineral.

The origins of tin also are lost in antiquity. Apparently, bronzes, which are copper–tin alloys, were used by man in prehistory long before pure tin metal itself was isolated. Bronzes were common in early Mesopotamia, the Indus Valley, Egypt, Crete, Israel, and Peru. Much of the tin used by the early Mediterranean peoples apparently came from the Scilly Islands and from Cornwall in the British Isles, where tin mining dates to at least 300–200 BC. Tin mines were operating in both the Inca and Aztec domains of South and Central America before the Spanish conquest.

Lead is mentioned often in early Biblical accounts. The Babylonians used the metal as plates on which to record inscriptions. The Romans used it for tablets, water pipes, coins, and even cooking utensils; indeed, as a result of the last use, lead poisoning was recognized in the time of Augustus Caesar. The compound known as white lead was apparently prepared as a decorative pigment at least as early as 200 BC. Modern developments date to the exploitation in the late 1700s of deposits in the Missouri–Kansas–Oklahoma area in the United States.

This article is divided into the following sections:

I. Comparative chemistry of the carbon group elements
  Electronic structure
  General properties of the group
    Crystal structure
    Uses
    Electron configurations and valences
    Bond formation
    Catenation
    Atomic size
    Reactions
    Biological and physiological significance
    General compounds
II. Individual carbon group elements and their compounds
  Carbon and its compounds
    Occurrence and distribution of the element
    Production of elemental carbon
    Structure of carbon allotropes
    Carbides
    Halides
    Oxides

I. Comparative chemistry of the carbon group elements

The properties of the carbon elements and their compounds are best discussed by reference to their atomic structures.

ELECTRONIC STRUCTURE

The atoms of a specific element have an identical number of positive charges on the nucleus, and this number is balanced by an equal number of negatively charged electrons moving around the nucleus, attraction between electrons and nucleus overcoming repulsion among the electrons. The number of positive charges is called the atomic number of the element. In the periodic table (see the Figure) the elements are arranged sequentially in order of their atomic numbers. As the nuclei increase in size, the increasing number of electrons moving about the nucleus occupy an orderly arrangement of orbitals (regions of maximum probability for occurrence of electrons of particular characteristics) or energy levels. These are organized into concentric shells numbered from one to seven, proceeding outward from the nucleus, with an increasing number of subshells, designated by the letters *s, p, d, f* (the letters themselves being of no special significance). The number of electrons within each subshell is generally indicated by a superscript. Thus, $4s^2$ indicates the two *s* electrons in the fourth shell. Each subshell is capable of holding only a limited number of electrons, viz., 2 in an *s* subshell, 6 in a *p*, 10 in a *d*, and 14 in an *f*. The first shell (closest to the nucleus) includes only an *s* subshell, or orbital. Therefore, it can contain only two electrons. The second shell holds both *s* and *p* orbitals, or eight electrons. Shell number three can hold *s*, *p*, and *d* orbitals, for a total of 18 electrons. The atoms of the carbon group elements have in common an identical arrangement of electrons in their outermost (valence) shell. As shown in Table 1, the outermost shell of carbon has the arrangement $2s^2 2p^2$, and that of lead has $6s^2 6p^2$.

Periodic table

No outermost shell of any atom contains more than eight electrons, called an octet. The element next in the table must add an electron in a new shell, but, after one or two electrons are positioned in the outermost *s* orbital of the 4th and higher shells, the inner octet may resume accepting electrons until it has acquired its allotted maxi-

Table 1: Some Properties of Carbon Group Elements

	carbon	silicon	germanium	tin	lead
Atomic number	6	14	32	50	82
Atomic weight	12.011	28.086	72.59	118.69	207.19

mum number. In the periodic table, the elements with eight electrons outermost form the group known as the noble gases (Group 0), the least reactive of the elements. The carbon group elements (Group IVa), with four electrons, occupy a middle position. Elements to the left of Group IVa have fewer than four electrons in the valence shell and tend to lose them (with their negative charges) to become positively charged ions, represented by the symbol for the element with a superscript indicating the number and sign of the charges—*e.g.*, Ca^{2+} for the calcium ion; such elements are called metals. The nonmetals (except boron) are in the groups to the right of Group IVa; each has more than four electrons in its outermost shell and tends to acquire electrons to complete its octet, forming negatively charged ions; *e.g.*, oxygen adds two electrons to its six, forming the ion O^{2-}.

Carbon's electron structure

Chemical reactions result from the exchange of electrons among atoms. In general, if a metal loses its few valence electrons to a nonmetal, the resulting oppositely charged ions are attracted to one another and form a bond, classified as ionic or electrovalent. Two nonmetals, neither of which can actually lose its valence electrons in chemical reaction, may nevertheless share them in pairs in such a way that what is called a covalent bond results. Metal atoms will bond to one another in a third type of bond, which releases their valence electrons in a way that allows them to conduct electricity.

All the carbon group atoms, having four valence electrons, form covalent bonds with nonmetal atoms; carbon and silicon cannot lose or gain electrons to form free ions, whereas germanium, tin, and lead do form metallic ions but only with two positive charges. Even lead, the most metallic of the carbon group atoms, cannot actually lose all four of its valence electrons, because, as each one is removed, the remainder are held more strongly by the increased positive charge. Because the distinction between covalent and electrovalent (ionic) bonds is often a matter of convenience for the chemist, and because the actual bond structure within a molecule may be quite complicated, it is often useful instead simply to count the total number of electrons an element gains or loses in bonding without regard to the nature of the bonds. This number is called the oxidation number, or oxidation state, of the element; many elements have more than one oxidation state possible, each oxidation state being found in different compounds. The oxidation state of an element is written as a Roman numeral following the name of the element in a compound—*e.g.*, lead(II) means lead in oxidation state plus two; with the chemical symbol of the element, the oxidation state may be written as a superscript, as in Pb^{II}. Covalent bonds generally are considered to be formed by interaction of the orbitals (generally, only the *s*, *p*, and *d* orbitals) in specific and varied ways. The most common are called sigma and pi bonds, written σ and π, respectively. The sigma bonds are symmetrical with respect to the axis of the bond, whereas the pi bonds are not. Examples of sigma and pi bonding as well as ionic bonding are found

among the compounds of the elements of the carbon group. (For a full general discussion and further information useful to an understanding of the following sections, see CHEMICAL BONDING; CHEMICAL REACTIONS; ATOMIC STRUCTURE; and PERIODIC LAW.)

GENERAL PROPERTIES OF THE GROUP

The properties of the carbon group elements and those of their compounds are intermediate between properties associated with the elements of the adjacent boron and nitrogen groups. In all groups the metallic properties, resulting from the tendency to hold valence electrons more loosely, increase with atomic number. Within the carbon group, more than in any other, the change from nonmetallic to metallic character with increasing atomic number is particularly apparent. Carbon is a true nonmetal in every sense. Lead is a true metal. Silicon is almost completely nonmetallic; tin is almost completely metallic. Germanium is metallic in appearance and in a number of its other physical properties (see Table 1), but the properties of many of its compounds are those of derivatives of nonmetals. These changes are consequences of increase in atomic size with substantial screening of the larger nuclear charge by intervening electronic shells, as evidenced by decrease in ionization energy (see Table 1) (energy required to remove an electron) and electronegativity power to attract electrons) with increasing atomic number.

Metals and nonmetals of the group

Crystal structure. In the solid state, elemental carbon, silicon, germanium, and gray tin (defined as alpha [α] tin; see Table 1) exist as cubic crystals, based upon a three-dimensional arrangment of bonds. Each atom is covalently bonded to four neighbouring atoms in such a way that they form the corners of a tetrahedron (a solid consisting of four three-sided faces). A practical result is that no discrete small molecules of these elements, such as those formed by nitrogen, phosphorus, or arsenic, can be distinguished; instead, any solid particle or fragment of one of these elements, irrespective of size, is uniformly bonded throughout, and, therefore, the whole fragment can be considered as a giant molecule. Decreasing melting points, boiling points, and decreasing heat energies associated with fusion (melting), sublimation (change from solid to gas), and vaporization (change from liquid to gas) among these four elements, with increasing atomic number and atomic size, indicate a parallel weakening of the covalent bonds in this type of structure. The actual or probable arrangement of valence electrons is often impossible to determine, and, instead, relative energy states of the electrons, in the ground, or least energetic, state of the atom are considered. Thus, the same trend of nonmetallic toward metallic states is indicated by decreasing hardness and decreasing single-bond energy between atoms. Carbon crystallizes in two forms, as diamond and as graphite; diamond stands apart from all other elemental forms in the extreme stability of its crystal structure, whereas graphite has a layer structure. As may be expected, cleavage between layers of graphite is much easier to effect than rupture within a layer. The crystal structures of white beta (β) tin and elemental lead are clearly metallic structures. In a metal, the valence electrons are free to move from atom to atom, and they give the metal its electrical conductivity.

Uses. All the carbon group elements and many of their compounds have important uses. Carbon as diamond, for example, is the most expensive and brilliant of all the natural gemstones and also the hardest of abrasives; carbon as graphite is important as electrodes in electrochemical cells, as a lubricant, and, in microcrystalline and nearly amorphous form, as a black pigment, an adsorbent, a fuel, a filler for rubber, and in pencils. Coals are elemental carbon mixed with varying amounts of carbon compounds; coke and charcoal are nearly pure carbon. All organic compounds, such as proteins, carbohydrates, and fats, contain carbon, and all plant and animal cells consist of carbon compounds and their polymers. (Polymers are macromolecules consisting of many simple molecules bonded together in specific ways.) Carbonate minerals are important sources of various metals, such as sodium, magnesium, calcium, copper, and lead.

The almost infinite number of carbon compounds

Elemental silicon is important largely as a semiconductor. Silica (silicon dioxide) is useful as an abrasive, in the production of glass and other ceramic bodies, as an adsorbent, and as sand in mortars and concretes; and these are only a few of its applications. Both naturally occurring and synthetically produced silicates are important in ceramics, building materials, absorbents, and ion exchangers.

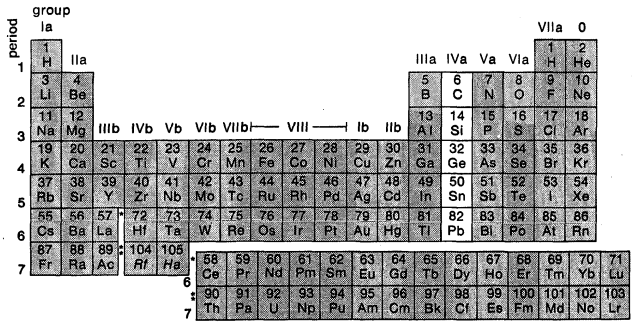
Applications of germanium have been limited to semiconducting devices, indicating its weak metallic nature.

Tin-plating of iron protects the latter from corrosion; tin piping and valves maintain purity in water and beverages; molten tin is the base for (float) plateglass production; and tin is a significant component of such alloys as bronzes, pewter, bearing metals, type metals, and lead-based solders. Tin exists in two oxidation states; tin(IV) oxide is useful in making ceramic bodies opaque, as a mild abrasive, and as a weighting agent for fabrics; tin(II) fluoride and tin(II) pyrophosphate are used in dentifrices. Organic tin compounds act as stabilizers in certain plastics and as wood preservatives.

Elemental lead finds extensive use. Together with the compound lead(IV) oxide and with lead–antimony or lead–calcium alloys, it is employed in common storage batteries. Type metals, bearing alloys, shot metal, and fusible alloys all contain lead. Tetraethyllead is the most important antiknock additive to motor fuels.

Electron configurations and valences. *Ionic valences.* The composition of any compound, radical, ion, complex, polymer, and so on is represented by its formula, which states the number and kinds of atoms bonded into the molecule or fragment of molecule. The formula lists the atoms by the symbols of the elements and indicates the number of atoms with subscripts following the symbols. Carbon dioxide (CO_2), for example, is a compound, the molecules of which consist of one atom of carbon and two of oxygen. Molecules of carbon monoxide (CO) contain one atom of carbon and one of oxygen. The composition of the most complicated molecule can thus be clearly stated in its formula. When a series of compounds have the same general formula, it can be expressed in general terms. All the alkanes (one of the hydrocarbon families of organic compounds), for example, have two more than twice as many hydrogen atoms as carbon atoms: CH_4, C_2H_6, C_3H_8, and so on. The general formula can therefore be written C_nH_{2n+2}. Also, if a simple molecule such as sugar, $C_6H_{12}O_6$, polymerizes (*i.e.*, links together in thousands of repeated bonds, in this case with the loss of H_2O from each such monomer), the formula of the resulting macromolecule may be written $(-C_6H_{10}O_5-)_n$, the subscript n representing any number.

The ground-state electronic configurations (see Table 1) of atoms of these carbon group elements show that each has four electrons in its outermost shells. As has been explained, if n represents the outermost shell (n being two for carbon, three for silicon, etc.), then these four electrons are represented by the symbols ns^2np^2. Such a configuration suggests the importance of referring to the relatively stable noble-gas-atom configuration preceding each element in determining the properties of the element, in particular its chemical properties. The loss of four electrons by either a carbon atom or a silicon atom to give ions having a positive charge of four (or +4, written C^{4+} or Si^{4+}) with the electron configurations of the preceding noble-gas atoms (see the Figure: helium and neon) is precluded by the sizable ionization energies as shown in Table 1. Ions of +4 charge do not exist, nor is there any evidence that carbon or silicon ions of charge +2 can form by the loss of only two unpaired (np; or outermost) electrons. Electron loss by atoms of the heavier elements of the family is easier, but it cannot lead to ions with noble-gas-atom configurations because of the presence of underlying (*i.e.*, d^{10}) arrangements of electrons inside the outermost shell. It is again unlikely that the +4 ions of germanium, tin, and lead (in symbols Ge^{4+}, Sn^{4+}, and Pb^{4+}) exist in known compounds, but it is true that the inertness of the ns^2 pair of electrons (which



The carbon group elements in the periodic table.

are, in terms of energy states, closer to the nucleus than the np^2 pair) increases substantially with increasing atomic number in the family and thus allows the np^2 electrons to be removed separately, to form at least the ions, Sn^{2+} and Pb^{2+}. Positive two and four oxidation states can be assigned in covalent unions of each of these elements with elements that are more electronegative (*i.e.*, having greater affinity for electrons). Typical examples for the group include (1) for the +2 state: carbon monoxide (CO), silicon monoxide (SiO), germanium dichloride ($GeCl_2$), tin monoxide (SnO), and lead monoxide (PbO); and (2) for the +4 state: carbon dioxide (CO_2), carbon tetrachloride (CCl_4), silicon tetrafluoride (SiF_4), silicate(IV) ion (SiO_4^{4-}), germanium tetrabromide ($GeBr_4$), tin tetrachloride ($SnCl_4$), hexahydroxostannate(IV) ion [$Sn(OH)_6^{2-}$], and lead dioxide (PbO_2). A true negative four (−4) anion is probably limited to carbon, and it is formed only among groups of atoms constituting molecules of certain compounds in which it would be the most electronegative and smallest atom in the group. Crystals of the methanide-type carbides, of which aluminum carbide (Al_4C_3) is a typical example, undoubtedly contain C^{4-} ions. No single atom or monatomic −2 ion (*e.g.*, C^{2-}) is known for any of the elements of the family. A formal −4 state exists in some covalent unions with less electronegative elements; *e.g.*, in methane (CH_4).

Covalences. Among the covalent compounds, 4-covalent examples predominate. In each of these species, four bonds, each formed by the sharing of an electron pair with another atom, are arranged tetrahedrally (toward the four corners of a tetrahedron) about the central atom of any element in the carbon group. The ground state, or lowest energy state, of the electronic arrangement indicated by ns^2np^2 does not suggest either the existence of four bonds or their observed geometrical distribution. The excited configuration, or higher energy state, of these electrons puts one *s* electron into a *p* orbital, to give an outermost arrangement indicated by ns^1np^3. This arrangement could allow for four bonds, but it suggests that three should lie mutually at right angles to each other, with the other, the fourth one (involving the *s* orbital), essentially undirected. It is therefore assumed, to account completely for experimental observation, that the *s* and *p* orbitals combine to produce four hybrid orbitals, each with some *s* and more *p* character, which are then oriented tetrahedrally (*i.e.*, in four directions with identical angles between them) about the central atom. The sp^3 hybrid is characteristic of all 4-covalent compounds of elements of this family—*e.g.*, methane (CH_4), silicon tetrafluoride (SiF_4), germanium tetrachloride ($GeCl_4$), tin tetrabromide ($SnBr_4$), and lead tetrafluoride (PbF_4). In terms of the fact that repulsions among the four bonding pairs of electrons should most reasonably push the four bonded atoms as far apart in space as possible, the observed tetrahedral arrays are also to be expected.

Orbital explanation for bonds

Because in the electronic configuration of carbon the outer shell can hold no more than eight electrons, in one *s* and three *p* orbitals, a covalency larger than four cannot exist for the carbon atom (it has four electrons and can bond covalently only four others to complete its eight). Higher energy orbitals are potentially available for atoms of the other elements of the family because, when *n* is more than two, more complicated *d* orbitals are also possible (3*d* for silicon, 4*d* for germanium, 5*d* for tin, 6*d* for lead), and higher covalences are not then unexpected. Six-covalent combinations, with octahedral geometry (eight-sided configurations derived by six bond directions), are well known and include such species as hexafluorosilicate(IV) ion (SiF_6^{2-}), hexafluorogermanate(IV) ion (GeF_6^{2-}), hexachlorostannate(IV) ion ($SnCl_6^{2-}$) or hexahydroxostannate(IV) ion ($Sn(OH)_6^{2-}$), and hexachloroplumbate(IV) ion ($PbCl_6^{2-}$). These species are said to exemplify bonds that can be described as sp^3d^2 hybridization. Geometrically, six groups about a central species repel each other least when they are octahedrally arranged.

Covalences lower than four are exemplified by compounds such as gaseous carbon monoxide (CO) or silicon monoxide (SiO), carbon dioxide (CO_2), ethylene (C_2H_4), and similar alkene-type organic compounds; acetylene (C_2H_2) and similar alkyne-type organic compounds; germanium(II) chloride ($GeCl_2$); and tin(II) chloride ($SnCl_2$). Molecules of carbon monoxide, silicon monoxide, carbon dioxide, the alkenes, and the alkynes are commonly formulated with multiple bonds between the carbon atoms. If the electrons in the *n* shell are represented by dots around the symbol of the element, examples of multiple bonds can be shown as:

carbon monoxide :C:::O:,

silicon monoxide :Si:::O:,

carbon dioxide $\ddot{O}::C::\ddot{O}$,

ethylene $H:\overset{H}{\overset{\cdot\cdot}{C}}::\overset{H}{\overset{\cdot\cdot}{C}}:H$,

acetylene H:C:::C:H,

the number of dots between two symbols signifying the number of electrons shared,—*i.e.*, the pairs shared—in carbon monoxide, three pairs; in silicon monoxide, three pairs; etc.

Bond formation. Described in terms of orbitals, each of these multiple bonds is believed to result from the end-on overlap of two appropriately oriented *p* orbitals to form a sigma (indicated as σ) type of single bond, plus the sidewise overlap of two or four appropriately oriented *p* orbitals to give one or two pi type (indicated as π) of additional bonds. In the ethylene molecule (C_2H_4), for example, the four electrons originally associated with each carbon atom are distributed as: (1) two shared with the *s* electrons of the two hydrogen atoms, as σ-bonds; (2) one shared with the other carbon atom through end-on overlap of singly occupied *p* orbitals as a σ-bond, and (3) one shared with the other carbon atom through sidewise overlap of singly occupied *p* orbitals at right angles to those involved in (2) as a π-bond. For the acetylene molecule (C_2H_2), the structure differs in the presence, for each carbon atom, of only one σ-bond to a hydrogen atom and two π-bonds to the other carbon atom. In the ethylene (C_2H_4) molecule, the arrangement of atoms around each carbon atom is triangular; in the acetylene molecule (C_2H_2), it is collinear (lying in the same straight line). These situations are said to exemplify sp^2 and *sp* hybridizations, respectively. The carbon dioxide molecule is a collinear species in which the central carbon atom is linked by a σ- and a π-bond to each oxygen atom. In the carbon monoxide and gaseous silicon monoxide molecules, the carbon group element is linked to the oxygen atom by one σ- and two π-bonds.

The sigma and pi bonds

The gaseous germanium dichloride ($GeCl_2$) and tin dichloride ($SnCl_2$) molecules are V-shaped entities that can be formulated electronically as

$$:\ddot{Cl}:\quad \overset{\cdot\cdot}{M}\quad :\ddot{Cl}:\ ,$$

in which M represents either germanium or tin. Although the covalence is apparently two, it is effectively three, since the unshared pair of electrons appears to occupy a position in which it and the two chlorine atoms are arranged in a planar triangle about the central M atom. The hybridization, including the unshared pair of elec-

trons in the same sense as the bonded pairs, is effectively sp^2. In the solid state, germanium dichloride molecules ($GeCl_2$) form infinite chains through bridging by chlorine atoms.

Catenation. Carbon is unique among the elements in the almost infinite capacity of its atoms to bond to each other in long chains, a process called catenation. This characteristic reflects the strength of the bond between adjacent carbon atoms in the molecule, both in relationship to similar bonds involving other elements of the carbon family and in relationship to bonds between carbon atoms and atoms of many other elements. Only the carbon–hydrogen, carbon–fluorine, and carbon–oxygen single bonds (C–H, C–F, and C–O) are stronger than the carbon–carbon single bond (C–C), and each of these is weaker than the carbon–carbon multiple bonds (C=C or C≡C). On the other hand, the silicon–silicon single bond (Si–Si) is weaker than other single bonds involving an atom of other elements with the silicon atom. The same is undoubtedly true of the germanium–germanium and tin–tin single bonds (Ge–Ge, Sn–Sn) in relationship to single covalent bonds between atoms of these elements and atoms of other elements. Experimentally, there appears to be no practical upper limit to catenation involving carbon. This phenomenon in three dimensions produces the diamond and in two dimensions the layers in graphite. Catenation is also exhibited to a high degree by elemental silicon, germanium, and tin, but it is strictly limited in compounds of these elements; silicon may have up to 14 atoms in a chain; germanium, 9; and tin, 2 or 3 only, largely in hydrides (compounds containing hydrogen). Double and triple bonds in catenated arrangements are limited to carbon.

Silicon chains

Catenation, via single or multiple bonds or both, combined with several other factors allows carbon to form more compounds than any other element. These factors are: (1) the stability of certain carbon bonds, in particular of the C–H bond; (2) the existence of carbon in both sp^2 and sp^3 hybridizations; (3) the ability of carbon to form both chain and cyclic compounds (in which the chain of atoms is joined end to end to form a ring) based upon either carbon atoms alone or carbon atoms in combination with those of other nonmetals (*e.g.*, oxygen, sulfur, nitrogen) and either upon single- or multiple-bond arrangements; and (4) the capability of many carbon compounds to exist in isomeric forms (isomers are molecules with identical numbers of the same atoms bonded in different arrangements; such molecules have quite different properties). All but a very few carbon compounds are called organic compounds, and they are discussed in such other articles as CHEMICAL COMPOUNDS, ORGANIC; POLYMERS; ALKALOIDS; ALDEHYDES AND KETONES; and CARBOXYLIC ACIDS AND THEIR DERIVATIVES.

Atomic size. Reference has been made to some of the physical properties of the carbon group elements (Table 1). Most of the variations in properties from carbon through lead parallel increase in atomic size and are comparable with elements in the boron, nitrogen, oxygen, and fluorine groups. The general trends apparent in Table 1 are roughly those found for the adjacent boron group and nitrogen group elements (see the Figure). The significantly higher melting and boiling points of the carbon group elements reflect their tendency to exist as giant molecules, as opposed to the tendencies of elements in the adjacent families to exist as smaller, discrete molecules.

Special physical properties of carbon

As is true of the lightest element in each group of elements, the physical properties of carbon differ substantially from those of the other members of its family. To a large degree, these differences reflect the substantially higher concentration of the positive charge on the carbon nucleus relative to the size of the carbon atom. That is, the nucleus of carbon holds only six electrons in two shells and, therefore, holds them close; the nucleus of lead, on the other hand, has 82 electrons distributed in six shells. The attraction between the nucleus of lead and its outermost electrons is less than in carbon, because intervening shells in lead shield the outer electrons. Structural differences between diamond and graphite produce profound differences between them in hardness, conductivity, density, heat capacity, and other properties. Inasmuch as graphite is a unique crystalline formation among the elements, its properties should not be compared directly with those of the other elements in the family. It is interesting and worth noting here that boron nitride—a compound formed by the two elements on either side of carbon in the periodic table, with formula $(B–N)_n$, n being any number—is isoelectronic with (has the same number of electrons as) carbon–carbon molecules $(C_2)_n$ and can be prepared in both cubic and hexagonal forms that are structurally analogous, respectively, to the diamond and graphite forms. Like diamond, cubic boron nitride is extremely hard and refractory; like graphite, hexagonal boron nitride is soft and lubricating because of the ease of deformation between layers. Like graphite, hexagonal boron nitride also forms many compounds by trapping metals, nonmetals, covalent compounds, and ionic compounds between layers in its crystal lattice. These formations are called intercalation compounds.

Reactions. Certain of the more common chemical reactions of the carbon group elements are summarized in Table 2. With a given reagent, diamond is generally less reactive than graphite and, thus, requires more rigorous conditions for reaction, such as a higher temperature; the ultimate products, however, are the same. Crystalline silicon is less reactive than finely divided and, possibly, amorphous silicon. Elemental germanium resembles silicon quite closely. Tin and lead behave in general as metals and thus yield at least some ionic products in reactions that are quite different from those of the other elements. Elemental carbon is of particular importance as a

Carbon in metallurgy

high-temperature reducing agent (a reagent that donates electrons) in metallurgical processing for metal oxides, a reaction that frees the metal. Thus to cite only a few of carbon's more important applications, carbon is used directly in the production of elemental phosphorus, arsenic, bismuth, tin, lead, zinc, and cadmium, and indirectly, as carbon monoxide, in the production of iron. Elemental silicon, in the iron–silicon alloy ferrosilicon, is also a strong reducing agent and has been used as such to liberate magnesium from its oxide.

Biological and physiological significance. The biological implications of carbon are so extensive that they can be discussed here only very briefly. All biological substances are based upon compounds in which carbon is combined with other elements, the nature of the combination determining the characteristics, function, and relative importance of the substance. To begin with the inorganic compounds of carbon, elemental carbon is nontoxic. Carbon monoxide (CO) is both more readily absorbed and more firmly bound to the hemoglobin of the blood than is oxygen and is thus, even in small concentrations, a dangerous asphyxiant. Carbon dioxide (CO_2) is an asphyxiant of significance only in relatively large concentrations; in small concentration, it stimulates breathing. Hydrogen cyanide (HCN) and its derivatives (cyanogen compounds, cyanides) are all very toxic as protoplasmic poisons through the inhibition of tissue oxidation. Carbon tetrachloride (CCl_4) and other chlorinated hydrocarbons damage the nervous system. Among organic compounds, the most toxic are derivatives that contain the halogen elements (fluorine, chlorine, bromine and iodine), sulfur, selenium, tellurium, nitrogen, phosphorus, arsenic, lead, and mercury. Most organometallic compounds are toxic, while oxygen-containing derivatives of the hydrocarbons are usually less toxic.

Elemental silicon and most silicon-containing compounds appear to be nontoxic. Indeed, human tissue often contains 6 to 90 milligrams (one milligram equals 0.001 gram) of silica (SiO_2) per 100 grams dry weight, and many plants and lower forms of life assimilate silica and use it in their structures. Inhalation of dusts containing alpha SiO_2, however, produces a serious lung disease called silicosis, common among miners, stonecutters, and ceramic workers, unless protective devices are used.

The toxicology of germanium and its compounds is poorly defined.

Elemental tin is apparently nontoxic, and quantities of tin up to 300 parts per million, as dissolved by foods packaged in tin-plated containers and cooking utensils, are not harmful. Organic tin compounds, however, commonly used as biocides and fungicides, are toxic to human beings.

Although elemental lead and difficultly soluble lead compounds are not absorbed by human tissue and are, therefore, quite innocuous, any soluble lead compound is toxic, with toxicity increasing as solubility increases. Symptoms of lead poisoning include abdominal pain and diarrhea followed by constipation, nausea, vomiting, dizziness, headache, and general weakness. Elimination of contact with a lead source is normally sufficient to effect a cure. The elimination of lead from insecticides and paint pigments and the use of respirators and other protective devices in areas of exposure have reduced lead poisoning materially. Low-level atmospheric and water pollution, stemming largely from the use of tetraethyllead, $[Pb(C_2H_5)_4]$ in motor fuels, was receiving increasing attention in the 1970s.

Tetraethyllead

General compounds. *Hydrides.* The monohydrides of the carbon group of elements, with the general formula MH_4 (in which M represents an atom of carbon, silicon, germanium, or tin), are colourless gases, the thermal stabilities of which decrease substantially with increasing molecular weight. Methane (CH_4) is stable up to relatively high temperatures; the others decompose to their elements at 450° C or below. The monohydrides are all reducing agents (donating electrons, the opposite of oxidizing agents), but methane is an effective reducing agent only at high temperatures. Monosilane (SiH_4) reduces water and many metal ions in aqueous solution. Monogermane (GeH_4) reacts similarly but less vigorously. All burn in air or oxygen. Each is a weak acid, but the acid strength increases with increasing molecular weight.

Catenated hydrides of the general formula M_nH_{2n+2} have similar properties. When M is carbon, n has no real upper limit, and this formulation corresponds to the huge family of saturated hydrocarbons, or alkanes. Both straight and branched chains are known, and isomerism is common. The chain may form rings (cyclization) to give compounds with the general formula C_nH_{2n}. When M is silicon, germanium, or tin, n is limited because of bond-energy values. Only straight-chain compounds of these elements have been described.

Unsaturated hydrides are known only for carbon; they are representative of the vast families of organic compounds called the alkenes, alkynes, and aromatics.

Halides. All possible compounds of the type MX_4 (X being any halogen element: fluorine, chlorine, bromine, iodine) are known except for the bromide and iodide of lead(IV). These compounds, which are polar covalent substances, are gases, liquids, or solids with low melting points. Each has a tetrahedral molecular geometry, reflecting sp^3 hybridization of the central atom. Each hydrolyzes, to a greater or lesser degree, either in water or in steam, to the corresponding dioxide or acid. Hydrolysis is rapid under alkaline conditions. The tetrafluorides of silicon, germanium, and tin readily attach two more fluoride ions to give hexafluoro complex anions, $[MF_6]^{2-}$. Hexachloro species are well known for tin(IV) and lead(IV).

Catenated halides of the type M_nX_{2n+2} (*e.g.*, hexachloroethane, C_2Cl_6) are well known for carbon, but only a few silicon and germanium analogues have been prepared and no tin or lead compounds. These compounds resemble the tetrahalides in their reactions.

Oxides. Each element in the carbon group forms a well-characterized monoxide with the general formula MO. Carbon monoxide is almost exclusively encountered as a gas. Both silicon and germanium monoxides are most stable in the gaseous state at very high temperatures. Condensation of these two gases to the solid state is accompanied by a reaction that results in the free element and the dioxide. Tin and lead monoxides, on the other hand, are stable solids at room temperature. Only these tin and lead compounds are sufficiently basic (alkaline) to be converted to salts by reaction with aqueous acids. Carbon monoxide is, in terms of its formula, the anhydride of formic acid, formula HCOOH (*i.e.*, if a molecule of water, H_2O, is removed from a molecule of formic acid, carbon monoxide, CO, is left), but the reverse conversion of carbon monoxide to formic acid is not easy. Tin monoxide and lead monoxide dissolve readily in alkali metal hydroxide solutions.

Dioxides

Dioxides (MO_2) are better characterized. Carbon dioxide is monomolecular and gaseous at ordinary temperatures. The other dioxides all form polymeric three-dimensional crystal lattices in which individual MO_2 groups cannot be distinguished. All of the dioxides are potential oxidizing agents, but only lead dioxide is active in this fashion. Each dioxide forms an acid by combination with water and also reacts with alkali metal hydroxides (bases) to give one or more negative ions containing oxygen; *e.g.*, carbonates, silicates, germanates. Acid strength decreases with increasing atomic number of the carbon group elements. Lead(IV) oxide (PbO_2) is unique in combining with lead(II) oxide (PbO) to give a mixed or saltlike form (Pb_3O_4)—two molecules of the latter combining with each molecule of the former.

Sulfides. Monosulfides of carbon group elements, with the general formula MS, S representing sulfur, are most characteristic of tin and lead. These compounds are precipitated from dilute acidic or alkaline solutions as brownish to black substances. They show no appreciable acidic behaviour and are soluble in strongly acidic solutions. A common mineral, lead(II) sulfide, called galena, is an industrial source of lead.

All the disulfides, general formula MS_2, are formed except lead sulfide. Again, lead(IV) is a sufficiently strong oxidizing agent to be reduced by the sulfide ion S^{2-}. Car-

bon disulfide (CS_2) is a low-boiling and foul-smelling liquid that yields a vapour consisting of single molecules. Silicon disulfide (SiS_2) is a polymeric solid made up of chains of the molecule held together through the sulfur atoms. Germanium disulfide (GeS_2) is a three-dimensional polymer comparable to germanium oxide. Tin disulfide (SnS_2) possesses a layer type of crystal lattice. Carbon disulfide reacts quite readily with water to form the carbonate ion. Silicon disulfide also hydrolyzes readily. Both germanium(IV) and tin(IV) sulfides resist hydrolysis and dissolve in dilute aqueous acids only with difficulty.

II. Individual carbon group elements and their compounds

CARBON AND ITS COMPOUNDS

The word carbon probably derives from the Latin *carbo*, meaning variously "coal," "charcoal," "ember." The term diamond, a corruption of the Greek word *adamas*, "the invincible," aptly describes the permanence of this crystallized form of carbon, just as graphite, the name for the other crystal form of carbon, derived from the Greek verb *graphein*, "to write," reflects its property of leaving a dark mark when rubbed on a surface. Before the discovery in 1779 that graphite when burned in air forms carbon dioxide, graphite was confused with both the metal lead and a superficially similar substance, the mineral molybdenite.

Occurrence and distribution of the element. On a weight basis, carbon is 19th in order of elemental abundance in the crust of the Earth, and there are estimated to be 3.5 times as many carbon atoms as silicon atoms in the universe. Only hydrogen, helium, oxygen, neon, and nitrogen are atomically more abundant in the cosmos than carbon. Carbon is the cosmic product of the "burning" of helium in which three helium nuclei, atomic number 4, fuse to produce a carbon nucleus, atomic number 12. In the crust of the Earth, elemental carbon is a minor component: carbon compounds (*i.e.*, carbonates of magnesium and calcium) form common minerals (*e.g.*, magnesite, dolomite, marble, or limestone). Coral and the shells of oysters and clams are primarily calcium carbonate. Carbon is widely distributed as coal and in the organic compounds that constitute petroleum, natural gas, and all plant and animal tissue. A natural sequence of chemical reactions called the carbon cycle—involving conversion of atmospheric carbon dioxide to carbohydrates by photosynthesis in plants, the consumption of these carbohydrates by animals and oxidation of them through metabolism to produce carbon dioxide and other products, and the return of carbon dioxide to the atmosphere—is one of the most important of all biological processes.

Carbon in all living tissue

Production of elemental carbon. Elemental carbon (see NATIVE ELEMENTS) is best considered in terms of its several crystalline forms—diamond, graphite, and "amorphous carbon"—since the widely different properties of these three substances require different approaches. (When an element exists in more than one crystal form, each is called an allotrope.)

Until 1955, all diamonds were obtained from natural deposits, most significant in southern Africa but occurring also in Brazil, Venezuela, British Guiana (now Republic of Guyana), and Siberia. The single known source in the United States, in Arkansas, has no commercial importance, nor is India, once historically a source of fine diamonds, a significant present-day supplier. The primary source of diamonds is a soft, bluish-coloured peridotic rock called kimberlite (after the famous deposit at Kimberley, South Africa), found in volcanic structures called pipes; but many diamonds occur in alluvial deposits presumably resulting from the weathering of primary sources. Isolated finds around the world in regions where no sources are indicated have not been uncommon. Natural deposits are worked by crushing, by gravity and flotation separations, and by removal of diamonds by their adherence to a layer of grease on a suitable table. The following products result: (1) diamond proper—distorted cubic-crystalline, gem-quality stones varying from colourless to red, pink, blue, green, and yellow; (2) bort—minute, dark crystals of abrasive but not gem quality; (3) ballas—randomly oriented crystals of abrasive quality; (4) macles—triangular, pillow-shaped crystals that are industrially useful; and (5) carbonado—mixed diamond–graphite crystallites containing other impurities.

Artificial diamonds

The successful laboratory conversion of graphite to diamond was made in 1955. The procedure involved the simultaneous use of extremely high pressure and temperature with iron as a solvent or catalyst. Subsequently, chromium, manganese, cobalt, nickel, and tantalum were substituted for iron. Synthetic diamonds are now manufactured in several countries and are being used increasingly in place of natural materials as industrial abrasives.

Graphite occurs naturally in many areas, the deposits of major importance being in the Republic of Korea, Austria, China, Mexico, Madagascar, West Germany, Sri Lanka (formerly Ceylon) and the U.S.S.R. Both surface- and deep-mining techniques are used, followed by flotation, but the major portion of commercial graphite is produced by heating petroleum coke in an electric furnace. A better crystallized form, known as pyrolytic graphite, is obtained from the decomposition of low-molecular-weight hydrocarbons by heat. Graphite fibres of considerable tensile strength are obtained by carbonizing natural and synthetic organic fibres.

Amorphous carbon, solid but not clearly crystallized, probably consists of microcrystals of graphite; it is common in commerce as coke; lampblack, or carbon black; and charcoal. These products are obtained by heating coal (to give coke), natural gas (to give blacks), or carbonaceous material of vegetable or animal origin, such as wood or bone (to give charcoal), at elevated temperatures in the presence of insufficient oxygen to allow combustion. The volatile by-products are recovered and used separately.

Structure of carbon allotropes. The crystal structure of diamond is an infinite three-dimensional array of carbon atoms, each of which forms a structure in which each of the bonds makes equal angles with its neighbours. If the ends of the bonds are connected, the structure is that of a tetrahedron, a three-sided pyramid of four faces (including the base). Every carbon atom is covalently bonded at the four corners of the tetrahedron to four other carbon atoms. The distance between carbon atoms along the bond is 1.54×10^{-8} centimetre, and this is called the single-bond length. The space lattice of the diamond can be visualized as carbon atoms in puckered hexagonal (six-sided) rings that lie roughly in one plane, the natural cleavage plane of the crystal; and these sheets of hexagonal, puckered rings are stacked in such a way that the atoms in every fourth layer lie in the same position as those in the first layer. The layer arrangement sequence is thus ABCABCA. . . . Such a crystal structure can be destroyed only by the rupture of many strong bonds: thus the extreme hardness, high sublimation temperature, the presumed extremely high melting point (extrapolated from known behaviour), and reduced chemical reactivity and insulating properties are all reasonable consequences of the crystal structure. Because of both the sense and the direction of the tetrahedral axis, four spatial orientations of carbon atoms exist, leading to two tetrahedral and two octahedral (eight-faced) forms of diamond.

The crystal structure of graphite amounts to a parallel stacking of layers of carbon atoms. Within each layer the carbon atoms lie in fused hexagonal rings that extend infinitely in two dimensions. The stacking pattern of the layers is ABABA. . .; that is, each layer separates two identically oriented layers. Within each layer the carbon–carbon bond distance is 1.42×10^{-8} centimetre, which is intermediate between the single bond and the double (1.33×10^{-8} centimetre) bond distances. All carbon-carbon bonds within a layer are the same (an observation that is interpreted in terms of complete π-bonding). The interlayer distance (3.37×10^{-8} centimetre) is suf-

ficiently large to preclude localized bonding between the layers; the bonding between layers is probably by van der Waals interaction (*i.e.*, the result of attraction between electrons of one carbon atom and the nuclei of neighbouring atoms). Ready cleavage, as compared with diamond, and electrical conductivity are consequences of the crystal structure of graphite. Other related properties are softness and lubricity (smoothness, slipperiness). A less common form of graphite, which occurs in nature, is based upon an ABCABCA . . . stacking, in which every fourth layer is the same. The amorphous varieties of carbon are based upon microcrystalline forms of graphite.

The greater degree of compactness in the diamond structure as compared with graphite suggests that by the application of sufficient pressure on graphite it should be converted to diamond. At room temperature and atmospheric pressure, diamond is actually less stable than graphite. The rate of conversion of diamond to graphite is so slow, however, that a diamond persists in its crystal form indefinitely. As temperature rises, the rate of conversion to graphite increases substantially, and at high temperatures it becomes (thermodynamically) favorable if the pressure is sufficiently high. At the same time, however, the rate of conversion decreases as the (thermodynamic) favourability increases. Thus, graphite does not yield diamond when heated under high pressure, and it appears that direct deformation of the graphite structure to the diamond structure in the solid state is not feasible.

Diamonds in meteorites

The occurrence of diamonds in iron–magnesium silicates in the volcanic structures called pipes and in iron–nickel and iron sulfide phases in meteorites suggests that they were formed by dissolution of carbon in those compounds and subsequent crystallization from them in the molten state at temperatures and pressures favourable to diamond stability. The successful synthesis of diamond is based upon this principle.

The temperature and pressure relationships of any substance can be plotted to show how, for example, the boiling point changes as pressure is changed; such graphs are called phase diagrams (see PHASE CHANGES AND EQUILIBRIA). They reveal conditions under which rearrangements in the atomic or molecular structure of a substance take place.

The crystal structure of graphite is of kind that permits the formation of many compounds, called lamellar or intercalation compounds, by penetration of molecules or ions. Graphitic oxide and graphitic fluoride are nonconducting lamellar substances not obtained in true molecular forms that can be reproduced, but their formulas do approximate, respectively, the compositions of carbon dioxide and carbon monofluoride. Graphite oxide appears to contain the groupings carbon–oxygen–carbon atoms, carbon–oxygen atoms with a double bond, and carbon–hydroxyl groups and to have the properties of the aliphatic compounds. Graphitic fluoride appears to contain one carbon–fluorine group of atoms and three carbon–carbon bonds per carbon atom. The products obtained by intercalation of the heavy alkali metals potassium, rubidium, cesium (K, Rb, and Cs), the halogens chlorine and bromine (Cl_2 and Br_2), and certain metal compounds such as aluminum chloride, iron disulfide, and molybdenum trioxide ($AlCl_3$, FeS_2, and MoO_3) conduct electric current as well as or better than graphite. In a metallic state, some of the valence electrons are free to move from atom to atom forming what is called the conduction band. At the same time, a position left vacant by an electron may be considered a positive "hole," and such holes also move about in the conduction band. The compounds just mentioned appear either to add or to remove electrons from the conduction band of graphite. Thus, in graphite treated as indicated above, the concentration either of conducting electrons or of positive holes is enhanced.

A type of chemical reaction in which one substance (an oxidizing agent) accepts electrons from another substance (a reducing agent) and is thereby reduced (while the reducing agent is oxidized) is frequently observed with carbon and its compounds. Although carbon is usually a reducing agent, under acidic conditions elemental carbon is a moderately strong oxidizing agent. The large energy of the carbon–carbon bond makes activation energy requirements for the reaction so high that direct reduction of carbon—*e.g.*, to methane (formula CH_4)—is impractical. Reduction of carbon monoxide to elemental carbon and oxidation of carbon monoxide to carbon dioxide are both feasible but impractical in solution. Under alkaline conditions, only the oxidation of formate ion (HCO_2^-) to carbonate ion (CO_3^{2-}) is a reasonable process.

Carbides. By convention, carbides are those binary compounds in which carbon has combined with elements of roughly equal or lesser electronegativity (affinity for electrons). Carbides can be classified as saltlike (saline), covalent, or interstitial. The saltlike carbides form transparent, nonconducting crystals that react with water to form the metal oxides or hydroxides and liberate hydrocarbons. The covalent carbides include the silicon compound known as Carborundum (SiC) and boron carbide (B_4C). Each of these is a refractory, extremely hard (on Mohs scale of hardness, diamond is 10, SiC is 9.15, B_4C is 9.32), and chemically inert substance, such properties being the consequence of the presence of a large number of strong bonds that must be broken. There are three crystalline forms of silicon carbide, and they have structures related to the diamond, the sphalerite, and the wurtzite arrangements of atoms, in each of which carbon and silicon atoms alternate in a tetrahedral environment. Crystals of boron carbide contain icosahedral groups of 12 boron atoms and linear carbon-atom chains of 3 atoms each. Complete covalent bonding between adjacent atoms occurs.

Carborundum

The interstitial carbides include most of the transition-metal carbides and in particular those derived from the transition metals of Groups IVb, Vb, and VIb in the periodic table. These compounds are characterized by very high melting points (3,000–4,800° C [5,400–8,600° F]), extreme hardness (on Mohs scale a hardness of 7 to 10), and chemical inertness. The crystals are formed by the entry of carbon atoms into octahedral holes in the crystal lattices of the metals. The composition by weight, or stoichiometric composition, is most commonly representable by the formula MC, in which M is the metal. Carbides formed by the metals chromium (Cr), manganese (Mn), iron (Fe), cobalt (Co), and nickel (Ni) differ in stoichiometry, as shown by the formulas Cr_3C_2, Mn_3C, Fe_3C, Co_3C, and Ni_3C, and are readily hydrolyzed by dilute acids to hydrocarbons and elemental hydrogen. Their crystals contain chains of carbon atoms in distorted metal lattices.

Halides. A number of more important physical properties of the simple halides, represented as CX_4, X being any halogen, are summarized in Table 3. The catenated halides are commonly considered simply as halogenated hydrocarbons and are better discussed in that context. Carbon tetrafluoride (CF_4) is a thermally stable, chemically unreactive gaseous compound that is obtained as the end product of the reaction of elemental fluorine with almost any carbon-containing compound. Carbon tetrachloride (CCl_4) is less stable to heat than the fluoride and quite susceptible to photochemical (light-induced) decomposition and loss of chloride ion. The tetrabromide and tetraiodide (CBr_4 and CI_4) are, respectively, yellow and red solids that undergo ready decomposition when heated. Such thermal instability is probably related both to reduced bond energies within the molecule and to the molecular structure in which large halogen atoms are crowded about the small carbon atom. That the tetrahalides of carbon hydrolyze less readily than those of silicon or germanium is caused by their containing a central atom with all its covalent bonds occupied and thus no orbitals left available for interaction with electrons from a water molecule or a hydroxide ion. No complex ions based upon the carbon tetrahalides are thus known.

Oxides. The most common and important oxides of carbon are carbon monoxide (CO) and carbon dioxide (CO_2). Carbon dioxide is the first member of a potential series of oxides with general formula C_nO_2, the n indicating any number of carbon atoms, while the number of

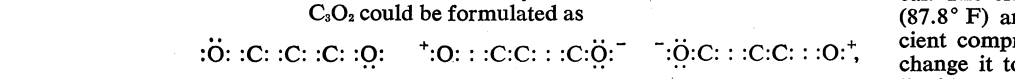
oxygen atoms is always two; but only one other member of the series is well characterized, namely carbon suboxide (C_3O_2). Although a substance of the formula C_5O_2 has been reported, evidence for its existence has been questioned. Resonance stabilization, meaning that the bond structure within a molecule cannot be expressed in a single mode but must be considered as an average of several possible structures, postulates for carbon dioxide the following formulations:

Resonance stabilization could be significant for species of the C_nO_2 series only where n is an odd number. Thus, C_3O_2 could be formulated as



but C_4O_2 or C_2O_2 could not be similarly formulated. It is significant that C_3O_2 is known, but no analogue where n is an even number has been described. An oxide with high carbon and high oxygen content, the compound $C_{12}O_9$ is also known.

The carbon monoxide molecule (CO) contains the same number of electrons as, or is isoelectronic with, the nitrogen molecule (N_2), the nitrosonium ion (NO^+), and the cyanide ion (CN^-). For each of these groups of atoms an electronic formulation containing a triple bond can be written:

The physical constants for carbon monoxide and elemental nitrogen are very nearly the same, thus reflecting structural similarities. The molecular species CO, NO^+, and CN^- resemble each other most closely in their abilities to form complexes with the same transition-metal ions (the transition metals, or elements, occupy the b groups in the periodic table and include many of the familiar metals).

Carbon monoxide is combustible and is a significant component of fuels such as water gas and producer gas. The reaction converting carbon monoxide to carbon dioxide is represented by the equation in which g stands for gas (as s symbolizes solid and l liquid):

Carbon monoxide as fuel

$$2CO_{(g)} + O_{2(g)} \longrightarrow 2CO_{2(g)}.$$

This reaction is characterized by a standard-enthalpy (heat-energy) change that is high enough to explain the usefulness of the gas as a fuel. Carbon monoxide is also an excellent reducing agent with metal oxides at elevated temperatures and is thus important in metallurgy for obtaining pure metals from their minerals. A typical reaction with the iron(III) oxide Fe_2O_3 is represented in the following equation:

$$Fe_2O_{3(s)} + 3CO_{(g)} \longrightarrow 2Fe_{(s)} + 3CO_{2(g)}.$$

At elevated temperatures and in the presence of a catalyst such as elemental iron, nickel, or palladium, carbon monoxide breaks up into elemental carbon and carbon dioxide according to the equation

$$2CO_{(g)} \rightleftharpoons C_{(s)} + CO_{2(g)}.$$

As the monoxide breaks up, the dioxide is also reduced by the carbon, and, at all times, the reaction is reversible —*i.e.*, taking place in both directions. As the temperature continues to increase, the percentage of carbon monoxide increases, reducing the percentage of carbon dioxide in the mixture. It is this shift that is responsible at high temperatures for the presence of carbon monoxide, often in toxic quantities, in the gaseous products of combustion when there is not an excess of oxygen to force the reaction to the right. In the presence of suitable catalysts, carbon monoxide is converted by elemental hydrogen to methanol (CH_3OH) and other organic compounds. Reaction of carbon monoxide with the halogens or sulfur gives compounds with the carbonyl group, symbolized as $\diagdown\!\!\!\!\diagup C = O$, in which each line represents a covalent bond. The two free bonds of the carbon atom may be bonded to hydrogen or other carbon atoms. Although the carbon monoxide molecule is weakly basic (according to the Lewis acid–base theory) it does behave as a donor to certain metal atoms to form carbonyl complexes; *e.g.*, nickel tetracarbonyl [$Ni(CO)_4$], iron pentacarbonyl [$Fe(CO)_5$], and dirhenium decacarbonyl [$Re_2(CO)_{10}$]. Carbon monoxide is obtained commercially in an admixture with hydrogen by the reduction at high temperatures of water vapour with coke.

The linear carbon dioxide molecule is isoelectronic (same number of electrons around the different nuclei) with the nitrogen(I) oxide molecule (N_2O). The physical constants of these two substances are very nearly identical. The critical constants of carbon dioxide are 31° C (87.8° F) and 73 atmospheres, which means that sufficient compression of the gas at room temperature can change it to the liquid. The triple point (at which gas, liquid, and solid phases can exist in equilibrium) is −56.6° C (−69.9° F) at 5.01 atmospheres. The high sublimation (transition from solid to gas without going through the liquid phase) pressure of the solid renders difficult the direct preparation of solid carbon dioxide, but rapid expansion of carbon dioxide gas by release of pressure above the liquid has a sufficient cooling effect to convert part of the material into solid. The white solid, known as Dry Ice, is useful as a refrigerant and is used in admixture with such liquids as acetone to maintain low temperatures in cryogenic systems.

Carbon dioxide is a comparatively weak oxidizing agent, and it does not support the combustion of carbonaceous substances, phosphorus, or sulfur. Rather, it extinguishes the combustion of such substances and is thus a highly useful fire extinguisher. Previously ignited active metals—*e.g.*, sodium, potassium, and magnesium—do burn in carbon dioxide, with the formation of oxides, carbonates, or oxalates and elemental carbon. Above 1,000° C (1,800° F), carbon dioxide dissociates appreciably to carbon monoxide and oxygen. Carbon dioxide

dissolves appreciably in water to give a mildly acidic solution. The solubility is substantial in alkaline solution where both the carbonate ion (CO_3^{2-}) and hydrogen carbonate or bicarbonate ion (HCO_3^-) can form. Solid hydrogen carbonate salts are limited to the alkali metals; *e.g.*, sodium bicarbonate ($NaHCO_3$), common baking soda.

Solid carbonates are known for many metals either as natural minerals or as synthetically produced compounds. Natural calcium carbonate ($CaCO_3$) and sodium carbonate (Na_2CO_3), the soda ash of commerce, are of particular industrial importance. Most carbonates have limited solubilities in water. That the carbonate and nitrate ions (NO_3^-) are isoelectronic and of similar size promotes similarities in crystal structure between certain of their salts (*e.g.*, $CaCO_3$ and $NaNO_3$). Carbonic acid (H_2CO_3) cannot be isolated as such because of its instability and ready decomposition to carbon dioxide and water. Carbon dioxide is an ultimate product of the complete reaction of carbon or organic compounds with oxygen. It is best obtained in a state of purity either by decomposing carbonates by heat, or by treating them with acids.

Soda ash

Carbon suboxide (C_3O_2) is a foul-smelling gas that condenses to a liquid with a boiling point of −6.8° C (19.8° F).

Sulfides. Carbon disulfied (CS_2) is an almost colourless, low-boiling liquid with a pronounced unpleasant odour. The compound has a low kindling temperature and is thus a hazardous chemical either as the liquid or the gas. With the sulfide ion it forms the thiocarbonate ion (CS_3^{2-}), and alkali and alkaline-earth metal thiocarbonates are sulfur analogues of carbonates. The arrangement of atoms in the CS_2 molecule is collinear and analogous to that in the CO_2 molecule. Resonance stabilization is important. Formation of carbon disulfide from elemental carbon and sulfur is endothermic (heat absorptive) to the extent of 22 kilocalories per mole.

Carbon oxosulfide (COS) is a toxic gaseous compound that condenses to a liquid boiling at −50.2° C (−58.4° F) and a solid melting at −138.8° C (−217.8° F). Its general properties are intermediate between those of carbon dioxide and carbon disulfide.

Nitrogen compounds. Hydrogen cyanide (HCN) is a colourless gas that condenses to a liquid boiling at 25.6° C (78.1° F) and freezing at −13.4° C (+7.9° F). The liquid has a low viscosity, measurable electrical conductivity, and a large dielectric constant (a measure of the ability to store electrical energy in an electrical field) and is thus an ionizing solvent like water. The cyanides contain the CN^- group and are either ionic, covalent, or complex in nature. Cyanogen (C_2N_2) is a related compound that in alkaline solution gives both cyanides and cyanates. All cyanides are toxic. The cyanide group reacts similarly to the carbon monoxide molecule in the blood stream. Sodium cyanide is a product of the fusion of calcium cyanamide ($CaCN_2$) with carbon and sodium carbonate. Calcium cyanamide results when calcium carbide is heated with elemental nitrogen. Hydrogen cyanide is important in the synthesis of organic nitriles. The cyanides are used in extractive metallurgy and electroplating.

Cyanides

Nuclear properties. The notation used for the nucleus of atoms places the atomic mass as a presuperscript to the symbol of the element and the atomic number as a presubscript; thus, the isotope carbon-12 is symbolized ${}^{12}_{6}C$. Of the stable nuclides (Table 1), the isotope carbon-13 is of particular interest in that its nuclear spin imparts response in a device called a nuclear magnetic resonance spectrometer, which is useful when investigating the molecular structures of covalently bonded compounds containing carbon. This isotope is also useful as a label in compounds that are to be analyzed by mass spectrometry, another device that is used extensively to identify atoms and molecules. Of the unstable nuclides, only carbon-14 is of sufficiently long half-life to be important. It is formed by the interaction of neutrons, produced by cosmic radiation, with nitrogen (N) in the atmosphere in a reaction that may be written as follows (neutron is symbolized as ${}^{1}_{0}n$, the nitrogen atom as ${}^{14}_{7}N$, and a hydrogen nucleus, or proton, as ${}^{1}_{1}H$):

$$ {}^{14}_{7}N + {}^{1}_{0}n \longrightarrow {}^{14}_{6}C + {}^{1}_{1}H $$

The carbon-14 atoms from this reaction are converted to carbon dioxide by reaction with atmospheric oxygen and mixed and uniformly distributed with the carbon dioxide containing stable carbon-12. Living organisms use atmospheric carbon dioxide, whether with stable or radioactive carbon, through processes of photosynthesis and respiration, and thus their systems contain the constant ratio of carbon-12 to carbon-14 that exists in the atmosphere.

Death of an organism terminates this equilibration process; no fresh carbon dioxide is added to the dead substance. The carbon-14 present in the dead substance decays in accordance with its 5,568-year half-life, while the carbon-12 remains what it was at death. Measurement of the carbon-14 activity at a given time thus allows calculation of the time elapsed after the death of the organism. Measurement of the carbon-14 activity in a cypress beam in the tomb of the Egyptian Pharaoh Snefru, for example, established the date of the tomb as *c.* 2600 BC. Many items of archaeological significance have been dated similarly.

The nuclides carbon-12 and carbon-13 are of importance in the carbon cycle of energy creation in certain stars. The cycle can be summarized in terms of nuclear equations, the separate steps being:

$$ {}^{12}_{6}C + {}^{1}_{1}H \longrightarrow {}^{13}_{7}N + \text{energy} $$

$$ {}^{13}_{7}N \longrightarrow {}^{13}_{6}C + {}^{0}_{+1}e $$

$$ {}^{13}_{6}C + {}^{1}_{1}H \longrightarrow {}^{14}_{7}N + \text{energy} $$

$$ {}^{14}_{7}N + {}^{1}_{1}H \longrightarrow {}^{15}_{8}O + \text{energy} $$

$$ {}^{15}_{8}O \longrightarrow {}^{15}_{7}N + {}^{0}_{+1}e $$

$$ {}^{15}_{7}N + {}^{1}_{1}H \longrightarrow {}^{12}_{6}C + {}^{4}_{2}He. $$

Summation of the equations allows the fusion process to be written as a reaction among four atoms of hydrogen to yield one atom of helium (He), two positrons (${}^{0}_{+1}e$), and energy:

$$ 4\,{}^{1}_{1}H \longrightarrow {}^{4}_{2}He + 2\,{}^{0}_{+1}e + \text{energy}; $$

this equation does not show that the process uses up and regenerates the carbon-12. In a sense, carbon acts as a catalyst for this mode of converting mass to energy.

Biological implications. The biological implications of the element and its simple compounds have been discussed earlier; the most significant implications are associated with organic compounds, which are discussed in such articles as ALKALOIDS; CARBOHYDRATE; LIPID; NUCLEIC ACID; PROTEIN; STEROIDS.

Analysis. Carbon, either elemental or combined, is usually determined quantitatively by conversion to carbon dioxide gas, which can then be absorbed by other chemicals to give either a weighable product or a solution with acidic properties that can be titrated.

SILICON AND ITS COMPOUNDS

The name silicon derives from the Latin *silex* or *silicis*, meaning "flint" or "hard stone."

Occurrence and distribution of the element. On a weight basis, the abundance of silicon in the crust of the earth is exceeded only by oxygen. Estimates of the cosmic abundance of other elements often are cited in terms of the number of their atoms per 10^6 atoms of silicon. Only hydrogen, helium, oxygen, neon, nitrogen, and carbon exceed silicon in cosmic abundance. Silicon is believed to be a cosmic product of alpha-particle absorption, at a temperature of about 10^9 K, by the nuclei of carbon-12, oxygen-16, and neon-20. The energy binding the particles that form the nucleus of silicon is about 8.4 million electron volts (MeV) per nucleon (proton or neutron). Compared with the maximum of about 8.7 million electron volts for the nucleus of iron, almost twice as massive as that of silicon, this figure indicates the relative stability of the silicon nucleus. The pure element silicon is too reactive to be found in nature. In compounds, the oxi-

Silicon minerals

dized form, as silicon dioxide and particularly as silicates, is common in the Earth's crust and is an important component of the Earth's mantle. Silicon dioxide occurs both in crystalline minerals (*e.g.*, quartz, cristobalite, tridymite) and amorphous or seemingly amorphous minerals (*e.g.*, agate, opal, chalcedony) in all land areas. The natural silicates are characterized by their abundance, wide distribution, and structural and compositional complexities. Most of the elements of the following groups in the periodic table are found in silicate minerals: groups Ia, IIa, IIIa, IIIb, IVb, Vb, VIb, VIIa. These elements are said to be lithophilic, or stone-loving. Important silicate minerals include the clays, feldspar, olivine, pyroxene, amphiboles, micas, and zeolites.

Production of elemental silicon. Elemental silicon is produced commercially by the reduction of silica (SiO_2) with coke in an electric furnace, and the impure product is then refined. Almost pure silicon is obtained by the reduction of silicon tetrachloride or trichlorosilane. For use in electronic devices, single crystals are grown by slowly withdrawing seed crystals from molten silicon.

Properties of the element. The more important physical and chemical properties of silicon have been summarized and related to the ground-state electronic configuration of the silicon atom and the position of silicon in the periodic table. Because silicon forms chains similar to those formed by carbon, silicon has been studied as a possible base element for silicon organisms. Another property resulting from the electronic structure of silicon is that it functions as an intrinsic semiconductor (see SEMICONDUCTORS AND INSULATORS, THEORY OF). Addition of an element such as boron, an atom of which can be substituted for a silicon atom in the crystal structure but which provides one less valence electron (boron is an acceptor atom) than silicon, allows silicon atoms to lose electrons to it. The positive holes created by the shift in electrons allow extrinsic semiconduction of a type referred to as positive (*p*). Addition of an element such as arsenic, an atom of which can also be substituted for a silicon atom in the crystal but which provides an extra valence electron (arsenic is a donor atom), releases its electron within the lattice. These electrons allow semiconduction of the negative (*n*) type. If *p*-silicon and *n*-silicon wafers are joined, in a manner called the *p–n* junction, and placed in sunlight, the absorbed energy causes electrons to move across the junction and an electric current to flow in an external circuit connecting the two wafers. Such a solar cell is a source of energy for space devices.

The solar cell

Unlike carbon, the only crystalline form in which silicon exists is an octahedral form based upon atoms in the diamond-type arrangement. The amorphous forms of silicon contain micro crystals of this type. The reduced bond energy in crystalline silicon renders the element lower melting, softer, and chemically more reactive than diamond.

Only the 0 and +4 oxidation states of silicon are stable in aqueous systems.

As is true with carbon, the bonds in elemental silicon are strong enough to require large energies to activate, or promote, reaction in an acidic medium, and the oxidation–reduction reactions do not appear to be reversible at ordinary temperatures. (See also SILICA MINERALS; SILICATE MINERALS.)

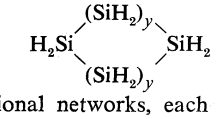
Silicides. A silicide is a binary compound in which silicon is combined with some less electronegative element. Like the carbides, silicides are most commonly prepared by direct combination of the elements or by the reduction of oxides by elemental silicon, both at elevated temperatures. Roughly, but with somewhat less well-defined distinctions, silicides may be classified as ionic, covalent, or metallic. The stoichiometric compositions are widely variable; *e.g.*, MSi, MSi_2, M_2Si, M_3Si, M_5Si, M_5Si_3, and $M_{15}Si_4$ (M symbolizing specific metals). They bear little systematic relationship to the electronic configuration of the metal atom present or to its position in the periodic table. Rather, composition appears to be related to stable crystal structure, as determined by size of the atoms and by the relationships among the charges.

Crystals of metal-rich silicides (*e.g.*, M_3Si) are constructed with silicon atoms nearly or completely surrounded by metal atoms, and these solids are therefore structurally similar to the metals. On the other hand, crystals of silicon-rich silicides (*e.g.*, some MSi_2) are based upon metal atoms surrounded by silicon atoms. In other silicides, the distances between silicon atoms are close to those in crystalline elemental silicon. In terms of crystal structural type, many silicides are closer to the borides than they are to the carbides.

The calcium silicides represent several structural and chemical types, including compounds with the formulas Ca_2Si, CaSi, and $CaSi_2$. The latter two yield the polymers $(SiH_2)_n$ and $(SiH)_n$ when treated with aqueous acids. The metallic silicides are commonly hard, refractory substances that are used as abrasives.

Analogies between silicon and carbon

Hydrides. The hydrides, called silanes, are silicon analogues of the alkanes, the hydrocarbon family of compounds with general formula C_nH_{2n+2}, and their general formula corresponds to the alkane type: Si_nH_{2n+2}. Compounds with *n* of 1 to 6 have been isolated and characterized, and there is evidence for the existence of higher members of the series. The melting points and boiling points of the lower members are comparable with those of the analogous compounds of germanium and the alkanes listed in Table 4. No cyclic or unsaturated (having more than one bond between adjacent silicon atoms) silanes are known with any degree of certainty, but solid and highly polymeric hydrides (*i.e.*, compounds composed of many hydride molecules bonded together into macromolecules) with the general formulas $(SiH_2)_n$ and $(SiH)_n$ have been described. These substances are not in any way comparable to the alkenes and alkynes (two other major carbon-compound families), and it is unlikely that any compounds with double and triple bonds between the silicon atoms exist. It is reasonable to assume, however, that either there exist linear arrangements, with the general formula $H_3Si(SiH_2)_xSiH_3$, and cyclic groups, with the general formula



or three-dimensional networks, each based upon four-bonded and saturated (only single bonds between adjacent silicon atoms) silicon atoms. Catenation (chain forming) to give simple, single-bonded molecules is limited by bond energies; the absence of multiple bonds reflects the difficulty of overlapping *p* orbitals to form π-bonds with the larger silicon atoms.

The lower silanes are obtained as a mixture by treating magnesium silicide with aqueous hydrochloric acid, and they are separated by fractional distillation, a process that

Table 4: Comparison of Alkanes, Silanes, and Germanes

compound	melting point (°C)	boiling point (°C)	compound	melting point (°C)	boiling point (°C)	compound	melting point (°C)	boiling point (°C)

iso-C_5H_{12}	−159.6	27.9	*iso*-Si_5H_{12}	−74.5		*iso*-Ge_5H_{12}		234

separates the vapours of liquids having different boiling points. The overall yields are low, in part because of reaction of silanes with aqueous solutions; and the yields of individual silanes decrease rapidly with increasing molecular weight. The lower silicon hydrides can be decomposed thermally, or in an electric discharge, to hydrogen and the higher hydrides.

The silanes burn spontaneously to silicon dioxide and water vapour on contact with oxygen. They react explosively with the lower halogens at room temperature and with the halogens yield compounds called halosilanes. The silanes do not react readily with neutral or acidic solutions but hydrolyze readily and completely with evolution of hydrogen in alkaline solutions. Many alkyl derivatives have been described.

Halides. The more important halides are the halosilanes of the type formula Si_nX_{2n+2}, X being any halogen. Compounds with n up to 6 and also 10 and 25 are known; all the halogens occur in the smaller molecules but only fluorine and chlorine in the larger ones. In addition, species with the general formula $(SiX_2)_n$ have been described. These compounds are large polymeric molecules that are solids at room temperature. The composition $(SiX_2)_n$ can be considered in terms of the series Si_nX_{2n+2}, in which n is so large in comparison with +2 that 2 is of no significance. Mixed tetrahalides comparable to carbon tetrahalides, with such formulas as SiF_3Cl and $SiFClBr_2$, are also known.

The numerical constants of the silicon tetrahalides, general formula SiX_4, are summarized in Table 3. The melting and boiling points of the catenated halides increase in general with total molecular weight, both as n increases for a given halogen and also in the series of the halogens from fluorine to iodine for a given n. Only two halides of silicon, SiF_4, and Si_2F_6, are gases at ordinary temperatures; those that are liquids are the compounds with formulas Si_3F_8, $SiCl_4$, Si_2Cl_6, Si_3Cl_8, Si_4Cl_{10}, and $SiBr_4$. The physical properties of all of these compounds are those of covalent substances.

Except for the fluorides, the silicon halides hydrolyze readily in aqueous medium to hydrous silicon dioxide and hydrohalic acid. Silicon tetrafluoride yields, in addition, a solution of the industrially useful hexafluorosilicic acid (H_2SiF_6), one of the stronger acids. The salts of this acid are soluble in water, except for those of barium, yttrium, and the lanthanides. Many heavy metals are conveniently electrodeposited from hexafluorosilicate baths. Some of its salts are useful as insecticides.

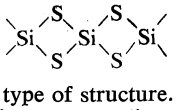
Silicon tetrafluoride is prepared in several ways; the other silicon tetrahalides are prepared by direct combination of the elements.

Oxides. Silicon dioxide and the silicates have been discussed earlier. Silicon monoxide is obtained in the gaseous state when silicon dioxide and silicon are heated *in vacuo* at 1,450° C (2,640° F). Slow cooling of silicon monoxide gas results in its condensation to a solid mixture of silicon dioxide and silicon. Rapid cooling of the monoxide, however, yields a dark-coloured, resinous, and apparently amorphous form of the compound that is hard and nonconducting and that, on reheating, reverts to silicon and silicon dioxide. The solid monoxide is used as a coating on mirrors and optical glass because it resists abrasion and tarnish.

Sulfides. Silicon disulfide, like silicon dioxide, differs markedly from its analogue, carbon disulfide. It is a colourless, fibrous, crystalline compound that reacts readily with water to form silicon dioxide and hydrogen sulfide. It is also readily converted to silicon dioxide by oxygen.

Silicon–sulfur chains

In the crystal, each silicon atom is surrounded tetrahedrally by four sulfur atoms, but two of those sulfur atoms serve as a bridge between each two silicon atoms, as shown in the structural formula



to build up a chain type of structure. Though interesting and of importance in understanding silicon chemistry, it has no practical uses.

Others. Silicon nitride (Si_3N_4), trisilylamine [$N(SiH_3)_3$], and other compounds containing silicon–nitrogen bonds are known, including organosilazanes, such as $R_3SiNHSiR_3$, $(R_3Si)_2NR$, R_3SiNHR, and $(R_2SiNH)_{3,4}$, in which R is an organic group. Complex species containing silicon are limited to the $[SiF_6]^{2-}$ ion and a few cations such as $[Si(C_6H_5)_3(2,2'\text{-dipyridyl})]^+$.

GERMANIUM AND ITS COMPOUNDS

The name germanium derives from the Latin word Germania (Germany) and was given to the element by its German discoverer, Clemens Winkler, in 1886.

Occurrence and distribution of the element. On a weight basis, germanium is a scarce but not an extremely rare element in the crust of the Earth, equalling in abundance beryllium, molybdenum, and cesium and exceeding the elements arsenic, cadmium, antimony, and mercury. In the cosmos, the atomic abundance of germanium is 50.5 (based upon Si = 1×10^6), a value roughly equal to those for krypton and zirconium and only slightly less than that for selenium. The cosmic abundance is much less than those of a number of the heavier elements; *e.g.*, bromine, strontium, tin, barium, mercury, and lead. All of the elements of lower nuclear charge than germanium, except beryllium, boron, scandium, and gallium, are cosmically more abundant than germanium. Cosmically, germanium is believed to be one of the many elements formed by neutron absorption after the initial processes of hydrogen and helium burning and alpha-particle absorption.

Natural sources of germanium

Germanium is widely distributed in nature but is too reactive to occur free. Primary minerals include argyrodite, germanite, renierite, and canfieldite, all of them rare; only germanite and renierite have been used as commercial sources for the element. Trace quantities of germanium are found in certain zinc blendes, in sulfidic ores of copper and arsenic, and in coals, the latter possibly a consequence of the concentration of the element by plants of the Carboniferous Period in geologic history. Certain present-day plants are known to concentrate germanium. Both zinc-process concentrates and ash and flue dusts from coal-burning installations provide commercial sources of germanium.

Production of germanium. Pure germanium is obtained from these sources in a complicated process that finally yields billets or blocks, which may be purified by further refining to the quality required for the manufacture of semiconductors. Single crystals of germanium are grown in an atmosphere of nitrogen or helium from the molten material. These are then transformed into semiconductors by being doped (infused) with electron donor or acceptor atoms, either by incorporating the impurities in the melt during growth of the crystal or by diffusing the impurities into the crystal after it has been formed.

Properties of the element. The physical and chemical properties of germanium have been summarized earlier. Like silicon, germanium crystallizes in the diamond type of structure. The trend in properties noted with silicon and related to reduced bond energy continues with germanium. The electrical and semiconducting characteristics of germanium are comparable to those of silicon.

Germanium(II) compounds are well characterized as solids, and in general they are readily oxidized. Elemental germanium can be electrodeposited from many solutions and melts of its compounds. It is of interest that as little as one milligram of dissolved germanium per litre seriously interferes with the electrodeposition of zinc.

Germanides. True germanides are less well defined than the silicides. The alkali metals, M, react with germanium by direct combination to yield compounds with the general formula MGe, which yield compounds with the formula MGe_4 when heated *in vacuo* or in an inert atmosphere. Magnesium forms Mg_2Ge by direct combination, and calcium forms both Ca_2Ge and CaGe. Lanthanide compounds and actinide compounds may be classifiable as germanides. The other metallic elements, such as copper (Cu), titanium (Ti), molybdenum (Mo), palladium (Pd), iridium (Ir), and ruthenium (Ru), form combinations with germanium that are presumably more

alloy-like, such as the compounds with formulas Cu_3Ge, Ti_5Ge_3, Mo_3Ge_2, Pd_5Ge_2, Ir_3Ge_4, and $RuGe_4$. Germanium does not react with carbon. Germanium and silicon are infinitely soluble in each other in both the liquid and solid states. Many metals form eutectic systems (mixtures that have a minimum melting point) with germanium.

Hydrides. The hydrides, or germanes, are comparable with their silicon analogues in most respects. They are, however, less stable to heat, less readily oxidized, and more resistant to hydrolysis under alkaline conditions than the silanes. The known germanes are all members of the saturated (containing no double bonds) series Ge_nH_{2n+2} (n being any number from 1 to 9), but physical data are known only for compounds with n up to 5. Evidences for chain branching in compounds to yield isomers (same molecular composition but different structure) have been presented. Yellowish-coloured, highly polymeric hydrides, with formulas $(GeH)_x$ and $(GeH_2)_y$, have been obtained, and, since their properties are comparable to those of the polymeric silicon hydrides, it is logical to assume that they are structurally similar. Mixed silicon–germanium hydrides are known.

The germanes react chemically very much as the silanes. Pyrolysis (decomposition through heat without presence of oxygen) results either in hydrogen and germanium or in cracking of the lower molecular weight species to those of higher molecular weight.

Halides. Well-characterized halides of germanium have been described for both oxidation states. Germanium(II) fluoride is a white, crystalline solid rapidly hydrolyzed by water; germanium(II) chloride is obtained as a white crystalline solid and is readily oxidized in air and hydrolyzed by water. Chlorine-bridged chains are present in the crystals. Germanium(II) bromide compares closely with the chloride; germanium(II) iodide is obtained as a yellow product that oxidizes easily in air.

The tetrahalides are closely comparable with their silicon analogues in both physical (Table 3) and chemical properties. The only well-characterized catenated halide is the colourless chloride Ge_2Cl_6 (melting point 40–42° C [104°–108° F]), which sublimes at room temperature.

Oxides. Germanium monoxide (GeO) and germanium dioxide (GeO_2) are, respectively, black and white solids. Germanium monoxide resists oxidation in moist air at room temperature but is converted to the dioxide at 550° C (1,020° F). It is insoluble in and unaffected by aqueous acidic and alkaline solutions. Above 700° C (1,300° F), it sublimes without decomposition. Germanium dioxide is obtained in three forms: a vitreous, or noncrystalline, glassy form; a hexagonal crystalline form; and a tetragonal crystalline form. Germanium disulfide and germanium monosulfide are, respectively, white and red to black solids.

Complexes. Complexes are formed with a variety of donor groups. In the majority of these, germanium(IV) is in an octahedral geometry (with coordination number 6). Examples include $[GeF_6]^{2-}$, $[Ge(C_2O_4)_3]^{2-}$, and $[Ge(OH)_2(On)_2]$, in which On represents 8-quinolinol.

TIN AND ITS COMPOUNDS

The symbol Sn for tin is an abbreviation of the Latin word for tin, *stannum*.

Occurrence and distribution of the element. On a weight basis, tin is a scarce but not rare element in the crust of the Earth, its abundance being of the same order of magnitude as such technically useful elements as cobalt, nickel, copper, cerium, and lead, and it is essentially equal to the abundance of nitrogen. In the cosmos, there are 1.33 atoms of tin per 1×10^6 atoms of silicon, an abundance roughly equal to that of niobium, ruthenium, neodymium, or platinum. Cosmically, tin is a product of neutron absorption. Its richness in stable isotopes is noteworthy.

The only mineral of commercial significance is cassiterite (SnO_2). No high-grade deposits are known. The major sources are alluvial deposits, averaging about 0.01 percent tin. Lode deposits, containing up to 4 percent, are found in Bolivia and Cornwall. The latter were worked at least as early as Phoenician times but are no longer of major consequence. Some 90 percent of world production comes from Malaysia, Thailand, Indonesia, Bolivia, Congo (Brazzaville), Nigeria, and China. The United States has no significant deposits. (For commerical production see TIN PRODUCTS AND PRODUCTION.)

Tin in Phoenician times

Properties of the element. The major physical and chemical properties of tin have been summarized earlier. The relationships among the allotropic modifications of tin can be represented as transformations from one crystal type to another at specific temperatures:

$$\text{gray or alpha } (\alpha) \text{ tin} \underset{}{\overset{13.2^\circ \text{ C } (55.8^\circ \text{ F})}{\rightleftharpoons}} \text{white or beta } (\beta) \text{ tin}$$

(cubic-diamond crystals) (tetragonal crystals)

$$\overset{161^\circ \text{ C } (322^\circ \text{ F})}{\rightleftharpoons} \text{brittle tin .}$$

(rhombic crystals)

(The double arrows signify that the transformation occurs in both directions, as tin is heated or as it is cooled.) Gray tin is easily crumbled, whereas white tin is malleable and ductile. The spontaneous conversion of the bright metal to a gray powder at low temperatures ("tin pest") seriously hampers the use of the metal in very cold regions. This change is rapid only below −50° C (−58° F), unless catalyzed by gray tin or tin(IV). As a consequence of internal friction, white tin emits a characteristic sound ("tin cry") when bent. Elemental tin is readily oxidized to the dipositive ion in acidic solution, but this tin(II) ion is converted to tin(IV) ion by many mild oxidizing agents, including elemental oxygen. Oxidation under alkaline conditions normally gives the tetrapositive (Sn^{4+}) state. In an alkaline medium, dipositive tin (Sn^{2+}) disproportionates readily to tetrapositive tin and the free element.

Intermetallic compounds. The compounds formed by tin with other metals are nearly all alloy-like and metallic rather than true stannides. The solid compound magnesium stannide, Mg_2Sn, is an insulator, but in the molten state it is comparable in electrical conductivity to molten tin. Although its crystal structure is like that of the ionic compound calcium fluoride (CaF_2), the crystals are not ionic. Crystals of the compounds with general formula MSn (in which M is copper, gold, iron, nickel, or platinum) have a structure in which each tin atom is surrounded by six M atoms and each M atom by six tin atoms but in different geometrical arrays.

Hydrides. The only known hydrides of tin are monostannane (SnH_4), distannane (Sn_2H_6), and the deuterated monostannes ($SnHD_3$ and SnD_4). Each of these compounds decomposes to its elements when heated—and at a lower temperature than its germanium analogue.

All of the halides of both tin(II) and tin(IV) are known. Some properties are summarized in Table 3. The fluorides are crystalline, ionic compounds, but the chlorides have covalent characteristics, and covalency increases through the bromides to the iodides.

Oxides. The monoxide of tin (SnO) is produced as a blue-black powder when the white hydroxide is dehydrated above 120° C (250° F) in the absence of air. At 550° C (1,020° F) and *in vacuo*, it changes to a red modification. Crystals of tin monoxide have layer structures in which four oxygen atoms lie in a square to one side of each tin atom. The white tin dioxide is obtained by the reaction of oxygen with the metal or the monoxide at elevated temperature, by the reaction of concentrated nitric acid with the metal, by the dehydration of the hydrous precipitate obtained by treating a tin(IV) halide solution with alkali, or by the hydrolysis of a tin(IV) halide or stannate(IV) solution.

Sulfides. Brown tin(II) sulfied (SnS) is precipitated by hydrogen sulfide from mildly acidic tin(II) chloride solution, and yellow tin(IV) sulfide (SnS_2) is precipitated from somewhat more acidic tin(IV) chloride solution. The latter is obtained as golden platelets, useful as a bronzing pigment, by direct reaction of the elements.

Complexes. Both tin(II) and tin(IV) complexes are numerous and include the species $[Sn_3(OH)_4]^{2+}$ and $[Sn(OH)_6]^{2-}$.

LEAD AND ITS COMPOUNDS

The symbol Pb for lead is an abbreviation of the Latin word for lead, *plumbum*.

Occurrence and distribution of the element. On a weight basis, lead has nearly the same abundance in the earth's crust as tin. Cosmically, there is 0.47 lead atom per 10^6 silicon atoms. The cosmic abundance is comparable with those of cesium, praseodymium, hafnium, and tungsten, each of which is regarded as a reasonably scarce element. Lead is formed both by neutron-absorption processes and the decay of radionuclides of heavier elements. Stable lead nuclides are the end products of radioactive decay in the three natural decay series: uranium (decays to lead-206), thorium (decays to lead-208), and actinium (decays to lead-207).

Although lead is not abundant, natural concentration processes have resulted in substantial deposits of commercial significance, particularly in the United States, but also in Canada, Africa, Australia, Spain, Germany, and South America. Significant deposits are found in the U.S. in the western states and the Mississippi Valley. Elemental lead is only rarely found in nature. The major minerals are galena (PbS), anglesite ($PbSO_4$), and cerussite ($PbCO_3$). (For commercial production see LEAD PRODUCTS AND PRODUCTION.)

Properties of the element. The major physical and chemical properties of lead and their relationships to electronic configuration and position in the periodic table have been summarized earlier. Only a single crystalline modification, with a close-packed metallic lattice, is known. Properties that are responsible for the many uses of elemental lead include its ductility, ease of welding, low melting point, high density, and ability to absorb gamma radiation and X-radiation. Molten lead is an excellent solvent and collector for elemental silver and gold. The structural applications of lead are limited by its low tensile and fatigue strengths and its tendency to flow even when only lightly loaded. Elemental lead can be oxidized to lead(II) ion by hydrogen ion, but the insolubility of most lead(II) salts makes lead resistant to attack by many acids. Oxidation under alkaline conditions is easier to effect and is favoured by the formation of the soluble lead(II) species. Lead(IV) oxide is among the stronger oxidizing agents in acidic solution, but it is comparatively weak in alkaline solution. The ease of oxidation of lead is enhanced by complex formation. The electrodeposition of lead is best effected from aqueous solutions containing lead(II) hexafluorosilicate(IV) and hexafluorosilicic acid.

Useful physical properties of lead

Hydrides and halides. All intermetallic compounds of lead are alloy-like with metallic properties.

The only lead(IV) hydride reported is monoplumbane (PbH_4), which is so unstable that no properties have been measured.

The lead(II) halides are all crystalline solids, the melting points of which generally decrease with increasing molecular weight (lead fluoride, 818° C [1,504° F]; lead chloride, 501° C [934° F]; lead bromide, 373° C [703° F]; lead iodide, 303° C [577° F]). The iodide is golden yellow; the others are colourless. Each is difficultly soluble in cold water. In the gaseous state, the molecules lead chloride ($PbCl_2$), lead bromide ($PbBr_2$), and lead iodide (PbI_2) have noncollinear structures.

Oxides. The oxides of lead include PbO (lead monoxide, red or yellow), Pb_2O_3 (lead sesquioxide, orange-yellow), Pb_3O_4 (red lead oxide, orange to red), and PbO_2 (lead dioxide, brownish black). The compounds Pb_2O_3 and Pb_3O_4 contain both lead(II) and lead(IV). Red PbO (with tetragonal crystal structure), called litharge, is the stable form of lead (II) oxide at room temperature. At 488° C (910° F), it transforms to the yellow modification (with rhombic crystal structure), called massicot, which has a melting point of 884° C (1,623° F) and boiling point of 1,470° C (2,680° F). Lead(II) oxide is the only stable oxide above 550° C (1,020° F), and all the other oxides lose oxygen when heated to form it. At 500° C (930° F), heating either lead(IV) oxide or lead(II) oxide in air gives Pb_3O_4 (red lead or minium), which is used extensively as a rust-inhibiting paint pigment.

The monoxides of lead are amphoteric (act as either acid or base depending on environment) and dissolve in both acidic and strongly alkaline solutions. Lead(IV) oxide is the active component of the positive plates in the rechargeable lead storage cell.

The only lead sulfide is the compound PbS, melting point 1112° C (2,034° F); both naturally occurring and synthetically produced samples vary in colour from silvery to black with a metallic lustre.

Miscellaneous compounds include the nitrate [$Pb(NO_3)_2$], which is the common, water-soluble salt; the acetate trihydrate [$Pb(C_2H_3O_2)_2 \cdot 3H_2O$], sugar of lead, which is also water soluble; the hexafluorosilicate [$(PbSiF_6) \cdot 2H_2O$], also water soluble; a basic carbonate [$2PbCO_3 \cdot Pb(OH)]_2$, white lead, the classic, universally used white paint pigment; the chromates, chrome yellow ($PbCrO_4$) and chrome red ($PbCrO_4 \cdot PbO$), both important as pigments in rust-inhibiting paints; and the sulfate ($PbSO_4$), which is difficultly soluble in water.

Lead(II) complexes are common; lead(IV) complexes are largely limited to the species $[PbCl_6]^{2-}$ and $[Pb(OH)_6]^{2-}$.

Nuclear properties. Of the radionuclides of lead, the following appear as members of the three natural decay series: (1) thorium series: lead-212; (2) uranium series: lead-214 and lead-210; (3) actinium series: lead-211. The atomic weight of natural lead varies from source to source, depending on its origin by heavier element decay.

(T.Mo.)

Carboniferous Period, Lower

The Carboniferous Period is the time interval between 345,000,000 and 280,000,000 years ago. It therefore comprises approximately 65,000,000 years of the Paleozoic Era, between the earlier Devonian Period (*q.v.*) and the later Permian Period (*q.v.*). It is divided into two parts, the Lower and Upper Carboniferous, which in North America are more often referred to under the names Mississippian and Pennsylvanian.

The Carboniferous System was defined by W.D. Conybeare and J. Phillips in 1822 in England and Wales as a class of rocks that

> . . . will contain not only the great coal deposit itself, but those of the limestone and sandstone also on which it reposes; which, though entitled to the character of distinct formations, are yet so intimately connected with the above, both geographically and geologically, that it is impossible to separate their consideration.

The name refers to the rich deposits in these strata.

The most characteristic biological feature of the Carboniferous is the development of terrestrial fauna. Until the beginning of the Carboniferous, water was the only realm of animal life, and the land was only sparsely inhabited by small plants. With the onset of Carboniferous time, a fauna began to develop on the land that grew ever richer in the course of the succeeding geological periods and moved toward its present complexity. The first dense plant cover on land and the first trees, some reaching heights of up to 30 metres (100 feet), appeared. Favourable geographic and climatic conditions gave rise to immense swamp forests and bogs, from which coal deposits were created. The lush vegetation was accompanied by the first insects and reptiles. Because crawling amphibians inhabited the swamp forests, the Carboniferous is sometimes termed the Amphibian Age.

Lower Carboniferous Time Designations in Europe, the Soviet Union, and North America

Western Europe		U.S.S.R.		North America	
Silesian	Namurian	Middle Carboniferous		Pennsylvanian	
Dinantian	Viséan	Lower Carboniferous	Namurian	Mississippian	Chesterian
			Viséan		Meramecian
	Tournaisian		Tournaisian		Osagian
					Kinderhookian

The term Lower Carboniferous denotes different periods of time in Europe, North America, and the Soviet Union. In Europe the time span treated by this article is termed the Dinantian; in North America the Mississippian; and in the Soviet Union it is simply called Lower Carboniferous. The lower limits of these three designations are approximately contemporaneous, but their upper limits differ (see Table). To the Dinantian is assigned about 25,000,000 years, constituting more than one-third of Carboniferous time. Because the investigation and systematization of the Carboniferous began in western Europe, by convention the Lower Carboniferous is internationally understood to mean the Dinantian. (For further treatment of these intervals, see below *Stratigraphic correlations.*)

Boundaries of Dinantian

The boundaries of the Dinantian are defined by the first appearance of certain molluskan species: its lower limit is based on the occurrence of the cephalopod *Gattendorfia subinvoluta* and its upper limit by that of the cephalopod *Eumorphoceras (Edmooroceras) tornquisti*. The localities in which these index species are commonly found are in Germany in the case of the lower limit and in England and Ireland in the case of the upper.

Lower Carboniferous rocks are primarily derived from marine sediments. Igneous and metamorphic rocks are much less common than sedimentary rocks and are nowhere dominant. The Lower Carboniferous sedimentary rocks contrast with those of most other geological ages by the strong predominance of two basic rock types, which are found in almost all occurrences of Lower Carboniferous strata. These are limestones rich in fossils and clastic rocks.

The noteworthy mineral fuel deposit that is characteristic of the Lower Carboniferous is coal, which is mined in Spitsbergen, the Scottish Midland Valley, and the European part of the Soviet Union. In the United States there are large deposits of petroleum as well as coal in the Lower Carboniferous rocks. Lower Carboniferous limestones are quarried on all the continents. In Scotland the oil shales have limited importance. Economically important ore deposits are not a prominent feature of the Lower Carboniferous. Near coal fields some iron ores of sedimentary origin occur; these are only locally important and were mined mainly in the 19th century.

This article treats the rocks, life, and environments of Lower Carboniferous time. Similar information on subsequent geological history is contained in the article CARBONIFEROUS PERIOD, UPPER. See also COALS and PETROLEUM for information on mineral fuels that formed during the Carboniferous, and CYCLOTHEMS for treatment of the rhythmic sedimentation so characteristic of Carboniferous deposits and coal measures.

LOWER CARBONIFEROUS ROCKS

Lower Carboniferous formations are scarce in the Southern Hemisphere. Marine conditions prevailed only intermittently in parts of South America and Australia. Terrestrial sediments are known at some localities in these regions. Lower Carboniferous rocks are primarily known over wide expanses of the Northern Hemisphere. The sea covered large parts of the present continents and extended far across the continental shields, upon which its deposits have been preserved in their original, near horizontal position.

Deposits on shield areas and in geosynclines

The continental shields were covered by shallow shelf seas in which limestones, several hundred metres in thickness, were formed. In most cases they are rich in fossils. Similar sediments were deposited over regions consisting of Lower Paleozoic rocks. The limestone sediments, which are often in the form of reefs or reef rubble, are called carboniferous limestones (Kohlenkalk) because of their connection to sediments rich in carbon: they underlie coal-bearing sediments or coal seams are embedded in them.

The largest of these Lower Carboniferous shelf regions is in North America; a smaller one is in eastern Europe. In both areas they occur on the continental shields. In North America the Lower Carboniferous shelf sea extended approximately from the Appalachians to the Rocky Mountains, in eastern Europe approximately from Poland to the Urals.

In contrast to the stable shelf regions, unstable, rapidly sinking basins also were sites of sediment deposition. Enormous masses of debris collected in these basins, and after they had been filled, mountains were later created by folding and uplift.

The extensive, deep ocean basins (geosynclines), from which high mountains subsequently arose during the Mesozoic Era are also identifiable in the Lower Carboniferous. The Tethys Geosyncline can be followed from the Mediterranean region through Turkey, Iran, and the Himalayas to Southeast Asia. The Cordilleran Geosyncline, the other principal oceanic trough, followed the north-south orientation of the coasts of North and South America.

Mountains arose from smaller geosynclines during the Upper Carboniferous. The Appalachian Geosyncline in Lower Carboniferous time already was restricted by earlier mountain-building processes. The northern part of this depression, which is preserved in Nova Scotia and New Brunswick, was sufficiently filled with sediments to have become dry land. This is attested by strata that contain freshwater fossils. Farther to the southwest, in Pennsylvania, this condition was not reached until Upper Carboniferous time. Circumstances in central Europe were quite similar at this time. A developing mountain range, extending from France to eastern Germany, supplied coarse debris to subsidence areas in which the coal bogs of the Upper Carboniferous were subsequently created. In the direction of the more stable shelf regions to the west (Belgium, Great Britain, Ireland) and to the east (Poland, Soviet Union), the coarser clastic sediments grade into the predominantly chalky series of the shelf sea.

Limestones, along with lime-rich clay rocks and sandstones, are surely the most widely distributed rocks of the Lower Carboniferous. They were formed almost exclusively in the shelf seas on the margins of the continental shields or over areas solidified before the Carboniferous Period. In many places—*e.g.*, in the European part of the Soviet Union—such series contain economically important coal strata. Less widely distributed, but usually of greater thickness, are the graywackes, sandstones, and clay rocks of the geosynclines.

Coal-bearing strata

Terrestrial deposits are rare in the Lower Carboniferous. Sandy formations are found in South America and Australia, and coal-bearing strata occur in some locations, mostly as forerunners of the Upper Carboniferous coal-bearing series. They appear in the more stable shelf regions (Belgium, Scotland, European part of the Soviet Union) and in the orogenic regions of Nova Scotia and New Brunswick.

The limestone strata in the stable regions and the predominance of clastic rocks such as shales and sandstones in the orogenic regions are the distinctive characteristics of Lower Carboniferous deposits. The thickness of the limestone series is more uniform that that of the sandy sediments of the orogenic facies. In the Northern Hemisphere the limestone is mostly between 500 and 1,000 metres (1,640 and 3,280 feet) thick. The marine series of North America and Great Britain are

about 1,000 metres (3,280 feet) thick, the coal-bearing series of the Moscow Basin about 250 metres (820 feet), and that of the Donetz Basin, in which coal also occurs, more than 1,000 metres (3,280 feet) thick. Marine and nonmarine deposits alternate rhythmically in these coal-bearing strata.

Even over short horizontal distances, the clastic facies vary greatly in thickness. Because these deposits represent debris of local origin they can vary greatly over short distances. In central Europe such deposits are up to 2,000 metres (6,560 feet) thick (Czechoslovakia, Germany); when a less abundant supply of sediment is available, an entire series of strata may be as thin as 500 metres (1,640 feet).

Intrusive and extrusive igneous rocks are of local to regional importance in the Lower Carboniferous. They occur in the geosynclines, on the shelf (Kazakhstan), and in nonmarine areas (Scottish Midland Valley, Eastern Siberia).

Metamorphic rocks from the Dinantian are known principally from the high mountains that originated from the great Cordilleran Geosyncline and from the Eurasian Tethys Geosyncline in Mesozoic or Cenozoic time. Knowledge of these rocks is limited, as they are altered by the high pressures and temperatures of folding and mountain formation. The formation of new minerals and mechanical deformation of the rocks have often altered beyond recognition or destroyed the fossils that would have aided the determination of the age of the rocks.

LOWER CARBONIFEROUS LIFE

The Lower Carboniferous is characterized principally, and especially as compared to that of all older geological formations, by the abundance and variety of its plants. These plants are excellently preserved in the coal-bearing strata. During the course of the Devonian, plants had indeed spread over large areas of the land surface (before this there had been only water plants); but in the Lower Carboniferous, because of particularly favourable climatic conditions, plant coverage was very dense. Trees appeared for the first time, grew to considerable heights, and developed woody trunks.

The Psilophytales, which had constituted a considerable portion of the pre-Carboniferous flora, died out in the Carboniferous. The "coal forests" of the Lower Carboniferous consisted of Lycopodiales, lower vascular plants whose trunks reached heights of 30 metres. High-growing trees with woody trunks also were found among the Articulata, but these also constituted the "reeds" in the vicinity of the coal bogs and in moist locations, including coastal areas. For this reason Articulata are also known from marine deposits, particularly of the detritus facies, although less well preserved.

A very notable advance in terms of evolutionary history was the appearance of the first seed plants (Pteridospermales or Cicadoficiles). Gymnospermae also appeared for the first time, as trees.

Among the algae (thallophytes), only those that precipitate lime are of geological significance. Sea algae existed in great quantity, sometimes forming reefs, and these became part of the limestone facies of the shelf regions.

General character of animal life

In the animal world, the great changes were afoot that led to the fauna of Mesozoic time. In the Carboniferous, animal life followed the plants onto the land. Crossopterygii-like amphibians appeared, inhabiting the swamp-forests; some were more than five metres long.

Of great importance for the history of life on Earth was the first appearance of the Goniatitidae (belonging to the Mollusca) at the lower border of the Carboniferous: these spiral-shelled animals, related to the cuttlefish of the present day, are among the decisive guide fossils for the determination of the age of strata from the beginning of the Carboniferous to the end of the Mesozoic.

In the rest of the animal world no fundamental changes were to be observed. Because of the wide distribution of favourable conditions for Lower Carboniferous life (in the shelf seas large areas were covered with shallow water rich in nutrients and oxygen), a number of animal groups expanded into a great multiplicity of forms. Among the single-celled animals this was true of the Foraminifera; among the Echinodermata, it applied to the crinoids and blastoids, which appear particularly on the North American midcontinent shelf as rock-forming agents. Among the mollusks, snails and mussels were richly developed. Surprisingly, the Brachiopoda declined in number of forms; this group inhabited the same environments as the Mollusca. Whereas they had been present in extraordinary variety in the pre-Carboniferous systems, they were represented by far fewer forms in the Carboniferous. Only the small systematic group of the Productoidea expanded in the Carboniferous; almost all other groups were impoverished. Not until the middle of the Mesozoic did the Brachiopoda again experience something of a heyday before contracting again to the few species that survive today.

In the series containing coal beds in the northeastern United States, in Scotland, and in the European part of the Soviet Union, brackish water and lacustrine (lake-dwelling) organisms were rather widely distributed and numerous for the first time in the Earth's history. The fauna consisted predominantly of mussels, which resembled in structure the brackish-water mussels of today.

The marine fauna known from the Lower Carboniferous constituted a very uniform group. The occurrences on what are now separate continents indicate that the more or less contemporaneous fauna often consists of dissimilar species; endemic species also occur. But at the same time a considerable number of genera are found throughout the world. There were as yet no faunal or floral provinces, which first began to develop in the Upper Carboniferous and which are so clearly delineated today. This uniformity is the more astonishing because similar fauna inhabited regions of dissimilar climate.

The Lower Carboniferous formations of North America, Europe (including Spitsbergen), and North Africa originated in the vicinity of the Equator, in tropical and subtropical climates. In these regions, coal beds are found that were formed in tropical or subtropical swamp forests and bogs during Carboniferous time. On the other hand, the similar marine fauna of eastern Australia must have developed in a significantly colder climate, for in the Upper Carboniferous there appear throughout the southern part of Australia traces of glaciation; this is also true in South Africa and South America.

Marine invertebrate faunas

The fauna contained in limestones, which formed in the shelf regions at the periphery of the continental shields or over substrata consolidated in pre-carboniferous time, consist mainly of benthonic organisms—those living on the ocean floor. Particularly richly developed in these facies are the calcareous algae, which also formed reefs: the Stromatopora, Tabulata, Coralla, and Bryozoa. A variety of forms developed in the Foraminifera, in the productid brachiopods and in the snails and mussels. The trilobites of these facies have not yet been thoroughly studied; the Phillipsiidae and Brachymetopus seem to predominate. Among the Echinodermata, the crinoids and blastoids of the North American midcontinent shelf are well known for their variety and good preservation.

The much poorer fauna of the predominantly clastic facies, which developed in the deeper seas of the orogenic regions, consisted mainly of swimming and floating types of life. The seawater at greater depths was so poorly supplied with oxygen that for the most part only a few specialized species, such as primitive burrowing animals, could live there. With the exception of these, the ocean floor was little inhabited. Cephalopods, relatives of the present-day cuttlefish, are particularly characteristic of these facies, which are also called Culm Facies. Mussels that lived attached to floating seaweed masses, swimming trilobites, and conodonts (*q.v.*) were numerous and widely distributed.

The two types of fauna, the benthonic of the shelf seas and the nektonic-planktonic of the deeper basins, hardly ever occurred together in the same region. The boundaries between shelf and basin are extraordinarily sharp. The compositions of the rocks and of the fauna change almost in a hairbreadth and as far as is known scarcely ever blend. Because the ages of rocks are determined with

the aid of the fossils that they contain, there was great difficulty in finding time relationships between the shelf deposits and the basin deposits. The discovery and study of distinctive microfossils, particularly the foraminifera and conodonts, ultimately made this possible.

STRATIGRAPHIC CORRELATION

Upper and lower boundaries and boundary problems

The limits of the Dinantian (see table) have been defined bindingly at international conferences of experts. Because the stratigraphy of the Lower Carboniferous was first developed in western Europe and because the geological relationships there seemed favourable, the type sections are located in western Europe. The type section for the lower boundary is in West Germany and that for the upper boundary is in England and Ireland. The definition of the upper limit is not questioned but that of the lower limit is in dispute. The disagreement is on questions of principle; in the series of strata the disputed interval seldom amounts to more than 60 metres (192 feet).

In North America the Lower Carboniferous is called the Mississippian, because strata of this age are extensively exposed in the Mississippi Valley and have been known and studied for many years. The lower limit of the Mississippian coincides with the lower limit of the Dinantian, but the Mississippian extends higher, including in its upper part strata, which, according to international terminology, belong to the Namurian Series in the Upper Carboniferous (the Silesian).

The different locations of the boundaries between Lower and Upper Carboniferous in North America, western Europe, and the Soviet Union is due primarily to historical reasons. Formerly, the boundaries between geological units were set at surfaces of discontinuity, at distinct changes of rock type, or at changes in the attitude of bedding. The boundary between the Upper and Lower Carboniferous in North America and western Europe was set at the base of the principal coal formation. In North America, with the exception of the Lower Carboniferous beds in Nova Scotia and New Brunswick, the age of this stratum was younger than in the "classical" region of western Europe (Belgium). Furthermore, in North America this change of facies is associated with an evident hiatus or gap in the series of strata, an elevation of a broad region above sea level, and mild folding. A hiatus in the series of strata also is found over a wide area in the Soviet Union.

Within the Lower Carboniferous, shelf facies sedimentation is often discontinuous. This applies particularly to the North American midcontinent shelf and presumably to the Soviet Union as well. Such gaps in the strata make the determination of series difficult because the succession is interrupted. The shoreline and bottom of the sea that covered North America and the European part of the Soviet Union was very sensitive to movements of the sea floor or alterations of the sea level because of its shallow character. Small local uplifts were sufficient to cause the formation of sea-floor rises or islands, and small local subsidences caused great distinctions between somewhat deeper basins and the shallower areas. Also, of course, the position of the shorelines changed, and this produced shifts in the boundary between marine and nonmarine sediments.

In the upper part of the Mississippian, shallow-water formations become more frequent and are interbedded with more widely distributed clastic sediments. This suggests an increase in the energy of the environment with respect to erosion and transportation of sediment. The tectonic phase that uplifted and mildly folded large parts of the North American sedimentation realm began at this time. In the Pennsylvanian, a completely new geological situation began.

Weak tectonic movements occurred in Europe at this time. In western Europe, the Dinantian strata were not folded until the Upper Carboniferous or later.

The Asiatic Dinantian is scarcely folded at the edge of the continental shield. Metamorphic remains of Lower Carboniferous strata are known from the Himalayas, but the exact time of the folding and alteration is not certain.

In eastern Australia the Carboniferous strata proceed without any break from the Devonian. The transitional strata are without fossils, however, and thus the position of the boundary cannot be established precisely. The upper boundary of the Dinantian also cannot be determined. In the upper part of the Lower Carboniferous, the sediments in the New England Geosyncline become successively more coarse grained, and the latest sediments, from approximately the end of the Namurian, show signs of terrestrial origin.

LOWER CARBONIFEROUS PALEOGEOGRAPHY

When the contemporaneity of Lower Carboniferous rocks is established it is possible to map the distribution of land and sea at this time in the past; however, terrestrial deposits are less often preserved than marine deposits because they tend to be removed by erosion. Their location and boundaries can only be inferred from some erosional remnants. It must be remembered that over large areas of the Earth's surface the Lower Carboniferous marine formations also have undergone erosion or have been masked by younger sediments. Finally, there are other areas of the Earth that are still really unknown geologically. Reconstructions of the distribution of land and sea in Lower Carboniferous time must, therefore, be understood as being to a large degree hypothetical.

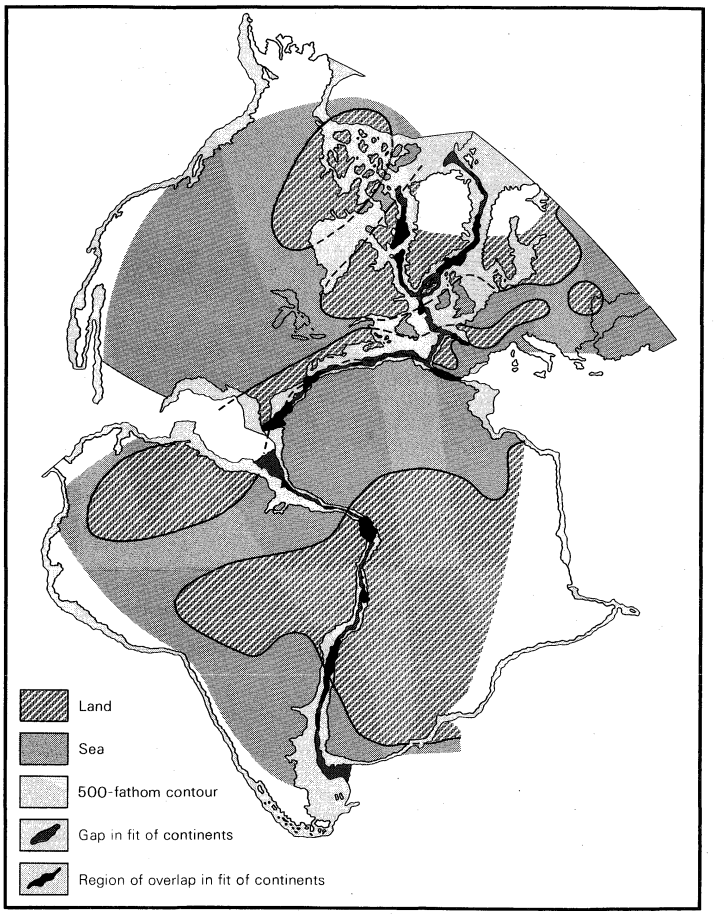

Figure 1: Distribution of land and sea bordering on the Atlantic Ocean in Lower Carboniferous time, plotted on a predrift reconstruction of continents. The fit is at the 500-fathom contour.

Figures 1 and 2 show the present conception of Lower Carboniferous paleogeography. The maps show the greatest extent of the sea during this period. In the course of time, the sea retreated more and more, particularly from the southern continents.

Figure 1 shows the continents bordering upon the Atlantic in their probable relative positions in the Lower Carboniferous. The connection across the Atlantic is difficult to demonstrate. The continuity of the upland ridge from the Appalachians to Bohemia is uncertain. The upland ridge need not be assumed to be a continuous moun-

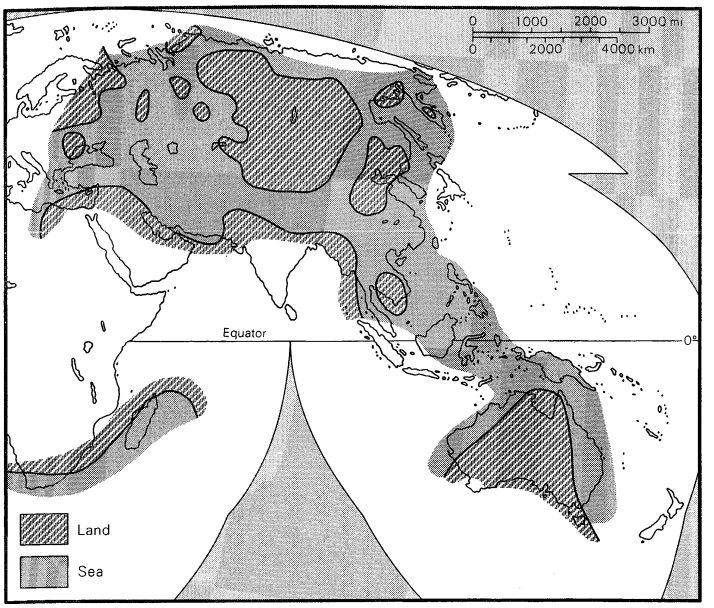

Figure 2: Distribution of land and sea in the Eastern Hemisphere during Lower Carboniferous time.

tain range but rather an uplift zone, which might be divided into sections and in some places covered by the ocean. The geological development and the nature and distribution of the fossils on the (northern) edge of the Appalachian-Bohemian uplift are so similar, however, that the assumption of a genetic connection appears justified.

Carboniferous Period, Upper

Definition and general nature of the record

The name Carboniferous is derived from coal-bearing strata in the type areas of England and Wales that form the upper part of the sequence described as "Carboniferous" by the British geologists William Conybeare and William Phillips in 1822. The Carboniferous is part of the Paleozoic Era of Earth history, which occurred from 225,000,000 to 570,000,000 years ago. The Upper Carboniferous refers to the rocks deposited during the time interval from about 315,000,000 to 280,000,000 years ago. It roughly coincides in time, and usage, with the Pennsylvanian Period, a name that is particularly applied to the time of formation of rocks of the same age in North America (see further GEOLOGICAL TIME SCALE). Boundaries of this system of rocks have been established by the International Congress of Carboniferous Stratigraphy and Geology. The base, or lowermost strata, of the Upper Carboniferous is defined by the first occurrence of the cephalopod species *Eumorphoceras (Edmoroceras) tornquisti*. There is no generally accepted definition of the upper limit. A variety of changes of floral and faunal assemblages occur and are useful in restricted regions, but are probably not strictly synchronous.

In Europe, North America, Australia, and to a much lesser extent North Africa, the Upper Carboniferous and overlying Permian strata contain a huge volume of coals —the greatest such concentration in the Earth's history. This can be related to the great Variscan (Hercynian) orogenic (mountain-building) episode that, in Carboniferous time, created new mountain chains flanked by deep sedimentary basins. Late in Carboniferous time, sediments from these new mountains had filled the associated basins, producing large flat areas near sea level and similar areas within some of the mountain-belt zones. These developments coincided with an explosive evolution of land plants and, following plant decomposition, with enormous accumulations of peat, especially in the equatorial regions during Late Carboniferous time. The peats were subsequently compressed and petrified, and thus became coals.

The southern continents were still united as the single landmass called Gondwana (see below) during Carboniferous time. This supercontinent was glaciated, and fossil moraines and tillites—ice-transported sedimentary deposits of clay, silt, sand, and gravel—are widespread in the southern continents today. There the Carboniferous and Permian strata are continuous in character, and the Northern Hemisphere's index fossils are lacking. It is often convenient to regard the "Permo-Carboniferous" of the southern continents as a single rock system.

Deposits of epicontinental (shallow) seas are preserved in the southern midcontinent region of North America, on the Russian Platform, and in eastern Asia. They include large volumes of fossiliferous limestone. The areas receiving shallow-water, calcareous sediment were, however, much restricted compared with pre-Upper Carboniferous sites of marine deposition.

Deposits of economic significance

The most significant economic deposits of the Upper Carboniferous are coals. An estimated 3×10^{12} metric tons, the major part of the Earth's coal reserves, occurs in Carboniferous strata and, to some extent, in Permian deposits. The process by which peat becomes coal frees large quantities of natural gas, and this can migrate into any suitably porous rocks that are available. This relationship, with Upper Carboniferous coals serving as the gas source, has been proved to hold for gas fields in The Netherlands, Germany, and the North Sea. Upper Carboniferous sandstones in Oklahoma and Montana are important reservoirs of oil.

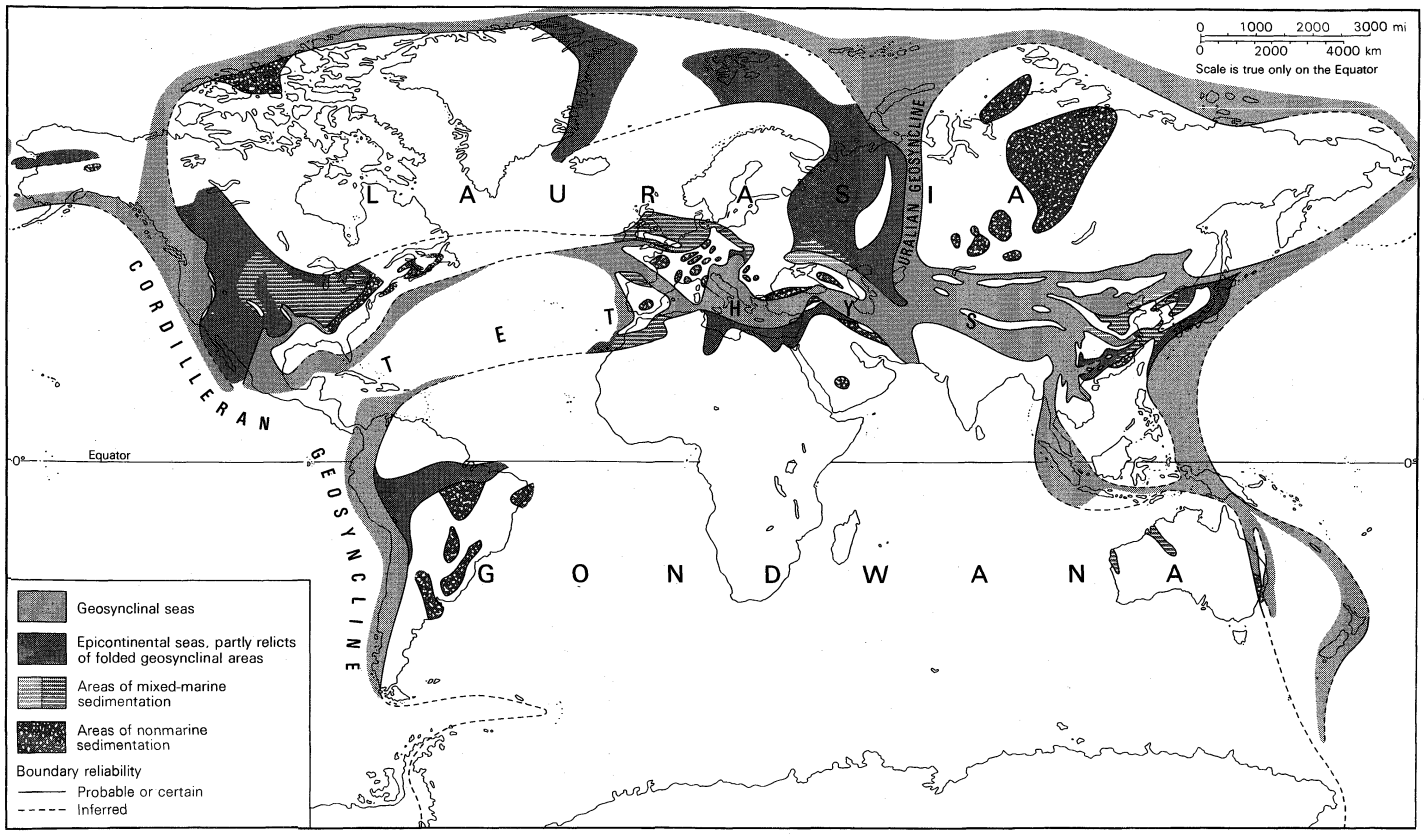
Occurrences of metallic ores in Europe, Asia, and Australia are related to large granite masses that were emplaced in the folded rocks that formed during the Late Carboniferous or Early Permian mountain-building episodes. Metal-bearing solutions deposited gold, silver, lead, copper, tin, zinc, tungsten, bismuth, and other metals. Only the tin ores of Southeast Asia are still economically important on a world scale however. But it should be remembered that the European ore fields in Cornwall (England), Germany, France, and Spain stimulated the development of the classical mining techniques, and from this geology emerged as a science.

This article treats the rocks, life forms, and paleogeography of the Upper Carboniferous. For additional information on prior and subsequent geological time intervals, see CARBONIFEROUS PERIOD, LOWER; PERMIAN PERIOD. See also EARTH, GEOLOGICAL HISTORY OF and PALEOZOIC ERA, UPPER for the relation of Upper Carboniferous events to Earth history in general. Further detail on life forms is presented in the article FOSSIL RECORD, and aspects of the correlation of sedimentary rocks and the elucidation of ancient environments are covered in the articles STRATIGRAPHIC BOUNDARIES; SEDIMENTARY FACIES; and PALEOGEOGRAPHY.

UPPER CARBONIFEROUS ROCKS

Geographic framework. The geography during the Upper Carboniferous Period was very different from that of the present. The continental masses that exist today were arranged in two great supercontinents. The Gondwana supercontinent comprised South America, Africa, Antarctica, Australia, and India south of the Himalayas. The present shapes of these fit almost perfectly (eastern South America to West Africa, South Australia to Antarctica, Western Australia to eastern India), and much geological and geophysical evidence supports the con-

Gondwana and continental drift



Distribution of lands and seas during Upper Carboniferous time.

cept that they did once fit together. No record of oceanic geography can, therefore, be expected to occur within this mass. It was a continental shield (stable continental nucleus) overlapped by the seas only peripherally, at its margins. Similarly, North America, Greenland, and western Europe were united. The position held by Asia relative to Europe is not certain. Asia appears to have been subject to rifting (separation) along north-south lines. An oceanic area still existed along the site of the Urals during Late Carboniferous time.

The Gondwana supercontinent centred on the South Pole. The North Pole was situated in the northern Pacific Ocean area, close to Siberia. The great ocean, called Tethys, which intervened between the two supercontinents, occupied equatorial latitudes. Tethys extended in an east-west direction from China to Spain and into the Caribbean. This major oceanic area of Carboniferous time later suffered reduction as the continents drifted and the sediments in this seaway were folded and uplifted to form new mountain chains.

Within this general geographical framework the Upper Carboniferous sediments accumulated as epicontinental deposits (marginal deposits in shallow areas) or as the fill received by basins flanking the major supercontinental blocs. Many of the Upper Carboniferous rocks originated in a system of basins that extended from western South America to southern Africa, and thence, probably, to western Antarctica and eastern Australia, thus girdling Gondwana. Branches of Tethys extended into central and western Europe and probably also into the site of the present Appalachian Mountains. Adjacent continental platforms (*e.g.*, the Russian Platform and a large part of North Africa) were covered by shallow areas.

The northern continents, like the southern, consisted of the one mass flanked by oceanic basins. But it is obvious that an elongate basin feature along the site of the Urals effected a connection of Tethys and the Arctic. The northern supercontinent (the so-called Laurasia) was thus divided into a western shield (comprising parts of Canada, Newfoundland, Greenland, northern Britain, Scandinavia, and the Baltic region) and an eastern shield (the Siberian platforms).

Sedimentary rocks. The Upper Carboniferous rocks for the most part document sedimentation in basins bordering the continents or on the stable platforms. The rapid crustal movements of Late Carboniferous time permitted local accumulation of great thickness of sediment. The basin sediments are of graywacke character (a type of sandstone with a clay-rich matrix; see further GRAYWACKES) where deepwater situations existed, or, where the deliveries of sediment outdid the ability of crustal subsidence to accommodate them, the upper surface of the sedimentary pile would remain close to sea level, resulting in a mixed, marine-nonmarine (paralic) sedimentary succession. Many of the mixed marine series grade landward into deltaic deposits and into dominantly marine sediments seaward. An example is found in the western slope of the Appalachians. The thin veneers of epicontinental marine sediments formed on the stable platforms consist predominantly of limestones and sandstones.

Graywackes. The Upper Carboniferous graywackes owe their character to the availability of bold relief at the time of their formation. Material derived from uplifted welts (narrow, geosynclinal folds) was deposited rapidly in deltaic flats and on narrow shelves bordering the subsiding basins. Where these piles of sediment locally exceeded the natural angle of rest or stability in the face of gravitational forces on slopes, the unconsolidated material on the continental shelves would collapse, be transformed into a relatively high density suspension, and would travel into the basins as high-velocity turbidity currents, a variety of density currents, in which the density results from large quantities of sediment carried in suspension. The resulting basin deposits are poorly sorted. They consist of angular grains of quartz, feldspar, and mica, together with fragments of previously existing igneous, metamorphic, or sedimentary rock. They may also include mud pebbles. Individual graywacke beds have a distinct grading, with a continuous decrease of grain size from bottom to top. Intervening between graywacke beds are fine-grained shales that represent slow, permanent, background sedimentation of the basin.

Implications of relief

Mixed marine series. Many coalfields formed under paralic conditions, and rocks of paralic type are even more widespread. They consist of thick beds of shale, sandstone, and sometimes limestone, interbedded with relatively thin coal seams that form only a small percentage of the total thickness. The succession of rocks and faunas is not random, but cyclic. Marine shales immediately overlie the coal seams, and the sequence then returns to terrestrial sandstone deposition with a new underclay and then a seam, which may or may not be overlain by marine rocks of the next transgression. Rhythmic sequences are called cyclothems (*q.v.*), and those of considerable thickness (several thousand metres), which can include more than a hundred seams, commonly occur in the large coalfields of the world.

Paralic sequences are often regarded as brackish water sediments but are more correctly termed mixed marine. Typical mixed marine sequences have been described from coalfields in North America, England and Wales, northern France, Belgium, The Netherlands, Germany, the Soviet Union, and North Africa. Similar rhythmic sequences are known from eastern Australia and other localities. The character of the mixed marine series, because it is so widespread and continuous over large areas, is so striking that some geologists have tried to attribute this type of sedimentation to recurrent global or even cosmic events. Thin layers of volcanic ash in some sequences yield reliable time checks, however, and show that the rhythmic cycles are not entirely synchronous.

Intermontane sequences. The intermontane basins contain sequences of clastic sediments (sandstones and relatively coarse sedimentary rock types) and coals that are somewhat similar to paralic cycles, but are less well differentiated. They are, in most cases, rich in plant and nonmarine fossils. Classical coalfields of the intermontane type occur in the northeasterly trending Variscan fold belt in western Europe and along the east coast of North America (in the Rhode Island and Acadian basins).

Limestones. Deposition of fossiliferous limestones occurred on continental shelves, if they were relatively stable, and generally in epicontinental or shallow sea areas. The calcareous sequences often show evidence of discontinuous sedimentation, with reworking (erosion and redeposition), interbedded conglomerates, and times of nondeposition. Shallow-water fossils are abundant in some areas. They include calcareous algae, large fusulinids—wheat-grain-like foraminiferans, and brachiopods. Echinoderms are rare by comparison with the Lower Carboniferous limestones.

Shallow-water limestones are found in the midwestern United States, on the Russian Platform, and in China and Southeast Asia. In some places limestones are interbedded with mixed marine sequences, as in the Donets Basin in the Soviet Union and in parts of England.

Evaporites and terrestrial sediments. In equatorial latitudes, the deposition of evaporites (sedimentary rocks formed by precipitation of salts from saline waters) under arid conditions began in the Upper Carboniferous but, generally, reached its maximum within the Permian. In the basins of North Dakota–Montana and southeast Utah–southwest Colorado of the United States, crustal movements during Pennsylvanian time produced conditions that favoured the accumulation of salts (of Upper Carboniferous and later age) in isolated basins.

Terrestrial sediments were deposited near the newly formed mountain chains, mostly as alluvial fans, fan-shaped accumulations of gravel, sand, and silt deposited by streams draining mountain basins. They grade into deltaic and mixed marine sediments toward the open sea.

A different type of terrestrial sediment formed in polar areas. Some conglomerates and sandstones and tillites of the great Permo-Carboniferous glaciation are locally regarded as Carboniferous. No definite proof exists, however, because guide fossils are lacking.

Igneous and metamorphic rocks. Rapid crustal development occurred during the Upper Carboniferous Period. The zones of the crust that had undergone geosynclinal development (subsidence and filling with sediment) during the Devonian and Lower Carboniferous periods (between 395,000,000 and 315,000,000 years ago) were progressively stabilized by folding, regional metamorphism (alteration by heat and pressure), igneous intrusion, and uplift. Orogenic belts originated in nearly all geosynclinal areas of the world, but the actual time of the folding varied considerably from one geosyncline to the other, as well as within the zone occupied by an individual geosyncline.

Hercynian and Alpine deformation

In North America, the Appalachian Mountains formed along the east coast of the continent. The folding, here, as elsewhere in the world, is called Hercynian with reference to events of this time. It was gradational from north to south and ended with the Wichita and Ouachita orogenies along the Gulf Coast of the continent. The Western Cordillera (site of the present Rocky Mountains) also contains cores of this Hercynian deformation, but the whole area experienced a second and much stronger orogeny during Mesozoic times (between 225,000,000 and 65,000,000 years ago). Hercynian structures that are parallel to the coast are known from various localities up to Alaska. These structures continue into northeastern Asia. Hercynian deformation is also present in South America, where it follows the trend of the Cordillera from Venezuela to western Argentina, and from there across the continent to the La Plata region. This Paleozoic fold belt very probably was continuous with the existing folds in the Cape district of South Africa.

The largest mountain system, however, formed in Asia and Europe. Garlands of Hercynian fold chains surround the stable blocks of Siberia along the Pacific coast, the Japanese islands, and China, extending into the giant chains of Central Asia, which continue toward the south in the mountains of Southeast Asia and toward the north in the Urals. With the folding of the Uralian Geosyncline, eastern Asia was joined to Europe during Upper Carboniferous time, and the old north–south arm of the ocean was closed.

South of the Urals the Hercynian chains continue through the Hindu Kush and Elburz mountains into Turkey. The tectonic structures of central and western Europe are greatly complicated by a large number of local arches, by rapidly changing degrees of deformation, and metamorphism.

Most of the Asian and European mountain belts were produced by the great Alpine orogeny of Tertiary age (between 65,000,000 and 2,500,000 years ago), which affected even larger areas than the Hercynian and produced greater deformation, but which in general followed the grain of the Hercynian orogeny. The Alpine orogeny complicated certain of the Hercynian structures by folding and metamorphosing the rocks a second time. Another system of mountains was formed by folding and uplift along the eastern coast of Australia and in New Zealand. This continued to Antarctica and was probably connected to the South American Cordillera (site of the present Andes Mountains).

The Hercynian orogeny was accompanied by the typical cycle of volcanism during initial geosynclinal activity (mostly submarine effusions) and post-orogenetic intrusion of igenous rocks that may result in the emplacement of enormous granitic plutons. Regional metamorphism may accompany these intrusions. In Upper Carboniferous time most of the geosynclinal volcanism was already over. Important volcanic rocks are known only from the western geosyncline of North America and from China, Japan, and Kashmir. Granitic intrusions and metamorphism are widespread, but the exact age relations are not easily determined, especially in areas affected by later diastrophism. Absolute age determinations by radiometric methods are important for identifying Hercynian granites and metamorphic rocks.

UPPER CARBONIFEROUS LIFE

Life forms and their distinctive character

Many of the Upper Carboniferous life forms represent a stable continuation of previously established groups. This was the case with such marine invertebrate groups as corals (especially the tabulates), brachiopods, lamellibranchs, gastropods, nautiloids, orthoceratids, and crinoids. Limulids achieved their characteristic form.

Evolutionary trends and index fossils. Protozoans appeared for the first time in relatively large forms, up to 15 millimetres (0.6 inch) long. These fusulinids were abundant and widely distributed. Often they contributed a large part of the content of limestones. A group of coiled decapods, the goniatites, developed steadily (thus providing for a suite of useful guide fossils), and, toward the end of Carboniferous time, forms transitional to the Mesozoic ammonites appeared.

Active sharklike fishes dominated the seas. There was rapid development of the ancestors of modern fishes, the paleoniscids. Large amphibians inhabited the coal swamps. Prominent among them were the plump labyrinthodonts and the slender leptospondyls. The first reptiles appeared in Late Carboniferous time. The greatest advances occurred among the plants. Algae formed much of the bulk of certain limestones because reef-building corals were essentially absent. Enormous swamps covering vast areas had well-developed associations of lycopsids, ferns, articulates, and cordaites. Their height was comparable to that of modern trees. Minor species of climbing or submerged habits were also present. Mosses were not important in this association.

The groups that combine wide distribution and rapid changes of form are utilized as guide, or index, fossils for correlation purposes. The preferred Upper Carboniferous groups are the goniatites of the open seas, the fusulinid foraminiferids of the shelf seas, and the higher plants on land. Each of these groups is restricted to its own environment, and it is, therefore, difficult to match the three schemes of indices. Recently, conodonts (small, toothlike, enigmatic fossils) also have revealed themselves to be useful index fossils, and they occur in abundance in open sea and epicontinental marine sediments as well as in marine transgression portions of the paralic succession of sediments.

Goniatites, fusulinids, and fossil plants

The suite of goniatites has the genera *Eumorphoceras*, *Homoceras*, *Reticuloceras*, *Gastrioceras*, *Anthracoceras*, and *Schistoceras*. The Carboniferous–Permian boundary may be set at the first appearance of *Properrinites*.

The fusulinid sequence begins in the Lower Carboniferous with *Millerella* and continues with *Profusulinella*, *Fusulinella*, *Fusulina*, and *Triticites*. *Pseudoschwagerina* marks the beginning of the Permian. These forms are identified by internal characteristics that must be examined in thin sections.

Fossil plants also are difficult to deal with, in this case because it is usual to find only parts of plant fronds, stems, and rhizomes. Individual parts were given names before the composition of the whole plant was known. The taxonomy of fossil plants is, therefore, complex. Also, plants are subject to local climatic controls, such as humidity. An observed change in fossil-plant associations may have been caused by ecological factors. The proliferative organs such as spores, on the other hand, are distributed freely by the wind and can be found fossilized in rocks that contain no larger plant material —for example, in marine shales. The importance of spores as guide fossils is rapidly increasing.

Faunal realms and migrations. No distinct faunal realms can be recognized at present. Plants break down into local regimes in Late Carboniferous times, presumably because of climatic deterioration. There are artificial sources of confusion in this matter. Paleontologists, if they neglect work done in other countries, may create "nomenclatorial" provinces (see correlation chart: plant zonation). Problems of this kind are known and their solution requires much time and effort.

STRATIGRAPHIC CORRELATION

Boundary and correlation problems. In the type areas in Europe a notable change of facies (rock type and associated environmental factors) occurs within the Carboniferous. Marine limestones change to black shales, siltstones, and graywackes. The separation of Lower and Upper Carboniferous is based on this change. The lowermost unit of the Upper Carboniferous is named Namurian after the type area in the Namur Basin of Belgium. The facies change, it is now known, is not strictly isochronous (*e.g.*, the sedimentary formations involved are not precisely of the same age—they are not time correlative) within Europe. Furthermore, it is known that the boundary defined in Belgium does not correspond with the Mississippian–Pennsylvanian boundary in North America—this is set later in time. The major change of facies is not in evidence in eastern Europe. Soviet geologists favour a three-fold subdivision of the Carboniferous and recognize a "Middle Carboniferous" that is roughly equivalent to the Lower and Middle Pennsylvanian.

The upper limit of the Carboniferous is not clearly defined. The Late Carboniferous was a time of drastic tectonic and climatic change. Nowhere is there a continuous record of Carboniferous to Permian pelagic (deepwater) sedimentation. Many local definitions of the Permo–Carboniferous boundary exist, but it is unlikely that the various definitions employed in intermontane basins and shallow marine areas will be found to match one another.

The major stratigraphical subdivisions of the Upper Carboniferous are shown on the correlation chart. In regions with continental and mixed-marine sediments, correlation is based on lithological evidence, and the boundaries are drawn at coal seams, layers of volcanic ash, or the beginnings of major sedimentary cycles. The correlation is controlled by the paleontological evidence available from interbedded marine or plant-bearing deposits. In marine areas with no widely effective, contemporaneous changes of sedimentary conditions, the stratigraphical subdivisions depend directly on the evidence of fossils. There is much work still to be done in improving intercontinental correlations of the units.

Mississippian-Pennsylvanian boundary

Unconformities and gaps in the record. The effect of an unconformity (discontinuous sedimentation) is best illustrated by the case of the pre-Pennsylvanian break in the midcontinent area of the United States. The boundary between the Mississippian and Pennsylvanian periods is placed at the surface of unconformity. The base of the Pennsylvanian is not everywhere of the same age, however, because of local accidents of renewal of deposition after the uplift and the erosion that produced the discontinuity.

Until recent years it was thought that orogenic events were catastrophic, concentrated in short passages of time, and worldwide in their effect. It is now generally accepted that deformation and uplift in orogenic zones is an evolutionary process that may occupy an interval as long as a geological period or more. Unconformities, therefore, can no longer be assumed to record widespread contemporaneous events.

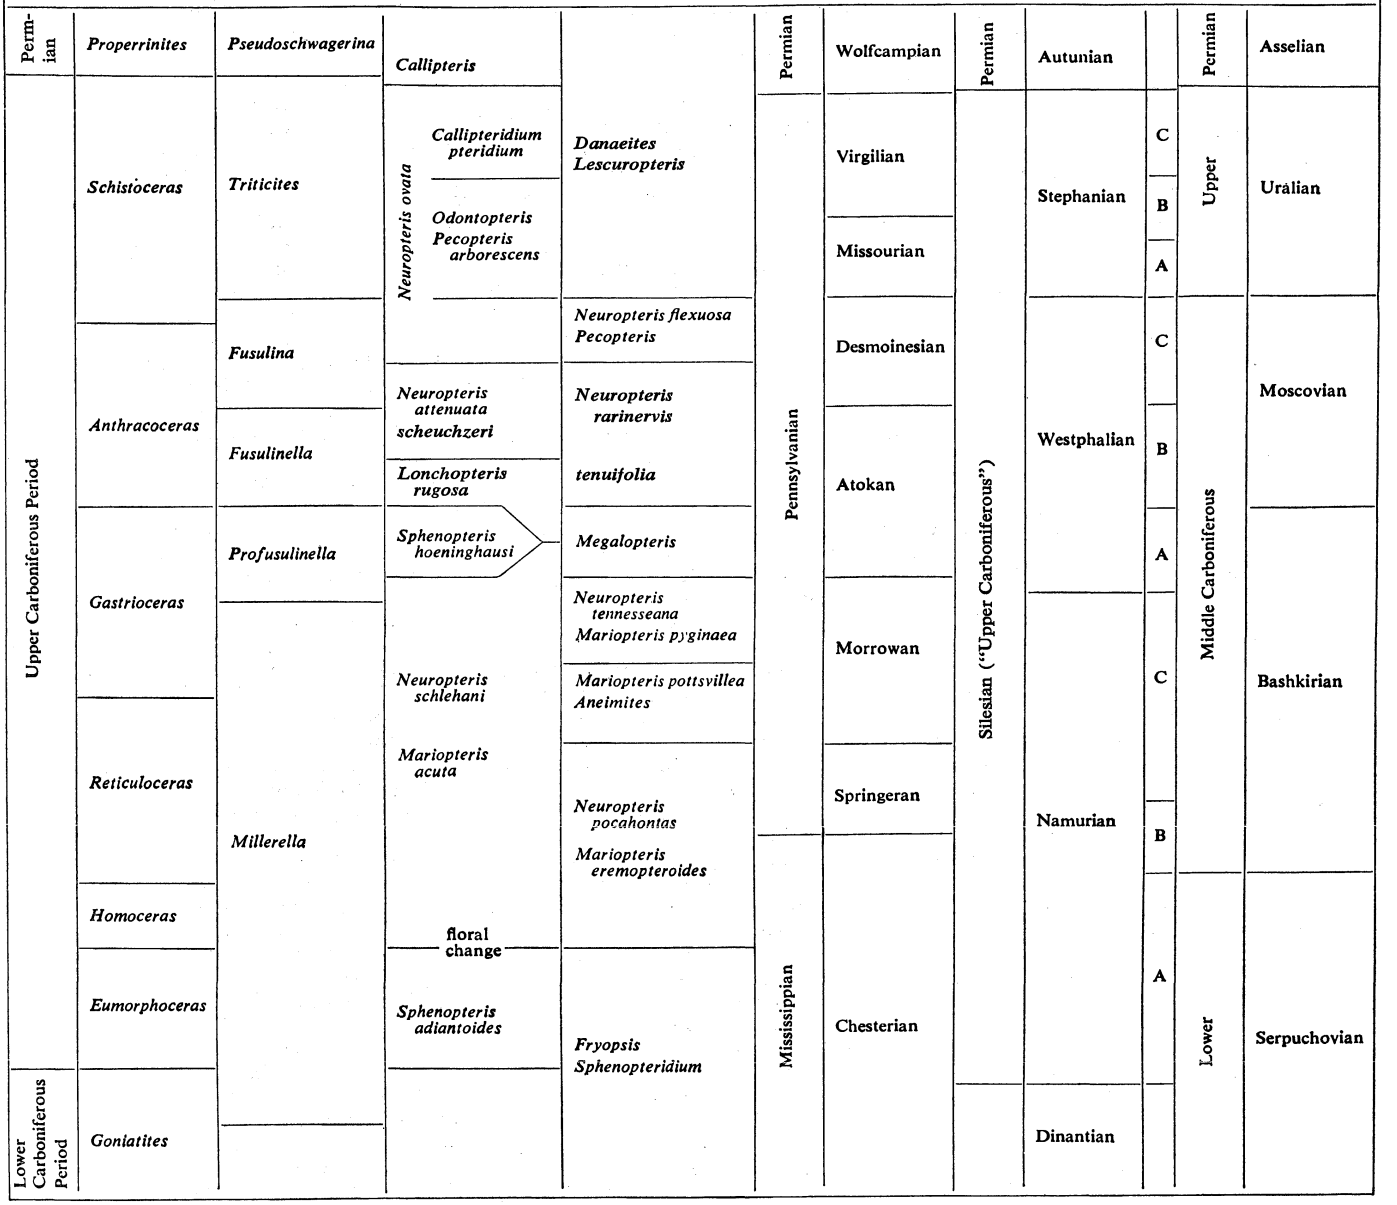
Gaps between Lower and Upper Carboniferous rocks exist in many parts of the world. The Carboniferous of the Himalayas and Southeast Asia down to Burma, for instance, is reported to include such a break. It is not unlikely that the unconformity on that regional scale will later be resolved into a number of local and individual breaks, as has happened in areas now intensively surveyed, such as the southeastern United States. Countless local breaks are known in areas of epicontinental, shallow-water sedimentation. In such cases (there are many examples in the American midcontinent), the Upper Carboniferous record is reduced to thin occurrences of heterogeneous and discontinuously developed sedimentary rocks.

UPPER CARBONIFEROUS CLIMATES

Floral indication of climatic change

A remarkable differentiation of climate begins within the Upper Carboniferous Period as indicated by the development of circumpolar floral assemblages (the southern, or Gondwana, and northern, or Angara, types), which contrast with the more equatorial floras. This differentiation increased during the Upper Carboniferous and resulted in a broad equatorial zone with arid conditions, reddish-coloured and other desert deposits, and evaporites, while at the same time the greater part of Australia, the eastern part of South America, Africa south of the present Equator, India, and Antarctica were covered by a polar ice cap. Little is known about the north pole of these times. Some indications of a cold, arid climate have recently been reported from evidence in the Upper Carboniferous

Upper Carboniferous Biostratigraphical Units



rocks of east Siberia. The maximum climatic differentiation occurred in the Permian Period.

The reason for this worldwide change of climate is not well understood. It was, however, preceded by a rapid shift of the magnetic poles and by extensive modifications of the configuration of the continents and oceans resulting from the worldwide Hercynian orogeny. The process of evolution of the Earth's crust may, therefore, have been the most effective cause of climatic and biological evolution during Upper Carboniferous time.

BIBLIOGRAPHY. Comprehensive books and monographs on the distribution and regional aspects of Upper Carboniferous formations include: G.M. BENNISON and A.E. WRIGHT, *The Geological History of the British Isles* (1969); D.A. BROWN, K.S.W. CAMPBELL, and K.A.W. CROOK, *The Geological Evolution of Australia and New Zealand* (1968); T.H. CLARK and C.W. STEARN, *The Geological Evolution of North America* (1960); R. FURON, *Géologie de l'Afrique*, 3rd ed. rev. (1968); S.H. HAUGHTON, *Geological History of Southern Africa* (1969); M. MINATO *et al.* (eds.), *The Geologic Development of the Japanese Islands* (1965); D.H. RAYNER, *The Stratigraphy of the British Isles* (1967); M.G. RUTTEN, *The Geology of Western Europe* (1969); and H.R. WANLESS, "Marine and Non-Marine Facies of the Upper Carboniferous of North America," *6th Congr. Int. Stratigr. Géol. Carbonifère, Compte Rendu*, 1: 293–336 (1969). Periodical reports on Carboniferous stratigraphy and geology are presented in *Congrès International de Stratigraphie et de Géologie du Carbonifère, Compte Rendu* (Heerlen, 1927, 1935, 1958; Paris, 1963; Sheffield, 1967; Krefeld, 1971).

Books presenting information on the background of Upper Carboniferous history that are of general interest include: A.L. DU TOIT, *Our Wandering Continents: An Hypothesis of Continental Drifting* (1937); B. KUMMEL, *History of the Earth* (1961); M. SCHWARZBACH, *Das Klima der Vorzeit*, 2nd ed. (1961); and A. WEGENER, *Die Entstehung der Kontinente und Ozeane*, 3rd ed. (1922; Eng. trans., *The Origin of Continents and Oceans*, 1924).

(D.M.)

Carbonium Ions

Carbonium ions are carbon-containing molecules with positive charges (cations). Certain carbonium ions can be prepared in such a way that they are stable enough for study; more frequently, however, they are only short-

lived transient forms (intermediates) occurring in the course of chemical reactions.

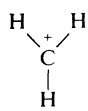
Carbonium ions are, in fact, one of the most common classes of intermediates in organic reactions, and knowledge of the structures and properties of these substances is fundamental to the understanding of the reactions in which they occur. Many of these reactions are of great synthetic, biochemical or industrial importance.

Discovery of carbonium ions as intermediates

The first carbonium ions (called triarylmethyl compounds) were observed in 1901, and their saltlike character was discerned shortly afterward. It was not until 21 years later, however, that the German chemist Hans Meerwein concluded that a neutral product (isobornyl chloride) was formed from a neutral reactant (camphene hydrochloride) by rearrangement involving a carbonium ion intermediate. This was the first conceptualization of a carbonium ion as an intermediate in an organic rearrangement reaction. The idea was generalized by the U.S. chemist Frank Clifford Whitmore from 1932 onward and placed on a firm experimental basis by the English chemists Sir Christopher Ingold and E.D. Hughes, beginning in the late 1920s. Although a great deal had been surmised about carbonium ions by indirect methods in the meantime, it was only after 1960 that general methods for the formation of stable, long-lived carbonium ions became available.

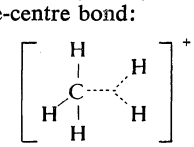
Classification. Two distinct classes of carbonium ions have come to be recognized. The first are the "classical" carbonium ions, which contain a trivalent instead of the usual quadrivalent carbon atom centre. The carbon atom is in an sp^2 state of hybridization—that is, the three bonding electrons of the carbon atom (the electrons in the outermost electron shell of the atom) occupy orbitals, or pathways, within the shell that are alike, each formed by the combination (hybridization) of three ordinary orbitals, one denoted *s* and two, *p*. All three orbitals lie in one plane; thus, the cationic centre of the molecule formed by bonding the carbon atom with three other atoms or groups tends to be planar. Since in most compounds the carbon atom centre has four pairs of bonding electrons, the carbonium ion is electron deficient; hence it carries a positive charge. The parent for these ions is the carbenium ion, or methyl cation, with the formula CH_3^+ (C being the chemical symbol for a carbon atom and H the symbol for hydrogen, with the subscript indicating the number of atoms in the structure and the plus sign the positive charge). Schematically, this structure is as shown below (the solid lines representing bonds between atoms):

Classical and nonclassical carbonium ions



carbenium ion
(methyl cation)

The second class of carbonium ions includes the pentacoordinated, or "nonclassical," carbonium ions, which have three single bonds, each joining the carbon atom to one other atom, and a triangular two-electron, three-centre bond—that is, a bond that connects three atoms, rather than the usual two, with a single electron pair. Such units are positively charged because they include an extra atomic nucleus, and the carbon atom generally maintains tetrahedral geometry; that is, the attached groups form the corners of a tetrahedron with the carbon atom at the centre, as in the parent structure for these ions, the methonium ion, CH_5^+, in which the dotted lines represent a three-centre bond:



methonium ion

It has been proposed that the term carbocation be used for all types of carbonium ions, with the name carbenium ion being used for the trivalent types and the name carbonium ion being reserved solely for the pentacoordinated substances. As of the early 1970s, however, this usage had not been generally adopted.

It is frequently possible to distinguish between these two types of carbonium ions experimentally, as, for example, by the use of certain instrumental methods—nuclear magnetic-resonance spectroscopy, which gives information about atomic nuclei; infrared and Raman spectroscopy, which are based on light absorption; and, more recently, X-ray-induced electron-emission spectroscopy, which gives information about bond energies.

Preparation and stability. Several methods are known for the generation of carbonium ions. They may all, however, be classified in one of the following categories: (1) heterolytic (unsymmetrical) cleavage of the two-electron bond between a carbon atom and an attached group; (2) electron removal from a neutral organic compound; (3) addition of a proton, or other cation, to an unsaturated system; and (4) protonation, or alkylation (addition of an alkyl, or hydrocarbon, group), of a carbon–carbon or carbon–hydrogen single bond. Since carbonium ions are positively charged species, they are most readily formed in relatively polar solvents (solvents consisting of molecules with unsymmetrical distribution of electrons), which help disperse their charges or the charges on the accompanying negatively charged ions throughout the medium. Commonly used solvents include methanol, aqueous acetone, acetic acid, and trifluoroacetic acid.

The fate of a carbonium ion produced by one of these methods is determined essentially by two factors: (1) the nature of the medium in which the ion is generated and (2) the inherent stability of the ion itself. Carbonium ions are generally produced in solvents in which they react rapidly with the solvent or with an available nucleophilic agent (a substance attracted to positively charged entities). Since, under these conditions, carbonium ions have only a fleeting existence, indirect methods must be used for their study. The commonly used methods are kinetics (measurements of rates of reaction), chemical analysis of the product formed by reaction of the carbonium ion (particularly, determination of spatial arrangements of atoms in a molecule), and isotopic labelling (that is, the use of radioactive isotopes to identify particular atoms).

Effects of solvent on carbonium-ion stability

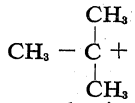
Recently, "superacid" solvents (solvents of low nucleophilicity) have been found that do not react with many carbocations. These solvents are hydrogen fluoride–antimony pentafluoride and fluorosulfuric acid–antimony pentafluoride with sulfur dioxide or sulfuryl chloride fluoride also present. In these solvents, the lifetime of many carbonium ions is sufficient to allow their direct observation. Modern instrumental methods have been particularly useful in this regard. The most widely used and the most important instrumental method has been nuclear magnetic-resonance spectroscopy, which gives information concerning the magnetic environment of the various nuclei in the carbonium ion as well as information about the charge distribution within the ion. Other spectroscopic methods that have been employed are X-ray crystallography; infrared, ultraviolet, and mass spectroscopy; and X-ray-induced photoelectron spectroscopy.

The stability of carbonium ions depends upon various electronic and steric (spatial) factors. Among the electronic factors are inductive effects (the simple attraction of electrons by positive centres), conjugation (interaction with electrons from double bonds), hyperconjugation (interaction with electrons from carbon–hydrogen or carbon–carbon bonds), and aromaticity (interaction with electrons from cyclic, electron-rich systems). The steric factors to be considered are strain (distortion of bonds for spatial reasons), deviations from planarity (for the sp^2 carbonium centre atom), and nonbonding interactions (influences between atoms not joined to one another by chemical bonds). It is the interplay of these factors that determines the stability of a particular carbonium ion.

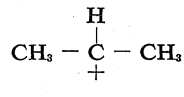
Effects of structure on carbonium-ion stability

Tertiary carbonium ions, for example, are generally more stable than secondary carbonium ions, which, in

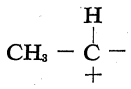
turn, are more stable than primary ones. In tertiary carbonium ions, the sp^2 carbon is bonded to three alkyl groups; in secondary carbonium ions, the sp^2 carbon atom is bonded to two alkyl groups and one hydrogen atom; in primary carbonium ions, the sp^2 carbon is bonded to either one alkyl group and two hydrogen atoms or, in the case of the methyl cation, three hydrogen atoms. Examples of each are shown below.



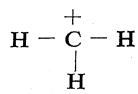
tertiary carbonium ion
tert-butyl cation



secondary carbonium ion
isopropyl cation



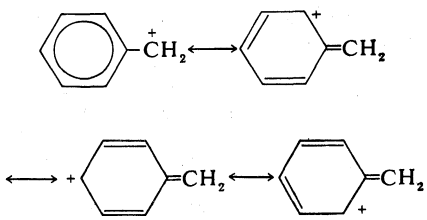
primary carbonium ion
ethyl cation



methyl cation

This relative order of stability is explained on the basis of the ability of an alkyl group to disperse the charge on the sp^2 carbon atom by hyperconjugation (an effect that overcomes the destabilizing inductive effect of the alkyl group).

Benzyl cations are more stable than most primary cations because the benzyl ions are stabilized by resonance —that is, the delocalized electrons in the aromatic ring make possible a distribution of the positive charge among the carbon atoms so the cation can exist in many forms, all of which contribute to the overall structure. Resonance forms of the benzyl cation are shown below:



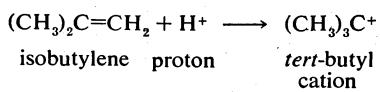
resonance forms of the benzyl cation

In these structures the benzene ring is indicated by a hexagon, each corner of which is considered to be a carbon atom (the attached hydrogens not being shown). The form with a circle in the hexagon represents structures with alternating double and single bonds in the ring; the other forms are those in which charges appear at various locations in the ring.

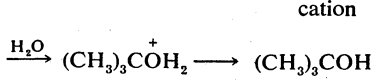
Reaction with nucleophiles

Reactions. Since carbonium ions are electron-deficient entities, they react with any electron-donor molecules, which are also referred to as nucleophiles. There are three types of nucleophiles; *n*-bases, pi bases, and sigma bases, in which *n*, pi, and sigma refer to the bonding state of the donor-electron pair in the nucleophile—that is, nonbonded, pi-bonded, and sigma-bonded, respectively. (Sigma bonds are ordinary covalent bonds between atoms and pi bonds are the special bonds that occur in unsaturated and aromatic systems.) The nucleophile may be either external or internal (that is, constituting a portion of the cation itself). In the latter case, rearrangement may occur. Examples of the various possible reaction types are shown below:

1. Reaction with external *n*-base: acid-catalyzed hydration (addition of water) of isobutylene. In this reaction, there is an unshared (nonbonded) electron pair on the oxygen atom of the water molecule:

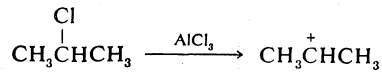


isobutylene proton *tert*-butyl cation

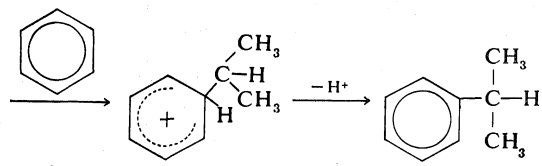


water *tert*-butyl alcohol

2. Reaction with external base: alkylation of benzene using isopropyl chloride (Friedel–Crafts reaction). Benzene acts as the donor molecule, with the donated electrons coming from the pi-bonded system of the benzene ring:



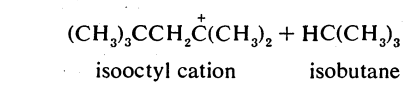
isopropyl chloride aluminum chloride isopropyl cation



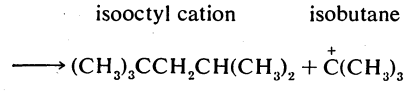
benzene proton cumene

In the above equation, the partial circle with the plus charge in the hexagon stands for those forms of the cation in which the positive charge is distributed around the ring (as in the benzyl cation, pictured above).

3. Reaction with external sigma base: hydride transfer reaction in which the donor electron pair comes from the carbon–hydrogen sigma bond in isobutane:

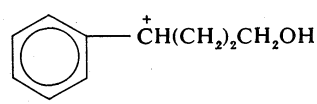


isooctyl cation isobutane

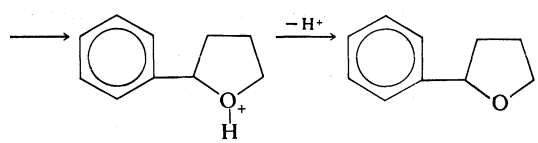


isooctane *tert*-butyl cation

4. Reaction with internal *n*-base: cyclization reaction, with nonbonded electron pair on an oxygen atom serving as donor:

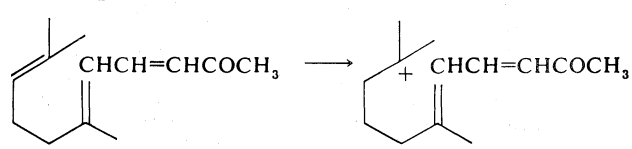


benzyl-type cation

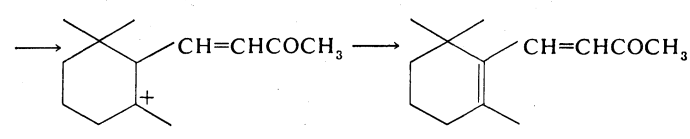


oxygen-protonated 2-phenyltetrahydrofuran 2-phenyltetrahydrofuran

5. Reaction with internal pi base: acid-catalyzed cyclization to form β-ionone, with the donor electrons coming from the pi electrons of the unsaturated system:

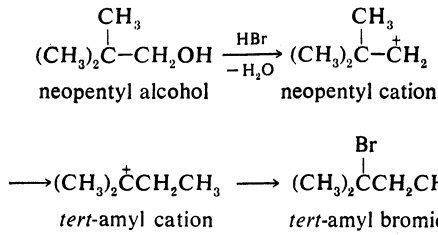


pseudoionone intermediate cation



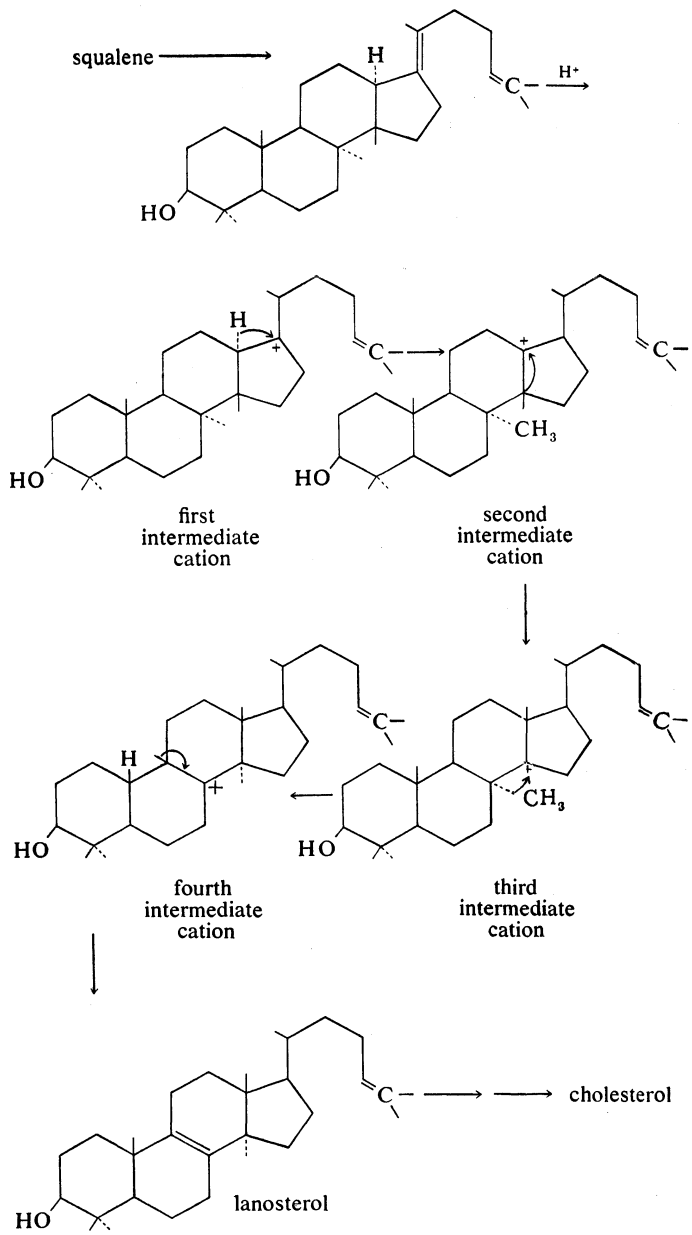
intermediate cation β-ionone

6. Reaction with internal sigma base: acid-catalyzed rearrangement of neopentyl alcohol, the electron pair coming from an internal carbon–carbon sigma bond:



Each of these reaction types is widely employed in synthetic organic reactions, and the many acid-catalyzed hydrocarbon transformation reactions are fundamental in petroleum chemistry and in vital bio-organic processes. An important process in the manufacture of high-octane gasoline, for example, consists of the acid-catalyzed isomerization of straight-chain hydrocarbons to branched-chain hydrocarbons. One example of the significance of carbonium ions in bio-organic processes may be found in the biological synthesis of the important material cholesterol from a precursor, squalene, by way of another compound, lanosterol. In this transformation, acid-catalyzed rearrangements—reaction type 6. above—occur repeatedly, as shown in the sequence below:

Carbonium ions in biological syntheses



BIBLIOGRAPHY. D. BETHELL and V. GOLD, *Carbonium Ions* (1967), is an excellent introduction to most aspects of carbonium-ion chemistry; includes an extensive bibliography. G.A. OLAH and P.V.R. SCHLEYER (eds.), *Carbonium Ions*, 4 vol. (1968), is a review of particular aspects of carbonium-ion chemistry, with individual chapters written by active researchers in the field. The initial chapter is a historical review of carbonium ions and a summary of major trends. G.A. OLAH, "Stable Carbonium Ions in Solution," *Science*, 168:1298–1311 (1970), summarizes much of the work concerning the direct observation of carbonium ions as stable, long-lived species.

(G.A.O./P.R.Cd.)

Carboxylic Acids and Their Derivatives

The carboxylic acids and their derivatives are organic chemical compounds, either prepared synthetically or found naturally in fats, vinegar, milk products, and fruit juices and flavours. They are used as solvents and in the preparation of other chemical compounds that are employed in the production of plastics, dyes, pharmaceuticals, and a large number of other products.

THE CARBOXYL GROUP

The molecules of the carboxylic acids contain a particular arrangement of carbon, oxygen, and hydrogen atoms, called a carboxyl group. It is this group that is responsible for the characteristic chemical behaviour of the carboxylic acids. In the carboxyl group, a carbon atom (designated by the symbol C) is joined to two oxygen atoms (symbol O), one of which also is joined to a hydrogen atom (H). In chemical symbols, this structure of the carboxyl group is written $-\overset{\overset{O}{\|}}{C}-O-H$, in which each line represents one chemical bond between the atoms. As indicated by this structure, the hydrogen atom forms only one bond (or, in chemical terminology, has a valence of 1); oxygen forms two bonds (valence, 2) and carbon four (valence, 4). In order to apportion the bonds properly, one of the oxygen atoms must be attached to the carbon by two bonds or, as it is commonly called, a double bond. The carbon atom has one unused bond left over after the carboxyl group is formed (as indicated by the line in front of the carbon symbol in the diagram above), and this bond must be used if the molecular structure is to be completed.

The simplest way that this can be done is to add a hydrogen atom, giving the simplest possible carboxylic acid, formic acid, the structure of which may be written $H-\overset{\overset{O}{\|}}{C}-O-H$, or in shorter form as HCOOH or HCO_2H. Formic acid is used as a disinfectant and as an acidifying agent in textile and paper manufacturing.

Alternatively, a carbon atom bearing three hydrogen atoms—*i.e.*, a methyl group—may be joined to the carbon of the carboxyl group to give acetic acid, with the structure $H-\overset{H}{\underset{H}{C}}-\overset{\overset{O}{\|}}{C}-O-H$ or CH_3COOH. A dilute form of acetic acid is commonly known as vinegar.

The structures of many other carboxylic acids may be made by joining other atoms to the methyl carbon in place of the hydrogen atoms. Such structures consist of chains of carbon atoms joined to one another in linear sequences, with side branches formed of other short chains and rings made when the chain doubles back and rejoins itself; each such structure represents the molecule of a different carboxylic acid. Often, for convenience, the symbol R is used to represent a general and unspecified arrangement of carbon and hydrogen atoms (a hydrocarbon unit) and the formula RCOOH is used as a general representation for all carboxylic acids.

The derivatives of the carboxylic acids all have molecular structures that contain variants of the carboxyl group. In general, these conform to the pattern $R-\overset{\overset{O}{\|}}{C}-Z$, in

which R has the same meaning as above and Z is some atom other than carbon or hydrogen (*i.e.*, a heteroatom), usually oxygen, nitrogen, or a halogen (*i.e.*, one of the group of elements including fluorine, chlorine, bromine, and iodine). Often hydrogen (or other) atoms must be attached to the heteroatom to complete its valence bonds, and in these cases the Z represents a group of atoms. The carboxylic acids themselves conform to the general formula $R-\overset{\overset{O}{\|}}{C}-Z$, the Z in this case being the hydroxyl, or $-OH$, group.

Esters

Probably the most familiar class of carboxylic acid derivatives is the family of compounds known as esters. In esters, the heteroatom is oxygen, and a hydrocarbon unit is joined to it. In the methyl esters (the simplest of the family), the hydrocarbon unit joined to the oxygen atom is simply a methyl ($-CH_3$) group. Perhaps the most important ester of commerce is ethyl acetate, in which an ethyl ($-C_2H_5$) group is attached to the oxygen atom. Ethyl acetate is an ester of acetic acid, CH_3COOH. Its structural formula is $CH_3COOC_2H_5$. Ethyl acetate is used as a solvent, a flavouring and perfume ingredient, and a chemical intermediate (substance converted to other chemical compounds).

Esters can be formed from carboxylic acids by reaction with other organic compounds called alcohols under conditions that remove a molecule of water from the two constituents. This process is indicated in the following equation, which represents the chemical reaction that occurs:

$$\underset{\text{carboxylic acid}}{R-\overset{\overset{O}{\|}}{C}-O-H} + \underset{\text{alcohol}}{H-O-R} \rightleftharpoons \underset{\text{ester}}{R-\overset{\overset{O}{\|}}{C}-O-R'} + \underset{\text{water}}{H-O-H}.$$

In this equation, as in other chemical equations, the structural formulas of the starting materials are written to the left of the arrow and the products to the right. The double arrows indicate that the chemical reaction proceeding from left to right may be reversed, the products reacting to produce the reactants. In the structural formulas, written as above, the letters represent atoms of the various elements and the lines represent bonds between the atoms. Also, as above, R represents an unspecified hydrocarbon unit and R′ a second hydrocarbon unit, which may be the same as the first or may be different from it. As the general formula for esters, RCOOR′, suggests, this family of compounds is large, since both the R and R′ groups can be varied to include a great many kinds of hydrocarbon structures, as well as units with heteroatoms of various kinds substituted in them. Many simple esters, liquids with fruity flavours and odours, are used extensively in flavourings and perfumes. Some are naturally occurring.

Other derivatives

The other principal classes of carboxylic acid derivatives are the anhydrides, halides, peroxy acids, amides, hydrazides, and azides. The general formulas of these derivatives are given in Table 1. Each class can be considered to be formed from a carboxylic acid and a second compound by the same type of dehydration (removal of water) reaction that gives esters from carboxylic acids and alcohols. The second molecule that reacts with a carboxylic acid to give the derivative in each case is as follows: anhydride, a second molecule of carboxylic acid; halide, a halogen acid; peroxy acid, hydrogen peroxide; amide, an amine; hydrazide, hydrazine; and azide, hydrazoic acid. The preparation of the various derivatives, in actual practice, may not follow this idealized scheme since more convenient methods of synthesis have been worked out. Amides (particularly proteins) and esters are the most important carboxylic acid derivatives found in nature. Many of these derivatives, however, are synthesized for important industrial uses.

Typically, the carboxylic acids themselves are readily converted to the various classes of derivatives, and the derivatives in most cases can be converted into one another. Thus, the carboxylic acids and their derivatives comprise a family of closely related and readily interconvertible compounds. In many ways, the chemistry of each class is the chemistry of all.

The following, more detailed discussion of carboxylic acids and their derivatives depends on certain knowledge of atomic and molecular structure and the nature of chemical reactions. Articles providing information on these subjects are CHEMICAL BONDING; CHEMICAL ELEMENTS; CHEMICAL REACTIONS; MOLECULAR STRUCTURE; CHEMICAL COMPOUNDS, ORGANIC; and PERIODIC LAW.

THE CARBOXYLIC ACIDS AND DERIVATIVES AS A GROUP

Nomenclature. Because many of the more familiar carboxylic acids were first isolated from natural sources before the development of systematic chemical nomenclature, they are known by common names that reflect their origin. For example, it has long been known that ants secrete formic acid (Latin *formica*, "ant"), that acetic acid is present in vinegar (Latin *acetum*, "vinegar"), and that lactic acid is produced by the souring of milk (Latin *lac*, *lactis*, "milk"). Systematic names, which are generally preferred—except for the most common acids—because they are directly related to the chemical structure of the acid, are derived from the name of the hydrocarbon with the same carbon skeleton. The name of the acid is derived by dropping the final "e" from the hydrocarbon name and replacing it with the ending "-oic acid." Thus, the name hexanoic acid is derived from that of the hydrocarbon hexane, to which it is formally related; this acid, however, usually is known by its common name,

Table 1: Formulas and Nomenclature of Carboxylic Acids and Their Derivatives

class	formula: $R-\overset{\overset{O}{\|}}{C}-Z$	common name		systematic name	
	Z=	add to root*		add to root†	
		prefix	suffix	prefix	suffix
Carboxylic acid	–OH		-ic acid		-oic acid
Ester	–OR′	alkyl	-ate	alkyl	-oate
Anhydride	$-O\overset{\overset{O}{\|}}{C}R$		-ic anhydride		-oic anhydride
Acyl halide	–Cl (–Br)		-yl halide		-oyl halide
Peroxy acid	–OOH	peroxy- (or per-)	-ic acid	peroxy-	-oic acid
Amide‡ (substituted amide)	$-NH_2$ (–NHR, $-NR_2$)	(*N*-alkyl-, *N*,*N*-dialkyl-)	-amide	(*N*-alkyl-, *N*,*N*-dialkyl-)	-amide
Hydrazide	$-NHNH_2$		-ohydrazide		-ohydrazide
Azide	$-N_3$		-yl azide		-oyl azide

E.g., acet-, propion-, etc. †*E.g.*, ethan-, propan-, etc. ‡Nitriles, another class of carboxylic acid derivative, may be considered to be dehydration products of amides. They have the general formula R–C≡N and are named -onitrile.

caproic acid (Latin *caper, capri*, "goat"). Systematic and common names of straight-chain saturated acids are given in Table 2.

Table 2: Straight-chain Saturated Acids and Their Methyl Esters

chain length	systematic name	common name	acid		methyl ester	
			melting point (°C)	boiling point* (°C)	melting point (°C)	boiling point* (°C)
1	methanoic	formic	8.4	101	−99.0	32

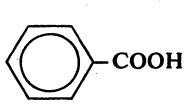
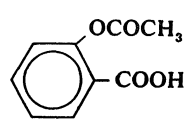
Naming of derivatives

Methods of naming carboxylic acid derivatives vary. Suffixes or prefixes are used, or both, as indicated in Table 1, to indicate the type of derivative; the root of the acid's name gives the acid from which the compound is derived. As an example, in the naming of esters, the alcohol portion of the ester is given first, as a radical or partial molecule—such as ethyl from ethyl alcohol—followed by the root of the acid name—as acet- from acetic acid—followed by the suffix -ate. The ester formed from ethyl alcohol and acetic acid, then, is called ethyl acetate. When the systematic name of the acid (-oic) is employed, the ending used is -oate. The systematic name of ethyl acetate is ethyl ethanoate.

Classification. Carboxylic acids and their derivatives are classified in different ways, depending on the purpose of the classification. Many of the acids with straight carbon chains, particularly those with even numbers of carbon atoms, are constituents of fats and are commonly classed together as fatty acids. Generally the carboxylic acids are classed as aliphatic (a term that means an ordinary hydrocarbon chain) if the rest of the molecule (other than the carboxylic acid group) is aliphatic. The fatty acids, by this definition, are aliphatic; aliphatic acids frequently are classified further as saturated or unsaturated depending upon whether or not they contain unsaturation—that is, multiple bonds (double or triple) between the atoms of the carbon chain. When the carboxyl group is directly attached to an aromatic system—*e.g.*, a benzene ring—a carboxylic acid is, however, classed as an aromatic acid. Benzoic acid is the parent compound of the aromatic acids. Acetylsalicylic acid, or aspirin, the best known aromatic carboxylic acid, is derived from benzoic acid. The structural formulas of benzoic acid and acetylsalicylic acid are:



benzoic acid



acetylsalicylic acid (aspirin)

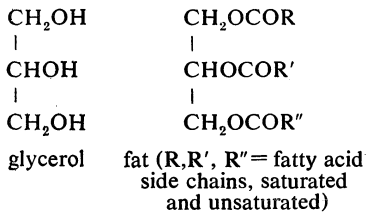
in which the hexagon containing a circle represents a benzene ring (that is, a circular structure of six carbon atoms each of which has one hydrogen atom attached to it).

Carboxylic acids are often categorized by the extra functional groups their molecules carry. Dicarboxylic and tricarboxylic acids are common. Carboxylic acids are classed as halo, keto, hydroxy, or amino acids when a halogen atom or a carbonyl, hydroxyl, or amino group is also part of the molecule.

Classification of derivatives

Generally carboxylic acid derivatives are placed in the same classes as the acids from which they are derived. Thus, aliphatic, aromatic, and various substituted esters, amides, and other derivatives are known. Exceptions occur when the acid-derived group makes up a relatively small part of the molecule. The derivative is then considered to be another type of substance altogether, modified by addition of the carboxylate grouping. Thus acetylsalicylic acid usually is considered a derivative of salicylic acid, not an ester of acetic acid.

Natural occurrence. Carboxylic acids occur widely in nature. In addition to acetic and formic acids, which are found in the free state, many of the fatty acids—straight-chain acids, saturated and unsaturated—occur as fats; that is, as esters of the trihydric alcohol glycerol (the term trihydric meaning that there are three hydroxyl or alcohol groups in each molecule of the substance). The structural formula of glycerol and a generalized formula of a fat derived from glycerol by the formation of ester bonds with three fatty acids are as follows:



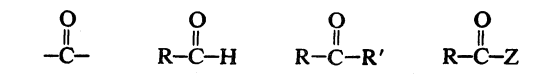
glycerol — fat (R,R', R" = fatty acid side chains, saturated and unsaturated)

Fatty acids occur also as esters and amides of long-chain alcohols and amines. Free fatty acids are readily obtained from these sources by hydrolysis—cleavage of the ester or amide bond with addition of a single molecule of water. The free acids, however, are almost invariably obtained from such sources in the form of mixtures that are very complex and difficult to separate.

Substituted carboxylic acids also are found extensively in natural materials. Lactic acid occurs in sour-milk products and citric acid in fruits. These, other hydroxy acids, and many keto acids, are important metabolic products and exist in most living cells. Amino acids are constituents of proteins, from which they can be secured by hydrolysis. Halogen-substituted acids also occur, as do polycarboxylic acids and a number of aromatic acids.

With the exception of esters and amides, few carboxylic acid derivatives appear in natural products. Esters, with their fruity and fragrant odours, are common constituents of plant flavours and essences. The carboxylic acids and their derivatives are all readily available by synthetic procedures (see below), often of such simplicity that even naturally occurring substances are prepared synthetically rather than isolated from natural sources.

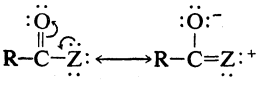
General chemical and physical properties. The carboxyl group, in a sense, is a special form of the carbonyl group, the doubly bonded carbon–oxygen function characteristic of aldehydes and ketones. Structural representations of the carbonyl group and the generalized formulas of aldehydes, ketones, and carboxylic acids (and derivatives) are all given here for purposes of comparison:



carbonyl group — aldehyde — ketone — carboxylic acid and derivatives

In the molecules of aldehydes and ketones, the carbonyl group is attached directly to carbon or hydrogen atoms, neither of which exerts a major influence on the chemical

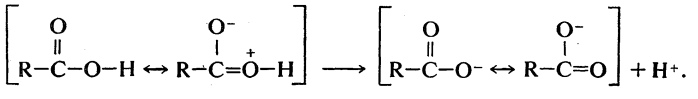
behaviour of that carbonyl group. In the carboxylic acids and their derivatives, however, the carbonyl carbon is joined directly to an atom with one or more pairs of electrons over and above those employed in the bond with the carbon atom. These so-called unshared pairs of electrons are able to interact with the electrons of the carbonyl group, thereby greatly modifying the chemical properties of that group and of the heteroatom as well. The nature of this interaction usually is represented in terms of the following diagrams:



In these diagrams the dots represent single electrons, situated in pairs; the curved arrows indicate a tendency for the electron pairs, or the bonds (which are equivalent to pairs of electrons), to migrate as shown; and the plus and minus signs stand for local electric charges brought about by the movement of the electrons. The double-headed arrow between the two representations implies that the complete structure of the molecule is a resonance hybrid of these two structures—that is to say, that the molecular structure incorporates aspects of both forms but duplicates neither. When such resonance forms exist for a molecule it is said to be stabilized by resonance. In this case, the most important feature of the electronic interaction represented by the resonance forms is that it gives this modified carbonyl group new chemical properties of its own, which justify classifying the group as a new and unique structure; *i.e.*, a carboxyl group.

As the name indicates, the chief characteristic of carboxylic acids is their acidity. As a class the carboxylic acids are more acidic than most other organic compounds containing hydroxyl (— OH) groups, but they are generally much weaker acids than the familiar mineral acids, such as nitric, sulfuric, and hydrochloric acids. The acidity of the carboxyl group results from the loss of a proton or hydrogen ion (that is, a hydrogen atom bearing a positive charge, as indicated by the symbol H^+), leaving behind a carboxylate anion—a negatively charged unit derived from the carboxyl group.

The carboxylate anion, like the carboxyl group, exists as resonance hybrid (see above) of several forms, two of which are shown below for each structure:



carboxylic acid carboxylate anion

The basis for acidity of carboxylic acids

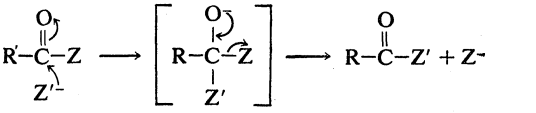
It is significant that the two resonance forms shown for the carboxylate anion are symmetrical and both carry a negative charge (as shown by the minus signs on the symbols for the oxygen atoms); this situation, which produces a structure of low energy content, means that the carboxylate anion is a relatively stable structure. In the carboxylic acid molecule itself, however, the resonance forms (as shown) are not symmetrical and one of them carries a separation of charge in its structure. This structure is less favourable (shows less resonance stabilization) than the symmetrical, equally charged structures of the carboxylate anion. As a result of this disparity in resonance stabilization, the carboxylic acid readily gives up a proton—acts as an acid—to produce the anion, which is favoured by its extra resonance energy.

The nature of the R group of the carboxylic acid has an effect on the acidity of the carboxyl group by making it more or less easy for the proton to depart. Generally speaking, electron-attracting groups increase acidity by withdrawing electrons from the vicinity of the proton, thereby facilitating its departure; the opposite is true of electron-repelling groups. In many of the carboxylic acid derivatives, the carboxyl group has been modified, with the result that the proton in question is no longer present, and such substances are not acidic.

Chemical properties

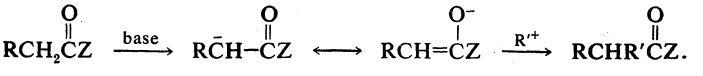
The chemical reactions undergone by the carboxylic acids and their derivatives can be put into two broad categories. The first is a nucleophilic (positive-charge-seeking) reaction directed at the carbonyl carbon atom. The overall effect of this type of reaction is the displacement of one group, Z, which is capable of carrying a negative charge by another, Z′. The reaction is customarily represented by the following equation:

The reaction proceeds, however, by way of attack on the carbonyl carbon as shown in the representation below:



in which the movement of electron pairs (or bonds) is indicated by curved arrows and the structure enclosed within brackets is an intermediate substance that is not isolated. It is by reactions of this type that carboxylic acid derivatives are interconverted, one variety being readily prepared from another under the proper chemical conditions.

Secondly, carboxyl compounds undergo the sort of reaction undergone by typical carbonyl compounds (aldehydes and ketones), in which the substituents are introduced into the so-called alpha position (the carbon atom adjacent to the carbonyl or, in this case, carboxyl group). Such reactions proceed by way of an intermediate resonance-stabilized anion (an anion being a negatively charged unit), which subsequently reacts with a positively charged unit. The latter is incorporated into the final structure. The reaction occurs as shown in the following equation:

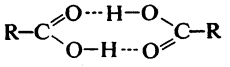


resonance-stabilized anion

Esters resemble carbonyl compounds more than the carboxylic acids—or the other derivatives—do, and, as a result, esters are more prone to undergo substitution reactions in this category.

Physical properties

The members of the carboxylic acid family with low molecular weight are liquids with boiling points appreciably higher than those of hydrocarbons of comparable molecular weight (see Table 2). This is because of extensive hydrogen-bond formation, a type of secondary association between molecules, which makes the acids behave as dimers (two molecules held together as one):



As would be expected from compounds whose molecules contain hydroxyl groups, the lower members of the series are extremely water-soluble—the hydroxyl group (— OH) being structurally similar to the water molecule (HOH) and therefore prone to solubility in it. This property diminishes as the non-carboxylic acid portion of the molecules increases in size, and acids containing nine or more carbon atoms are insoluble. Because of their solubility and acidity, members of the series containing few carbon atoms—such as acetic acid, found in vinegar—have a sour taste. The carboxylic acids with one to three carbons have sharp odours, whereas those with four to eight carbons have rank, disagreeable odours. Rancid butter and strong cheese contain the latter carboxylic acids.

Many carboxylic acid derivatives are less associated (that is, their molecules are held together less strongly) than the free acids. This is especially true of the esters and halides, whose boiling points are much lower than those of the acids from which they are derived (see Table 2). Typical esters of lower molecular weight are volatile liquids.

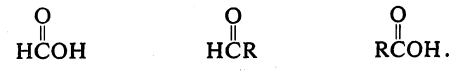
THE MAJOR CLASSES OF CARBOXYLIC ACIDS

Saturated acids. Formic acid, the simplest member of the carboxylic acid family, was first prepared by distilling ants with water. The stinging nettle owes its irritating

quality to the formic acid content of the juice. On a commercial scale, the acid is prepared by adding carbon monoxide under pressure to hot sodium hydroxide. The free acid is liberated by careful reaction with sulfuric acid. The series of reaction is shown below:

$$CO \xrightarrow{NaOH} HCOONa \xrightarrow{H_2SO_4} HCOOH$$

in which the symbols NaOH and H_2SO_4 written above the arrows indicate that the successive reactions occur in the presence of sodium hydroxide and sulfuric acid, respectively. In addition to its acidic properties, formic acid shows pronounced reducing activity (reduction being the chemical opposite of oxidation), a quality not shared by other carboxylic acids. The reducing action stems from the fact that formic acid is in a sense an aldehyde as well as an acid, as shown in the following structural formulas:



formic acid aldehyde carboxylic acid

Formic and acetic acids

Acetic acid, the next higher homologue—that is, the compound with one more carbon atom in its molecule—can be produced by oxidation of ethyl alcohol and is present as a dilute solution in vinegar, where it is formed by bacterial oxidation of dilute alcoholic liquors. Acetic acid may also be isolated from the liquid called pyroligneous acid, which is formed by the destructive distillation of wood. The most important commercial preparation of acetic acid involves the catalytic atmospheric oxidation of acetaldehyde, itself prepared from acetylene. These reactions are shown below:

$$CH{\equiv}CH \xrightarrow[HgSO_4]{\text{dilute } H_2SO_4} CH_3CHO$$

$$\xrightarrow[Mn(CH_3COO)_2]{\text{air}} CH_3COOH.$$

Acetic acid is extensively employed in the preparation of metal salts and in the form of acetyl chloride or acetic anhydride in the production of esters and amides. Aspirin, the acetic ester of salicylic acid, is a good example of a commercially important ester prepared from acetic acid. Acetic acid is also recognized as an important substance in the biosynthesis of many biologically important materials. In this case it chiefly appears as an acetyl group bound to coenzyme A—*i.e.*, a molecule necessary for the action of certain enzymes. Acetyl-S-coenzyme A takes part in the biological production of fatty acids, many aromatic compounds, and isoprenoids and steroids. The natural fatty acids have an even number of carbon atoms in their molecules because they are produced from acetyl-S-coenzyme A, which adds carbon atoms to the molecules two at a time.

With increasing numbers of carbon atoms per molecule, the carboxylic acids have increasing possibilities for alternate arrangements of the atoms within the molecules (isomerism), and many branched-chain acids, both natural and synthetic, are known. The straight-chain compounds are, nevertheless, more common, especially those with even numbers of carbon atoms in the chain, and these make up the great percentage of the fatty acid content of common fats.

Carboxylic acids and their derivatives

The lower fatty acids (with four to ten carbon atoms) occur mainly in milk fats and a few seed fats. Cow's milk contains 10 percent (on a molecular-weight basis) of butyric acid (a four-carbon acid) with smaller amounts of the acids containing six, eight, ten, and 12 carbon atoms; sheep's-milk and goat's-milk fats contain these same acids, with capric (containing ten carbon atoms) in greatest amount (up to 10 percent). Capric acid also is a major component (60 percent) in the seed fat of the elm, and caprylic and capric acids (each 5–10 percent) accompany the higher proportion of lauric acid (12 carbon atoms) in coconut oil and, to a lesser extent, in palm-kernel oil. Lauric acid and myristic acid (14 carbon atoms) occur extensively in seed fats of the Lauraceae (laurel family) and Myristicaceae (nutmeg family) respectively. Lauric acid, for example, can be obtained from cinnamon oil (80–90 percent), coconut oil (45–50 percent), or palm-kernel oil (45–55 percent) and myristic acid from nutmeg butter (60–75 percent) or from the more readily available coconut and palm-kernel oils (15–18 percent). Palmitic acid (16 carbon atoms), the most widely occurring of the saturated acids, is present in almost every fat examined. Useful sources include cottonseed oil (22–28 percent), palm oil (35–40 percent), and Chinese vegetable tallow (60–70 percent).

Palmitic and stearic acids

Stearic acid (18 carbon atoms) is less common than palmitic acid. It occurs in most vegetable fats but is a major component in only a few, such as cocoa butter (35 percent). It is present in most animal fats but attains major proportions only in the tallows of ruminants (30 percent). Stearic acid is conveniently obtained by hydrogenation of readily accessible unsaturated fats.

Still higher fatty acids are less common but occur in a few seed fats or in some waxes as esters of long-chain alcohols. Acids with odd numbers of carbon atoms in their chains are even rarer, but modern methods of investigation have revealed their presence, often as trace components, in many fats. Acids with hydrocarbon chains containing short branches (side chains of carbon atoms) or rings (circular sequences of carbon atoms) also are uncommon. Those that are found include a series of acids with one or more methyl groups in various positions along the chain, as well as acids with cyclopropane groups. Many branched-chain acids have been synthesized.

Unsaturated acids. Although most of the important unsaturated acids (acids with multiple bonds) are long-chain compounds obtained from fats, some shorter chain acids, such as acrylic, crotonic, methacrylic, and the isomeric angelic and tiglic acids, are also important. The formulas of these acids are shown below:

$CH_2{=}CHCOOH$	acrylic acid
$CH_3CH{=}CHCOOH$	crotonic acid
$CH_2{=}C(CH_3)COOH$	methacrylic acid
	angelic acid
	tiglic acid

Acrylic acid polymers

Acrylic acid, employed as its methyl ester in the production of polymers known as acrylates, is prepared on a large scale from acetylene, carbon monoxide, and water in the presence of a nickel catalyst, as well as by hydrolysis of the substance acrylonitrile ($CH_2 = CHCN$), an even more important monomer.

Methacrylic acid, in the form of its methyl ester, is also used as a monomer, furnishing Perspex or Plexiglas when polymerized. Crotonic acid exists in *cis* and *trans* forms, which differ in the arrangement of substituents about the double bond. Only the *trans* isomer occurs naturally, in croton oil. Angelic and tiglic acids also are a pair of *cis* and *trans* isomers, both of which occur naturally.

Natural unsaturated acids number more than 200 and are subdivided into three groups: (1) acids with only one unsaturated centre; (2) conjugated (conjugation being an alternation of single and double bonds), polyunsaturated acids; (3) multiply unsaturated, or polyunsaturated, acids that are nonconjugated.

Mono-unsaturated acids

Apart from two acetylenic (triple-bonded) acids, tariric and stearolic, the natural monounsaturated acids are olefinic (double bonded) and almost entirely *cis* isomers.

Oleic acid, with 18 carbon atoms and a double bond between the ninth and tenth carbon atoms in the chain, is the most common of all fatty acids and the prototype for all monoolefinic acids:

$$CH_3(CH_2)_7CH = CH(CH_2)_7COOH \qquad \text{oleic acid.}$$

More than 90 monoenoic acids, containing ten to 30 carbon atoms, have been identified in lipid sources. Nature appears to have a preference for certain chain lengths, es-

pecially those of 16 and 18 carbons, and for particular positions for the unsaturation, especially between C_9 and C_{10}. These circumstances are a natural consequence of the enzymatic oxygen-dependent desaturation process whereby double bonds are most commonly introduced into fatty acids between carbons 9 and 10, and of the readiness by which natural acids undergo chain elongation by one or more two-carbon units at the carboxyl end of the molecule. In addition to these natural acids, many isomers that do not occur in nature have been synthesized.

The monounsaturated acids show the properties expected of olefins, in addition to those of carboxylic acids. As acids, they form salts, are reduced to primary alcohols, and are converted directly or indirectly to the various types of acyl compounds listed in Table 1. As unsaturated compounds they undergo hydrogenation (that is, the addition of hydrogen to the multiple bond) with hydrogen and a catalyst or with hydrazine; hydroxylation (introduction of hydroxyl groups) with potassium permanganate, osmium tetroxide, performic acid, or peracetic acid; and halogenation (introduction of halogen atoms) with chlorine or bromine or with iodine monochloride. Vigorous oxidation by potassium permanganate or ozone leads to breaks in the carbon chains (chain fission). Atmospheric oxidation first gives unsaturated hydroperoxides (molecules containing two joined oxygen atoms), followed by a variety of secondary reaction products. Among these are volatile short-chain compounds (aldehydes and other substances) responsible for both the acceptable and unacceptable flavours that develop in fat-containing foods.

Polyunsaturated acids

Over 90 nonconjugated, polyunsaturated acids occur naturally. Most are acids with 16, 18, 20, or 22 carbons and two to four double bonds, although more highly unsaturated members are also known. Unsaturation is almost entirely *cis* in the compounds and usually is methylene interrupted; *i.e.*, with successive double bonds separated by single methylene ($-CH_2-$) groups. These structural features are clearly apparent in linoleic acid, linolenic acid, and arachidonic acid, the most important members of this class, the structures of which are shown below:

linoleic acid

$$CH_3(CH_2)_4CH=CHCH_2CH=CH(CH_2)_7CO_2H$$

linolenic acid

$$CH_3CH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_7CO_2H$$

arachidonic acid

$$CH_3(CH_2)_4CH=CHCH_2CH=CHCH_2CH=CHCH_2CH=CH(CH_2)_3CO_2H.$$

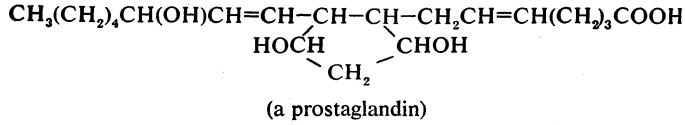
Interest in acids of this type has increased since the recognition that some of them, called essential fatty acids, are required for the maintenance of normal animal growth, reproduction, and permeability of the skin. The particular requirement is for methylene-interrupted polyolefinic acids, with unsaturation beginning at the sixth carbon from the methyl end of the chain.

Arachidonic acid is the most effective of the fatty acids for meeting the essential fatty acid requirements. Many authorities consider it likely that essential fatty acids are converted to other compounds before fulfilling their as yet unknown biological function.

Of possible significance in this regard is the discovery of a series of compounds called prostaglandins, which cause certain muscles to contract and lower the blood pressure. These compounds are produced in vivo from essential fatty acids such as arachidonic:

$$CH_3(CH_2)_4(CH=CHCH_2)_4(CH_2)_2CO_2H \longrightarrow$$

arachidonic acid



(a prostaglandin)

Conjugated polyunsaturated acids are much less common. About 40 are known to occur naturally, almost all of them being 18-carbon acids of plant origin. The best known is eleostearic acid from tung oil.

Substituted acids. Carboxylic acids, particularly those with long hydrocarbon chains, may contain one or more other groups, such as halo, hydroxy, alkoxy, epoxy, or keto groups. The several functional groups usually operate independently, and most substituted acids show only those properties that would be expected from the two functional groups. Sometimes, however, the two functional groups interact to give new properties.

Halogen-substituted acids

Acids substituted with chlorine in the alpha position are prepared by the reaction of chlorine or sulfuryl chloride on an acyl chloride or on the acid itself under reaction conditions that produce an acyl chloride. For example:

$$RCH_2COCl \xrightarrow{Cl_2,\ I_2} RCHClCOCl \xrightarrow{H_2O} RCHClCOOH$$

$$RCH_2COOH \xrightarrow{Cl_2,P} [RCH_2COCl] \longrightarrow RCHClCOCl \xrightarrow{H_2O} RCHClCOOH$$

$$RCH_2COOH \xrightarrow[SOCl_2]{SO_2Cl_2} [RCH_2COCl] \longrightarrow RCHClCOCl \xrightarrow{H_2O} RCHClCOOH.$$

The corresponding bromo acids are prepared by reactions with bromine and phosphorus, phosphorus trihalide, or thionyl chloride:

$$RCH_2COOH \xrightarrow{Br_2,\ P} [RCH_2COBr]$$

$$\longrightarrow RCHBrCOBr \begin{cases} \xrightarrow{H_2O} RCHBrCOOH \\ \xrightarrow{R'OH} RCHBrCOOR' \end{cases}$$

Iodo acids are best prepared by halogen exchange between potassium iodide and the chloro acid or bromo acid.

Acids substituted with halogen in other positions are produced by standard procedures for preparing alkyl halides, such as the addition of halogen acid to a double bond, or by the conversion of a hydroxyl group to halogen. Examples are:

$$RCH=CHCOOH \xrightarrow{HBr} RCHBrCH_2CO_2H$$

$$RCH(OH)(CH_2)_4COOH \xrightarrow{SOCl_2} [RCHCl(CH_2)_4COCl] \xrightarrow{H_2O} RCHCl(CH_2)_4COOH$$

The reactions of halogen-substituted acids and other acyl derivatives include dehydrohalogenation, nucleophilic substitution, and the formation of certain organometallic derivatives:

$$CH_2BrCH_2(CH_2)_nCOOH \xrightarrow{\text{pyridine}} CH_2=CH(CH_2)_nCOOH$$

$$RCHBrCOOH \xrightarrow[\text{of } Z^-]{\text{HZ or source}} RCHZCOOH$$

$$(Z=-NH_2, -OH, -CN, \text{etc.})$$

$$RCHBrCOOCH_3 \xrightarrow{Zn} RCH(ZnBr)COOCH_3 \xrightarrow{R'CHO} R'CH(OH)CH(R)COOCH_3 \xrightarrow[\text{hydrolysis}]{-H_2O} R'CH=C(R)COOH.$$

The presence of the carboxyl group influences the reactions of the 2-, 3-, and 4-halo acids so that each of these furnishes a different type of product when it reacts with alkalies:

$$RCHBrCOOH \xrightarrow{NaOH} RCH(OH)COOH \quad \text{(2-hydroxy acid)}$$

$$RCHBrCH_2COOH \xrightarrow{NaOH} RCH=CHCOOH \quad (\alpha, \beta\text{-unsaturated acid})$$

$$RCHBrCH_2CH_2COOH \xrightarrow{NaOH} \begin{matrix} CH_2-CH_2 \\ | \quad\ | \\ RCH \quad CO \\ \quad\ \backslash\ / \\ \quad\ O \end{matrix} \quad (\gamma\text{-lactone})$$

Among the few naturally occurring halo acids is fluoroacetic acid, a highly toxic compound that occurs as the potassium salt in the African shrub *Dichapetalum cymosum*. Compounds that undergo degradation in vivo to fluoroacetic acid are also highly toxic, and 18-fluorooleic acid, for example, is the poisonous principle in certain unusual seeds.

Hydroxy and amino acids

Hydroxy acids can be prepared from the appropriate carboxylic acid intermediates by standard methods of preparing hydroxy compounds, or from the appropriate hydroxy compounds by methods for producing carboxylic acids. Some of the more important general methods include (1) the hydrolysis of halo acids, (2) the hydrolysis of cyanohydrins, (3) the reaction with α-bromo esters in the presence of zinc, and (4) the reduction of keto esters or half esters of dibasic acids:

(1) $RCH_2COOH \xrightarrow{Br_2,\ P} RCHBrCOOH \xrightarrow{NaOH(aq)} RCH(OH)COOH$

(2)
$$\begin{cases} RCHO \xrightarrow{HCN} RCH(OH)CN \xrightarrow{\text{hydrolysis}} RCH(OH)COOH \\ RCH{=}CH_2 \xrightarrow{HOCl} RCH(OH)CH_2Cl \\ \xrightarrow{KCN} RCH(OH)CH_2CN \xrightarrow{\text{hydrolysis}} RCH(OH)CH_2COOH \end{cases}$$

(3) $RCHO \xrightarrow{BrCH_2COOC_2H_5} RCH(OH)CH_2COOH$

(4)
$$\begin{cases} RCO(CH_2)_nCOOCH_3 \xrightarrow[\text{hydrolysis}]{NaBH_4;} RCH(OH)[CH_2]_nCOOH \\ HOOC(CH_2)_nCOOCH_3 \xrightarrow{SOCl_2} ClCO(CH_2)_nCOOCH_3 \\ \xrightarrow[\text{hydrolysis}]{NaBH_4;} HOCH_2(CH_2)_nCOOH \end{cases}$$

The 2-, 3-, 4-, and 5-hydroxy carboxylic acids differ in their behaviour on heating and give, respectively, a lactide, α, β-unsaturated acid, a γ-lactone, and a δ-lactone:

$$2RCH(OH)COOH \longrightarrow \begin{matrix} RCH & CO \\ | & | \\ OC & CHR \\ \diagdown & \diagup \\ & O \end{matrix}$$

lactide

$$RCH(OH)CH_2COOH \longrightarrow RCH{=}CHCOOH$$

α, β-unsaturated acid

$$RCH(OH)(CH_2)_nCOOH \longrightarrow RCH(CH_2)_nC{=}O$$

lactone

There are many naturally occurring hydroxy acids, including glycolic, lactic, and ricinoleic:

$HOCH_2COOH$ — glycolic acid

$CH_3CH(OH)COOH$ — lactic acid

$CH_3(CH_2)_5CH(OH)CH_2CH{=}CH(CH_2)_7COOH$

ricinoleic acid

Ricinoleic is the major acid present in castor oil and provides a source of other useful chemicals prepared on an industrial scale. These include the diene glycerides resulting on dehydration of castor oil, as well as the products of pyrolysis—heptanal and 10-undecenoic acid—and alkali fusion—2-octanone, 2-octanol, 10-hydroxydecanoic acid, and sebacic acid.

The α-amino acids, $RCH(NH_2)COOH$, are of great importance since they are the monomeric units that make up the peptides and proteins. Twenty different amino acids commonly occur in these materials.

Keto acids

Carboxylic acids that also carry carbonyl groups (aldehydes or ketones) usually can be prepared by oxidation of the corresponding hydroxy acids. The β-keto compounds (in the form of their esters) are of considerable importance and are prepared by special condensation procedures.

Among the more important shorter chain acids bearing extra carbonyl groups are glyoxylic acid (OHCCOOH), pyruvic acid ($CH_3COCOOH$), levulinic acid ($CH_3COCH_2CH_2COOH$), and especially acetoacetic acid (CH_3COCH_2COOH).

Ethyl acetoacetate and most β-keto esters exhibit tautomerism—that is, the esters exist as equilibrium mixtures of two compounds and exhibit the properties of both. The keto form, which preponderates in most cases, contains a normal carbonyl group; the other form, called the enol form, bears an alcoholic group attached directly to one of the carbons of a double bond. The enol form is usually present in small amounts, but it can be detected by its reactions. As the enol form is consumed in a reaction, more is generated from the keto form by re-establishment of the equilibrium:

$$CH_3COCH_2COOC_2H_5 \rightleftharpoons CH_3\overset{OH}{\overset{|}{C}}{=}CHCOOC_2H_5.$$

keto form — enol form

Typical reactions of the keto form include reactions with hydrogen cyanide and with hydroxylamine to give cyanohydrins and oximes respectively. On the other hand, reaction with diazomethane to give an *O*-methyl ether and with ferric chloride to yield a coloured complex are considered to be typical of the enolic form.

Of major importance chemically (because it is the basis for many chemical reactions) is the fact that the methylene ($-CH_2-$) group of a β-keto ester, which is flanked by two electron-withdrawing groups ($-CO-$ and $-COOC_2H_5$), can give up one of its protons to a strong base to yield a resonance-stabilized carbanion. Intermediates of this type react readily with alkyl and acyl halides to give alkylated or acylated derivatives of the original β-keto ester, as follows:

$$CH_3COCH_2COOC_2H_5$$

$$\xrightarrow{\bar{O}C_2H_5} CH_3\bar{C}HCOOC_2H_5 \longleftrightarrow CH_3C(O^-){=}CHCOOC_2H_5$$

resonance-stabilized carbanion

$$\xrightarrow{RX} CH_3COCHRCOOC_2H_5$$

$$\xrightarrow{RCOX} CH_3COCH(COR)COOC_2H_5$$

The monoalkylated and monoacylated compounds formulated in the above sequence also contain a second hydrogen atom, which can be replaced by a second alkyl or acyl group, not necessarily the same as the first. These alkylated or acylated derivatives yield valuable products after hydrolysis, a reaction that can follow two different courses:

1. Under mild conditions—*i.e.*, with dilute acid or alkali—the ester function is hydrolyzed in the usual way, but the β-keto acid so formed is unstable and decarboxylates readily to give a ketone:

$$CH_3COCH_2COOC_2H_5 \longrightarrow CH_3COCHRCOOC_2H_5$$

ethyl acetoacetate — mono-alkylated derivative

$$\longrightarrow CH_3COCHRCOOH \longrightarrow CH_3COCH_2R.$$

free acid — ketone

Reactions of this type are used to prepare monosubstituted and disubstituted derivatives of acetone (CH_3COCH_2R and CH_3COCHR_2) or 1,3-diketones (CH_3COCH_2COR).

2. With stronger alkali, the molecule is attacked at both carbonyl groups to produce acetic acid and alkylated derivatives of that substance, as in the following examples:

$$CH_3COCH_2COOC_2H_5 \begin{cases} \longrightarrow CH_3COCHRCOOC_2H_5 \longrightarrow CH_3COOH + RCH_2COOH \\ \longrightarrow CH_3COCR_2COOC_2H_5 \longrightarrow CH_3COOH + R_2CHCOOH. \end{cases}$$

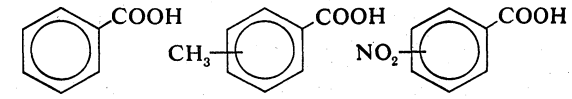
The polyfunctional nature of ethyl acetoacetate and related β-keto esters makes them valuable intermediates in the preparation of many heterocyclic compounds.

Aromatic acids. In addition to the typical reactions undergone by the carboxyl group, aromatic acids also enter into the electrophilic substitution reactions commonly displayed by aromatic compounds.

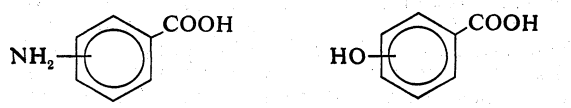
Reaction of aromatic carboxylic acids

A carboxyl group directly attached to an aromatic ring exerts a deactivating influence and directs substituents to one of the two *meta* positions in the ring (that is, not to the adjacent carbon but the one next to that). Nitration of benzoic acid, for example, requires moderately vigorous conditions and gives first *m*-nitrobenzoic acid and then 3,5-dinitrobenzoic acid.

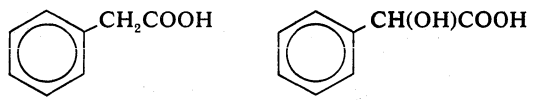
The simplest and best known aromatic acid is benzoic acid; this compound may be considered to be the parent of a wide range of substituted benzoic acids. Those acids in which the carboxyl group is part of an aliphatic side chain and not directly attached to the aromatic ring, such as phenylacetic, mandelic, and cinnamic acids, often are not classed as aromatic acids. Many polybasic acids, such as the isomeric phthalic acids, are commercially important. The most important aromatic acids are:



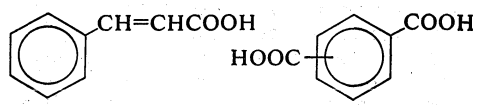
benzoic acid — toluic acids* — nitrobenzoic acids*



aminobenzoic acids* — hydroxybenzoic acids*



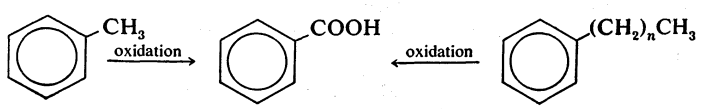
phenylacetic acid — mandelic acid

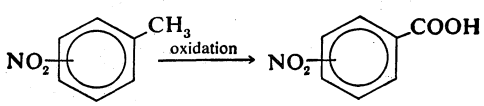


cinnamic acid — phthalic acids*

*These are convenient representations of the three isomeric acids (*ortho-*, *meta-*, and *para-*), which differ in the relative positions of attachment of the two groups on the ring.

Aromatic carboxylic acids, like their aliphatic counterparts, can be prepared by hydrolysis of nitriles or by the addition of carbon dioxide to organometallic compounds, usually derived from the appropriate halide; also, they often are obtained from aromatic hydrocarbons by oxidation. The aromatic ring is so resistant to oxidation that it remains intact while carbon-linked side chains are degraded to carboxyl groups. Certain noncarbon constituents such as nitro and halo groups survive this treatment, so that nitrotoluenes or halotoluenes may be oxidized to nitrobenzoic or halobenzoic acids:





Benzoic acid

Benzoic acid has been known for centuries, having been first obtained from gum benzoin, a resin extracted from an Indonesian tree. The well-known aromatic hydrocarbon benzene can be prepared by decarboxylation of benzoic acid. By standard procedures benzoic acid can be converted to the usual range of acyl derivatives, including benzoyl chloride, benzoate esters, and benzamides. The acid also enters into several aromatic substitution processes, although certain of the substituted benzoic acids are prepared preferably by alternative routes. Several of these substituted acids, such as salicylic acid (*o*-hydroxybenzoic) and anthranilic acid (*o*-aminobenzoic), are of considerable commercial importance. The latter, which is used as an intermediate in the preparation of many dyes, is generally prepared from phthalimide, itself a derivative of the dibasic acid phthalic acid. Salicylic acid is manufactured chiefly by the reaction of sodium phenolate (C_6H_5ONa) with carbon dioxide under pressure at 120°–140° C. Derivatives of salicylic acid, especially phenyl salicylate, acetylsalicylic acid (aspirin), and 4-aminosalicylic acid are used medicinally.

Phthalic acids

The phthalic acids are prepared by oxidation of appropriate aromatic hydrocarbons. The *ortho* isomer (in which the substituents are on adjacent positions on the ring) readily forms an anhydride. The *para* isomer (in which the substituents are located directly across from one another on the ring), which is also known as terephthalic acid, is used with dihydric alcohols to produce polymers, such as Terylene, which is a linear polymer that is made by the condensation of terephthalic acid and ethylene glycol.

Cinnamic acid, one of the more important acids in which the carboxylic group is not directly attached to the aromatic ring, is prepared from benzaldehyde by several condensation procedures, one of which is carried out as follows:

$$C_6H_5CHO \xrightarrow[CH_3COONa]{(CH_3CO)_2O} C_6H_5CH{=}CHCOOH.$$

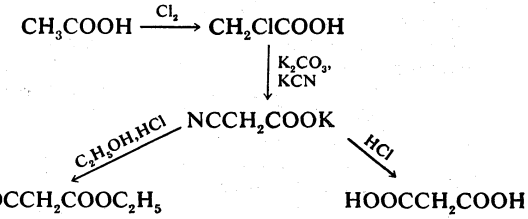
Such compounds as 2,4-dichlorophenoxyacetic acid (2,4-D), which are used as selective weed killers, are made by reaction of the appropriate halogenated phenol and chloroacetic acid.

Polycarboxylic acids. The most common dicarboxylic acids belong to the series of compounds with carboxyl groups at both ends of a hydrocarbon chain; that is, compounds with the general structural formula $HOOC(CH_2)_nCOOH$, in which n can be any of many numbers. Though they can be named systematically, several are generally designated by their common names, including oxalic ($n = 0$), malonic ($n = 1$), succinic ($n = 2$), glutaric ($n = 3$), adipic ($n = 4$), azelaic ($n = 7$), and sebacic ($n = 8$) acids.

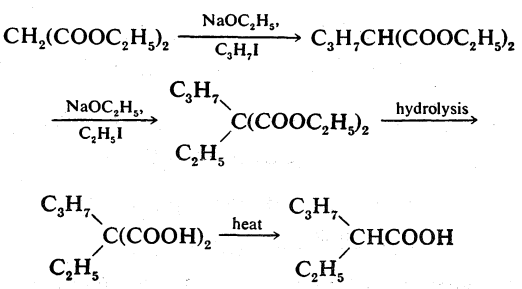
Oxalic acid, a common natural product, is readily obtained by oxidation of table sugar, or other carbohydrates, or by heating sodium formate. Oxalyl chloride (ClCOCOCl) is a useful reagent for preparing acyl halides from other carboxylic acids.

Malonic acid

Malonic acid and its more important ethyl ester are usually prepared from acetic acid by the following synthetic sequences:



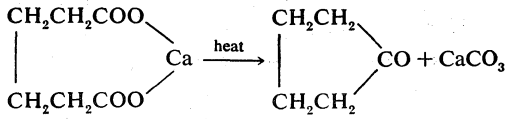
The importance of diethyl malonate is that, like ethyl acetoacetate, it readily forms a resonance-stabilized carbanion, which readily can be alkylated and, by way of the corresponding free acid, decarboxylated. Diethyl malonate, therefore, can be used to prepare monosubstituted and disubstituted derivatives of acetic acid, as in the following example:

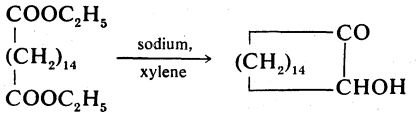


Succinic and glutaric acids differ from the other members of this series in that they readily give cyclic anhydrides (see below *Anhydrides*) when heated. Oxalic and malonic acids fail to form cyclic anhydrides, and the members of the series above glutaric usually give linear polymeric anhydrides:

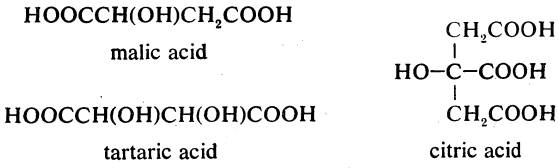
succinic anhydride glutaric anhydride

Dibasic acids with six or more carbon atoms undergo cyclization reactions of various kinds. The examples given below show the production of a cyclic ketone, cyclopentanone, from the calcium salt of adipic acid and of an α-hydroxyketone (or acyloin) from a 16-carbon dicarboxylic acid ester:





Adipic acid is used in the production of the most common form of nylon—a polyamide made from that dibasic acid and 1,6-hexanediamine. Maleic and fumaric acids are isomeric unsaturated dibasic acids. Malic acid, tartaric acid, and citric acid are important hydroxy-polycarboxylic acids of natural origin:



malic acid citric acid

tartaric acid

THE CARBOXYLIC ACID DERIVATIVES

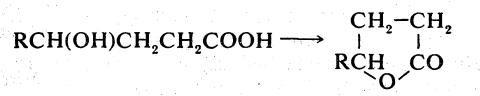
Esters. Formally, an ester with the structure RCOOR′ may be thought to be derived from a carboxylic acid of structure RCOOH, by replacement of hydrogen, − H, by an alkyl group, − R′, but the nature of the esterification process is such that it is more appropriate to describe the change as the replacement of the hydroxyl group, − OH, by an alkoxy group, − OR′. It is established experimentally in most esterification procedures that the alkoxy oxygen atom in an ester does, in fact, come from the alcohol—that is, that it remains attached to the R′ group.

Esterification

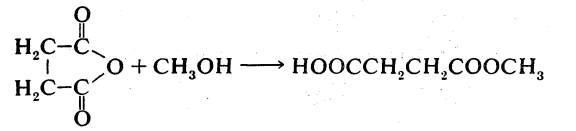
Esters are prepared most often by interaction of an acid and an alcohol in the presence of a catalyst, but other useful procedures also are available. The reversible reaction between alcohols and carboxylic acids is shown by the following equation:

$$RCOOH + R'OH \rightleftharpoons RCOOR' + H_2O.$$

Because the equilibrium is attained only slowly, it is usual to add a catalyst, such as hydrogen chloride or sulfuric acid, and to arrange the experimental conditions so that the equilibrium is shifted to the right. This shift is generally achieved by removal of water by distillation or by adding a large excess of one of the reactants. Hydroxy acids in which the hydroxyl group is three or four carbons from the carboxyl group undergo intramolecular reaction to give cyclic esters known as lactones:



Since acyl halides and acid anhydrides are more reactive than carboxylic acids, they can be esterified without the use of acidic catalysts. This method is especially useful for preparing the half esters of dibasic acids from their cyclic anhydrides and for producing the esters of phenols, which cannot be obtained directly from the acids:



succinic anhydride methyl hydrogen succinate

acetyl chloride phenol phenyl acetate

The salts of carboxylic acids react with alkyl halides to form esters. The silver salts are most commonly employed for this purpose, but sodium salts may be used when the alkyl halide is a reactive one, *p*-nitrobenzyl bromide, for example:

$$p\text{-}NO_2C_6H_4CH_2Br + NaOOCCH_3 \longrightarrow p\text{-}NO_2C_6H_4CH_2OCOCH_3.$$

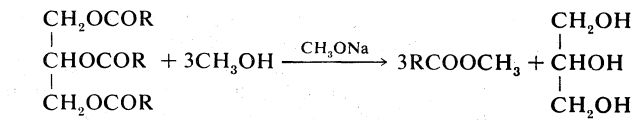
p-nitrobenzyl acetate

Methyl esters are conveniently obtained by reaction of carboxylic acids with diazomethane in ether solution:

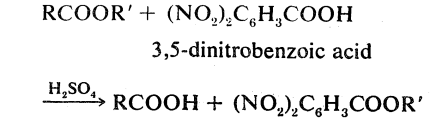
$$RCOOH + CH_2N_2 \longrightarrow RCOOCH_3 + N_2.$$

Since esterification is a catalytic, reversible process, one ester can be prepared from another by reaction with an alcohol (alcoholysis), with an acid (acidolysis), or with a second ester (transesterification) in the presence of a suitable acidic or basic catalyst:

alcoholysis

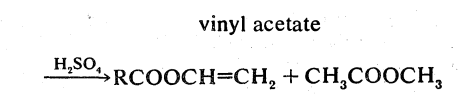


acidolysis



3,5-dinitrobenzoic acid

transesterification



vinyl acetate

Esters are neutral compounds. The esters of long-chain acids occur naturally as waxes (esters of long-chain alcohols), as glycerides or fats (esters of glycerol), and as phosphoglycerides (esters of glycerophosphoric acid).

Reactions of esters

Esters can be converted to amides by reaction with ammonia, to hydrazides by reaction with hydrazine, and to

acids by hydrolysis. They are not converted easily to acid chlorides or anhydrides:

$$RCOOCH_3 + NH_3 \longrightarrow RCONH_2 + CH_3OH$$
$$RCOOCH_3 + N_2H_4 \longrightarrow RCONHNH_2 + CH_3OH$$
$$RCOOCH_3 + NaOH \longrightarrow RCOONa + CH_3OH.$$

Hydrolysis, the most important reaction, is brought about slowly by water and more quickly in the presence of acid or alkali. The alkaline hydrolysis, or saponification, of fats produces salts of long-chain acids, which are known as soaps. In common with many other long-chain compounds, these substances show surface-active properties and have long been used as cleansing agents. The enzyme-catalyzed hydrolysis of esters is important in the metabolism of lipids.

The mechanism of alkaline hydrolysis of esters is as follows:

$$R-\overset{\overset{O}{\|}}{C}(OR') \overset{OH^-}{\rightleftharpoons} R-\overset{O^-}{\underset{OR'}{\overset{|}{C}}}-OH \rightleftharpoons R-\overset{\overset{O}{\|}}{C}-OH + \bar{O}R'$$

$$\longrightarrow R-\overset{\overset{O}{\|}}{C}-O^- + R'OH.$$

With sodium in an inert solvent, esters give acyloins (α-hydroxy ketones). Esters can be reduced to primary alcohols (RCH_2OH) by several methods, either catalytically with hydrogen and copper oxide–chromium oxide (300° C and 250 atmospheres pressure), or chemically by reaction with sodium and alcohol or lithium aluminum hydride or diborane.

As is true of other carbonyl compounds, most esters undergo self-condensation in the presence of a base. The reaction involves the formation of a resonance-stabilized carbanion and reaction of this material with a second molecule of ester to give, finally, a β-keto ester. The best known example of this reaction is the preparation of ethyl acetoacetate from ethyl acetate:

$$CH_3COOC_2H_5 \overset{NaOC_2H_5}{\rightleftharpoons} CH_2C(=O)OC_2H_5 \longleftrightarrow CH_2{=}C(O^-)OC_2H_5 \overset{CH_3COOC_2H_5}{\rightleftharpoons}$$

$$CH_3\overset{O^-}{\underset{OC_2H_5}{\overset{|}{C}}}CH_2COOC_2H_5 \rightleftharpoons CH_3COCH_2COOC_2H_5.$$

ethyl acetoacetate

Most β-keto esters contain a reactive methylene group that readily can be alkylated or acylated.

Anhydrides. Although thermal dehydration of acids is not usually a satisfactory process, anhydrides can be made from carboxylic acids by reaction with acetic anhydride, ketene, methoxyacetylene or ethoxyacetylene, or isopropenyl acetate:

$$2RCOOH + 2CH_2{=}C{=}O$$

ketene

$$\longrightarrow 2RCOOCOCH_3 \longrightarrow (RCO)_2O + (CH_3CO)_2O$$

mixed anhydride

$$2RCOOH + HC{\equiv}COR' \longrightarrow (RCO)_2O + CH_3COOR'.$$

From acyl halides, anhydrides can be produced by reaction with the appropriate acid salt ($RCOCl + RCOONa \rightarrow (RCO)_2O + NaCl$). Acyl halides also react with carboxylic acid and pyridine or with acetic anhydride to produce anhydrides.

Acetic anhydride

Acetic anhydride, $(CH_3CO)_2O$, is of sufficient commercial importance to be prepared industrially by atmospheric oxidation of acetaldehyde in the presence of a metal acetate, as well as from acetic acid by reaction with acetylene or ketene:

$$CH_3CHO \xrightarrow{O_2} CH_3COOOH \xrightarrow{CH_3CHO} (CH_3CO)_2O + H_2O$$

$$2CH_3COOH + HC{\equiv}CH \longrightarrow CH_3CH(OCOCH_3)_2 \longrightarrow (CH_3CO)_2O + CH_3CHO$$

$$CH_3COOH \xrightarrow{700°-800°} CH_2{=}C{=}O \xrightarrow{CH_3COOH} (CH_3CO)_2O.$$

The anhydrides generally are useful acylating agents, being more reactive for this purpose than acids or esters, but less so than acyl halides. They react with water to give carboxylic acids, with alcohols or phenols to give esters, and with ammonia and amines to give amides. Acetic anhydride, a widely used acetylating agent, for example, reacts with water, an alcohol, and ammonia, according to the following equations:

$$(CH_3CO)_2O + H_2O \longrightarrow 2CH_3COOH$$
$$(CH_3CO)_2O + ROH \longrightarrow CH_3COOH + CH_3COOR$$
$$(CH_3CO)_2O + NH_3 \longrightarrow CH_3COOH + CH_3CONH_2.$$

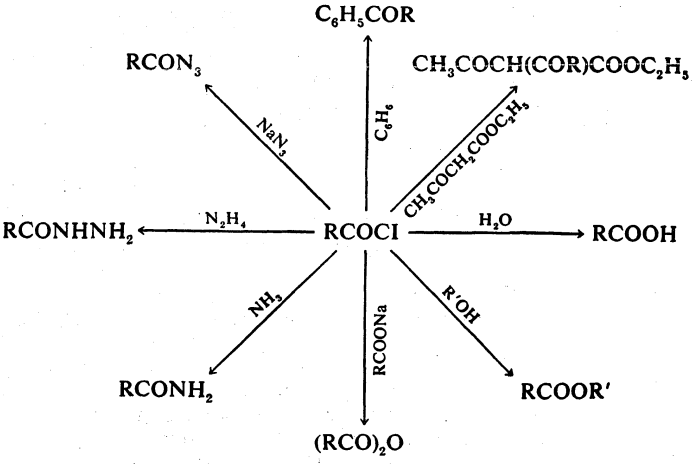
Anhydrides can also be used to acylate aromatic compounds in the presence of aluminum chloride.

Halides. The acyl halides, of which the chlorides are the best known, are among the most reactive of acyl compounds. They are easily made from carboxylic acids or their salts by reaction with phosphorus pentachloride, phosphorus trichloride, thionyl chloride (usually in the presence of pyridine), or oxalyl chloride. The reaction with thionyl chloride may be taken as typical:

$$RCOOH + SOCl_2 \longrightarrow RCOCl + SO_2 + HCl.$$

Reactions of acyl halides

Acyl halides generally are vigorous acylating agents and react with water to give carboxylic acids; with alcohols and phenols to give esters; with sodium salts of carboxylic acids to give anhydrides; with ammonia and amines to give amides; with hydrazine to give hydrazides; and with sodium azide to give azides. They are also employed, with aluminum chloride as a catalyst, for the acylation of aromatic compounds; they interact with carbanions, such as that derived from ethyl acetoacetate, to give acyl derivatives. A summary of these reactions is shown below:



Acyl chlorides furnish ketones with organometallic compounds, especially those of zinc and of cadmium. They also are reduced to (1) aldehydes, by reaction with hydrogen, using a catalyst; or (2) alcohols, with lithium aluminum hydride or sodium borohydride. Aldehydes also can be prepared from acyl halides by way of *N,N*-dialkylamides, which are reduced with lithium aluminum hydride only to the aldehyde stage:

$$RCH_2OH \xleftarrow{LiAlH_4} RCOCl \xrightarrow{R'_2NH} RCONR'_2 \xrightarrow{LiAlH_4} RCHO.$$

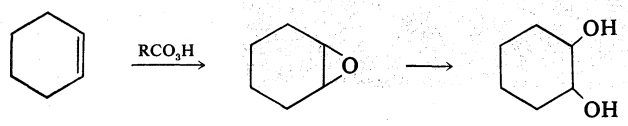
alcohol — acyl chloride — *N,N*-dialkylamide — aldehyde

Peroxy acids. The peroxy acids, or peracids as they are sometimes called, may be considered as monoacyl derivatives of hydrogen peroxide. They are important oxidizing agents and are prepared from carboxylic acids and hydrogen peroxide in the presence of acidic catalysts (usually sulfuric acid or methanesulfonic acid) or from acid anhydrides and hydrogen peroxide. It is not always necessary to isolate the peracid, and mixtures of carboxylic acid and hydrogen peroxide may be employed as oxidizing agents.

Peracetic acid is manufactured by the atmospheric oxidation of acetaldehyde.

Reactions of peracids

As oxidizing agents, the peracids are used (1) to prepare epoxides and 1,2-diols from alkenes; (2) to convert ketones to esters; and (3) to oxidize amines to amine oxides, nitroso compounds, or nitro compounds. Epoxides result when alkenes are treated with aromatic peracids, such as peroxybenzoic or monoperoxyphthalic acid, or with aliphatic peracids in a buffered solution. Without a buffer the reaction mixture containing the aliphatic acid is so acidic that the epoxide ring is cleaved to give the 1,2-diol:



cyclohexene epoxycyclohexane cyclohexane-1,2-diol

The aliphatic peracids most widely used are peroxyformic, peroxyacetic, and peroxytrifluoroacetic.

Nitrogen-containing derivatives. *Nitriles.* Nitriles, or cyanides, with the general structure RC ≡ N, are made (1) from alkyl halides (or sulfates) by reaction with sodium or potassium cyanide, (2) from acids by dehydration of the corresponding amides, or (3) from aldehydes by dehydration of the aldoximes. These reactions are shown below:

$$RX \longrightarrow RCN$$

$$RCOOH \longrightarrow RCONH_2 \longrightarrow RCN$$

$$RCHO \longrightarrow RCH{=}NOH \longrightarrow RCN.$$

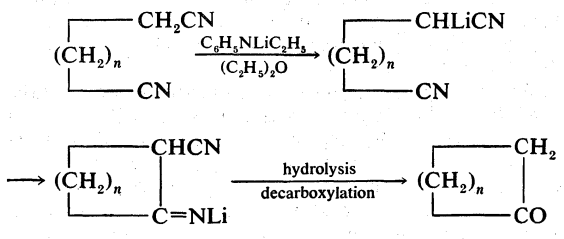
Reactions of nitriles

Nitriles can be hydrolyzed to amides and to acids, or they can be converted directly to esters. They are reduced easily to primary amines; but reaction occurs via imines and, under suitable conditions, reduction can be halted at this stage, with the imine being hydrolyzed subsequently to an aldehyde:

$$RCOOR' \xleftarrow{R'OH,H^+} RCN \xrightarrow{\text{hydrolysis}} RCONH_2 \xrightarrow{\text{hydrolysis}} RCOOH$$

$$RCH_2NH_2 \xleftarrow{LiAlH_4} RCN \xrightarrow[(C_2H_5)_2O]{SnCl_2,HCl,} RCH{=}NH \xrightarrow{H_2O} RCHO.$$

Nitriles share with esters the ability to undergo base-catalyzed self-condensation, one molecule acting as a nitrile and the second as a source of carbanion. Dinitriles undergo internal condensation and are used to prepare cyclic compounds in this way:



Amides. The preparation of amides from acyl halides or anhydrides (or sometimes esters) is generally accomplished by reaction with ammonia or with a primary or secondary amine. Amides also are the products of the partial hydrolysis of nitriles, and they can be obtained directly from carboxylic acids by reaction with urea, sulfamide (in the presence of pyridine), thiourea, or hexamethylphosphoramide.

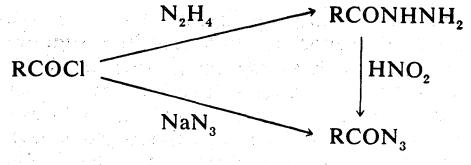
Amides are hydrolyzed by acid or alkali to carboxylic acids, and they are dehydrated readily to nitriles. Amides are normally reduced to amines, but *N,N*-dialkylated amides give aldehydes. With bromine and alkali, amides are degraded to amines with one less carbon atom, as follows:

Reactions of amides

$$RCONH_2 \xrightarrow{Br_2,NaOH} [RCONHBr] \longrightarrow [RNCO] \longrightarrow RNH_2 + CO_2.$$

Urea (NH_2CONH_2) is an amide present in mammalian urine and is the form in which many animals excrete waste nitrogen.

Hydrazides and azides. Hydrazides ($RCONHNH_2$) may be considered formally to be derived from carboxylic acids and hydrazine, and acyl azides ($RCON_3$) are analagous to the acyl chlorides, the azide (N_3) group having replaced a chlorine (Cl) atom. In actual practice, the hydrazides and azides are prepared from acyl halides by reaction with hydrazine and sodium azide, respectively. Nitrous acid converts hydrazides to azides:



THE IDENTIFICATION AND ANALYSIS OF CARBOXYLIC ACIDS AND DERIVATIVES

In the qualitative analysis of organic compounds, carboxylic acids are recognized by their solubility in aqueous alkali and by their ability to liberate carbon dioxide from bicarbonate solutions. When treated with potassium hydroxide and hydroxylamine, esters give hydroxamic acids, which are easily recognized by the deep red or purple colours they give with ferric salts.

Infrared spectra of carboxyl compounds

All acyl compounds have distinctive bands in their infrared spectra (particular patterns of light absorption, instrumentally determined). The absorption is believed to result from energy taken up by certain carbonyl stretching motions in the molecules. The exact frequency of this absorption depends on the molecular environment of the carbonyl group, and it is sometimes possible to distinguish the various types of carbonyls by the frequency of the infrared absorption (see Table 3). A double bond, or an aromatic system in the alpha position with reference to the carbonyl group, causes the absorption in each case to appear at the lower end of the range.

Table 3: Characteristic Infrared Absorption Bands of Selected Classes of Carbonyl Compounds

class	infrared absorption frequency, C=O stretching (cm^{-1})
Anhydrides	1850–1740*
Acyl halides	1815–1750
Esters	1750–1710
Aldehydes	1740–1680
Ketones	1725–1660
Carboxylic acids	1720–1660
Amides	1680–1630

*Two peaks, about 60 cm^{-1} apart.

Carboxylic acids can be characterized by the preparation of a wide range of solid derivatives. Among the most commonly employed are the

amides	($RCONH_2$),
anilides	($RCONHC_6H_5$),
p-toluidides	($RCONHC_6H_4CH_3$),
p-nitrobenzyl esters	($RCOOCH_2C_6H_4NO_2$),
S-benzylthiuronium salts	$[RCOO^-(NH_2)_2CSCH_2C_6H_5]$,
p-bromophenacyl esters	($RCOOCH_2COC_6H_4Br$),
and hydrazides	($RCONHNH_2$).

Esters and other acyl derivatives usually furnish these compounds after hydrolysis to the acid; or, in some cases, they are converted directly to the compound without production of the free acid.

The reaction of carboxylic acids and esters with alkali is the basis of several procedures for the quantitative estimation of these groups. Acids react quickly at room temperature and can be titrated directly in aqueous or alcoholic solution. Alternatively, they can be treated with excess of alkali, the excess being titrated with standard acid solution. Esters usually react with hot alkali, and the normal procedure for their quantitative determination is heating with excess alkali and titration of the surplus. This procedure is the basis of the standard method for determining the saponification (hydrolysis) equivalent, or saponification value, of fats. Carboxylic acids can also be quantitatively estimated by determination of (1) the methane liberated during reaction with methylmagnesium iodide or (2) the water formed during esterification.

Chromatography of carboxyl compounds

Chromatography is a method of separation based on differential adsorption of substances from solution by a solid material (such as alumina). Most of the known chromatographic procedures have been used to separate mixtures of carboxylic acids, as well as mixtures of the various derivatives, and many of the methods have been adapted for qualitative or quantitative identification or both. Indeed many useful developments in chromatography have come about from the need to analyze the mixed amino acids resulting from protein hydrolysis and the mixed fatty acids produced by lipid hydrolysis.

The most important analytical procedure for esters is the form of chromatography known as gas–liquid chromatography. By the use of an appropriate stationary phase, and long capillary columns when necessary, even closely related esters can be separated and quantitatively analyzed. In difficult cases this technique may have to be allied with other separation procedures.

Limited information about the carboxyl group (and other acyl groups) is obtainable by nuclear magnetic resonance spectroscopy, an instrumental technique that gives information about the magnetic properties of atomic nuclei. Although this method may not reveal much about the carboxyl group, it may provide considerable useful information about the remainder of the molecule. Mass spectrometry, the separation of substances on the basis of their respective masses, is an increasingly important tool in the recognition of complex compounds containing carboxyl and other acyl groups, especially those derived from lipids and other natural sources. Fragmentation of the molecule during the mass spectrometry procedure frequently gives valuable information about the molecular structure of the compound or compounds under investigation. Esters, particularly methyl esters, have been more extensively used in mass spectrographic studies than the acids themselves or the other derivatives.

BIBLIOGRAPHY. A modern comprehensive treatise dealing with all classes of organic compounds is E.H. RODD (ed.), *Chemistry of Carbon Compounds*, 2nd ed. by S. COFFEY (1965). Volume 1, parts C and D are particularly relevant to this article. Several monographs devoted exclusively to carboxylic acids and their derivatives are: S. PATAI (ed.), *The Chemistry of Carboxylic Acids and Esters* (1969); and F.D. GUNSTONE, *An Introduction to the Chemistry and Biochemistry of Fatty Acids and Their Glycerides*, 2nd ed. (1968). Additional material may be found in selected chapters in the following review series: R.T. HOLMAN (ed.), *Progress in the Chemistry of Fats and Other Lipids;* R. PAOLETTI and D. KRITCHEVSKY (eds.), *Advances in Lipid Research;* and F.D. GUNSTONE (ed.), *Topics in Lipid Chemistry*.

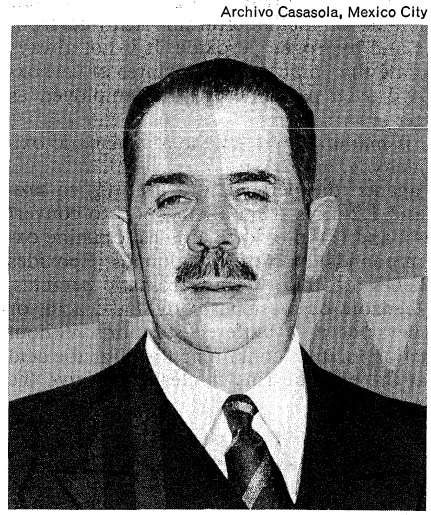
(F.D.G.)

Cárdenas, Lázaro

Lázaro Cárdenas, during his six-year term as president of Mexico (1934–40), did more than any other president to carry out the Mexican Revolution's promises of land reform, strong organized labour, mass education, and government control of the economy. His administration ended one phase of the revolution started by Francisco Madero in 1910 and opened another.

Cárdenas, born on May 21, 1895, in Jiquilpan, in the state of Michoacán, was largely of Indian descent. After

Archivo Casasola, Mexico City



Cárdenas.

a rudimentary education, he received his first job in a local branch of the Public Revenue Office.

In January 1913 Pres. Francisco Madero, who had led the struggle to overthrow the long dictatorship of Porfirio Díaz, was taken prisoner and assassinated by the orders of the rebellious Gen. Victoriano Huerta, who now seized control of the government. Huerta's repressive military dictatorship provoked civil war almost immediately, and Venustiano Carranza headed the new revolutionary forces. At the age of 18, Cárdenas joined a branch of the revolutionary army led by one of Carranza's principal lieutenants, Gen. Álvaro Obregón, and within a year he had risen to the rank of captain. In 1923 he was appointed general, the highest rank in the Mexican Army, and continued to participate in military campaigns until 1929.

Revolutionary activities

Like most of the revolutionary military leaders, Gen. Lázaro Cárdenas was also active politically, and in 1928, at the age of 33, he was elected governor of his native state of Michoacán. He served in that position for a full term, until 1932. Cárdenas also played an important role in forming a nationwide party to reinforce the revolutionary regime. Under the leadership of former president Plutarco Elías Calles, in office from 1924 to 1928, the Partido Nacional Revolucionario (PNR) was launched in 1929; and in the following year, Governor Cárdenas was chosen to be the party's new chairman. Cárdenas worked hard to transform the PNR from a loose federation of state parties, each led by a military-political caudillo ("boss"), into a truly national party and a major element of stability in the revolutionary regime. After his retirement as governor of Michoacán, Cárdenas was appointed minister of the interior in 1931 and minister of war and marine in 1933. It was from the latter job that he retired to become the PNR's candidate for president in the 1934 election.

Cárdenas turned out to be an extraordinary presidential candidate. Although his election was assured, he spent the year between his nomination and polling day carrying out an intensive campaign. He visited virtually every city, town, and village in the country, meeting with local leaders and ordinary citizens, and building up an extensive personal following in all parts of the country. During this campaign, he made clear his intention to carry out PNR's six-year plan of social and economic reform.

Reforms during presidency

Once elected president, General Cárdenas moved cautiously at first. The army, the civil administration, and much of the political structure of the regime remained under the control of former president Calles, who had wielded vast influence while in power. During his first year in office, President Cárdenas spent much of his time

establishing his own influence in these branches of the administration. Finally, he felt strong enough to have Calles sent into exile in the United States.

As president, Cárdenas carried out a wide range of reforms. Under the agrarian reform program, he distributed more land than all of his predecessors put together, with the result that by the end of his administration about half of the country's cultivated land was in the hands of previously landless farmers. He also extended the services of government banks so that the peasants who had received land under the reform could borrow money. In an effort to provide a political base for the land redistribution program, he organized all of its beneficiaries in a new National Peasant Confederation (Confederación Nacional Campesina, CNC). This was but one more step in strengthening the general political structure of his new regime. Another major step in this direction was taken early in 1936 when most of the country's dispersed central labour groups were organized into the Confederación de Trabajadores de México (CTM), which, for the next generation, continued to represent at least half of the country's organized workers.

Cárdenas also reorganized the government party. In 1938 a national convention restructured the party and renamed it the Partido de la Revolución Mexicana (PRM). Whereas in the past only government employees and aspiring politicians were members of the party, the new organizational scheme allowed mass groups to join the PRM directly. Four "sectors" of the party were established: labour, peasant, "popular," and "military." Most national labour groups were affiliated with the first; the CNC constituted the second; a variety of middle-class groups made up the third; and the armed forces were incorporated into the last. In the next administration the military sector was suppressed, and since then the military role in Mexican politics has been reduced considerably.

The Cárdenas administration was most famous abroad for its efforts to expropriate foreign-owned industries and place them under Mexican control. In 1937 the government expropriated the nation's principal railways, and in March 1938 President Cárdenas signed a decree nationalizing the country's oil industry. After short-lived experiments of putting both of these industries under the control of their workers' unions, they were placed under autonomous public corporations, which were to function more or less like any other large private industry.

When his term in office came to an end, President Cárdenas presided over the election of his successor, Gen. Manuel Ávila Camacho. He intended to withdraw from active political life. With the outbreak of World War II, however, in which Mexico became an active participant early in 1942, Cárdenas returned to public office. He served as minister of national defense from 1943 to 1945, and in the last year of his term he was made commander in chief of the Mexican Army. He retired once again late in 1945.

Political influence after retirement

For the following 16 years, he held no public office. In 1961, however, when Pres. Adolfo López Mateos gave each living former president of Mexico an important position in the national administration, Cárdenas became the executive member of the Comisión del Río Balsas, which ran one of the country's major regional electrification and development agencies, in the state of Guerrero. His sharply diminished responsibilities notwithstanding, he remained a major figure in national politics. He became the symbol of the left in the government party, renamed Partido Revolucionario Institucional in 1946. He remained the major supporter of the cooperative type of agrarian reform, and the chief opponent of the United States' economic and political influence in Mexico. Cárdenas never withdrew from the government party, although he continued to support alternative political organizations. In the early 1960s he sponsored a rival group to the CNC, the Independent National Peasant Confederation (Confederación Nacional Campesina Independiente, CNCI), and patronized—but never joined—a left-wing political coalition, the National Liberation Movement.

In the years following his retirement as minister of national defense, Cárdenas maintained a strongly anti-United States position also in international affairs, which won him the Stalin Peace Prize in 1955. After the victory of the Castro Revolution, he became the most forceful ally of the Cuban revolutionaries in Mexico. Basically, however, Cárdenas' political influence had substantially declined during the last years of his life. Nevertheless he remained a highly controversial figure and a rallying point for those who were critical of the policies of succeeding administrations. In the last half decade of his life, Cárdenas spoke out on public affairs only less and less frequently, spending most of his time at his estate in Jiquilpan, Michoacán. Cárdenas died on October 19, 1970.

BIBLIOGRAPHY. Several books have been written in English about Lázaro Cárdenas and his administration, during and after his period in power. These include NATHANIEL and SYLVIA WEYL, *The Reconquest of Mexico: The Years of Lázaro Cárdenas* (1939); EVELYN WAUGH, *Mexico: An Object Lesson* (British title, *Robbery Under Law: The Mexican Object-Lesson*, 1939); WILLIAM CAMERON TOWNSEND, *Lázaro Cárdenas: Mexican Democrat* (1952); HENRY A. PHILLIPS, *New Designs for Old Mexico* (1939); and J.H. PLENN, *Mexico Marches* (1939). Aspects of the Cárdenas administration have been dealt with in various sources. Organized labour is handled in JOE C. ASHBY, *Organized Labor and the Mexican Revolution Under Lázaro Cárdenas* (1967). Agrarian reform under Cárdenas is treated in CLARENCE O. SENIOR, *Land Reform and Democracy* (1958). Mexican industrialization during and after the Cárdenas period is dealt with in SANFORD A. MOSK, *Industrial Revolution in Mexico* (1950); and FRANK TANNENBAUM, *Mexico: The Struggle for Peace and Bread* (1950). The oil problem was discussed by DONALD R. RICHBERG, an attorney for the expropriated oil companies, in *The Mexican Oil Seizure* (1939); as well as in ROSCOE B. GAITHER, *Expropriation in Mexico: The Facts and the Law* (1940); and WENDELL C. GORDON, *The Expropriation of Foreign Owned Property in Mexico* (1941). Political matters are dealt with in ROBERT E. SCOTT, *Mexican Government in Transition*, rev. ed. (1964); KARL M. SCMITT, *Communism in Mexico* (1965); and ERNST HALPERIN, *Communism in Mexico* (1963).

Cardiovascular System, Human

The cardiovascular system is a closed tubular system in which blood, propelled by a muscular heart, flows through vessels to and from all parts of the body. Two circuits, one that is called pulmonary and the other systemic, consist of arterial, capillary, and venous components.

The primary function of the heart is to serve as a muscular pump propelling blood into and through vessels to and from all parts of the body. The arteries, which receive this blood at high pressure and velocity and conduct it throughout the body, are thickly walled with elastic fibrous tissue and a wrapping of muscle cells. The arterial tree—the branching system of arteries—terminates in short, narrow, muscular vessels called arterioles, from which blood enters simple endothelial tubes (*i.e.*, tubes formed of endothelial, or lining, cells) known as capillaries. These microscopically thin capillaries are permeable to vital cellular nutrients and waste products and serve as both distributing and receiving points for nutrients and wastes. From the capillaries, the blood, now depleted of oxygen and burdened with waste products, moving more slowly and under low pressure, enters small vessels called venules, which converge to form veins, ultimately guiding the blood on its way back to the heart.

HEART

Description. *Shape and location.* The human adult heart is normally slightly larger than a clenched fist with average dimensions of 5 × 3½ × 2½ inches (about 13 × 9 × 6 centimetres) and weighing approximately 300 grams (10.5 ounces). It is cone shaped in appearance, with the broad base directed upward and to the right and the apex pointing downward and to the left. It is located in the chest (thoracic) cavity behind the breastbone, or sternum, in front of the windpipe, or trachea, the esoph-

agus, and the descending aorta, between the lungs and above the diaphragm, which is the muscular partition between the chest and abdominal cavities. About two-thirds of the heart lies to the left of the midline.

Fibrous pericardium

Pericardium. The heart is suspended in its own special membranous sac, the pericardium. The strong outer portion of the sac, or fibrous pericardium, is firmly attached to the diaphragm below, the mediastinal pleura on the side, and the sternum in front and gradually blends with the coverings of the superior vena cava and the pulmonary (lung) arteries and veins leading to and from the heart. (The space between the two lungs, the mediastinum, is bordered by the mediastinal pleura, a continuation of the membrane lining the chest. The superior vena cava is the principal channel for venous blood from the chest, the arms, the neck, and the head.)

Smooth, serous (moisture-exuding) membrane lines the fibrous pericardium, then bends back and covers the heart (Figure 1). The portion of membrane lining the fibrous pericardium is known as the parietal serous membrane, that covering the heart as the visceral serous layer, or the epicardium.

The two layers of serous membrane are normally separated only by ten to 15 millilitres (0.6 to 0.9 cubic inch) of pericardial fluid, which is secreted by the serous membranes. The slight space created by the separation is called the pericardial cavity. The pericardial fluid lubricates the two membranes with every beat of the heart

as their surfaces glide over each other. Fluid is filtered into the pericardial space through both the visceral and parietal peritoneum.

Chambers of the heart. The heart is divided by septa, or partitions, into right and left halves, and each half is subdivided into two chambers. The upper chambers, the atria, are separated by a partition known as the interatrial septum; the lower chambers, the ventricles, are separated by the interventricular septum (Figure 2).

The atria serve as receiving chambers for blood from the various parts of the body and pump blood into the ventricles. The ventricles, in turn, pump blood to the lungs and to the remainder of the body.

The right atrium, or right superior portion of the heart, is a thin-walled chamber receiving blood from all tissues except the lungs. Three veins empty into the right atrium, the superior and inferior venae cavae, bringing blood from the upper and lower portions of the body, respectively, and the coronary sinus, draining blood from the heart itself. Blood flows from the right atrium to the right ventricle.

The right ventricle, the right inferior portion of the heart, is the chamber from which the pulmonary artery carries blood to the lungs.

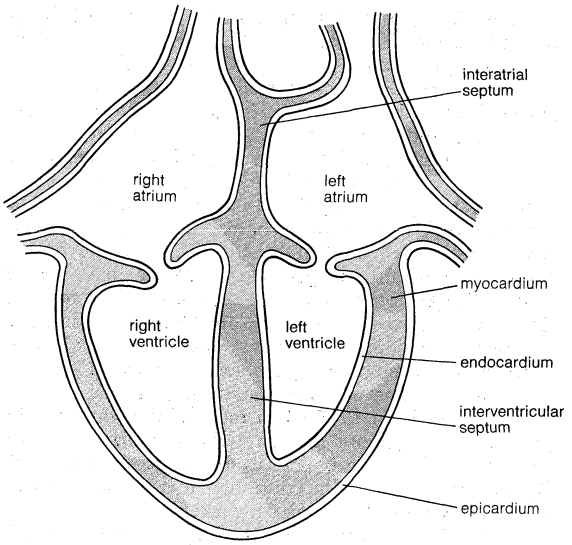

Figure 2: The walls and chambers of the heart.
From S. Jacob and C. Francone, *Structure and Function in Man* (1970); W.B. Saunders Co.

The left atrium, the left superior portion of the heart, is slightly smaller than the right atrium and has a thicker wall. The left atrium receives the four pulmonary veins, which bring oxygenated blood from the lungs. Blood flows from the left atrium into the left ventricle.

The left ventricle, the left inferior portion of the heart, has walls three times as thick as those of the right ventricle. Blood is forced from this chamber through the aorta to all parts of the body except the lungs.

External surface of the heart. Shallow grooves called the interventricular sulci, containing blood vessels, mark the separation between ventricles on the front and back surfaces of the heart. There are two grooves on the external surface of the heart. One, the atrioventricular groove, is along the line where the right atrium and the right ventricle meet; it contains a branch of the coronary artery (the coronary arteries deliver blood to the heart muscle). The other, the anterior interventricular sulcus, runs along the line between the right and left ventricles and contains a branch of the left coronary artery.

On the posterior side of the heart surface, a groove called the posterior longitudinal sulcus marks the division between the right and left ventricles; it contains another branch of the coronary artery. A fourth groove, between the left atrium and ventricle, holds the coronary sinus, a channel for venous blood.

Origin and development. In the embryo, formation of the heart begins in the pharyngeal, or throat, region. The first visible indication of the embryonic heart occurs in the undifferentiated mesoderm, the middle of the three primary layers in the embryo, as a thickening of invading cells. An endocardial (lining) tube of flattened

Four primary chambers in embryo

cells subsequently forms and continues to differentiate until a young tube with forked anterior and posterior ends arises. As differentiation and growth progress, this primitive tube begins to fold upon itself, and constrictions along its length produce four primary chambers. These are called, from posterior to anterior, the sinus venosus, atrium, ventricle, and truncus arteriosus (Figure 4). The characteristic bending of the tube causes the ventricle to swing first to the right and then behind the atrium, the truncus coming to lie between the sideways dilations of the atrium. It is during this stage of development and growth that the first pulsations of heart activity begin.

Endocardial cushions (local thickenings of the endocardium, or heart lining) "pinch" the single opening between the atrium and the ventricle into two portions, thereby forming two openings. These cushions are also responsible for the formation of the two atrioventricular valves (the valves between atria and ventricles), which regulate the direction of blood flow through the heart.

The atrium becomes separated into right and left halves first by a primary partition with a perforation and later by a secondary partition, which, too, has a large opening, called the foramen ovale, in its lower part. Even though the two openings do not quite coincide in position, blood still passes through, from the right atrium to the left. At birth, increased blood pressure in the left atrium forces the primary partition against the secondary one, so that the two openings are blocked and the atria are completely separated. The two partitions eventually fuse.

The ventricle becomes partially divided into two chambers by an indentation of myocardium (heart muscle) at its tip. This developing partition is largely muscular and is supplemented by membranous connective tissue that develops in conjunction with the subdivision of the truncus arteriosus by a spiral partition into two channels, one for systemic and one for pulmonary circulation (the aorta and the pulmonary artery, respectively). The greater portion of blood passing through the right side of the heart in the fetus is returned to the systemic circulation by the ductus arteriosus, a vessel connecting the pulmonary artery and the aorta. At birth this duct becomes closed by a violent contraction of its muscular wall. Thereafter the blood in the right side of the heart is driven through the pulmonary arteries to the lungs for oxygenation and returned to the left side of the heart for ejection into the systemic circulation.

A distinct median furrow at the apex of the ventricles marks the external subdivision of the ventricle into right and left chambers.

Hearts in lower animals

Hearts in lower animals are found in forms corresponding closely to the various stages described in human embryonic development. Fish have a primitive heart, four chambers in series (the sinus venosus, atrium, ventricle, and truncus arteriosus) with some folding. Valves are present between all chambers, and contraction occurs in all chambers except the truncus. The heart receives deoxygenated blood at the rear and pumps it forward for aeration in the gills.

The heart becomes more specialized when associated with the use of lungs for oxygenation of the blood, bringing about partial or complete anatomic separation of chambers within the heart, which is associated with the separate return of oxygenated and deoxygenated blood. In amphibians the atrium is at least partially subdivided into two chambers. The left chamber receives blood directly from the lungs, while the right receives venous blood. The ventricle is undivided, but the pulmonary and systemic streams are kept reasonably well separated by ridges and pockets in the ventricular wall. Atrioventricular valves, with fibrous cords called chordae tendineae, prevent the backflow of blood, as do valves in the pulmonary vessels.

From S. Jacob and C. Francone, *Structure and Function in Man* (1970); W.B. Saunders Co.

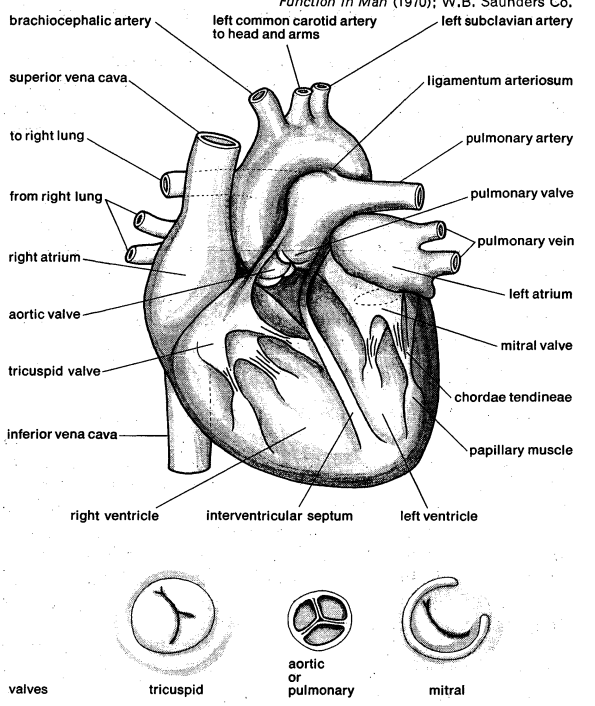

Figure 5: Schematic "transparent" drawing of the heart showing the relations of the various heart valves.

The muscular walls of the hearts of both fish and amphibians are sufficiently irrigated by the blood within the heart so that there exists no need for an additional separate system of vessels that serve the heart muscle itself. Reptiles, however, representing a step up the evolutionary scale, possess two coronary arteries branching from the right aortic trunk, and the reptilian heart has four chambers. The atrium is completely divided into right and left chambers, but the ventricle remains only partially divided by a septum, or partition. As a result, some mixing of the venous and systemic blood occurs.

The truncus arteriosus has become subdivided by a spiral partition into a pulmonary trunk and two aortic trunks.

In birds and mammals, four completely separate heart cavities are formed. Venous blood flows through the right atrium and ventricle through the pulmonary arteries to the lungs; then it flows back to the left atrium via

pulmonary veins, then to the left ventricle, and then, by way of the aorta, into the systemic circulation. With the complete separation of the ventricles, the thickness of the muscular wall of the left ventricle becomes greater than that of the right.

Structure and function. *Valves of the heart.* To prevent backflow of blood, the heart is equipped with special valves that permit the blood to flow in only one direction (Figure 5). There are two types of valves located in the heart: the atrioventricular valves (tricuspid and mitral) and the semilunar valves (pulmonary and aortic).

The atrioventricular valves are thin, leaflike structures located between the atria and the ventricles. The right atrioventricular opening is guarded by the tricuspid valve, so called because it consists of three irregularly shaped cusps, or flaps.

The leaflets consist essentially of folds of endocardium (heart lining) reinforced with a flat sheet of dense connective tissue. At the base of the leaflets, the middle supporting flat plate becomes continuous with that of the dense connective tissue of the ridge surrounding the openings.

Chordae tendineae and papillary muscles

Tendinous cords of dense tissue (chordae tendineae) covered by thin endocardium extend from the nipple-like papillary muscles to connect with the ventricular surface of the middle supporting layer of each leaflet. The chordae tendineae and the papillary muscles from which they arise limit the extent to which the portions of the valves near their free margin can billow toward the atria.

The left atrioventricular opening is guarded by the mitral, or bicuspid, valve, so named because it consists of two flaps. The mitral valve is attached in the same manner as the tricuspid, but it is stronger and thicker because the left ventricle is by nature a more powerful pump.

Blood is propelled through the tricuspid and mitral valves as the atria contract. When the ventricles contract, blood is forced backward, passing between the flaps and walls of the ventricles. The flaps are thus pushed upward until they meet and unite, forming a complete partition between the atria and the ventricles. The expanded flaps of the valves are restrained by the chordae tendineae and papillary muscles from opening into the atria.

The semilunar valves are pocket-like structures attached at the point at which the pulmonary artery and the aorta leave the ventricles. The pulmonary valve guards the orifice between the right ventricle and the pulmonary artery. The aortic valve protects the orifice between the left ventricle and the aorta. The leaflets of the aortic semilunar and pulmonary valves are thinner than those of the atrioventricular valves, but they are of the same general construction with the exception that they possess no chordae tendineae.

Closure of the heart valves is associated with an audible sound. The first sound occurs when the mitral and tricuspid valves close, the second when the pulmonary and aortic semilunar valves close. These characteristic heart sounds have been found to be caused by the vibration of the walls of the heart and major vessels around the heart. The first heart sound, or "lubb," is heard when the ventricles contract, causing a sudden backflow of blood that closes the valves and causes them to bulge back. The elasticity of the valves then causes the blood to bounce backward into each respective ventricle. This effect sets the walls of the ventricles into vibration, and the vibrations travel away from the valves. When the vibrations reach the chest wall where the wall is in contact with the heart, sound waves are created that can be heard with the aid of a stethoscope.

The second heart sound results from vibrations set up in the walls of the pulmonary artery, the aorta, and, to a lesser extent, the ventricles as the blood reverberates back and forth between the walls of the arteries and the valves after the pulmonary and aortic semilunar valves suddenly close. These vibrations are then heard as the "dupp" sound as the chest wall transforms the vibrations into sound waves.

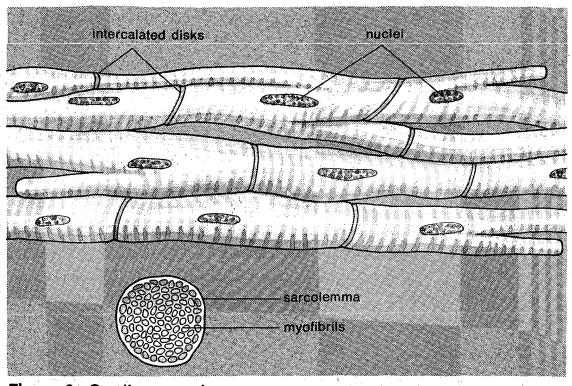

Figure 6: Cardiac muscle.
From S. Jacob and C. Francone, *Structure and Function in Man* (1970); W.B. Saunders Co.

The first heart sound is followed after a short pause by the second. A pause about twice as long comes between the second sound and the beginning of the next cycle. The opening of the valves is silent.

Three layers of the heart wall

Wall of the heart. The wall of the heart consists of three distinct layers—the epicardium (external layer), the myocardium (middle layer), and the endocardium (inner layer). Coronary vessels supplying arterial blood to the heart penetrate the epicardium before entering the myocardium. This outer layer, or visceral pericardium, consists of a surface of flattened epithelial (covering) cells resting upon connective tissue.

The myocardium consists of interlacing bundles of cardiac muscle fibres (Figure 6) possessing the appearance of striated muscle (striped skeletal muscle) with intermittent dark plates crossing the fibres, but these highly specialized fibres differ fundamentally from those of skeletal muscle in the arrangement of nuclei and in the smaller calibre of the individual fibre. The nuclei are oval in appearance and situated along the central axis of the fibre, which may range in size from 12 to 21 microns in diameter (there are about 25,000 microns in one inch). Each fibre consists of a bundle of smaller fibres, called myofibrils, each of which passes through the full length of the fibre and is covered by an external limiting membrane known as the sarcolemma.

The individual cardiac muscle cells are striped crosswise throughout, with alternating dark bands that are opaque to light and with light bands that permit the passage of light. Prominent plates of condensed dark bands called intercalated disks, crossing the muscle fibre at uneven intervals, are perhaps the most conspicuous feature unique to cardiac muscle.

It is the myocardial layer that causes the heart to contract; the bundles of the muscle fibres are so arranged as to result in a wringing type of movement that efficiently squeezes blood from the heart with each beat. The thickness of the myocardium varies according to the pressure generated to move blood to its destination.

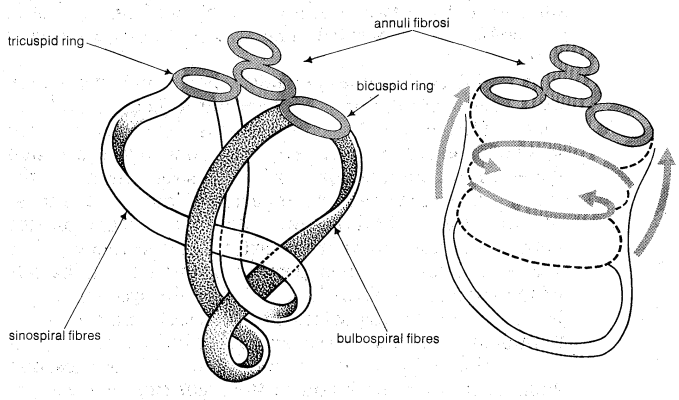

Figure 7: *The myocardium of the ventricles.*
(Left) Spiral muscles of ventricles. (Right) Dotted lines indicate changes in shape of heart due to contraction of ventricular muscle (arrows).

The myocardium of the left ventricle, which must drive blood out into the systemic circulation, is, therefore, thickest; the myocardium of the right ventricle, which propels blood to the lungs, is moderately thickened, while the atrial walls are relatively thin.

Forming the inner surface of the myocardial wall is a thin lining called the endocardium. This layer lines the cavities of the heart, covers the valves and small muscles associated with opening and closing of the valves, and is continuous with the lining membrane of the large blood vessels.

Blood supply to the heart. Because of the presence of the watertight lining of the heart (the endocardium) and the thickness of its muscular walls, the heart cannot depend for oxygen and nourishment on the blood contained in its chambers but must possess a vascular (vessel) system of its own. Two coronary arteries branch from the aorta as it leaves the heart and curl back across the chambers of the heart, sending twigs through the muscular walls. These coronary vessels are "end arteries"; that is, they follow their own course and have few cross connections with other nearby branches.

Branches of the coronary arteries

The left coronary artery remains intact for a short distance and then branches into two main arteries. One of these, the anterior descending coronary artery, supplies the front of the heart, particularly the left ventricle; the other, the left circumflex branch, supplies the left ventricle and the left atrium. The right coronary artery provides blood for the right side of the heart and the lower posterior portion of the left ventricle. Venous blood is returned to the heart through veins called cardiac veins that empty into a channel known as the coronary sinus, which then delivers the blood to the right atrium.

Heartbeat. *Regulation of heartbeat.* Proper functioning of the heart necessitates the presence of several unique characteristics. One quality is the inherent rhythmicity of cardiac muscle; no nerves are located within the heart itself, and no outside regulatory mechanisms are necessary to stimulate the muscle to contract rhythmically. That the heartbeat originates in the cardiac muscle can be substantiated by observing cardiac development in the embryo; cardiac pulsations begin before adequate development of nerve fibres. In addition, it can be demonstrated in the laboratory that even fragments of cardiac muscle in tissue culture continue to contract rhythmically. Furthermore, there is no gradation in degree of contraction of the muscle fibres of the heart, as would be expected if they were primarily under nervous control.

The mere possession of this intrinsic ability is not sufficient, however, to enable the heart to function efficiently. Proper function requires coordination, which is maintained by an elaborate conducting system within the heart that consists primarily of two relatively large masses of tissue, or nodes, from which impulses originate; of nerve-like conduits for the transmission of impulses; and of terminal portions of branches of the conduits at the inner surface of the ventricles.

From S. Jacob and C. Francone, *Structure and Function in Man* (1970); W.B. Saunders Co.

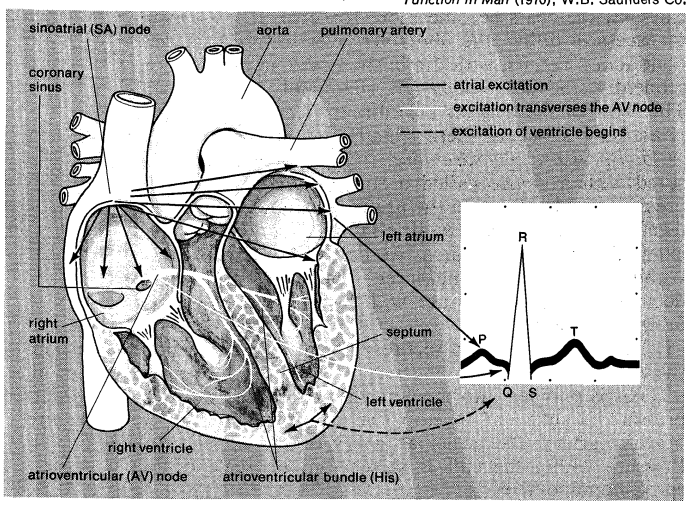

Figure 8: Conducting system of the heart showing source of electrical impulses produced on electrocardiogram.

A basic understanding of the method by which an impulse is transmitted is essential before the conduction system that exists within the heart can be properly understood.

Electrical potentials exist across membranes of essentially all cells of the body—that is, there is an electric tension created, generally by an excess number of negative ions immediately inside the cell membrane and an equal number of excess positive ions on the outside of the membrane, also known as a resting potential. (Ions are atoms or groups of atoms in solution that carry positive or negative electrical charges.) Further, some cells, such as nerve and muscle cells, have the additional distinction of being "excitable"—*i.e.*, capable of conducting impulses along their membranes.

Any factor that suddenly increases the permeability of the cell membrane and allows positive ions to flow through the membrane to the inside, while negative ions flow to the outside, is likely to bring about a sequence of rapid changes in the membrane potential, lasting only a fraction of a second. This change is followed by the return of the membrane potential to its resting value. This sequence of changes in potential is called an action potential and is responsible for the initiation of impulses transmitted, in the case of the heart, along the muscle fibres and the special conducting tissue fibres. Electrical stimulation, application of chemicals, mechanical damage, heat, and cold are among the various factors that can bring about a change in the state of a cell membrane, momentarily disturbing its normal resting state and creating an action potential.

The action potential occurs in two separate stages called depolarization and repolarization.

Depolarization and repolarization

During the process of depolarization, the normal negative potential inside the muscle fibre is lost, and the membrane potential actually reverses, or becomes slightly positive inside and negative outside the membrane. This process of depolarization proceeds as a wave along the length of the muscle fibres. It lasts only a fraction of a second before the positive ions begin to resume their original position on the outside of the membrane, necessary before another impulse can pass. This process is termed repolarization. An action potential is necessary to generate each depolarization wave.

The sinoatrial node (Figure 8) possesses the ability to generate an action potential spontaneously. This highly important structure is a small strip of specialized muscle located in the posterior wall of the right atrium, immediately beneath the point of entry of the superior vena cava. As an action potential is generated in the sinoatrial node, the impulse immediately spreads through the atrial muscle in the form of a ripple pattern similar to the pattern of waves generated when a stone is thrown into a pool of water.

A few specialized fibres possess the responsibility of subsequently relaying this potential, or impulse, to the atrioventricular node, located in the lower part of the right rear atrial wall. To permit sufficient time for complete contraction of the atria before subsequent simultaneous contraction of the ventricles, the impulse is delayed slightly in its passage through the atrioventricular node. The fibres that leave this node constitute the Purkinje system. These fibres pass between the atrioventricular valves and lead into the interventricular septum, where bundles of fibres in right and left branches project downward beneath the endocardium on either side of the septum. They then curve around the tip of the ventricles and back toward the atria along the side walls. These fibres terminate in the ventricular muscle, and depolarization in the muscle fibres is initiated.

Conducting system of the heart. Both the atrioventricular node, with an intrinsic beat of 40–60 beats per minute, and the Purkinje fibres, with an intrinsic beat of 15–40 beats per minute, are self-stimulating and capable of

rhythmic contraction, but at a rate slower than that of the sinoatrial node, which possesses an intrinsic capacity to beat 72 times per minute. Therefore, since recovery time is faster in the sinoatrial node, it controls the rate of the heartbeat, serving as the primary pacemaker. The atrioventricular node, with its 40-60 beats per minute, is termed the secondary pacemaker.

Effect of ions on heart function. Potassium, sodium, and calcium have a marked influence on transmission of action potential within cardiac muscle. In addition, calcium-ion concentration is important in the contractile process. The concentration of ions in extracellular fluids (those outside the cells) also affects cardiac function to a degree.

Excess potassium and excess calcium

Excess potassium ions in extracellular fluid slow the heart rate and cause the heart to dilate and become flaccid (flabby). There is general weakness of cardiac muscle. This weakening of the strength of contraction is caused by a decreased resting membrane potential with resulting decrease in the intensity of the action potential.

Calcium ions in excess produce just the opposite effect; the heart goes into spastic contraction. There is, however, little danger of the presence of excess calcium ions within the extracellular fluid in cardiac muscle, for excess calcium is precipitated as salts in the body tissues before a dangerous level is reached in the heart.

A depressed cardiac function occurs when sodium ions are present in excess. These ions interfere with the effectiveness of calcium in bringing about normal muscular contraction.

Presumably because of an increased permeability of muscle membrane to ions, temperature may also affect heart function. An increased heart rate occurs as temperature increases, and, conversely, heart rate decreases with decreased temperature.

Electrocardiogram. As an impulse travels along the cardiac muscle fibres, an electric current is generated by the flowing ions. This current spreads into the fluids around the heart, and a minute portion actually flows to the surface of the body. An electrocardiogram is a record of this electrical activity (Figure 8) as measured by a device called a galvanometer. Leads (*i.e.*, wires to the galvanometer) are placed on the surface of the body at various points, depending on the type of information desired. An electrocardiogram thus has the prime function of assessing the ability of the heart to transmit the cardiac impulse. Each portion of the cardiac cycle produces a different electrical impulse, causing the characteristic deflections of an electrocardiographic recording needle. The deflections, or waves, on the recording apparatus are, in order, the P, QRS complex, and T waves. As a wave of depolarization passes over the atria, the impulse is recorded as the P wave. As it continues on through the ventricles, it is registered as the QRS complex. The T wave is caused by currents generated as the ventricles recover from the state of depolarization. This repolarization process occurs in the muscle of the ventricles about 0.25 second after depolarization. There are, therefore, both depolarization and repolarization waves represented in the electrocardiogram.

The atria repolarize at the same time that the ventricles depolarize. The atrial repolarization wave is, however, obscured by the larger QRS wave.

Nervous control of the heart. Nervous control of the heart is maintained by the parasympathetic fibres in the vagus nerve (parasympathetic) and by the sympathetic nerves. The vagus nerve is the cardiac inhibitor, and the sympathetic nerves are the cardiac excitors. Stimulation of the vagus nerve depresses impulse formation and atrial contractility and thereby reduces cardiac output and slows the rate of the heart. Parasympathetic stimulation can also produce varying degrees of heart block in diseases of the heart. (In heart block the atria and the ventricles beat independently.) Stimulation of the sympathetic nerves increases contractility of both atria and ventricles.

Diastole and systole

The cardiac cycle is defined as that time from the end of one heart contraction to the end of the subsequent contraction and consists of a period of relaxation called diastole followed by a period of contraction called systole. During the entire cycle, pressure is maintained in the arteries; however, this pressure varies during the two stages, the normal diastolic pressure being 80 millimetres of mercury and the normal systolic pressure being 120 millimetres of mercury.

Blood-pressure regulation. Variation in blood pressure may depend on several regulating mechanisms. Arterioles represent the main resistance to blood flow. Blood pressure can, therefore, only be maintained if resistance in these arterioles falls each time cardiac output increases. The nerves that control the action of the small muscle fibres of the vessels maintain resistance at a level sufficient for satisfactorily high arterial blood pressure by constricting the channel, or lumen, of the arteriole. During dilation of the vessel pressure is decreased. Arterial pressure is also affected by the chemical composition of the blood. A decreased oxygen or increased carbon dioxide tension (pressure) causes a reflex elevation of blood pressure. Respiratory activity is, therefore, an important regulator of arterial pressure.

The renin–angiotensin system provides hormonal control of blood pressure. Decreased blood flow to the kidney, changes in posture, or blockage of one or both renal (kidney) arteries may lead to increased production of the enzyme renin by the kidney. This substance causes development in the circulating blood of the substance angiotensin II, which causes blood vessels to contract, with resultant increase in blood pressure.

Receptors in great veins, in the aortic arch (the bend in the aorta above the heart), and the carotid sinus are sensitive to changes in blood pressure as blood is forced from the ventricles. These receptors, known as pressoreceptors, function as an aid in modifying shifts in pressure. When the receptors are stimulated by a rise in arterial pressure, which distends the arterial wall, they have an inhibiting effect on the heart, causing it to beat more slowly and with less force. At the same time there is a decrease in the contraction of the blood vessels. A fall in pressure, on the other hand, causes increased sympathetic and decreased parasympathetic stimulation, with resultant increased heart rate and also a subsequent constriction of the blood vessels.

Force of cardiac contraction. The force of the heartbeat depends on the initial length of the heart muscle fibres, the length of the pause in diastole, the oxygen supply, and the integrity and mass of the heart muscle, or myocardium. The greater the initial length of the muscle fibres in the heart, the more forceful will be the contraction. Artificially increasing venous return of blood to the heart distends the heart and intensifies the force of the beat. The greater inflow is handled by an increased output of the heart, without a change in its rate. When the ventricle does not completely fill (for example, after loss of blood), the force of the heartbeat is reduced. When the venous inflow during diastole is increased, as in muscular exercise, the beats become more forceful. If, as a result of excessive filling, the fibres are overstretched, a weak contraction results, with diminished cardiac output; consequently, the heart does not adequately empty itself. The force of the heart is also diminished if the diastolic phase is too short and there is inadequate filling.

Blood-pressure measurement. Blood pressure is measured with a device called a sphygmomanometer. The pressure of blood within the artery is balanced by an external pressure exerted by air contained in a cuff applied externally around the arm. Actually, it is the pressure within the cuff that is measured. The steps employed in determining blood pressure with a sphygmomanometer are the following:

Steps in determining blood pressure

1. The cuff is wrapped securely around the arm above the elbow.
2. Air is pumped into the cuff with a rubber bulb until pressure is sufficient to stop the flow of blood in the brachial artery (the principal artery of the upper arm). Pressure within the cuff is shown on the scale of the sphygmomanometer.
3. The observer places a stethoscope over the brachial artery just below the elbow and gradually releases the

air from within the cuff. The decreased air pressure permits the blood to flow, filling the artery below the cuff. Faint tapping sounds corresponding to the heartbeat are heard. When the sound is first noted, the air pressure within the cuff is recorded on the scale. This pressure is equal to the systolic blood pressure.

4. As the air in the cuff is further released, the sounds become progressively louder, until the sounds change in quality from loud to soft and finally disappear. At the point at which the sounds change from loud to soft, the instrument reading corresponds directly to the diastolic pressure.

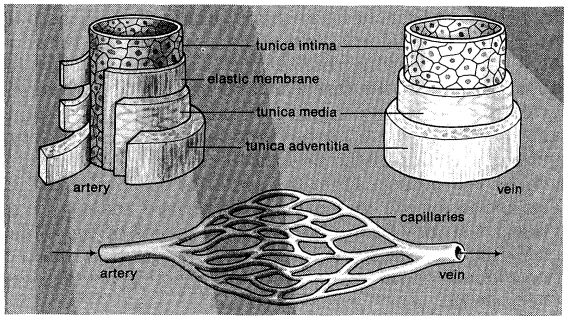

Figure 9: Component parts of arteries and veins.
From S. Jacob and C. Francone, *Structure and Function in Man* (1970); W.B. Saunders Co.

The American Heart Association recommends that, when a large disparity exists between the level at which the sound becomes dull or muffled and the point at which the sound completely disappears, the level at which the sound completely disappears should also be recorded as diastolic blood pressure. If the two levels are identical, only one level is recorded.

BLOOD VESSELS

Because of the need for the early development of a transport system within the developing embryo, the organs of the vascular system are among the first to appear and to assume their functional role. In fact, this system is established in its basic form by the fourth week of embryonic life.

At approximately the 18th day of gestation, cells begin to group together between the outer skin (ectoderm) and the inner skin (endoderm) of the embryo. These cells soon become rearranged so that the more peripheral ones join to form a continuous flattened sheet enclosing more centrally placed cells; these cells remain suspended in a fluid medium as primitive blood cells. The tubes then expand and unite to form a network; the primitive blood vessels thus appear.

Structure. The blood vessels consist of a closed system of tubes functioning to transport blood to all parts of the body and back to the heart. As in any biological system, structure and function of the vessels are so closely related that one cannot be discussed without the other's being taken into account.

Arteries function to transport to the various body tissues blood under high pressure that is exerted by the pumping action of the heart. The heart forces blood into these elastic tubes, which recoil, sending blood on in pulsating waves. It is, therefore, imperative that the vessels possess strong, elastic walls to ensure fast, efficient blood flow to the tissues.

Three layers of the artery wall

The wall of an artery consists of three layers, the innermost consisting of an inner surface of smooth endothelium and an outer surface of elastic tissues: the two form the tunica intima. The tunica media, or middle coat, is thicker in arteries, particularly in the large arteries, and consists of smooth muscle cells intermingled with elastic fibres. The muscle-cell and elastic fibres circle the vessel. In larger vessels the tunica media is composed primarily of elastic fibres. As arteries become smaller, the number of elastic fibres decreases while the number of smooth muscle fibres increases. The outer layer, the tunica adventitia, is the strongest of the three layers. It is composed of collagenous and elastic fibres. (Collagen is a connective-tissue protein.) The tunica adventitia provides a limiting barrier, protecting the vessel from overexpansion (Figure 9). Also characteristic of this layer is the presence of small blood vessels called the vasa vasorum that supply the walls of larger arteries and veins; the inner and middle layers are nourished by diffusion from the blood as it is transported. The thicker, more elastic wall of arteries enables them to expand with the pulse and to regain their original size.

The transition from artery to arteriole is a gradual one, marked by a progressive thinning of the vessel wall and a decrease in the size of the lumen, or passageway. The tunica intima is still present as a lining covered by a layer of thin, longitudinal fibres. A single layer of circular or spiral, smooth muscle fibres now comprises the tunica media, and the tunica adventitia consists of connective-tissue elements.

Being the last small branches of the arterial system, arterioles must act as control valves through which blood is released into the capillaries. The strong muscular wall of arterioles is capable of completely closing the passageway or permitting it to expand to several times its normal size, thereby vastly altering blood flow to the capillaries. Blood flow is by this device directed to tissues that require it most.

As the arterioles become smaller in size, the three coats become less and less definite, the smallest arterioles consisting of little more than endothelium, or lining, surrounded by a layer of smooth muscle.

The microscopic capillary tubules consist of a single layer of endothelium, a continuation of the innermost lining cells of arteries and veins.

As the capillaries converge, small venules are formed whose function it is to collect blood from the capillary beds (*i.e.*, the networks of capillaries). The venules consist of an endothelial tube supported by a small amount of collagenous tissue and, in the larger venules, by a few smooth muscle fibres as well. As venules continue to increase in size, they begin to exhibit the wall structure that is a characteristic of the arteries, although they are much thinner.

In veins, which function to conduct blood from the peripheral tissues to the heart, an endothelial lining is surrounded by the tunica media, which contains less muscle and elastic tissue than is found in the arterial wall. The outermost layer, tunica adventitia, is composed chiefly of connective tissue. Blood pressure in these vessels is extremely low as compared with that in the arterial system, and blood must exit at an even lower pressure. This creates a need for a special mechanism to keep blood moving on its return to the heart.

Venous valves

To achieve this, many veins possess a unique system of valves. These valves, formed by semilunar folds in the tunica intima, are present in pairs and serve to direct the flow of blood to the heart, particularly in an upward direction. As blood flows toward the heart, the flaps of the valves flatten against the wall of the vein; they then billow out to block the opening as the pressure of the blood and surrounding tissues fills the valve pocket. These valves are more abundant in the veins of the extremities than in any other parts of the body.

The veins are more distensible than arteries, and their walls are so constructed as to enable them to expand or contract. A major function of their contractility appears to be to decrease the capacity of the cardiovascular system by constriction of the peripheral vessels in response to the heart's inability to pump sufficient blood.

Veins tend to follow a course parallel to that of arteries but are present in greater number. Their channels are larger than those of arteries, and the walls are thinner. Seventy-nine percent of the blood volume is in the systemic circulation, and 59 percent is normally present in the veins.

Pulmonary circulation. The pulmonary circuit comprises the right ventricle, the exiting pulmonary artery and its branches, the arterioles, capillaries, and venules of the lungs, and the pulmonary veins that empty into the left atrium.

The pulmonary trunk, the common stem of the pulmonary arteries, arises from the upper surface of the right ventricle and extends some four to five centimetres (1.6 to two inches) beyond this origin before dividing into the right and left pulmonary arteries, which supply the lungs. Three semilunar valves guard the opening between the right ventricle and the pulmonary trunk. The trunk is relatively thin walled for an artery, having walls approximately twice the thickness of the vena cava and one-third that of the aorta. The right and left pulmonary arteries are short but possess a relatively large diameter. The walls are distensible; the vessels are able, therefore, to accommodate the stroke volume of the right ventricle, which is a necessary function equal to that of the left ventricle.

Pulmonary arteries and their branchings

The pulmonary trunk passes diagonally upward to the left across the route of the aorta. Between the fifth and sixth thoracic vertebrae (at about the level of the bottom of the breastbone), the trunk divides into two branches—the right and left pulmonary arteries—which enter the lungs. After entering the lungs, the branches go through a process of subdivision, the final branches being capillaries. Capillaries surrounding the air sacs (alveoli) of the lungs pick up oxygen and release carbon dioxide. The capillaries carrying oxygenated blood join larger and larger vessels until they reach the pulmonary veins, which carry oxygenated blood from the lungs to the left atrium of the heart.

Arteries. *The aorta and its principal branches.* The aorta is the largest vessel in the systemic circuit, arising from the left ventricle. For the sake of convenience, it is commonly divided into the ascending aorta, the arch of the aorta, and the descending aorta; the latter may be further subdivided into the thoracic and the abdominal aorta.

Originating from the ascending portion of the aorta are the right and left coronary arteries, which serve the heart. Branching from the arch of the aorta are three large arteries named, in order of origin from the heart, the innominate, the left common carotid, and the left subclavian. These three branches serve to supply the head, neck, and arms. As the innominate (sometimes referred to as the brachiocephalic) artery travels upward toward the clavicle, or collarbone, it divides into the right common carotid and right subclavian arteries. The two common carotid arteries, one branching from the innominate and the other directly from the aorta, then extend in a parallel fashion on either side of the neck to the top of the thyroid cartilage (the principal cartilage in the voice box, or larynx), where they divide, each to become an internal and an external carotid artery. The external carotid artery gives off branches that supply much of the head and neck, while the internal carotids are responsible for supplying the forward portion of the brain, the eye and its appendages, and the forehead and nose. The two vertebral arteries, one arising as a branch of the innominate and the other as a branch of the left subclavian artery, unite at the base of the brain to form the basilar artery, which in turn divides into the posterior cerebral arteries. The blood supply to the brain is derived mainly from vessels that may be considered as branches of the circle of Willis, which is made up of the two vertebral and the two internal carotid arteries and connecting arteries between them.

The arms are supplied by the subclavian artery on the left and by the continuation of the innominate on the right. At approximately the border of the first rib, both of these vessels become known as the axillary artery; this, in turn, becomes the brachial artery as it passes down the upper arm. At about the level of the elbow, the brachial artery divides into two terminal branches, the radial and ulnar arteries, the radial passing downward on the distal (thumb) side of the forearm, the ulnar on the medial side. Interconnections (anastomoses) between the two, with branches at the level of the palm, supply the hand and wrist.

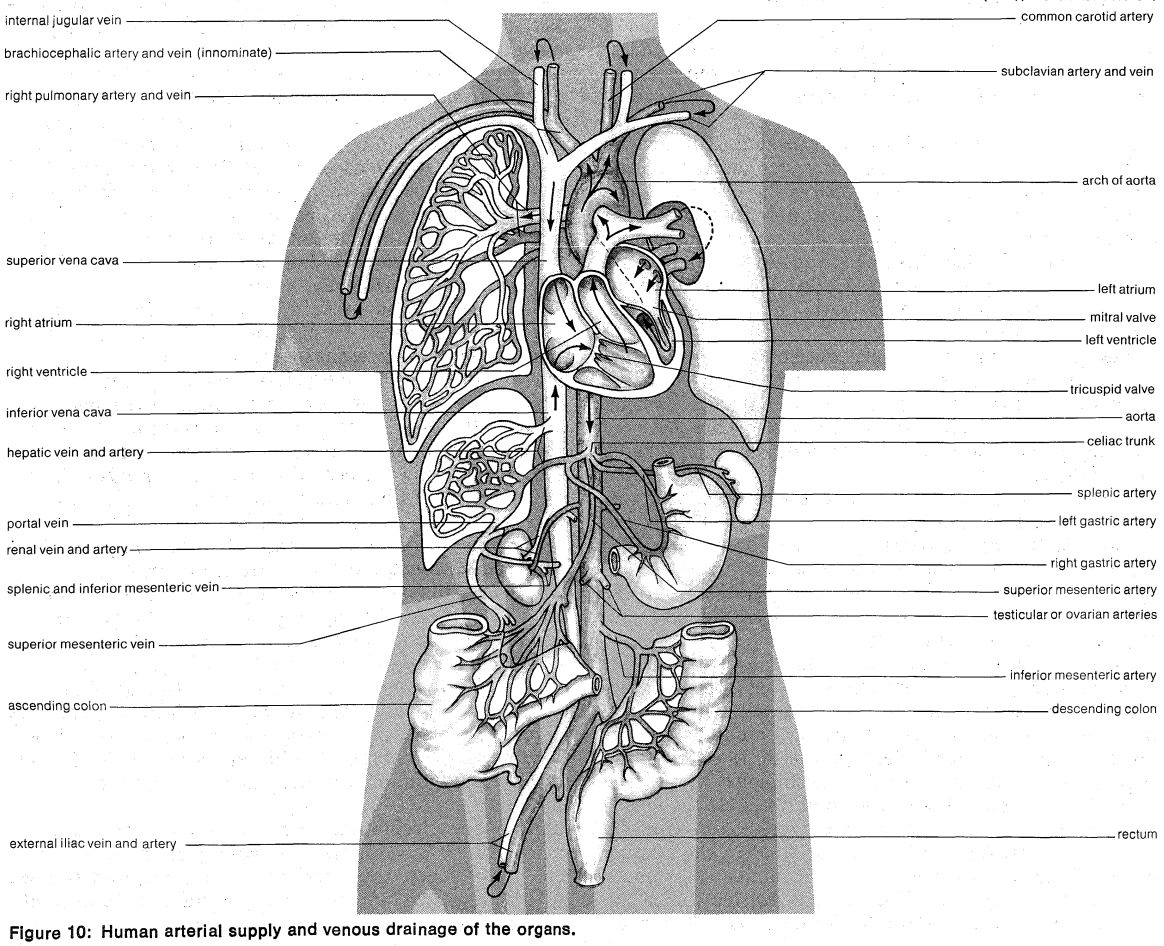

Figure 10: Human arterial supply and venous drainage of the organs.

Thoracic aorta

The thoracic (chest) portion of the descending aorta gives off branches (Figure 10) that supply the viscera (visceral branches) and the walls surrounding the thoracic cavity (parietal branches). The visceral branches provide blood for the pericardium, lungs, bronchi, lymph nodes, and esophagus. The parietal vessels supply the intercostal muscles (the muscles between the ribs) and the muscles of the thoracic wall; they supply blood to the membrane covering the lungs and lining the thoracic cavity, the spinal cord, the vertebral column, and a portion of the diaphragm.

As the aorta descends through the diaphragm, it becomes known as the abdominal aorta and again gives off both visceral and parietal branches. Visceral vessels include the celiac, superior mesenteric, and inferior mesenteric, which are unpaired, and the renal and testicular or ovarian, which are paired. The celiac artery arises from the aorta a short distance below the diaphragm and almost immediately divides into the left gastric artery, serving part of the stomach and esophagus; the hepatic artery, which primarily serves the liver; and the splenic artery, which supplies the stomach, pancreas, and spleen.

The superior mesenteric artery arises from the abdominal aorta just below the celiac artery. Its branches supply the small intestine and part of the large intestine. Arising several centimetres above the termination of the aorta is the inferior mesenteric artery, which branches to supply the lower part of the colon. The renal arteries pass to the kidneys. The testicular or ovarian arteries supply the testes in the male and the ovaries in the female, respectively.

Parietal branches of the abdominal aorta include the inferior phrenic, serving the suprarenal (adrenal) glands, the lumbar, and the middle sacral arteries. The lumbar arteries are arranged in four pairs and supply the muscles of the abdominal wall, the skin, the lumbar vertebrae, the spinal cord, and the meninges, or spinal-cord coverings.

The abdominal aorta terminates by dividing into two common iliac arteries, each of which descends laterally and gives rise to external and internal branches. The right and left external iliac arteries are direct continuations of the common iliacs and become known as the femoral arteries after passing through the inguinal region, giving off branches that supply structures of the abdomen and lower extremities. At a point just above the knee, the femoral artery continues as the popliteal artery; from this arise the posterior and anterior tibial arteries. The posterior tibial artery is a direct continuation of the popliteal, passing down the lower leg to supply structures of the posterior portion of the leg and foot. Arising from the posterior tibial artery a short distance below the knee is the peroneal artery; this gives off branches that nourish the lower leg muscles and the fibula (the smaller of the two bones in the lower leg) and terminates in the foot. The anterior tibial artery passes down the lower leg to the ankle, where it becomes the dorsalis pedis artery, which supplies the foot.

Pulse. An impulse can be felt over an artery that lies near the surface of the skin. The impulse results from alternate expansion and contraction of the arterial wall because of the beating of the heart. When the heart ejects blood into the aorta, the blood's impact on the elastic walls creates a pressure wave that continues along the arteries. This impact is the pulse. All arteries have a pulse, but it is most easily felt at points where the vessel approaches the surface of the body. The pulse is readily distinguished at the following locations: (1) at the point in the wrist where the radial artery approaches the surface; (2) at the side of the lower jaw where the external maxillary (facial) artery crosses it; (3) at the temple above and to the outer side of the eye, where the temporal artery is near the surface; (4) on the side of the neck, from the carotid artery; (5) on the inner side of the biceps, from the brachial artery; (6) in the groin, from the femoral artery; (7) behind the knee, from the popliteal artery; (8) on the upper side of the foot, from the dorsalis pedis artery.

Where pulse can be distinguished

The radial artery is most commonly used to check the pulse. Several fingers are placed on the artery close to the wrist joint. More than one fingertip is preferable because of the large, sensitive surface available to feel the pulse wave. While the pulse is being checked, certain data are recorded, including the number of beats per minute, the force and strength of the beat, and the tension offered by the artery to the finger. Normally, the interval between beats is of equal length. Irregularity occurs when there is abnormal heart rhythm.

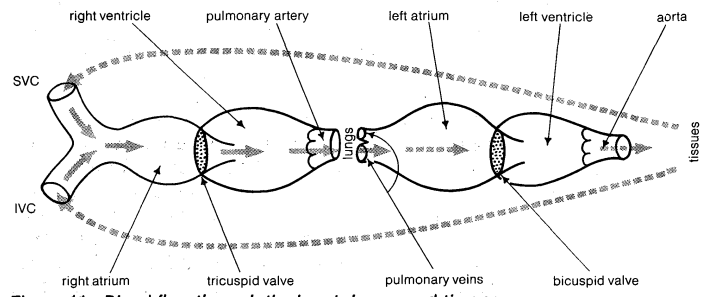

Figure 11: *Blood flow through the heart, lungs, and tissues of the body.*
Pulmonary circulation is indicated by solid arrows; systemic circulation by dashed arrows. SVC is superior vena cava; IVC is inferior vena cava.

Veins. Venules collect blood from the capillaries and the blood channels known as sinusoids and unite to form progressively larger veins that terminate as the great veins, or venae cavae. In the extremities there are superficial and deep veins; the superficial lie just under the skin and drain the skin and superficial fasciae (sheets of fibrous tissue), while the deep veins accompany the principal arteries of the extremities and are similarly named. Interconnections between the superficial and the deep veins are frequent.

Venous blood enters the right atrium from three sources: the heart muscle by way of the coronary sinus; the upper body by way of the superior vena cava; and the lower body by way of the inferior vena cava.

Superior vena cava and its tributaries. Tributaries from the head and neck, the arms, and part of the chest unite to form the superior vena cava. Venous channels called venous sinuses lie between the two layers of the dura mater, the outer covering of the brain; they possess no valves. Venous drainage of the brain is effected by these sinuses and communicating vessels. The internal jugular vein is a continuation of this system downward through the neck; it receives blood from parts of the face, neck, and brain. At approximately the level of the collarbone, each unites with the subclavian vein of that side to form the innominate veins.

The external jugular vein is formed by the union of its tributaries near the angle of the lower jaw, or mandible. It drains some of the structures of the head and neck and pours its contents along with the subclavian into the innominate vein of the same side.

All of the veins of the arm are tributaries of the subclavian vein of that side. They are found in both superficial and deep locations and possess valves. Most of the deep veins are arranged in pairs with cross connections between them.

Superficial and deep veins of the arm

Venous drainage of the hand is accomplished superficially by small anastomosing (interconnecting) veins that unite to form the cephalic vein, coursing up the radial (thumb) side of the forearm, and the basilic vein, running up the ulnar side of the forearm and receiving blood from the hand, forearm, and arm. The deep veins of the forearm include the radial veins, continuations of deep anastomosing veins of the hand and wrist, and the ulnar veins, both veins following the course of the associated artery. The radial and ulnar veins converge at the elbow to form the brachial vein; this, in turn, unites with the basilic vein at the level of the shoulder to produce the axillary vein. At the outer border of the first rib, the axillary vein becomes the subclavian vein, the terminal

point of the venous system characteristic of the upper extremity.

The subclavian, external jugular, and internal jugular veins all converge to form the innominate vein. The right and left innominate veins terminate in the superior vena cava, which opens into the upper posterior portion of the right atrium.

In addition to the innominate veins, the superior vena cava receives blood from the azygous vein and small veins from the mediastinum (the region between the two lungs) and the pericardium. Most of the blood from the back and from the walls of the chest and abdomen drains into veins lying alongside the vertebral bodies (the weight-bearing portions of the vertebrae; Figure 12). These veins form what is termed the azygous system, which serves as a connecting link between the superior and inferior vena cava. The terminal veins of this system are the azygous, hemi-azygous, and accessory hemi-azygous veins. At the level of the diaphragm, the right ascending lumbar vein continues upward as the azygous vein, principal tributaries of which are the right intercostal veins, which drain the muscles of the intercostal spaces. It also receives tributaries from the esophagus, lymph nodes, pericardium, and right lung, and it enters into the superior vena cava at about the level of the fourth thoracic vertebra.

The left side of the azygous system varies greatly among individuals. Usually the hemi-azygous vein arises just below the diaphragm as a continuation of the left ascending lumbar vein and terminates in the azygous vein. Tributaries of the hemi-azygous drain the intercostal muscles, the esophagus, and a portion of the mediastinum. The accessory hemi-azygous usually extends downward as a continuation of the vein of the fourth intercostal space, receiving tributaries from the left intercostal spaces and the left bronchus. It empties into the azygous vein slightly above the entrance of the hemi-azygous.

Inferior vena cava and its tributaries. The inferior vena cava is a large, valveless, venous trunk that receives blood from the legs, the back, and the walls and contents of the abdomen and pelvis.

The foot is drained primarily by the dorsal venous arch, which crosses the top of the feet not far from the base of the toes. The arch is connected with veins that drain the sole. Superficially the lower leg is drained by the large and small saphenous veins, which are continuations of the dorsal venous arch. The small saphenous vein extends up the back of the lower leg to terminate usually in the popliteal vein. There is some interconnection with deep veins and with the great saphenous vein. The latter vein, the longest in the body, extends from the dorsal venous arch up the inside of the lower leg and thigh, receiving venous branches from the knee and thigh area and terminating in the femoral vein.

Superficial veins of the leg

Most blood from the lower extremity returns by way of the deep veins. These include the femoral and popliteal veins and the veins accompanying the anterior and posterior tibial and peroneal arteries. The anterior and posterior tibial veins originate in the foot and join at the level of the knee to form the popliteal vein; the latter becomes the femoral vein as it continues its extension through the thigh.

At the level of the inguinal ligament (which is at the anterior, diagonal border between the trunk and the thigh), the femoral vein becomes known as the external iliac vein; the latter unites with the internal iliac vein to form the common iliac vein. The internal iliac vein drains the pelvic walls, viscera, external genitalia, buttocks, and a portion of the thigh. Through the paired common iliac veins, the legs and most of the pelvis are drained. The two common iliacs then unite at a level above the coccyx (the bottommost bone in the spine) to become the inferior vena cava. As it courses upward through the abdomen, the inferior vena cava receives blood from the common iliacs and from the lumbar, renal, suprarenal, and hepatic veins before emptying into the right atrium.

The pairs of lumbar veins (which drain blood from the loins and abdominal walls) are united on each side by a vertical connecting vein, the ascending lumbar vein; the right ascending lumbar vein continues as the azygous and the left as the hemi-azygous. These veins usually enter separately into the inferior vena cava.

Renal veins lie in front of the corresponding renal artery; the right renal vein receives tributaries exclusively from the kidney, while the left receives blood from a number of other organs as well. The right suprarenal

vein terminates directly in the inferior vena cava as does the right phrenic, above the gonadal vein. Two or three short hepatic trunks empty into the inferior vena cava as it passes through the diaphragm.

Portal system. The portal system may be described as a specialized portion of the systemic circulatory system. It is unique in that blood from the spleen, stomach, pancreas, and intestine first passes through the liver before it goes to the heart. Blood flowing to the liver comes from the hepatic artery (20 percent) and the portal vein (80 percent); blood leaving the liver flows through the hepatic vein and then empties into the inferior vena cava. The hepatic arterial blood supplies oxygen requirements for the liver. Blood from the abdominal viscera, particularly the intestinal tract, passes into the portal vein and then into the liver. Substances in the portal blood are processed by the liver (see LIVER, HUMAN).

Hepatic artery and portal vein

Venous pulmonary system. From the pulmonary capillaries, in which blood takes on oxygen and gives up carbon dioxide, the oxygenated blood is collected first into venules and then into progressively larger veins; it finally flows through four pulmonary veins, two from the hilum of each lung. (The hilum is the point of entry on each lung for the bronchus, blood vessels, and nerves.) These veins then pass to the left atrium, where their contents are poured into the heart.

Capillaries. The vast network of some 10,000,000,000 microscopic capillaries functions to provide a method whereby fluids, nutrients, and wastes are exchanged between the blood and the tissues. Even though microscopic in size, the largest capillary being approximately 0.2 millimetre in diameter (about the width of the tip of a pin), the great network of capillaries serves as a reservoir normally containing about one-sixth of the total circulating blood volume. The number of capillaries in active tissue, such as muscle, liver, kidney, and lungs, is greater than the number in tendon or ligament, for example; the cornea of the eye, epidermis, and hyaline cartilage (semitransparent cartilage such as is found in joints) are devoid of capillaries.

The interconnecting network of capillaries into which the arterioles empty is characterized not only by microscopic size but also by extremely thin walls only one cell in thickness. The vessels are simply tubular continuations of the inner lining cells of the larger vessels, normally uniform in size, usually three to four endothelial cells in circumference, except toward the venous terminations, where they become slightly wider, four to six cells in circumference. A thin membrane, called a basement membrane, surrounds these cells and serves to maintain the integrity of the vessel.

A single capillary unit consists of a branching and interconnecting (anastomosing) network of vessels, each averaging 0.5 to one millimetre (0.02 to 0.04 inch) in length. The wall of the capillary is extremely thin and acts as a semipermeable membrane allowing substances having small molecules, such as oxygen, carbon dioxide, water, and glucose, to pass through the membrane. Oxygen and nutritive material pass into the tissues through the wall at the arteriolar end of the capillary unit; carbon dioxide and waste products move through the membrane into the vessel at the venous end of the capillary bed.

Constriction and dilation of the arterioles is primarily responsible for regulating the flow of blood into the capillaries. Muscular gatekeepers, or sphincters, in the capillary unit itself, however, serve to direct the flow to those areas in greatest need.

Two routes through capillary wall

There are two modes of transport across the cellular membrane of the capillary wall. Substances soluble in the lipid (fatty) membrane of the capillary cells can pass directly through these membranes by a process of diffusion. Other substances needed by the tissues and soluble in water but completely insoluble in the lipid membrane pass through minute water-filled passageways, or pores, in the membranes, by a process called ultrafiltration. Only $\frac{1}{1,000}$ of the surface area of capillaries is represented by these pores.

Fetal circulation. The circulatory system of the fetus differs from that of the adult, since the lungs and alimentary canal of the fetus are nonfunctional. These differences disappear at birth or shortly thereafter.

Oxygenated blood is carried from the placenta to the fetus by the umbilical vein. It then passes to the inferior vena cava of the fetus by way of a vessel called the ductus venosus. From the inferior vena cava, the blood enters the right atrium, then passes through the foramen ovale into the left atrium; from there it moves into the left ventricle and out the aorta, which pumps the oxygenated blood to the head and upper extremities. Blood from the upper extremities returns via the superior vena cava into the right atrium, where it is largely deflected into the right ventricle.

From the right ventricle, a portion of the blood flows into the pulmonary artery to the lungs. The largest fraction flows through an opening, the ductus arteriosus, into the aorta. It enters the aorta beyond the point at which the blood of the head leaves. Some of the blood supplies the lower portion of the body. The remainder returns to the placenta via the umbilical arteries, which branch off from the internal iliac arteries.

The changes that take place at birth and that permit routing of the blood through the pulmonary system instead of the umbilical vessels have been touched upon above in the section on the origin and development of the heart.

TECHNIQUES OF EVALUATING THE HEART AND VASCULAR SYSTEM

Certain diagnostic techniques with respect to the heart require an exact knowledge of the anatomy of the circulatory system.

Right-heart catheterization. Right-heart catheterization is performed by insertion of a catheter (a long tube) into the cubital vein (at the bend of the elbow), the saphenous vein (in the inner thigh), or the femoral vein (at the groin). The catheter, which is opaque to X-ray, is advanced into the right atrium, right ventricle, and pulmonary artery while the surgeon is guided by X-ray views. This procedure makes it possible to measure pressure and oxygen saturation in the right heart chamber itself, so that abnormalities in the valves of the right side of the heart can be diagnosed.

Left-heart catheterization. Left-heart catheterization is accomplished by introducing a catheter into the brachial or femoral artery (in the upper arm and thigh, respectively) and advancing it through the aorta across the aortic valve and into the left ventricle. Mitral and aortic valvular defects and myocardial disease can be evaluated by this technique.

Angiocardiography. X-ray outlines of the cardiac chambers and great vessels (the large vessels opening directly into the heart) are provided by rapidly injecting X-ray-opaque material through an arm vein or through a catheter threaded into the right or left side of the heart. This procedure is followed by a series of rapid exposures to X-ray (angiocardiography) or to X-ray movies, called cineangiography. Angiocardiography permits direct visualization of the cardiac chambers and great vessels. By outlining abnormal circulatory pathways, it provides one of the best methods of detecting the site and extent of congenital abnormalities of the heart. It can also be used to study arteries and veins.

Cardiovascular System Diseases and Disorders

The cardiovascular system, by which the blood is circulated, consists of the heart and the blood vessels. There are two subsystems of vessels in the system: (1) those that carry oxygenated blood out from the heart to the bodily tissues and bring back to the heart the blood laden with carbon dioxide and low in oxygen, and (2) those that convey blood to the lungs and from the lungs back to the heart. The first of these subsystems makes up the systemic circulation; the second, the pulmonary circulation. The vessels conveying blood from the heart to the tissues are, in descending order of size, the arteries, arterioles, and capillaries; those returning blood to the heart from the tissues are, in ascending order, capillaries, venules, and veins.

Each side of the heart is a pump, and each has two chambers, an upper chamber (atrium) and a lower chamber (ventricle). Blood low in oxygen and high in carbon dioxide enters the right atrium through two large veins, the venae cavae. From the right atrium the blood passes into the right ventricle, which pumps it through the pulmonary artery to the lungs. There it receives oxygen and loses carbon dioxide. From the lungs the blood returns to the left atrium through the pulmonary vein. It then passes into the left ventricle, which pumps it out into the systemic circulation through the aorta. The heart muscle (myocardium) is supplied with oxygenated blood through the coronary arteries (see also CARDIOVASCULAR SYSTEM, HUMAN; RESPIRATION, HUMAN).

Significance. Diseases of the heart and blood vessels constitute one of the major health problems of modern man. Because life depends on the function of the heart, the stopping of its activity has been a major criterion of death for centuries. Thus, the heart is involved in all death, but this does not account for its prominence in causing death. To some degree, as medical science advances, more and more people are saved from other illnesses, only to die from one of the unsolved and uncontrolled disorders of the cardiovascular system. Whether the rising incidence of heart disease represents an actual increase in disease or only a redefinition related to the eradication of other diseases cannot now be answered. Fortunately, some forms of cardiovascular diseases are receding as causes of death, and there is hope that continued research and preventive measures may provide even greater benefits.

History. Heart disease as such was not recognized by primitive man, but he did appreciate the beating heart and its relationship to death. Sudden death, now usually attributed to heart disease, was recognized as early as the 5th century BC by the Greek physician Hippocrates, and noted to be more common in the obese. The role of disease in affecting the heart itself did not become apparent until examination of the body after death became acceptable in the 17th century. Gradually, the involvement of the heart valves, the blood vessels, and the heart muscle itself was observed and categorized in an orderly fashion. The recognition of the manifestations of heart failure came later, as did the ability to diagnose heart ailments by physical examination through the techniques of percussion (thumping), auscultation (listening) with the stethoscope, and other means. Not until early in the 20th century did the clinical determination of arterial blood pressure and the use of X-rays for diagnosis become widespread.

Early knowledge of heart disease

In 1912 James Bryan Herrick, a Chicago physician, first described in clinical terms what he called coronary thrombosis (he was describing symptoms actually caused by myocardial infarction; see below). Angina pectoris (described and discussed in a later section) had been recorded centuries earlier. Cardiovascular surgery in the modern sense began in the 1930s, and open-heart surgery in the 1950s.

Incidence. The exact incidence of heart disease in the world population is difficult to ascertain, because complete and adequate public health figures for either prevalence or deaths are not available. In the more highly developed countries of the world, such as the United States, Great Britain, and most European countries, arteriosclerotic heart disease (heart disease resulting from thickening and hardening of the artery walls; see below) constitutes by far the most predominant form and is increasing in incidence. Whether this represents a true increase in the incidence of the disease itself or merely reflects the eradication of other diseases cannot yet be answered. In other areas, such as the countries of Equatorial Africa, arteriosclerotic heart disease is far less common; other forms of heart disease, however, are frequently reported as the cause of death. In the Orient and islands of the Pacific, hypertensive cardiovascular disease, disease involving high blood pressure, constitutes a major health hazard.

Consideration of the diseases and disorders of the heart, the pericardium (the membranous sac enclosing the heart), and the vessels that open directly into the heart makes up the first major division of this article. A section on surgical treatment of the heart is also included in this division. The remainder of the article is concerned with the diseases of the rest of the blood vessels.

The heart and the great vessels

CONGENITAL HEART DISEASE

The heart's complicated evolution during embryologic development from a long tubular structure into an organ with four chambers and many vessels presents the opportunity for many different types of congenital defects to occur. Congenital heart disease is one of the important varieties of cardiovascular system diseases, although its frequency is less than that of some forms of acquired heart disease. Congenital disturbances are varied and involve almost all components of the heart and great vessels. At times, the incompletely developed cardiovascular system is incapable of sustaining life and the infant is stillborn.

Those systems that are compatible with life have been classified into the cyanotic and the noncyanotic varieties. In the cyanotic variety, the body turns blue. The blue colour may result from the presence of a shunt that bypasses the normal circulation and delivers venous (deoxygenated) blood into the arterial circulation. Cyanosis (manifested by the dusky blue appearance of the skin) may also occur in congenital heart disease in which there is inadequacy of blood flow, or in disease of the pulmonary vascular bed that prevents adequate oxygenation of the arterial blood. The last of these forms of cyanosis usually comes later in life and is not considered a part of the cyanotic group of disturbances at birth. Some congenital anomalies may exist and those having them may have a full life expectancy. Many can be corrected by surgery.

Classification with respect to cyanosis

A classification of the many types of recognized abnormalities follows.

Abnormalities of individual chambers of the heart. Abnormalities of the heart chambers may be serious, and even incompatible with life. They are often found combined with other defects. The group includes incomplete development of the right ventricle; infundibular stenosis of the right ventricle (narrowing of the right ventricle in the area from which blood flows into the pulmonary artery); the presence of an accessory left atrial chamber; and subaortic stenosis, a narrowing of the left ventricle near the valve that opens into the aorta.

Abnormalities of the atrial septum. The atrial septum is the wall between the two atria, the upper chambers of the heart. Defects in the septum are one of the more important congenital malformations. During normal intrauterine life, the blood passes through the atrial septum via an aperture called the foramen ovale. This aperture normally closes at the time of birth, but may remain open and, in effect, is a form of atrial septal defect. Other forms of atrial septal defect may persist into adult life. Some are small; others are large, with almost no septum remaining and with significant effects on the circulation of the blood. An atrial septal defect is a noncyanotic type of congenital heart disease; it may occur in later life as a result of complications. Septal defects, unless they

are major, are compatible with a long life. In the presence of a major defect there is shunting of blood from the left side of the heart to the right, and the blood flow in the pulmonary circulation may greatly increase. This condition places an added burden on the right side of the heart and may result in high blood pressure in the pulmonary artery. If this pressure persists, disease of the pulmonary vascular system may follow, and interference with the oxygenation of blood may occur, causing cyanosis to occur later in life.

Abnormalities of the ventricular septum. Small defects in the interventricular septum, the partition that separates the lower chambers of the heart, are common and are compatible with long life. They often create loud murmurs, but unless the defect is sizable, no significant changes in the blood circulation occur. If the defect is sizable, a significant amount of blood is shunted from the left ventricle to the right and a circulatory situation similar to that in the large atrial septal defect occurs. In the most severe form there is, in effect, a common ventricle, with mixing of arterial and venous blood. An additional hazard in septal defect, moreover, is that it increases the possibility of bacterial endocarditis, inflammation of the heart lining as a result of bacterial infection.

The tetralogy of Fallot

A septal defect is often combined with other congenital defects. The most widely known of these is the tetralogy of Fallot, named after the French physician, Étienne Louis Arthur Fallot, who first described it. In this condition (1) a ventricular septal defect is combined with (2) pulmonary stenosis, the narrowing of the opening into the pulmonary artery, with (3) the opening into the aorta more to the right than normal, and (4) with right ventricular hypertrophy—a thickening of the muscle of the right ventricle, thus completing the tetralogy. The pulmonary stenosis causes venous blood to be shunted from the right to the left side of the heart, whence it is pumped out into the systemic circulation. This defect of the cyanotic type is the most common form of cyanotic congenital heart disease compatible with survival beyond infancy; approximately three-fourths of the cyanotic persons over ten years of age have this defect or a variant of it. The prominent features besides cyanosis are difficulty in breathing on exertion, retarded growth, an abnormally high level of red blood cells, and a characteristic easing of respiration by squatting. It is the classic type of defect treated surgically by the so-called blue-baby operations.

Abnormal origins of arteries. Abnormal points of origin of arteries, such as transposition of the origin of the aorta and that of the pulmonary artery, are serious defects causing cyanotic disease. In other instances, both the aorta and the pulmonary artery originate from the right ventricle, and there is a ventricular septum defect; this combination of defects presents a severe form of cyanotic heart disease. Some palliation may be possible by surgery.

Abnormalities of valves. A heart valve may be abnormal or completely absent. Some valve defects are minor and not important except as a possible site for the development of bacterial endocarditis. Others are more severe and may result in circulatory impairment such as that which occurs in acquired valve disease. Treatment is surgical.

Abnormalities of the myocardium (the heart muscle). Several types of heart muscle abnormality may occur. Hypertrophy (enlargement) is present in almost all heart disease, because enlargement is the compensatory mechanism for the heart that is failing to provide an adequate circulation to the rest of the body organs. Hypertrophy of the myocardium is not in itself bad, but it indicates some type of cardiac (heart) disease. Glycogen storage diseases and congenital tumours of the myocardium are extremely rare problems associated with the heart muscle. (In the glycogen storage diseases abnormal amounts of the carbohydrate glycogen build up in the tissues because enzyme defects prevent its normal breakdown into lactic acid. Treatment is largely by regulation of the diet.) Congenital tumours may be surgically removed but are often so extensive that surgery is not helpful.

Abnormalities of the endocardium. Abnormalities of the endocardium, the membrane lining the heart, may be present, although they are rare. The abnormalities include fibroelastosis, a disease in which the endocardium becomes a thick fibrous coat, causing interference with the normal contraction of the heart. Endocardial cords that support the heart valve structure may also thicken, become fibrous, and interfere with the normal heart valve function. There is no known treatment for these rare abnormalities.

Thickening of the endocardium

Abnormalities of the pericardium. Abnormalities of the pericardium, the membraneous sac containing the heart, may be congenital. The most frequent abnormality, absence of the pericardium, however, is without functional significance.

Abnormalities of the coronary arteries. Various abnormalities are found in the coronary arteries, the blood vessels supplying oxygen to the heart muscle itself. One is the significant reduction in size or the absence of one or more of the three main vessels, a condition leading to failure of sufficient oxygen to reach sections of heart muscle, with consequent death of these tissues (see below *Myocardial infarction*). The coronary arteries may arise abnormally from a pulmonary artery rather than from the aorta, causing unoxygenated rather than oxygenated blood to flow through (perfuse) the heart muscle. Congenital weak spots may be present in the coronary arteries, which thus become susceptible to rupture. The coronary sinus, the common vein that collects blood that has perfused the heart muscle, may be unusually enlarged or absent. Finally, abnormal openings may be present between the coronary arteries and the coronary sinus or a chamber of the heart. Remarkably, most of the congenital abnormalities of the coronary arteries cause no symptoms and may well be associated with long life. Rarely, surgery is employed to correct a coronary-artery abnormality.

Abnormalities of the aorta. Abnormalities of the aorta, the major blood vessel arising directly from the left ventricle of the heart and supplying blood to the systemic circulation, may also occur on a congenital basis. The early part of the aorta, the ascending aorta, may be stenotic (that is, unusually narrowed), usually as a result of a defect in the wall of the aorta itself or of the presence of fibrous tissue that narrows the valve. There may be an opening between the aorta and the pulmonary arteries that did not close at the appropriate time during embryologic development of the cardiovascular system; this defect is called a truncus arteriosus. The aortic arch, the curving portion of the aorta immediately above the heart, may have several congenital defects. It may be incompletely developed embryologically, or there may be an opening, known as a patent ductus arteriosus, at this point between the aorta and the pulmonary artery. This opening between the two vessels is necessary during uterine life, but normally closes at the time of birth and the clamping of the umbilical cord. Coarctation of the aorta, a deformity of the aortic wall resulting in severe narrowing of the blood vessel, may also occur. Any of the congenital abnormalities of the aorta may be present for a long time before being identified, and almost all are surgically correctable.

Stenosis of the ascending aorta

Anomalous pulmonary venous return. Of the abnormalities of the pulmonary veins, the most common is the anomalous pulmonary venous return. In this condition, the pulmonary veins normally draining oxygenated blood from one or more lobes of the lung to the left side of the heart abnormally return to the right side of the heart. Occasionally an arteriovenous fistula may occur, an abnormal opening between the pulmonary artery and the pulmonary vein. These abnormalities frequently cause no significant cardiac disease by themselves, but they are frequently associated with other congenital abnormalities. Surgical correction is occasionally employed.

Abnormalities of the venae cavae. The most common abnormalities of the venae cavae, the major veins returning venous blood to the right side of the heart, are a persistent left superior vena cava (normally there is but

one superior vena cava, opening into the right side of the heart), and an abnormal termination of the vena cava. If these cause significant symptoms, surgical correction is possible.

ACQUIRED HEART DISEASE

The coronary arteries and the heart. The blood vessels supplying the muscle of the heart are called the coronary arteries and veins. Disease involving the coronary arteries may result from several possible causes, arteriosclerosis being by far the most common. Because arteriosclerosis and the other processes involving the coronary arteries produce an inadequacy of blood flow (ischemia), the term ischemic heart disease has been used virtually synonymously to indicate that the clinical manifestations are due to the lack of blood flow to the heart.

Arteriosclerotic heart disease. Arteriosclerosis is a disease in which lesions known as atheromas develop in the arterial wall and undergo a sequence of changes that may lead to "hardening of the arteries" and, eventually, to arterial obstruction. The atheromas are characterized by localized thickening of the blood vessel wall with variable deposits of lipid (fatty) material. This thickening and deposition result in a deterioration of the normal structures of the wall, so that formation of scar tissue (fibrosis); deposits of calcium salts; tortuosity (*i.e.*, a twisting or turning of the vessel); and, later, bleeding under the inner coat (intima) of the vessel, obstruction, and clot formation may occur. Such vascular lesions may be widespread in the body, but severe lesions are more likely to be found in the coronary vessels. The development of vascular disease of this type is so common with advancing age that it has been thought by many to be a part of the aging process itself. Modern medical opinion, however, describes it as a disease that begins as an abnormal metabolic process of the vascular wall and leads to the various types of blood vessel deformity that, in the case of the coronary arteries, in turn leads to interference with the blood supply to the heart muscle (ischemia) and to the group of symptoms associated with ischemia.

Whether arteriosclerosis is a part of aging

The cause of coronary arteriosclerosis is not clear, but it undoubtedly does not spring from a single cause. A wide variety of studies of causes has been carried out, some demonstrating that ischemic heart disease is much more frequently found in the temperate zones of the world, and that in relatively advanced and affluent cultures it is much more common in men than in women, although the incidence in women rises appreciably after the menopause. A number of additional notable correlations have been made. The disease is more common in those countries in which the diet is substantial and high in animal fat. It has been demonstrated that the lipid content of the blood is altered with a notably high level of cholesterol in persons from these areas. (Cholesterol is a substance present in all animal fat and prominent in the lipid material in the atheromas.) It has similarly been noted that there is a substantially increased hazard of developing the clinical manifestations of coronary artery disease in those individuals with a history of heavy cigarette smoking and in those with arterial hypertension (high blood pressure). Additional, but less well documented, positive correlates include excessive weight, a sedentary rather than an active existence, and, in certain circumstances, a life of unusual stress. Certain racial groups, such as Jewish populations, appear to be more susceptible to the disorder, and it is less common in the black races, except when arterial hypertension is present. In general, the medical profession feels that these factors contribute to the rapidity of the development of the disease, but that they are not primarily causative.

Asymptomatic coronary artery disease. Considerable coronary artery disease may be present without symptoms, particularly in the male. Autopsy studies conducted on U.S. soldiers who died of battle wounds in Korea and Vietnam (average age of 24 years) indicated an appreciable degree of coronary artery disease in a majority of them. In an older population group, the incidence would undoubtedly be much higher and the involvement more severe. It is suspected that as high as 40 percent of all myocardial infarctions (death of sections of heart muscle) fail to cause symptoms and that the affected person is not aware of them. The conventional diagnostic tools of the physician are unable to detect the presence of coronary artery disease unless there has been some element of muscular involvement that generally, but not always, causes changes in the electrocardiogram, a tracing reflecting the electric current produced when the heart muscle is contracted. Special coronary X-rays give a reasonably exact picture of the coronary blood vessel pattern, but do not indicate the small nonobstructive lesions that may be the forerunner of more serious involvement. The procedure for making coronary X-rays is complicated, moreover, and somewhat hazardous, and it is not applied on a widespread basis in persons who do not have symptoms. No entirely satisfactory method of evaluating the presence and degree of coronary artery disease in a person who has no symptoms is available.

Angina pectoris. Angina pectoris, resulting from severe underlying coronary artery disease or, much less commonly, from other types of impairment of coronary flow, is characterized by paroxysms of deep seated, aching pain beneath the breastbone and in the region over the heart and stomach. These paroxysms are usually distinctive in character, location, and radiation, and are generally induced by walking, other physical exercise, or emotional stress. The pain is characteristically an oppressive type, often associated with a sense of strangulation or anxiety. Affected persons often use a clenched fist to describe the sense of heaviness and constriction, and some deny that it is a "pain." The discomfort may spread from the chest, particularly in the leftward direction, down the left arm and up into the left side of the jaw. On rare occasions, pain may be noted only in the more peripheral areas. Persons affected often attribute the discomfort to indigestion, and, at times, similar discomfort can be caused by spasm of the esophagus and by other disorders. The characteristic pattern of anginal pain, its occurrence upon physical exertion, especially in cold weather, and its relief by nitroglycerin form a pattern that is usually quickly identified by the physician. At times the pain may occur while a person is at rest, particularly when he is under emotional stress, but it may occur at night while he is lying quietly in bed.

Characteristics of angina pectoris

Physical examination may reveal no abnormalities. The electrocardiogram may show transient changes; but, more often than not, there is no distinctive alteration in the electrocardiographic pattern while the affected person is resting. The use of coronary X-rays has demonstrated that persons with angina pectoris usually have widespread involvement of the coronary arteries, with obstruction of two or more of the major vessels. On occasion, a physician may elect to have the patient exercise while his electrocardiogram is being recorded to bring out abnormalities that may make the diagnosis more certain.

Treatment of angina pectoris includes a change in the affected person's pattern of exercise and activity. The drug nitroglycerin usually provides remarkably effective immediate relief from the pain. Other drugs, often less effective, may provide long-term diminution of the symptoms.

Myocardial infarction (heart attack). A syndrome (symptom complex) of prolonged, severe chest pain was first described in the medical literature in 1912 by James Bryan Herrick, as noted above. He attributed the syndrome to coronary thrombosis, the development of a clot in a major blood vessel serving the heart. Although aspects of this common disease had been described earlier, it remained for Herrick to put the information together in a concise and direct fashion. As a result of Herrick's convincing description, the disorder was termed coronary thrombosis or coronary occlusion (blockage of a coronary artery). Later evidence indicated, however, that, although arteriosclerosis of the coronary arteries is by far the most common cause of the disorder, the manifestations are in reality the result of the death of an area of heart muscle (infarction).

The term myocardial infarction, therefore, is more appropriate. Indeed, it has been demonstrated that a coronary thrombosis in the true sense is not present in many such patients. The more general and less specific term heart attack may, thus, be more desirable because of these difficulties in describing the causation of the disease entity.

Characteristics of myocardial infarction

Myocardial infarction occurs as a result of arteriosclerosis of the coronary arteries and is characterized pathologically by cellular death (necrosis) of a segment of the heart muscle. Generally, it involves an area in the forward wall of the heart related to the blood distribution of the anterior descending coronary artery, although in other instances, the posterior wall or the septum (partition) of the ventricle is involved. The exact immediate cause of the myocardial infarction is not clearly understood. Coronary thrombosis is present in a majority of the hearts examined at autopsy and undoubtedly plays an important role in some cases. In others, changes in metabolic demands of the heart muscle in the presence of a restricted blood flow may be enough to cause death of ischemic cells.

The outstanding clinical feature is pain, similar in many respects to that of angina pectoris. The important difference is that the pain lasts for a much longer period, at least half an hour, and usually for several hours and perhaps for days. The pain is often described as "crushing," "compressing," "like a vise," and is associated with some difficulty in breathing. As with angina pectoris, the pain may radiate to the left arm or up the neck into the jaws or head. There is occasional nausea, vomiting, and weakness. The affected person frequently is pale, and he may perspire profusely. On the other hand, most of these symptoms may be absent, and the occurrence of an infarction can then be detected only by laboratory means. The physical examination at the time of the painful episode may not provide the physician with positive evidence that an infarction has occurred. Laboratory studies may show an elevation of the white-blood-cell count in the blood or a rise in the enzyme content of the blood, indicating leakage from damaged heart muscle cells. The electrocardiogram in many instances shows distinct and characteristic abnormalities, but the electrocardiographic abnormalities may be less characteristic or totally absent.

Physical signs of infarction

In most persons who experience an acute myocardial infarction, the circulation remains adequate, and only by subtle evidence such as rales (abnormal respiratory sounds) in the lungs or a gallop rhythm of the heart beat may the evidence of some minor degree of heart failure be detected. In a relatively small percent of cases, the state of shock occurs, with pallor, coolness of the hands and feet, low blood pressure, and rapid heart action. In these cases, myocardial infarction is highly lethal, with survival rates of only 20–40 percent, in contrast to the current survival rate in many hospitals of 70–80 percent. Mortality is also related to age, for the process is more lethal in the elderly. Another cause of death is sudden arrhythmia, or irregularity, of heart action, which constitutes one of the situations in which death comes suddenly. In a small number of persons there may be death from heart rupture caused by thromboembolism (obstruction caused by a clot that has broken loose from its site of formation). In some individuals, the damage caused by the infarction may interfere with functioning of the mitral valve, the valve between the left upper and lower chambers, and result in a form of valvular heart disease, or it may cause a rupture of the interventricular septum, the partition between the left and right ventricles, with the development of a ventricular septal defect, such as is seen in some forms of congenital heart disease.

In the modern treatment of acute myocardial infarction, the affected person is admitted to a hospital coronary-care unit, where the use of appropriate electronic devices for monitoring heart rhythm and detecting abnormalities enables an experienced nursing staff to reduce the possibility of sudden death. Drugs are used to control arrhythmias and to strengthen myocardial function.

Convalescence from an acute myocardial infarction may last several weeks to several months, allowing time for scar tissue to form in the area of an infarction and a gradual return to activity. Although some persons may have residual evidence of heart failure or other cardiac malfunction, the majority of individuals may return to an active life after a period of weeks and are not in any way invalided by the process. They do, however, have an increased potential for subsequent myocardial infarction.

Sudden death. The term "sudden death" as used in medicine is not explicit and may be used to describe death that is almost instantaneous or in which rapidly fatal disease processes may occupy as much as two or three days. In heart disease both may occur, but the term characteristically refers to relatively instantaneous death, similar to turning off a light switch. This type of demise is frequent in coronary artery disease and constitutes one of the major hazards of this disease. Sudden death from coronary artery disease occurs so frequently that less than half of the persons who die from heart attacks each year in the United States survive long enough to reach the hospital.

Relatively instantaneous sudden death is usually related to an arrhythmia of the heart, with either total mechanical and electrical standstill of the heart or ventricular fibrillation (an uncontrolled and uncoordinated twitching of the ventricle muscle), with total mechanical inadequacy of the heart and erratic and ineffective electrical activity. Sudden death may occur without any previous manifestations of coronary artery disease. It may occur in the course of angina pectoris and causes about one half of the deaths due to acute myocardial infarction in hospitalized patients, although this number is decreasing with the more widespread use of coronary-care units. A reduced supply of blood to the heart undoubtedly is the precipitating factor, but there does not have to be acute myocardial infarction. In a vast majority of persons who have died almost instantaneously, no infarction was present, but there was widespread coronary artery disease. In rare instances, sudden death occurs without a major degree of coronary artery disease.

Resuscitation after apparent death

The use of closed chest cardiopulmonary massage (massage of heart and lungs without making an opening in the chest wall), coupled with electrical defibrillation (the use of electrical shocks), if applied within a few minutes of the sudden death episode, may resuscitate a person and provide a possibility of long-term survival. In coronary-care units where the facilities and trained personnel are immediately available, the percentage of successful resuscitations is high. In general hospitals where resuscitation teams have been established, the percentage is less satisfactory. Sudden death outside the hospital is, of course, a more difficult problem, but mobile coronary-care units responding as emergency ambulances to the site of a sudden death were on trial in the 1970s. Effective resuscitation depends upon the prompt arrival of the unit. The use of drugs and other means to prevent the onset of sudden death has been relatively successful in the coronary-care unit, except in situations in which the disease has been present for a long period of time.

Arteriosclerotic heart disease with congestive failure. The ischemic process of arteriosclerotic heart disease may render the heart less effective as a pump, and the constellation of findings indicating congestive failure occurs (see below). Congestive heart failure may be present for a number of years and may be treated with good symptomatic relief. It may be caused by impaired function of the mitral valve or by a ventricular septal defect resulting from myocardial infarction. These difficulties can be treated surgically with relief of congestive failure, but, unfortunately, this treatment is afforded only to a minority of the persons with heart failure resulting from arteriosclerotic heart disease.

In the past, the diagnosis of arteriosclerotic heart disease was often used loosely for a large group of persons who had unexplained congestive heart failure. As medical knowledge advanced, however, more specific diagnoses became applicable, so that the number of patients in the category is diminishing.

Treatment of coronary artery disease. The specific treatment of angina pectoris and myocardial infarction

has already been discussed. Attempts to prolong life and diminish the likelihood of an additional or recurrent myocardial infarction are commonly undertaken on a long-term basis. Primary prevention, relating to measures taken to prevent even the first clinical manifestation of coronary artery disease, has as yet shown limited measurable success. Although a number of correlates have been noted, there is not yet unequivocal proof that changing one's mode of life will result in greater life expectancy. In persons whose hypertension is successfully treated, however, there appears to be excellent evidence that the incidence of clinical manifestations of coronary artery disease will be retarded and that life expectancy will be extended. There is also some evidence, although much less convincing, to indicate that the cessation of cigarette smoking, the reduction of blood cholesterol levels, and other similar factors may result in greater life expectancy. Substantiation of such evidence requires large-scale studies involving many persons, including controlled observations on a group of untreated persons.

Relief of high blood pressure

Other disease of the coronary arteries. Although coronary artery disease is by far most frequently caused by arteriosclerosis, there are many types of inflammation of the blood vessels that may rarely cause obstructive lesions of the coronary vessels. In persons with cardiovascular syphilis, the disease process may involve the mouth of the coronary vessels as they leave the aorta and cause obstruction to blood flow. On rare occasions, clots arising from some other part of the body may enter the coronary vessels and cause acute obstruction and clinical manifestations.

Rheumatic heart disease. Rheumatic heart disease results from inflammation of the heart lining, heart muscle, and pericardium occurring in the course of acute rheumatic fever, an infection with *Streptococcus pyogenes* organisms. The disease includes those later developments that persist after the acute process has subsided, and may result in damage to a valve, which may in turn lead to heart failure.

Rheumatic fever is poorly understood. The disease process occurs days or weeks following the initial streptococcal infection. Later infections may bring recurrences of the rheumatic fever that damage the heart. Immunologic processes (reactions to a foreign protein) are thought to be responsible for the response that damages the heart and particularly the heart valves. Rapid and effective treatment or prevention of streptococcal infections stops the acute process.

Many other factors of a geographic, economic, and climatic nature influence the incidence of rheumatic fever, but are not primarily causative. Rheumatic fever is becoming less common in the second half of the 20th century. With better control of streptococcal infections, there is indication of a sharp decline, with only one-fifth as many deaths as occurred in the 1930s and only one-half as many deaths as occurred in the 1960s. It is currently estimated, however, that about 1,000,000 people in the United States have rheumatic heart disease of one form or another.

It is thought that the basic pathologic lesion involves inflammatory changes in the collagen, the main supportive protein of the connective tissue. There is also inflammation of the heart lining (the endocardium) and the pericardium, the sac containing the heart. Only a relatively small percentage of deaths occur in the acute phase, with evidence of overwhelming inflammation associated with acute heart failure. There may be a disturbance of the conduction system of the heart and involvement of other tissues of the body, particularly the joints. About one half of the persons found to have late rheumatic valvular disease give some indication that they have had acute rheumatic fever.

Major effect of rheumatic fever

The major toll of rheumatic fever is in the deformity of the heart valves created by the initial attack or by frequently repeated attacks of the acute illness. Although there may be valve involvement in the acute stages, it usually requires several years before valve defects become manifest as the cause of heart malfunction. The valve most frequently affected is the mitral valve, less commonly the aortic valve, and least common of all, the pulmonic and tricuspid valves. These valves are, respectively, the valve between the left atrium and left ventricle; the valve at the opening into the aorta; the valve at the opening into the pulmonary artery; and the valve between the right upper and lower chambers. The lesion may cause either insufficiency of the valve, preventing it from operating in a normal fashion, or stenosis (narrowing) of the valve, preventing a normal flow of blood and adding to the burden of the heart.

Mitral valve involvement is the most common effect of rheumatic fever. The presence of mitral involvement is indicated by symptoms of heart failure, with shortness of breath and edema (abnormal accumulations of fluid in the bodily tissues). Heart murmurs are reasonably accurate signposts for specific valvular diagnoses. A murmur during the diastolic, or resting, phase of the heart, when blood normally flows through the mitral valve to fill the ventricle, generally indicates the presence of mitral stenosis. On the other hand, a murmur during the systole, or contraction, of the left ventricle, indicates an abnormal flow of blood back through the mitral valve into the left atrium (mitral insufficiency). When this latter condition is present, each beat of the heart must pump enough blood to supply the body as well as the wasted reflux into the pulmonary vascular system. This additional work load causes dilation and enlargement of the ventricle and leads to the development of congestive heart failure.

In addition to the clinical findings, X-rays of the heart and electrocardiographic findings may give evidence of the presence of mitral-valve disease. The passage of a long flexible tube or catheter through the venous or arterial system into the heart allows for pressure measurements and blood flow determinations that more specifically verify the clinical impression of mitral-valve disease. The injection of radiopaque contrast material into the blood stream (angiocardiography) to outline the blood-containing part of the heart in X-rays as the contrast material passes through makes possible the diagnosis of valvular defects, hypertrophy, and dilation, as well as any abnormal shunts or paths of blood flow.

Involvement of the aortic valve is also common, and again there may be evidence of stenosis or insufficiency. The presence of aortic stenosis may lead to a marked hypertrophy (enlargement) of the left ventricle of the heart. Involvement of either the tricuspid or pulmonic valve occurs in a similar fashion. In many persons with rheumatic valvular disease, more than one valve is involved. The specific type of valve involved influences the clinical picture of congestive failure (see the section on congestive failure).

Surgical treatment of heart valves

For many years the only therapy available for rheumatic heart disease was the treatment of the resultant heart failure by digitalis and other drugs. As the result of the spectacular development of cardiovascular surgery since the mid-1940s, it is now possible to treat many valve defects by surgery and by the installation of artificial replacement valves.

The heart, the pulmonary artery, and the aorta. *Pulmonary heart disease (cor pulmonale).* An obstruction to blood flow through the network of vessels in the lungs develops in various types of lung disease. Impingement on blood flow in this integral part of the total path of blood flow through the body impairs the total circulation and places a particular burden on the right side of the heart, which normally pumps against a low-pressure load with little impedance to blood flow. Pulmonary-artery pressures are low compared to those in the aorta.

Pulmonary heart disease may be divided into acute and chronic forms. The classic form of acute pulmonary heart disease (acute cor pulmonale) occurs when there is sudden obstruction to the pulmonary blood-flow pattern, as occurs with a massive embolus—a blood clot that has broken loose from its point of formation. This impairs blood flow through the lungs, causes additional reflex changes that add to the heart's burden, and creates an acute form of high blood pressure in the pulmonary arteries, with dilation and failure of the right ventricle. The

right ventricle's pumping ability is acutely depressed, and, therefore, the amount of blood available for the left side of the heart is equally restricted, so that systemic circulatory failure occurs. Respiratory symptoms are not prominent, and the disorder in its early stages is not accompanied by edema in the lung. The clinical picture in the more severe form is one of shock, with cold, pale, and clammy skin, low arterial pressure, and high pulse rate. The heart may be acutely dilated. The electrocardiogram may show the characteristic changes of acute right ventricular strain. In some instances, surgical removal of the obstruction may be life-saving. In others, the disorder may become less severe, but if recurrent, a more chronic form of cor pulmonale may develop.

In chronic cor pulmonale the causative factors may be either a form of pulmonary disease, such as emphysema (abnormal distension of the lungs with air), which obstructs flow through the pulmonary circulation, multiple blood clots in the vessels of the lung, or pulmonary vascular disease. The net result is a form of heart failure based primarily on obstruction to flow through the pulmonary blood vessels. Pulmonary arterial hypertension is common to most all of these forms. In many there may be cyanosis, with evidence that the arterial blood is not saturated with oxygen. The manifestations of heart failure are present, particularly when there is edema, except that shortness of breath as it is seen in ordinary congestive failure is not prominent, since the pulmonary blood vessels are not congested.

The right side of the heart is enlarged, the valve sounds from the pulmonic valve are loud, and there is electrocardiographic evidence of chronic strain on the right side of the heart. This condition is a form of chronic heart disease that is difficult for the physician to control and that may last for many years.

Hypertensive heart disease. Arterial hypertension (high blood pressure) is a disease in which the regulation of blood pressure is abnormal, resulting in the chronic maintenance of a higher-than-normal arterial pressure.

Types of hypertension

Transient elevations of blood pressure occur in the normal individual, but in the hypertensive individual the blood pressure, although still rising and falling in various circumstances, maintains a level that is on the average higher than normal. The disorder may result from one of several possible causes. In certain structural abnormalities of the aorta, such as coarctation, in which the artery's middle coat is deformed, with resultant narrowing of the channel, arterial pressure in the upper half of the body is abnormally high, as it is also in some tumours of the adrenal glands and, rarely, of other organs. Hypertension results also in a number of types of chronic renal (kidney) diseases. All these types of hypertension collectively, however, form only a relatively small percentage of the clinical occurrences of high blood pressure. A majority of occurrences, in which the cause is not obvious, are termed essential hypertension. Regardless of the cause, but in some ways coloured by it, the effects on the cardiovascular system are similar. The impact on the vascular system varies from person to person. In some persons, for unknown reasons, the body withstands the abnormal elevation of blood pressure with minimum change in the heart and blood vessels. In other situations, blood vessel damage is early and severe, coupled with serious deterioration of heart function. In general, the rule is that the higher the blood pressure, the higher the degree of cardiovascular damages, although there are many exceptions. In certain persons, a vicious and damaging form of hypertension occurs, often called malignant hypertension, which results in small blood vessel damage throughout the body, but particularly affecting the heart, brain, and kidneys. Persons with hypertensive disease have an increased susceptibility to atherosclerosis (a lesion of large and medium-sized arteries, with deposits in the intima—the inner coat—of yellowish plaques containing cholesterol, other lipid material, and cells that absorb fat) of the coronary arteries, thus making it difficult to separate the cardiac manifestations from those caused by hypertension, per se. Hypertensive persons, therefore, may eventually have congestive heart failure following enlargement of the heart caused by chronic increase in arterial pressure. In addition, they may suffer the effects of a decline in blood supply to the heart because of coronary artery disease and the classic manifestations of coronary arteriosclerosis, such as angina pectoris or death of a portion of heart muscle, myocardial infarction. There is clear evidence that treatment of hypertension with antihypertensive drugs reduces the likelihood that the heart will be affected, and it improves the condition of those who have a chronically elevated arterial pressure. Hypertensive cardiovascular disease may also become manifest through defects in the vessels supplying the brain, leading to stroke or other abnormalities of the brain. Furthermore, hypertensive cardiovascular manifestations may be complicated by the development of kidney failure and resultant abnormal retention of fluid in the tissues, adding to the problems of congestive heart failure.

Syphilis of the heart and aorta. Syphilis, a disease caused by infection with a micro-organism, *Treponema pallidum*, in its early phases becomes widespread in the human body. At this time, there may be transient inflammation of the heart muscle, but usually with little or no impairment of the circulation. In the late stages of the disease, there may be syphilitic involvement of the heart, confined almost purely to the aorta and aortic valve. A particularly severe form of aortic insufficiency may develop, with subsequent dilation and enlargement of the heart and, eventually, heart failure. The disease process often involves the base of the aorta and the blood flow through the openings into the coronary vessels from the aorta, causing impairment of the coronary circulation, with resultant angina pectoris and, on rare occasions, myocardial infarction, the death of portions of heart muscle. The syphilitic process may also involve the wall of the aorta, resulting in the loss of the elastic properties, in dilation, and, at times, in the formation of aneurysms of the aorta. (An aneurysm is a bulging of the vessel wall at a point of weakness.) The aneurysms may become large and interfere with blood flow through the tributaries of the aorta in the involved area. They may be the source of pain and eventually may rupture, causing sudden death from loss of blood into the thoracic cavity. Syphilis of the aorta was common in the past, but with the advent of more modern control mechanisms, plus effective early treatment with the use of penicillin, the disorder has become much less common. The rise in the incidence of syphilis and other venereal diseases in the late 1960s and early 1970s has not yet involved an increased incidence of the late complications. These can be effectively avoided by early antisyphilitic treatment.

Aneurysms of the aorta

Other diseases of aorta and pulmonary arteries. Arteriosclerosis may involve the aorta and its major branches. Indeed, it seems to be an almost inevitable process with increasing age, but the rate of development and the extent of involvement vary greatly. The process may merely limit the elasticity of the aorta and allow for some dilation and tortuosity as age advances. In more severe instances, there may be a major degree of dilation or localized formation of aneurysms, generally in the abdominal portion of the aorta. These aneurysms may result in pain and may occasionally rupture, causing sudden death. The arteriosclerotic process may impair the flow of blood to the tributaries of the aorta and lead to a variety of ischemic states—*i.e.*, result in various types of damage that come from an insufficient supply of blood. This condition is particularly notable when the renal vessels are involved, creating a state of renal ischemia, occasionally creating hypertension, and possibly terminating in renal failure.

Medial necrosis is a lesion of the aorta in which the media, the middle coat of the artery, deteriorates and, in association with arteriosclerosis and often hypertension, may lead to a dissecting aneurysm. In a dissecting aneurysm a rupture in the intima, the innermost coat of the artery, permits blood to enter the wall of the aorta, causing separation of the layers of the wall. Obstruction to tributaries may occur, which is usually associated with severe chest pain. In many instances, there is a secondary

rupture of the exterior wall, which may lead to fatal internal bleeding. Inflammation of the aortic wall may occur as an isolated process.

Deposition of calcium salts in the aorta wall may occur as a part of the arteriosclerotic process or of other disease involvement, such as syphilis. The pulmonary artery may be the seat of similar disease processes, but it is less frequently involved by syphilis. In certain conditions, such as congenital heart disease, blood clots (thrombi) may form in the pulmonary artery, and these may break loose. Blood clots in the lungs (pulmonary emboli) may arise from this and other sources in the systemic venous circulation. These fragments of clot may be small, causing no detectable manifestations, or large, causing obstruction of either the total pulmonary arterial flow (see the section on cor pulmonale, above) or of flow to an area of lung.

Blood clots in the lungs

Other diseases of endocardium and valves. Bacterial endocarditis, a disease in which bacterial or fungus infection becomes established on the surface of a heart valve or, less commonly, in a blood vessel wall or in the endocardium (lining) of the heart, usually occurs where there has been some previous lesion, either congenital or acquired. Most frequently, the location is at the line of closure of the valve. The disease may be acute and severe, or may be a more chronic situation, often referred to as subacute bacterial endocarditis. It may erode the valve structure, or it may be of an inflammatory nature, producing nodules with the ulcerative surface of active infection. Because the bacteria are imbedded in the lesion, the normal body defenses contained in the blood have difficulty entering into play; for this reason, certain types of bacterial endocarditis become more chronic and more slowly progressing. The effects of the lesion are complex, relating to the presence of a bacterial infection in the body, local damage to the valve, and systemic damage caused by fragments of blood clot breaking off and travelling through the blood stream to distant organs, causing infarctions or abscesses, a type of kidney disease, or other small areas of bleeding and necrosis in the skin, eyes, and other parts of the body. Before the advent of antibiotic therapy, bacterial endocarditis was almost always a fatal disease. Many affected persons can now be successfully treated, given the best conditions, although the mortality rate still remains relatively high. Inflammation of the heart lining, endocarditis not caused by infection, may occur in some illnesses, but it does not result in formation and breaking loose of blood clots.

In the course of rheumatoid arthritis, a chronic inflammation of the joints of unknown cause, a type of valvular damage has been recognized. It is different from that caused by rheumatic fever but leads to valvular insufficiency and stenosis (narrowing) in much the same fashion and is particularly likely to attack the aortic valve. The tendencies toward heart failure and toward impairment of heart function are the same as in rheumatic valvular disease.

In a variety of cardiovascular disorders, the heart becomes dilated and the blood flow inside the atrial and ventricular cavities may become sluggish. These conditions render the heart more susceptible to the formation of blood clots on the wall of the heart (mural thrombi). They are particularly likely to occur in the presence of atrial fibrillation, a disturbance in heart rhythm that causes ineffective contractions of the atrium. When mural thrombi occur, the local lesion is of little consequence unless it reaches great magnitude. The major hazard to the affected person is the fragmentation of the thrombus to form detached clots (emboli) in the peripheral circulation.

Other diseases of the myocardium. There has been increasing recognition of a type of heart disease characterized as primary myocardial disease. The disorders, called cardiomyopathies, directly affect the muscular tissue of the heart, resulting in heart disease and heart muscle failure. The process may be related to a disseminated disorder that involves the entire body.

The cardiomyopathies may cause no symptoms, and may be detected only by evidence of an enlarged heart and disturbances in cardiac conduction mechanisms detected on electrocardiography. In other instances, extensive involvement may lead to heart failure. Some cases may be chronic, with exacerbations and remissions over a period of years. Cardiomyopathies constitute a major segment of heart disease in the temperate climates. In some instances, therapy aimed at the underlying disease will produce what is in effect a cure, as in myxedema or thyrotoxicosis, conditions caused, respectively, by underactivity and overactivity of the thyroid gland. In most other instances, no specific remedies are available.

Cardiomyopathies

Infections, such as acute rheumatic fever, early stages of syphilis, and several viral infections, may cause any of a number of types of myocarditis. Myocarditis may also occur as a manifestation of a generalized hypersensitivity (allergic or immunologic) reaction throughout the body.

A large number of cardiomyopathies are apparently not related to an infectious process, but are not well understood. A number of these are congenital and many cause enlargement of the heart. About one-third of these diseases are familial, and some of these are transmitted as a non-sex-linked autosomal dominant trait (*i.e.*, a person may be affected if he inherits the tendency from one parent). They are particularly common in the black races. A number of metabolic diseases associated with endocrine disorders may also cause cardiomyopathies. Other metabolic disorders that may contribute to cardiomyopathy include beriberi, caused by a nutritional deficiency; cobalt poisoning in heavy beer drinkers; or a form of cardiomyopathy in chronic alcoholics. There are also rare cardiomyopathies caused by drugs.

The heart may be affected by any of a considerable number of collagen diseases. Collagen is the principal connective-tissue protein, and collagen diseases are diseases of the connective tissues. They include diseases primarily of the joints (*e.g.*, rheumatoid arthritis); primarily of the skin (*e.g.*, scleroderma); and systemic disease (*e.g.*, systemic lupus erythematosus).

The collagen diseases

Diseases of the pericardium. The pericardium is the membranous sac that encloses the heart. Pericardial disease may occur as an isolated process or as a subordinate and clinically unsuspected manifestation of a disease elsewhere in the body. Acute pericarditis—inflammation of the pericardium—may result from invasion of the pericardium by one of a number of agents (viral, fungal, protozoal, or tuberculous in nature); as a manifestation of certain connective tissue and allergic diseases; or as a result of chemical or metabolic disturbances. Cancer and injury to the pericardium are also potential hazards.

Pain is the most common symptom in acute pericarditis, although pericarditis may occur without pain. A characteristic sound, called friction rub, aids in the diagnosis of pericarditis. There are also characteristic electrocardiographic findings. Acute pericarditis may be accompanied by an outpouring of fluid into the pericardial sac. The presence of pericardial fluid in excessive amounts may enlarge the silhouette of the heart in X-rays but not impair its function. If the fluid accumulates rapidly or in great amounts, however, or if the pericardium is diseased so that it does not expand, the heart is compressed, a state called pericardial tamponade. There is interference with the heart's ability to fill with blood and reduction of cardiac output. In its more severe form, cardiac tamponade causes a shocklike state that may be lethal. Removal of the fluid is lifesaving in an emergency and aids in the identification of the cause.

Impairment of cardiac function is present in chronic constrictive pericarditis, caused by scar tissue in the pericardium that restricts the activity of the ventricles. In many instances, the cause of this type of disorder is not known, but in some it is the result of tuberculosis and other specific infections. It is treated most effectively by surgery. Tumours that either arise directly from the pericardium or are secondary growths from other sources may impair cardiac function and cause pericardial effusion (escape of fluid into the pericardium).

Disturbances in rhythm and conduction. The heart's rhythmical beat is initiated and regulated from centres

within the organ. The primary pacemaker, the sinoatrial node, is a small mass of specialized muscle cells located at the juncture of the upper vena cava and the right atrium. Electrical impulses are emitted by this group of cells. The excitation spreads through the two atria and, by way of a band of fibres called the bundle of His, into the ventricles. The bundle of His, named for the German anatomist Wilhelm His, Jr., who described it in 1893, has its beginning in a small mass of cells, the atrioventricular node, located beneath the lining of the right atrium. Normally initiated heart rhythm, originating in the sinoatrial node, is called sinus rhythm.

Normal variations in heart beat

Under stimulation from the central nervous system and other metabolic factors, heart rate may normally rise and fall, with a slight variation, in part related to respiratory activity. In young individuals in excellent physical condition, the resting heart rate may fall as low as 40 to 50 beats per minute, and, under stressful psychologic stimulation, the heart rate may rise to as high as 200 beats per minute. These situations are to be differentiated from pathologic variations in heart rate. Sinus bradycardia (a slow sinus rhythm with a rate below 60, caused by disturbance of the sinoatrial node) or tachycardia (excessive rapidity in the action of the heart with a pulse rate of above 100 beats per minute) without abnormality in mechanism may occur in a wide variety of disease states, and either is merely symptomatic of the underlying disease.

Extra beats arising from the atrium, the nodal tissues, or the ventricle are not in themselves abnormal, although beats arising from the ventricle are more often associated with organic heart disease. Occasional extra systoles (contractions) occur in many normal individuals. In cardiovascular disease they are much more common. They do not interfere with normal cardiovascular function if infrequent. It has been noted that continued psychologic stress, excessive smoking, and drinking of large amounts of tea and coffee enhance the tendencies for premature contractions of the atria. Premature contractions of the ventricles are more ominous, especially those that occur after exercise. They have been found to be associated with coronary artery disease in a large percentage of instances. If frequent enough, they may be the harbinger of more serious ventricular arrhythmias.

Abnormalities in the rhythm of atrial contractions include atrial tachycardia (swift heartbeat), atrial flutter, and atrial fibrillation (see below). As noted earlier, atrial tachycardia may be a manifestation of underlying disease such as thyrotoxicosis or may be merely a matter of stressful stimulation in a normal individual. Some individuals have characteristic episodes of paroxysmal atrial tachycardia of varying frequency and duration, with a rapid onset and termination. Ordinarily the episodes occur in the absence of any other heart abnormality. Occasionally, especially when the episodes are prolonged or when they occur in the presence of organic cardiovascular disease, they may be accompanied by evidence of heart failure or, in rare instances, of the shock state.

Atrial flutter

Atrial flutter represents a form of tachycardia associated with very rapid atrial activity. The atrial activity is regular, but the conduction of the impulses to the ventricle may be delayed and impaired so that only one of two, three, or four impulses excite ventricular activity. This disorder is most often, but not always, seen in persons with organic heart disease.

Atrial fibrillation is another form of atrial tachycardia, in which there is wildly erratic and ineffective atrial contraction. The ventricular response is also erratic, so that the pulse is irregular without a basic underlying rhythm. This disorder is seen most frequently in persons with organic heart disease, such as rheumatic heart disease with mitral involvement and thyrotoxicosis, but also occurs in normal individuals, often on a paroxysmal basis. It renders the atrium ineffective, and therefore the contribution of this chamber to the normal pumping of blood is negated. This condition may be of no real functional importance in the normal heart, but may have a significant detrimental effect in the failing heart. The circulation functions reasonably well, although, in the case of severe mitral stenosis, a rapid heart action is not well tolerated because of the limited speed of ventricular filling through a small mitral opening. A complication of atrial fibrillation is the development of blood clots within the walls of the fibrillating atria. Because these clots may eventually fragment and pass into the circulation, atrial fibrillation is a condition that should be treated if possible. The abnormal rhythm may be slowed by digitalis or terminated by the use of electrical shocks (electrical defibrillation).

Atrioventricular node mechanisms. Normally, the impulse for ventricular contraction arises from a focus in the atria, passes through a conduction system that slightly delays progression, and then excites ventricular activity. This mechanism may not operate properly in various pathologic states. In some instances, more rapidly firing (*i.e.*, impulse-emitting) tissue in the atrioventricular node may initiate the ventricular activity, supplanting the normal atrial focus and resulting in tachycardia, called nodal tachycardia because of the part played by the atrioventricular node. More frequently, the abnormal mechanism is one of delay or obstruction in progression of the impulse, creating "heart block," a lack of synchronization between atria and ventricles; there may be varying degrees of severity. In first-degree heart block, there is merely a short delay over the normal conduction time from the atrium to the ventricle. This condition does not result in clinical manifestation but is detected electrocardiographically by a longer than normal period of time between the P wave, which is associated with atrial activity, and the QRS complex, which is associated with ventricular excitation.

Three degrees of heart block

In a more severe (second-degree) form, the impulse may travel relatively normally through the conduction system, but some beats are blocked. Alternate beats may be blocked, resulting in what is known as a two-to-one heart block, or the ratio may be three-to-one, four-to-one, etc. The degree of blockage may be influenced by stimulation from outside the heart, such as from the carotid sinus or the central nervous system, and is dependent in part on drug action. (The carotid arteries are the principal arteries to the head. The carotid sinus, located at the fork where the common carotid divides into the external and internal carotid arteries, is an important centre for monitoring and regulating blood pressure.)

The conduction system below the atrioventricular node divides into two major branches, to the two ventricles, and, therefore, blockage of either of these is termed right or left bundle branch block. This condition again is primarily determined by an electrocardiographic diagnosis and is most frequently associated with organic heart disease, although it may occur rarely in normal individuals.

A final major form of heart block, complete heart block, is characterized by total dissociation of atrial activity and ventricular activity. In this situation, atrial activity usually continues at a normal or higher than normal rate. Independently the ventricle establishes its own rate, usually slower than normal, but in some instances within the normal range. If the latter is the case, the difficulty is without major consequence on the circulation. More frequently, however, it is at a slower rate, and there may be some resultant inadequacy of the circulation. This condition is usually associated with forms of organic heart disease, and the slowness of the rate may precipitate congestive heart failure or other manifestations. It may be treated by the use of drugs or electrical pacemakers to increase the rate of ventricular activity. At times, the degree of heart block or its occurrence may be variable and erratic. This condition may result in considerable pauses in left-ventricular depolarization and contraction, the basic mechanism that precipitates the Adams-Stokes syndrome, which leads to occasional episodes of unconsciousness. (The syndrome is named for the Irish physicians Robert Adams and William Stokes, whose descriptions of the disease are celebrated.)

Ventricular arrhythmias. The ventricle may respond regularly or erratically to atrial or nodal (atrioventricu-

lar) disturbances of rhythm. In addition, it is subject to other intrinsic forms of abnormal rhythm. In the course of severe heart disease, such as coronary artery disease, ventricular tachycardia (fast beating of the ventricles) may occur. The beat is regular, but may be so rapid that it interferes with normal cardiac filling and ejection, and, therefore, results in either congestive failure, if prolonged, or in the development of a shock state, if severe and acute. Ventricular tachycardia is perhaps most important because it may be the forerunner of ventricular fibrillation, in which, as in atrial fibrillation, the contractions are widely erratic and ineffective, so that essentially ventricular fibrillation is a form of ventricular standstill with respect to the movement of blood. Unless stopped within seconds or minutes, it is lethal. The recognition of the forerunners of ventricular tachycardia has been the basis for the success of modern coronary-care units. It is treatable either by drugs or, more frequently, by the use of external electrical defibrillation, the application of electrical shocks.

Ventricular tachycardia and fibrillation

Some of the major recognized forms of arrhythmia have been presented. There are many special variants on this pattern, but even with the most complex electrocardiographic studies, some arrhythmias defy explanation.

Congestive heart failure. Congestive heart failure, a syndrome resulting from disease that has caused the heart to be inadequate as a pump, is characterized by manifestations distant from the heart, predominantly related to salt and water retention in the tissues. It may vary from the most minimal symptoms to sudden pulmonary edema (abnormal accumulation of fluid in the lungs) or to a rapidly lethal shocklike state. Chronic states of varying severity may last years. The symptoms relate predominately to secondary manifestations resulting from retention of fluid and vascular congestion throughout the body, rather than to the direct effect of lessened blood flow. In most instances, congestive failure results from a diseased heart, although on occasion the burden of other systemic diseases may exceed the capacity of the previously adequate heart and produce the condition. A physiologic characteristic of the normal heart is its ability to meet the fluctuating demands of the body for blood flow. The diseased heart may no longer be able to respond in this way. This failure may be the result of severe and acute damage, such as an acute myocardial infarction, or of chronic and lesser impairment, such as scarring of a valve in the course of a long-standing rheumatic heart disease.

The possible causes of the underlying heart disease are numerous. In the United States, the largest percentage of persons with congestive heart failure have manifestations of coronary artery disease that has interfered with the blood supply to the heart muscle and resulted in failure of the heart as a pump. Other common causes are rheumatic valvular disease, hypertensive vascular disease with involvement of the heart, or one of the multitudinous but less common types of primary disease of the myocardium. Regardless of the cause, the common denominator leading to heart failure is altered function of the heart muscle, with lessened ability to pump blood. In many sophisticated studies, clear-cut disturbances in the mechanics of heart muscle contraction have been demonstrated.

The presence of cardiac failure becomes apparent largely by signs and symptoms not directly related to the heart. With early and untreated heart failure, the person with congestive heart failure usually has a normal salt and water intake, but his ability to regulate and promptly excrete excess sodium and water is impaired. The nature of this impairment is not entirely clear.

Salt and water accumulate in the body as extracellular fluid that manifests itself as clinically detectable edema. If the person is active and in the upright position, the fluid may gather particularly about the ankles and legs. If he is in bed, it may be in the back overlying the sacrum. If the left ventricle is particularly affected by the heart disease, there is marked congestion of the vessels in the lungs, with respiratory symptoms. In heart failure, there may also be low blood sodium levels.

The pulmonary circuit (the blood vessels in the lungs) usually becomes congested in heart failure, because heart diseases most frequently affect the left ventricle in one way or another. If disease impedes the left ventricle's pumping of blood out into the systemic circulation, the left side of the heart is unable to receive the normal flow of oxygenated blood from the lungs, there is consequent back pressure, and blood accumulates in the lung's blood vessels. If this congestion of the pulmonary vessels occurs, it lessens the amount of space available in the lungs for air, and tends to stiffen the lungs. Finally, pulmonary capillary pressure may reach the point at which fluid flows into the tissues outside the vessels, a condition called pulmonary edema. These phenomena account for the frequency of difficulty in breathing, inability to breathe except in an upright position, attacks of respiratory distress without apparent cause during sleep at night (paroxysmal nocturnal dyspnea), and other respiratory symptoms in congestive heart failure.

Effect on the lungs

A person affected rarely speaks of symptoms that can be directly related to the inadequacy of cardiac output. In severe and chronic heart failure, there may be a general deterioration of the body with a form of general ill health and malnutrition that simulates that seen in cancer. There is rarely evidence that blood flow is insufficient to provide adequate tissue function except in the shock state that occurs in acute and severe heart failure, in which there is acute inadequacy of flow to some critical tissues. Although heart failure may occur in certain circumstances, such as severe anemia, in which there is a high cardiac output, in general, heart failure occurs when the cardiac output is reduced from the normal value for the particular person. The inadequacy of the heart may not be constant but may occur, especially in early heart failure, only under the stress of exercise.

The degrees of heart failure

Incipient heart failure. Persons in the early stages of heart failure may have no circulatory impairment, although the heart may be dilated or enlarged. Such persons may eventually be unable to respond to stressful situations that demand a high cardiac output. Difficulty in breathing may occur during exertion, but usually edema is not present.

Mild to moderate congestive heart failure. The person with mild to moderate congestive heart failure may have a heart that has an adequate pumping function for the demands at rest, but that is unable to meet circulatory needs under stress. Such a person may experience difficulty in breathing during exertion and other early manifestations of heart failure, and these symptoms may even be present to a limited degree at rest. In those situations affecting primarily the left ventricle, episodes of paroxysmal nocturnal dyspnea indicating temporary inadequacy of the left ventricle may be present. There may be mild edema of the ankles at the end of the day. The manifestations are not severe or grossly disabling. As the condition becomes more severe, increasing frequency of difficulty in breathing (dyspnea) and greater amounts of edema may be present.

Severe congestive heart failure. Heart failure may become totally disabling, with severe respiratory distress and inability to lie flat and to exercise. Gross edema including abnormal amounts of fluid in the abdomen (ascites) and in the chest cavity (hydrothorax) are present. When such circumstances are prolonged, general body deterioration may develop, with various secondary effects, such as appetite loss or diarrhea.

Cardiogenic shock. A degree of heart failure from mild to severe may occur after acute and severe cardiac damage, such as an acute myocardial infarction. In some instances, this condition may progress to a shocklike state, with such classic manifestations as low blood pressure, a rapid, thready (thin) pulse, and pallor, a condition known as cardiogenic shock. It may or may not be accompanied by respiratory symptoms or evidence of edema. No edema from congestion in the peripheral vessels develops if the condition is of short duration, but acute pulmonary edema may be experienced.

Pulmonary edema. Acute pulmonary edema developing in the course of heart failure may be severe, occa-

sionally even fatal. It occurs particularly in such situations as arterial hypertension and aortic valve disease. Peripheral edema may or may not be present. This combination of events is often called left heart failure.

Right heart failure. In heart disease affecting primarily the right side of the heart, such as cor pulmonale or disease of the tricuspid valve, between the right atrium and right ventricle, the effect on respiration may be less, and there is greater evidence of edema, congestion of the liver, and high pressure in the veins. Although actually the circulation as a whole is failing, those factors that produce manifestations in the lungs are not prominent.

(J.V.W.)

SURGICAL TREATMENT OF THE HEART

The heart-lung machine. The heart-lung machine serves as a temporary substitute for a patient's heart and lungs during the course of open-heart surgery. The patient's blood is pumped through it for artificial introduction of oxygen and removal of carbon dioxide. Before its first successful application to operations on the human heart in the early 1950s, all heart operations had to be done either by the sense of touch or with the heart open to view but with the patient's whole body held to a subnormal temperature (hypothermia).

The latter procedure was feasible only for very brief periods (less than ten minutes). An open-heart operation with the aid of the heart-lung machine may last for an hour or more.

The first heart-lung machine (pump oxygenator) resembled only slightly the complicated apparatus currently used for correction of cardiac defects. With this machine the blood bypasses the heart and lungs (cardiopulmonary bypass) so that the surgeon has an unobstructed view of the operative field. Cardiopulmonary bypass (Figure 1) is accomplished by use of large drainage tubes (catheters) inserted in the superior and inferior venae cavae, the large veins that return the blood from the systemic circulation to the right upper chamber of the heart. The deoxygenated blood returning to the heart from the upper and lower portions of the body enters these tubes, and by gravity drainage flows into a collecting reservoir on the heart-lung machine. Blood then flows into an oxygenator, the lung component of the machine, where it is exposed to an oxygen-containing gas mixture or oxygen alone. In this manner, oxygen is introduced into the blood and carbon dioxide is removed in sufficient quantities to make the blood leaving the oxygenator similar to that normally returning to the heart from the lungs. From the oxygenator, blood is pumped back to the body and returned to the arterial tree through a cannula (small tube) introduced in a major systemic artery, such as the femoral (groin) artery. Oxygenated blood then flows to the vital organs, such as the brain, kidneys, and liver. Meanwhile, the heart may be opened and the corrective operation performed. A small quantity of blood, which may be present in the bronchial circulation, is returned to the heart-lung machine through a separate pump section.

The oxygenator

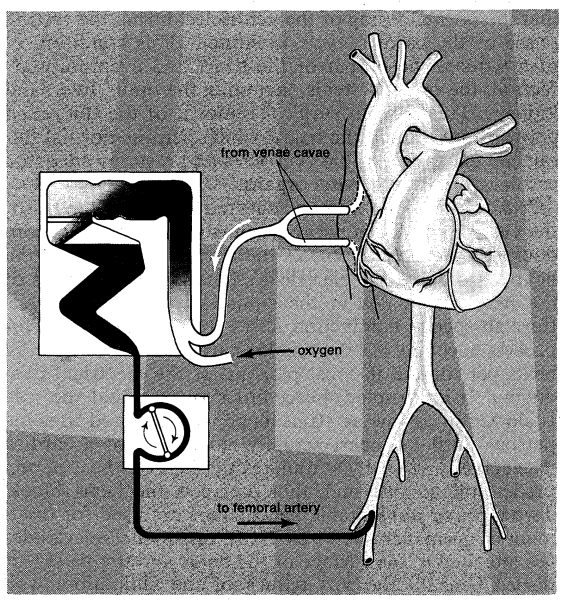

Figure 1: Cardiopulmonary bypass. At left wastes are removed from the blood and oxygen added (see text).

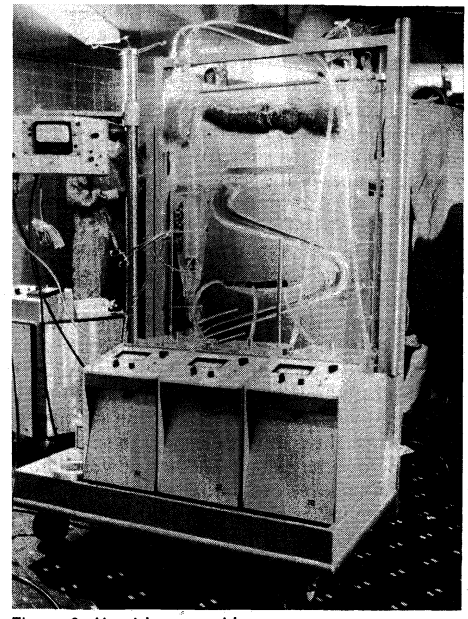

Figure 2: Heart-lung machine.
M.E. DeBakey and E.B. Diethrich

The assemblage and sterilization of the components of the heart-lung machine are essential considerations, because the blood comes in contact with the apparatus outside of the body. Many heart-lung machines have totally disposable tubing and plastic bubble oxygenators (Figure 2), which make it possible for each patient to have new tubing and oxygenators. Even the latest models, however, have limitations on the duration of bypassing the patient's blood.

Most cardiac operations can be performed in less than one hour, but occasionally longer periods of cardiopulmonary bypass are required. In these circumstances, there is a tendency for the blood to be damaged by destruction of its red blood cells and denaturation (modification) of its proteins.

Administration of an anticoagulant (heparin) prevents clotting of the blood while it is circulating in the heart-lung machine. Upon completion of the operation, the patient is given a coagulant (protamine) so that the normal coagulation properties of the blood are restored. Researchers in the 1970s were working on development of pump-oxygenators that will provide longer periods of partial, as well as total, support of the circulation (see below *Artificial heart*).

Congenital cardiac defects. Cardiac defects are congenital (present at birth) or acquired (developing later in life). A number of congenital cardiac defects were surgically corrected long before the heart-lung machine became available.

Patent ductus arteriosus. During fetal life and the early days after birth, a channel (the ductus arteriosus) exists between the pulmonary artery and the first segment of the descending thoracic aorta. Before birth, blood flows from the right ventricle, out the pulmonary artery, and across the ductus arteriosus to the aorta. The function of this ductus is to shunt blood away from the lungs, because the process of oxygen-carbon dioxide gaseous exchange is initiated only at the time of birth. Normally, the ductus closes spontaneously within the first few weeks after birth. If it remains open, a variety of symptoms may occur, including those resulting from severe cardiac failure.

Treatment for patent ductus arteriosus is ligation (tying

off) of the ductus, an operation first performed successfully in 1938.

Coarctation of the aorta. Coarctation of the aorta, a constriction of the aorta usually found in the same region of the aorta as patent ductus arteriosus, is a common congenital defect. It often reduces the blood flow to the abdominal and pelvic organs and to the legs. The opposite effect occurs above the coarctation—the blood pressure may be greatly elevated, and symptoms of hypertension may be manifested.

In 1945 Robert E. Gross and Charles Hufnagel performed the first successful operations for coarctation of the aorta in the United States. In most infants and adolescents the constricted portion of the aorta is cut out and the two normal ends are sewed together. In adults it is often necessary to bridge the defect with a Dacron graft or to use a bypass graft. In the latter case, a Dacron tube is attached to the aorta above and below the narrowed segment. The blood is, thus, able to bypass the defect to reach the organs below the defect and the lower limbs. Both of these techniques restore satisfactory blood supply to structures in the lower part of the body and relieve the high blood pressure in the arms.

Pulmonary valvular stenosis. The most common congenital defect of the valves is a narrowing of the pulmonary valve (the valve opening into the pulmonary artery), resulting in obstruction of blood flow from the right ventricle to the lungs. In this condition, the valve leaflets, usually pliable and delicate, are fused in a conelike fashion. Blood is expelled from the right ventricle across the narrow valve with great force, so that often the pulmonary artery beyond the diseased valve is dilated. Shortness of breath on exertion is the most common symptom in those affected. The original surgical treatment consisted in inserting a special dilating instrument through the apex of the right ventricle and through the valve. Today, except in very young infants with severe heart failure, the valvular stricture is corrected under direct vision with use of the heart-lung machine.

Effects of stenosis of the pulmonary valve

Atrial and ventricular septal defects. "Holes in the heart," or abnormal openings between the right and left chambers of the heart, are common congenital cardiac anomalies. The upper chambers of the heart (the atria) are separated by a partition called the interatrial septum, and the lower chambers (the ventricles) by the interventricular septum. During embryonic development the tissues of the heart normally fuse to form intact membranes (septa) between these chambers, so that blood is directed from the right atrium and ventricle through the pulmonary circulation to the left atrium and ventricle and out the aorta into the systemic circulation. Failure of the tissues to form complete septa results in an opening between the chambers that permits the abnormal mixing of blood from the right and left sides of the heart. This admixture of blood can cause cyanosis, which is typical when the pressure in the right side of the heart exceeds the pressure in the left side (see below *Tetralogy of Fallot*).

Interatrial and interventricular septal defects may be closed surgically with the patient's circulation supported by the heart-lung machine. If the defect is small, the tissues on either side of it can be sewed together. A patch of Dacron material must be sutured over larger defects to close the opening and redirect the flow of blood in the normal direction.

Tetralogy of Fallot. Of the congenital cardiac anomalies that cause cyanosis, the tetralogy of Fallot, described earlier, is the most common. The first attempt to treat children affected with it was an operation to relieve cyanosis introduced in 1945. This procedure made it possible for many critically ill infants to live to an age when the heart-lung machine could be used, and the complex defects could be surgically repaired under direct vision. The results of surgical treatment of patients with tetralogy of Fallot have been excellent. The operation represents an important chapter in the history of surgical correction of congenital cardiac anomalies.

Acquired heart defects. *Valvular disease.* Among the diseases that can affect the heart after birth, rheumatic fever is one of the most serious. It has a predilection for the two major valves of the heart, the aortic and mitral. Although the bacteria responsible for rheumatic fever invade the blood stream and attack these valves during childhood or adolescence, the destructive effects are usually not apparent until young adulthood or even later in life. Normal function of the aortic and mitral valves may be altered because they are too tight (stenotic) or too loose (insufficient). In the stenotic valve, the flow of blood past the valve is obstructed; the result is increased pressures and damage to the heart. When the valve is insufficient, leakage of blood back into the ventricles places increased stress on the heart with resultant cardiac failure.

Destroyed heart valves can be replaced with artificial valves (prostheses) made of stainless steel, Dacron, or other special materials (Figure 3). The heart-lung machine is used during these operations, in which one, two, or even three cardiac valves may be removed and replaced with the appropriate artificial valve. In the 1970s cardiac researchers were investigating the use of some substitute for the heart valve other than the artificial valve. The use of both homograft valves (valves obtained from human beings after death) and heterograft valves (valves secured from other animals) was being investigated. One of the advantages of such valves is the absence of clotting, which occurs occasionally with use of artificial valves. The long-term durability of the homograft and heterograft valves, however, had not yet been determined.

Substitutes for damaged valves

Chronic constrictive pericarditis. Another inflammatory process, chronic constrictive pericarditis, can affect the surface of the heart and the sac (pericardium) surrounding it. The pericardium becomes thickened and fibrotic, and over a period of time constricts the heart so that the normal filling of the ventricles during the resting phase of the cardiac cycle is limited. This condition in turn reduces the output of the heart and eventually affects all the organ systems, including the brain, liver, and kidneys. Treatment is surgical removal of the thickened pericardium around the heart, which permits normal filling and expansion of the ventricles and restores adequate cardiac output to the vital organs.

Heart block. A common acquired disease of the heart, the cause of which is poorly understood, affects the conduction system that controls the rhythmic beating of the heart. Normally, the electrical stimulus for each beat of the heart originates in the sinoatrial node and passes through special conduction fibres to the ventricles. This process accounts for the regular cardiac rate of about 72 beats per minute in most persons. If the electrical conduction is interrupted, heart block occurs, and the rate is slowed to as low as 30 beats per minute, and in some persons until the heart actually stops. Use of a cardiac pacemaker artificially stimulates the heart to beat at any predetermined rate and, thus, corrects the heart block. Two types of implantable pacemakers are used for treatment of permanent heart block. In one model, electrodes are attached to the surface of the heart and the battery is buried beneath the soft tissues of the abdominal wall (Figure 3). In the other model, electrodes are passed through a vein in the neck directly into the heart, and a

Two types of pacemakers

battery is implanted beneath the skin of the armpit or the forward chest wall. Several types of battery units (pulse generators) are available, depending on the type of electrical stimulus desired for the individual patient. These batteries, like any other, must be changed periodically.

Heart arrest. Cessation of the heart beat, in addition to occurring in heart block, may occur in numerous other circumstances and require emergency treatment. Until the early 1960s, when the heart stopped (cardiac arrest) the chest was opened, frequently with a pen knife or any other available instrument, and the heart was massaged with the hands until beating was resumed. A new technique (closed cardiac massage) has been developed whereby pressure is applied to the breastbone (sternum) directly over the heart. The sternum is compressed intermittently about 60 times a minute while the lungs are expanded with oxygen. Persons may be kept alive with normal blood pressure and circulation for hours by this method. So effective is closed cardiac massage that many laymen are trained in its use for emergency support of the circulation.

Heart wounds. Heart wounds are caused by blunt or penetrating instruments. Rapid deceleration, often experienced in automobile accidents, is a common cause of injury to the heart muscle, resulting in bruising and even disruption of a valve or the ventricular septum. Both bullet and stab wounds account for many patients treated in the emergency clinics of major hospitals. Prompt diagnosis and effective surgical treatment, usually consisting of control of bleeding by sewing the heart muscle at the point of entry of the foreign object, have resulted in a high rate of successful treatment of these persons.

Coronary arterial disease. The most important acquired disease of the heart is hardening (atherosclerosis) of the coronary arteries. More than 600,000 persons in the United States die each year of this disease, and countless others suffer from one or more of its complications. The basic problem in coronary atherosclerosis is narrowing of one or more of the coronary arteries, which reduces the blood flow to the heart muscle and produces severe pain in the chest (angina pectoris). If the blood supply is reduced below a critical level, the artery may become blocked by a blood clot (coronary thrombosis) and the person has a heart attack (myocardial infarction).

Provision of new blood supply to the heart

Operations have been devised to bring a new blood supply into the heart when the coronary arteries become narrowed by atherosclerosis. One of the earliest and still occasionally performed operations is myocardial revascularization. In this operation, an artery beneath the breastbone (sternum) is dissected free and then is implanted into the heart muscle. One or more of these arteries can be implanted, depending on the extent of arterial disease.

Another technique is to use a vein removed from the leg as a bypass around the diseased portion (Figure 4). The vein is attached to the aorta above as it leaves the left ventricle. The other end of the vein is then sutured directly to any one of the coronary arteries. Large quantities of blood can be delivered to the heart muscle by this direct form of myocardial revascularization.

The latest advance in coronary arterial surgery is the carbon dioxide endarterectomy operation. Carbon dioxide, which in the bloodstream is readily absorbed and does not cause blockage of the small vessels, is injected directly into the obstructed coronary artery. The gas tends to loosen the inner atheromatous core from the outer adventitial wall of the artery. The atheromatous core is then totally removed, and blood flow is restored through the artery. The heart-lung machine is used to support the circulation during most operations on the coronary arteries.

Heart transplantation. If the heart muscle has been damaged beyond surgical repair, heart transplantation may be performed. The diseased heart is removed and the donor's heart is sewed in position. More than 173 human heart transplantations have been performed since the initial operation in Cape Town, South Africa, December 3, 1967. Several patients have lived more than three years after heart transplantation. It is hoped that results will improve as more is learned about tissue matching and recognition and control of tissue rejection.

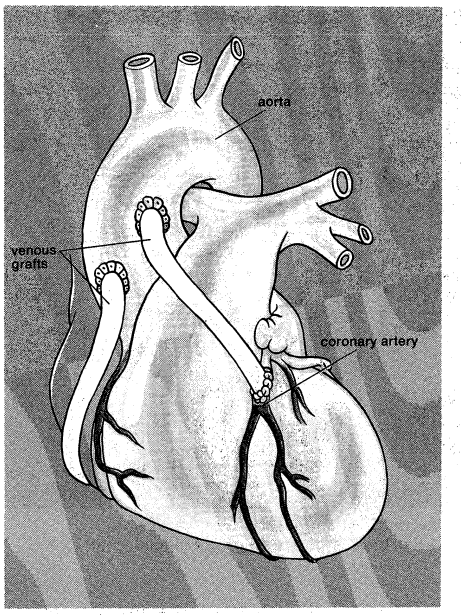

Figure 4: Restoration of blood supply to heart muscle. The vessels shown in white are venous grafts leading from the aorta to coronary vessels (see text).

Artificial heart. Many scientists are directing their efforts toward development of an artificial heart. The heart-lung machine effectively supports the circulation for a few hours; if it is used for longer periods, the blood is damaged by the pumping and oxygenation. Current research is directed toward development of pumps and oxygenators that can be used for partial or total support of the circulation for long periods without damage to the blood.

Partial cardiac assistors have been used successfully to aid the heart after operation until it has had sufficient time to recover. One of these is the left ventricular bypass pump (Figure 5). It reduces the work load of the heart, because blood is removed from the left atrium of the heart and pumped back to the body through the axillary artery. No oxygenator is required, because the lungs are not bypassed.

A totally implantable mechanical heart is the ultimate goal of scientists working on the artificial heart, but many problems must be solved before a completely satisfactory mechanical heart becomes available. One of the newest experimental models (Figure 5) replaces both the atria and ventricles but requires external power to activate the pump. Ultimately, both the pumping chamber and the driving mechanism will be implanted within the body to enable the patient to move about freely and carry on normal activities. (M.E.DeB./E.B.D.)

The blood vessels

DISEASES OF THE ARTERIES

There are many types of arterial disease. Some are generalized and affect arteries through the body, although often there is variation in the degree they are affected. Others are localized. These diseases are frequently divided into those that result in arterial occlusion (blockage) and those that are nonocclusive in their manifestations.

Occlusive disease. *Arteriosclerosis.* The various types of arteriosclerosis are by far the most common occlusive diseases of the arterial system. It is a major cause of death in one form or another. Arteriosclerosis of the coronary arteries has already been discussed. Arteriosclerotic lesions of the cerebral vessels may lead to formation of blood clots and stroke.

Medial (Mönckeberg's) arteriosclerosis is the condition

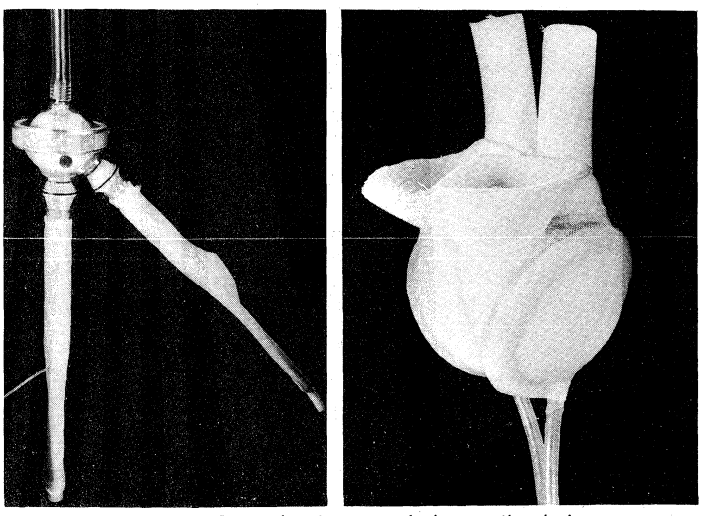

Figure 5: *Surgical and post-surgical supportive devices.* (Left) Left ventricular bypass pump. (Right) Artificial heart.
M.E. DeBakey and E.B Diethrich

affecting the media (middle coat) of the main arteries. There are deposits of calcium salts in the media, but in general the channel (lumen) is not blocked. This disease is quite common and may contribute to the other major form of widespread arteriosclerosis, atherosclerosis obliterans, in which there is complete obliteration of the vessel channel.

Intermittent claudication

The classic manifestation of arteriosclerosis affecting the legs is called intermittent claudication (intermittent lameness), which results from inadequate blood flow to the muscles involved in walking. In such individuals a cramplike discomfort associated with a limp occurs in the calf of the leg on exercise and is relieved by rest. The vascular disease may lead to changes in the extremities caused by reduced blood supply. These may be manifest as ulcerated areas and eventually gangrene, and most frequently involve the lower extremities. The lack of adequate blood flow renders the extremities susceptible to infection, and, therefore, the manifestations of reduced blood supply (ischemia) are frequently combined with those of infection. There is no specific therapy available.

Thromboangiitis obliterans (Buerger's disease). Thromboangiitis obliterans is a disease of an inflammatory nature, poorly understood, which involves the arteries of the extremities, although other vessels, including those of the heart, may be involved. It is thought to be a disease of hypersensitivity, and the persons who are afflicted with it are often heavy cigarette smokers. It almost exclusively affects men of any race between the ages of 17 and 45 years. The symptoms are similar to those of arteriosclerosis of the peripheral vessels, with intermittent claudication, later pain during periods of rest, and eventually gangrene. An inflammation of the veins, phlebitis, occurs in almost 50 percent of those affected.

Polyarteritis nodosa. Polyarteritis nodosa, also called periarteritis nodosa and essential polyangiitis, is an uncommon disease of unknown cause; hypersensitivity may play an important role. It is more common in males and may occur at any age. Small arteries and veins in various parts of the body are affected, producing effects as a result of occlusion or bleeding or a combination of the two.

Effects of polyarteritis nodosa

The course may be rapid, involving only weeks or months, or it may be highly prolonged. The involvement of the blood vessels may affect blood flow to the skin, the gastrointestinal tract, the kidneys, and the heart. There are associated symptoms of arthritis, and involvement of almost all organs has been noted. There is an associated fever in most instances, an increase in the number of leukocytes in the blood, and evidence of inflammation. No recognized specific mode of therapy is available.

Arteritis. Arteritis is an inflammation in localized segments of arteries. One particularly notable type is cranial arteritis (temporal arteritis), a disease of variable duration and unknown cause that is accompanied by fever and involves the temporal and occasionally other arteries of the skull. In general, older persons are affected. Excision of the involved artery may be carried out, but the general symptoms may remain.

Ergotism. Ergotism results from the excessive ingestion of ergot (a fungus that grows on rye and other cereals), and its derivatives. There is evidence of lack of blood flow and eventual gangrene in the small peripheral arteries, particularly in the legs, the nose, and the ears. Treatment includes use of measures to improve the circulation.

Hypertensive vascular disease. Severe arterial hypertension may result in a variety of lesions in the arteries of affected persons. It is a contributing factor to the development of the arterial diseases already described and to cerebral arterial disease in particular. The small arteries of the kidney may be involved, leading to kidney failure. In addition, a variety of lesions may occur in small arteries throughout the body. Measures that may be used to combat hypertension include administration of antihypertensive drugs and restriction of dietary sodium chloride.

Arterial thrombosis. Arterial thrombosis, the formation of blood clots in arteries, may occur in either a normal or a diseased vessel. More frequently, however, it is related to injury, either by physical means or by X-rays or local infection. Such alterations in the blood as an abnormally high level of red blood cells may predispose to thrombosis, and any situation such as heart failure or local vessel disease may be a predisposing factor because of the diminished blood flow. The clots may be removed by surgery or a channel may open through them while the patient is under therapy with anticoagulant drugs. The clots may, however, lead to gangrene and necessitate amputation of an extremity.

Frostbite. Frostbite may occur after exposure to subfreezing temperature momentarily or to less severe temperature for a longer period. It occurs more readily if blood vessels are diseased. Several degrees of frostbite produce thrombosis of the arteries and arterioles and also may involve veins. Symptoms may vary from a mild stage of reddening to gangrene and eventual loss of the extremity.

Types of embolus

Arterial embolism. An embolus, a foreign or abnormal particle circulating in the blood, may block a vessel too small to permit further passage. The sources of emboli include blood clots from the chambers of the diseased or abnormally functioning heart. Fat emboli may occur after fracture of bones and discharge of fatty marrow. Air emboli may be suspected after major injury, especially when large veins are opened during accidents or during vascular surgery of the neck or chest cavity. Bacterial emboli occur in bacterial endocarditis and occasionally in other infections. Cancers may produce minute emboli of tumour cells. Fungus growth or foreign materials, such as fragments of bullets, may become emboli. These emboli may cause transient local symptoms from diminished blood flow and may result in death of tissue. Treatment may include anticoagulant therapy and surgical removal of the clot.

Nonocclusive disease. *Aneurysm and dissecting aneurysm.* Certain disease processes, notably arteriosclerosis and syphilis, may cause damage to the wall of the aorta and large vessels so that they become dilated and, at times, form large bulges (aneurysms). These may produce pain and disturbances to blood flow in tributary vessels; they may rupture, leading to fatal internal bleeding. Treatment is surgical removal of the defective section of the artery and its replacement with a fabric tube. In general, syphilitic involvement occurs predominantly in the thoracic (chest part of the) aorta, whereas arteriosclerotic involvement is more likely to occur in the abdominal part of the aorta and in peripheral vessels. A smaller, more localized form of aneurysm may occur at the site of bacterial infections in the vessel wall.

Dissecting aneurysm

Dissecting aneurysms occur as the result of deterioration of the medial layer of the large vessels, primarily the aorta. A splitting of the arterial wall caused by a rupture of the lining (intima)

and escape of blood under high pressure into the middle layer (media) in the presence of arterial high blood pressure causes sudden enlargement of the vessel. Such dissection often causes obstruction to blood flow, particularly to the tributaries of the aorta, and may lead to secondary lethal hemorrhage from the vessel into the chest or other body cavities. The aortic valve is at times involved in such a lesion, or there may be hemorrhage into the pericardial cavity, causing compression of the heart (pericardial tamponade). When there is a dissecting aneurysm, drugs may be given to lower arterial pressure and ultimately lessen the stresses on the arterial wall, or surgery may be resorted to.

Arteriovenous fistula. A penetrating injury such as that caused by a bullet or a sharp instrument may result in an opening between an artery and its immediately adjacent vein (an arteriovenous fistula). Large amounts of blood may be shunted from the artery to the vein. Arteriovenous fistulas are particularly common in war time as a result of shell fragments and other types of injury involving the arms and legs. They may also occur as a complication of surgery. Others are congenital in origin. The physician may hear a loud murmur caused by the turbulent flow of blood from the artery to the vein. Enlargement of the heart and all of the manifestations of congestive heart failure may occur if the amount of blood shunted is large. In the area around the site of the arteriovenous fistula, the blood vessels become dilated and bacterial infection of the artery lining may develop. A cure can usually be achieved by surgery, although in some situations the remaining arterial flow may be impaired. A special kind of arteriovenous fistula occurs from the pulmonary artery to the pulmonary vein. Here the situation is complicated by the fact that unoxygenated venous blood is being shunted into a vessel normally containing oxygenated blood. Cyanosis results, and produces a stimulation for formation of red blood cells, leading to a form of secondary polycythemia, abnormally high red-blood-cell level. Arteriovenous fistulas are treated by surgery.

Physical injuries. Physical injuries to arteries may lead to damage of the vascular wall, with consequent formation of blood clots and blockage. On other occasions, a form of inflammation may develop that may lead to rupture and may be the source of emboli in the peripheral arteries. Sudden disastrous external stress such as in severe automobile accidents, airplane crashes, and underwater explosions may cause death through rupture of the major arteries, such as the aorta, rupture of the heart valves, or rupture of the heart itself.

Radiation injuries. X-ray, radium, and other radioactive substances in large dosages have marked effects on the vascular system. Initial reactions are inflammatory, and secondary changes caused by scarring and retractions may occur, which in turn lead to vascular occlusion (obstruction). The effects may be progressive for a period of years and are, at times, complicated by the development of cancer.

Raynaud's phenomenon and Raynaud's disease

Functional disease. *Vasoconstriction.* Raynaud's phenomenon is said to occur when the extremities, including occasionally even the ears, nose, or cheeks, become pale, cyanotic, and numb under the influence of cold or emotion. Pain is also present at times. On cessation of the stimulus redness develops and there is a tingling or burning sensation lasting some minutes. This sequence of events is apparently caused by the excessive constriction of the small arteries and arterioles of the fingers upon stimuli that ordinarily cause only a minor degree of vasoconstriction (constriction of blood vessels). Raynaud's disease, which is initially manifested by this phenomenon, is a disease in which there is spasmodic contraction of the blood vessels, usually beginning in early adulthood and affecting women about three times as often as men. The limb involvement is usually symmetrical (on both sides), and may lead to gangrene. Attacks may subside after return to a warm environment or release from tension.

The symptoms associated with Raynaud's disease may occur in people without other evidence of organic disease, especially in cold and moist climates. It may result from the operation of pneumatic hammers, or may occur in individuals with various disorders such as a cervical rib, a supernumerary (extra useless) rib arising from a neck vertebra. It may appear as a complication of arteriosclerosis, thromboangiitis obliterans, and syphilitic aortitis. Various substances, such as nicotine, arsenic, ergot, and lead, have occasionally been blamed. Therapy includes treatment of the primary condition and avoidance of the precipitating cause.

Acrocyanosis is a similar condition, characterized by episodes of coldness and cyanosis of the hands and feet. It is often associated with profuse sweating and, at times, with local edema. It is a form of local sensitivity to cold, and is frequently seen in mentally or emotionally disturbed people or in those with neurocirculatory asthenia (a symptom-complex in which there is breathlessness, giddiness, and a sense of fatigue, pain in the chest over the heart, and palpitation, a fast and forcible heart beat of which the affected person is conscious). Reassurance and avoidance of cold help to eliminate attacks.

Cause and relief of erythermalgia

Vasodilation. Erythermalgia (erythromelalgia) is an uncommon condition in which the extremities, especially the palms of the hands and the soles of the feet, are red, hot, painful, and often somewhat swollen. Dilation of the blood vessels (vasodilation) is the underlying factor. The condition is relieved by elevation of the extremity and cooling. Usually it occurs in middle and later life and is chronic in the primary form; it may occur as a secondary manifestation of underlying vascular disease. It may also occur as a manifestation of an abnormally high red-blood-cell level and, occasionally, as the result of injury or a variety of other disorders.

DISEASES OF THE VEINS

Organic disease. In thrombophlebitis there is thrombosis (clot formation) in the veins and a variable amount of inflammatory reaction in the vessel wall. In some instances, the inflammatory reaction is predominant and thrombosis is secondary. In other instances, thrombosis appears before reaction in the vein wall. Embolization—breaking loose of a blood clot—is most likely to occur during this period, although it may occur at any stage of the disease. A form of the disease in which little or no inflammatory reaction or pain develops is called phlebothrombosis. Thrombophlebitis most frequently involves the veins of the legs. It may occur without apparent cause and tends to recur. At times, it occurs as a result of local injury, either from a penetrating wound or from an external blow without a break in the skin. It may occur as a result of severe muscular effort or strain and in the course of infectious diseases, thromboangiitis obliterans, and a wide range of underlying diseases. Thrombophlebitis may develop in various parts of the body if there is cancer, especially cancer of the pancreas. The presence of varicose veins (see below) in the legs causes a tendency to the development of thrombophlebitis. Treatment includes bed rest and anticoagulant therapy.

Pulmonary embolism may occur in bedridden persons as a result of a clot from a thrombophlebitic lesion, or it may occur in an apparently healthy individual. If the embolus is small, it may not have any effect on the systemic circulation. With larger pulmonary emboli, there may be massive bleeding from the lungs and the development of a large area of pulmonary infarction, resulting in sudden death. Getting up and walking soon after an operation or after congestive heart failure is the best method for avoiding pulmonary embolism. Anticoagulant therapy is useful both as prevention and as therapy after the condition has developed. Surgical removal of a massive pulmonary clot has, on rare occasions, been spectacularly successful.

Varicose veins

Varicose veins are permanently tortuous (twisted) and enlarged. The medium and large veins, especially in the legs, are most likely to be affected. The condition may occur without obvious cause or as a result of postural changes, occupation, congenital anomaly, or localized causes of increased venous pressure. The veins may be near the surface and easily seen or they may be hidden

and unrecognized. Without complication, they rarely cause symptoms, but they may become the site of thrombophlebitis with inflammatory changes and the production of emboli in the peripheral circulation. The veins may rupture on occasion, with bleeding into the surrounding tissues. Varicose veins may occur around the rectum and anus, producing hemorrhoids. If they occur within the scrotal sac in the region of the testes, they are called varicocele. In all forms of varicose veins, the walls of the veins become hardened, and a certain amount of inflammation develops through the years. Dilated veins in the legs may be supported by appropriate elastic-type stockings or bandages, or they may be treated by surgery.

Functional disease. Direct mechanical injury or an infection or other disease process in the neighbouring tissues may produce spasms in the veins (venospasms). Local venospasm is usually of relatively minor significance because of the adequacy of alternate pathways for the blood. If venospasm is widespread, however, involving an entire extremity, or the veins in the lungs, it may impair blood flow and therefore be of greater significance.

DISEASES OF THE CAPILLARIES

The capillaries are the smallest blood vessels. Through their thin walls oxygen and nutrients pass to the tissue cells, in exchange for carbon dioxide and other products of cellular activity. Despite the small size and thin walls of the capillaries, the blood pressures may be quite high as, for instance, in the legs of a person in a motionless, upright position. In certain disease states, there is increased fragility of the capillary wall, with resultant hemorrhages into the tissues. These hemorrhages are referred to as petechiae when small or, if large, may become a large area of discoloration of the skin. Vitamin C deficiency and a variety of blood disorders may be associated with increased capillary fragility. Small petechial hemorrhages occur in bacterial endocarditis and certain other infectious processes. In some instances, petechiae are caused by minute emboli; in others, they appear to be directly related to capillary fragility itself. Treatment is of the underlying disorder.

Capillary fragility

The capillaries are freely permeable to water and small molecules but ordinarily are not highly permeable to proteins and other materials. In some pathologic situations, such as in certain allergic states (*e.g.*, hives) or because of local injury as in burns, there may be local areas of permeability, with escape of fluid high in protein into the surrounding tissues. If the disease affects the entire body, a significant amount of plasma (the blood minus its cells) leaks into the nonvascular spaces, with resultant loss in blood volume. Again, treatment is of the underlying disorder.

HEMODYNAMIC DISORDERS

Hypertension. Hypertension has been discussed in the sections on hypertensive heart disease and on hypertensive vascular disease.

Hypotension. Moderate hypotension (low blood pressure) may occur in persons who are weak and enfeebled, but more often does not represent a diseased state. Indeed, life insurance figures demonstrate that the life expectancy of people with such a condition is greater than average. Hypotension of a severe degree may develop in heart failure, after hemorrhage, in overwhelming infections, and in a variety of circumstances that lead to the development of the clinical picture of shock. In shock, the circulation is inadequate, blood pressure is low, heart rate is rapid, and irreversible tissue damage from insufficient blood supply may occur if the condition is not terminated. (For a discussion of the treatment of shock, see SHOCK, PHYSIOLOGICAL.) Transient hypotension may occur as a normal reaction in certain forms of syncope (see below), but is not necessarily associated with organic disease.

Syncope. Syncope is the sudden loss of consciousness associated with a transient disorganization of circulatory function, as differentiated from other brief losses of consciousness associated with abnormal central nervous system activities, as in certain forms of epilepsy. Syncope may be related to a transient cessation of circulatory activity as in the Adams-Stokes attacks described earlier. Other forms of syncope occur as a result of lowered blood pressure upon assumption of an upright position, a condition often called orthostatic hypotension. In some individuals, disease of the autonomic nervous system prevents appropriate postural adjustments for the upright stance. The disorder may be caused by vascular or central nervous system involvement of the autonomic system. In other instances, postural hypotension may occur as a result of inadequate blood volume, of taking various drugs that affect the nervous control of the circulation, and from a wide variety of other causes. Transient hypotension also may result from hypersensitivity of the carotid sinus. The most common kind of syncope is ordinary fainting. Some individuals are more susceptible than others. Blood loss, exhaustion, the presence of other illness, and psychologic factors may contribute to a tendency to faint. An affected person is usually in the upright position, becomes weak, pale, and sweaty, and may have nausea. The heart rate at this time is usually relatively rapid, but with the abrupt onset of syncope, the heart rate falls often to below the normal level and the person collapses as if he were dead. There is usually a rapid recovery without complications. (J.V.W.)

Cards and Card Games

For centuries one of man's principal social and intellectual diversions, cards and card games, fit every degree of skill, from the simplest children's games to advanced games requiring inferential reasoning of a high order, psychology, and speculation. Card games remain popular despite the proliferation of other forms of entertainment, and cards are also used for education, divination, and conjuring.

In most games the cards are dealt out face downward and are subsequently played with the object of capturing other cards or acquiring varying combinations of cards, according to the game being played. Modern cards are divided into four suits—spades, hearts, diamonds, and clubs—with 13 cards in each suit. The set of 52 cards together is known variously as the pack or the deck, the term used in Shakespeare's day. Two jokers, bearing the image of a medieval court jester, are usually included with the standard 52-card deck, although they are not always used in play. Millions of decks are sold annually throughout the world.

This article first traces the history of cards, then studies the general principles of different kinds of games. A brief guide to the vast literature on the subject is included. For more information on specific games, see BRIDGE; CRIBBAGE; POKER; and RUMMY GAMES; see also RELATED ENTRIES under CARDS AND CARD GAMES in the *Ready Reference and Index*.

PLAYING CARDS

Origins. Though where and when cards originated is uncertain, China seems the most likely place, and the 7th

Two round ivory cards, the *avatāra* (top) and ten of Paraśurāma, painted in miniature technique. Probably from Deccan, India, 18th century.

By courtesy of the Deutsches Spielkarten Museum, Bielefeld, Germany

to the 10th century the earliest probable time. An Indian origin has been suggested by the resemblance of symbols on some early European decks to the ring, sword, cup, and baton classically depicted in the four hands of Hindu statues. Yet another theory is that both cards and chess are derived from ancient divinatory procedures used by primitive peoples.

Nor is it known how cards were introduced to Europe. Some early decks had symbols resembling the Chinese markings and may have been taken back by a Venetian, possibly Niccolò Polo or his more famous son Marco, during travels to and from China in the latter half of the 13th century. Another speculation is that cards may have been brought from Arabia by the Gypsies, but the Gypsies did not reach western Europe in appreciable numbers until after cards had become firmly established. If an Arab origin is to be sought, the Saracen invasion of Sicily or the Moorish conquest of Spain could provide a link. The Spanish word for cards, which is *naipes*, and an earlier Italian word, which is *naibi*, are probably of Arab origin.

Cards in Europe

There are references to cards in Italy from 1299, in Spain, from as early as 1371, the Low Countries, from 1379, and in Germany from 1380. A French manuscript of the early 14th century contains a reference to cards, and in 1392 the registers of the Chambre des Comptes of Charles VI recorded the purchase of three games of cards "in gold and diverse colours." In England by 1465 the use of cards was well enough established for manufacturers to petition for protection against imports.

Cards may have first reached America with Columbus; they became firmly established with the arrival of the English, French, and Dutch colonists; after which they gradually became known and were played throughout the world.

Among many notable collections of historic playing cards are those of the British Museum; that of the United States Playing Card Company, presented to the Cincinnati Art Museum; as well as that of the Morgan Library, New York; and that of the Bibliothèque Nationale, Paris.

The Tarot deck. One type of deck appears to be indigenous to Italy—the Tarot or picture cards, as distinct from the number cards of the East. Called *attutti* ("trumps") or *naibes* and numbered consecutively from 1 to 21, they allegorically represent material forces, virtues, and vices, with the addition of a card unnumbered or numbered 0 or 22, the Fool—precursor of the modern joker. It is probable that the Venetians were the first to add 56 numeral cards to the Tarot deck, thus producing the 78-card deck still used in some parts of the world.

In comparison to the Tarot deck, the numeral cards were divided into four suits (cups, coins, swords, and cudgels), each containing a king, queen, knight, page or valet, along with cards numbered from 1 to 10.

The 22 Tarots could be used for fortune-telling and simple games, the full deck for the earliest form of a game called Tarocchi (German Tarok, French Tarot) that is still played in central Europe. The full deck, too, was and still is used for fortune-telling, for which it provides more scope than other decks. When so used, the Tarots are known as the greater or major arcana, and the 56 suit cards as the lesser or minor arcana, since in interpretation the Tarots exercise a controlling influence over the suit cards. Each suit is attributed with an overall character and each card with a more specific meaning. Thus, hearts may represent the aristocracy, ecclesiastics, and politicians, also pleasure and happy marriage, whereas the seven of hearts may indicate broken promises, disappointment, and betrayal. The Tarots themselves, after many changes, now show pictures of various conventionalized personages and objects to which are attached meanings. For example, the Fool represents Everyman on the path of life, which is folly. In telling a fortune, the cards are interpreted according to the meanings assigned to them, modified by the combination of one card with others, when drawn or dealt, and by the seer's assessment of the client.

Fortune telling with cards

The French scholar Count de Gébelin in *Le Jeu des Tarots* (1781) attempted to trace Tarot cards to an Egyptian origin embodying an ancient philosophical system. His work inspired a Parisian wigmaker named Alliette, who redesigned the old Tarot cards described

by the Count and enjoyed enormous success at court with his divinations. In the 1970s Tarot decks were being used in about 60 countries, their revival attributable in part to renewed interest in the occult and in Eastern philosophies, especially among the young.

Development of modern cards. The 52-card French deck, now standard throughout the world, evolved from the numbered cards of the Tarot deck. The deck, in usual descending order of rank, consists of an ace, king, queen, jack (formerly knave), and nine numerals (10 to 2) in each of four suits. A German deck of 32 cards and a Spanish deck of 40 also evolved, but modern games requiring a short deck are usually played by removing cards from a standard deck.

Suits

The suits had different names and often different symbols in the various countries. The English adopted the French symbols but gave them different names; the French (*pique*, "pike") looked like a spade to the English; the French (*carreau*, "square") became the English diamond, and the French (*trèfle*, "trefoil") became the English club. The traditional suit designations are shown in the Table. The spread of games such as Whist and Piquet, and later Contract Bridge, made the 52-card deck current among card players throughout the world.

Traditional Suit Designations

English	French	German	Spanish	Italian
spade	pique	Grün ("leaf")	espada	spada ("sword")
heart	coeur	Herz	copa ("cup")	coppa ("cup")
diamond	carreau	Schelle ("bell")	oro ("gold")	denaro ("money")
club	trefle	Eichel ("acorn")	basto	bastone ("rod")

Card manufacture. The making of cards has been closely linked with the development of printing. The earliest cards were hand-painted, but it would appear that German production in the 15th century almost certainly was so large as to mean that wood-block printing must have been employed. German cardmakers may, in fact, have been the first wood-block engravers in Europe.

The great diversity of early decks gradually lessened, influenced by 15th century French exporters, whose simple designs became widely popular. Modern variations of those designs may be found primarily in the design of the court cards (kings, queen, and jacks); those in English decks for instance, show figures dressed in the style of Henry VII. The traditional superstition of gamblers and the more modern tendency to preserve fragments of the past have tended to prevent change, including official attempts in some countries to provide proletarian substitutes for the court cards.

Manufacture of cards

Cards were manufactured by laborious methods until 1832, when Thomas de la Rue was granted letters patent by William IV of England for production by typographical processes. The standard modern card measures about 2½ × 3½ inches (6 × 9 centimetres) and is double-headed to aid recognition, with indices at two opposite corners. The backs are printed with identical designs or pictures and frequently are used for advertising.

A full deck, including two jokers, is printed on pasteboard consisting of two sheets gummed together with black paste to ensure opaqueness. The spades and clubs normally are printed in black, the hearts and diamonds in red. Each card is stamped out with a die and simultaneously given a knife edge; sometimes the edges are lacquered. Almost invariably the manufacturer's seal is affixed to the wrapped deck.

Many novel ideas have been tried in connection with cards, such as the addition of a fifth suit or the use outdoors of metal cards played onto a magnetized board. Braille cards enable blind players, especially in tournament play, to compete with sighted opponents on almost equal terms.

Taxation. Governments have often found cards to be a useful source of revenue. In 1615 James I of England granted letters patent for a duty on imports, and in 1628 Charles I taxed manufacturers at a rate gradually increased to the considerable sum of half-a-crown per pack. After 1765, the tax paid was shown in the design of the ace of spades, printed officially by the commissioner of stamps. The heavy impost caused a boom in second-hand sales and a traffic in forged aces of spades, but since 1862 the tax has been moderate. In some countries, however, manufacture is a state monopoly. The high taxes imposed in Austria led to the printing of oversized cards, which were trimmed and cleaned when their edges became soiled, and encouraged the invention in the 1930s of playing cards printed on plastic, which far outlasted those printed on pasteboard.

Cards and society. Card games catering to social and competitive inclinations have proved vastly more important than other uses of cards. It is frequently suggested that one prime ingredient of their success is that such games allow women to compete with men on equal terms and in mixed society.

Cards have been popular with all classes, despite spo-

The bells are equivalent to diamonds, acorns to clubs, and leaves to spades. Hearts are the same in English and German decks. (Right) The king of spades from a pack made by Hardy of London, 1800. Modern international packs are based on this design, traceable to the 15-century Norman variety of French playing cards.

Laws forbidding card playing

radic attempts by monarchs, nobles, and governments to discourage their use by stringent laws. When cards were first introduced into Europe, some of the clergy condemned them; others dismissed them as harmless. Some cards bore religious texts, and religious foundations derived funds from their sale. Puritans called them the "Devil's Picture Book" or "Devil's Tickets" and held that the Second Commandment was violated by the court cards. By many it was considered a sin to have them in the house, and in early Puritan settlements in America cardplayers frequently were punished.

Both governments and churches condemned card playing in later years when gaming fever became widespread, bringing with it reckless wagering and a cruelly strict code of honour. Quarrels led to duels and to many causes célèbres, including the Tranby Croft Baccarat Scandal of 1890, a libel suit over charges of cheating, which, because it involved royalty, rocked Victorian England. In modern times the social and intellectual prestige of games such as Bridge, and the fact that the attention of gamblers was engaged by other means of speculation, led to an abatement of objections to card playing.

Education. From earliest times, cards have been used for instruction in diverse subjects. A cardinal, for example, used playing cards, each bearing a full-length figure with a description below, to instruct the young Louis XIV in the names of the kings and queens of France, geography, and Greek myths. Heraldry was also a popular subject for instruction by cards. Today there are many games, played mainly by children, based on the assembly of sets of pictures, while other decks—printed with the letters of the alphabet—are used for word games by adults as well as children.

Conjuring and sleight of hand. The use of playing cards to perform "magical" tricks was no doubt originally connected with their use in fortune-telling, perhaps to impress the client with the powers of the seer. The rise of gaming led to cardsharping, in which cards were marked surreptitiously and then dealt or played unfairly; today unscrupulous operators can cheat the gullible with such ruses as the "three-card trick," similar to the shell game, in which a victim is led to think that he can successfully keep his eye on a card, usually a queen, in face of the operator's attempt to shuffle the cards. Card tricks are more innocently employed in the repertoire of the professional stage magician, while the clearly defined patterns of playing cards are also used for transmission in psychic experiments, both serious and lighthearted.

CARD GAMES

Early games. Card games are probably coeval with cards themselves and may have been invented by the Chinese when they began shuffling paper money into various combinations. The Chinese are thought to have played both for and with this money, and in China today the general term for playing cards means paper tickets.

Early playing cards proper were mostly numeral cards. In China they were used for games in which the higher cards captured the lower or in which they were formed into winning combinations. Those two principles are still the basis for the two great families of card games.

Circular cards from India are said to have been used on chess boards in a game of pure skill, from which games of chance evolved, but no book gives any account of them. A Persian game, As Nas, has also been called a link in the development of modern games.

Development of modern card games. The number of possible games is practically unlimited, and a vast number of them have been devised. All depend either upon the concept of rank or that of cards in combinations. Some are designed for a specified number of players, a popular number being four; others may be played by any reasonable number. In most games a player's cards are known only to himself until exposed in conformity with the rules.

Games based on rank. In these games each card may defeat or be defeated by other cards when played to a trick. A trick consists of a card from each participant, usually played in clockwise rotation, although in games of Spanish origin, such as Ombre, the cards are played and dealt anticlockwise. Each trick is taken by the highest ranking card of the suit led. Often a trump suit, determined by the rules of the game, may predominate; in this case, any card of that suit may capture any card of the other suits. Except for the trump suit, suits have no order of precedence in the capture of tricks but may have relative values in other matters, such as scoring.

Trump

One of the earliest games of this type was an English game called Triumph, popular in the 16th and 17th centuries, although it seems likely that similar French and Spanish games preceded it. A three-handed Spanish game, Ombre, then became very fashionable, and this, in turn, was followed by a still-enduring family of games of which Loo in England and Spoil Five in Ireland had by the 18th century become "national" games, while in the 19th century Écarté in France, Napoleon in England, and Euchre in the United States achieved similar status, the last seriously rivalling Bridge at the end of the century. In all of these the player receives five cards, a card is turned to fix the trump suit, and the object is to win a specified number of tricks. Even more significant, in terms of the evolution of card games, is that the player's ability to value his cards is vital. Thus, in Napoleon the player assesses his hand with a view to bidding, or declaring, whether he is prepared to win two, three, four or five tricks. The highest caller plays his cards against the combined attempts of the others to defeat him. Players found the challenge of assessing the mathematical relationship between their own cards, those of the other players, and any undealt cards so appealing that the idea of a declared contract, or covenant to take a certain number of tricks resulting from competitive bidding, became a prominent feature in a host of other games, such as Boston, Vint, and Plafond. The very popular German game of Skat incorporates the same idea, each player bidding his hand in competition with the others but with a wide range of options.

Bidding games

In terms of the actual battle for tricks, however, it appears that no game was as satisfying as Whist. By employing the partnership principle of two against two, Whist catered to propensities for both cooperation and opposition, and it also involved the limitless permutations of the complete deck. The combination of the competitive bidding of other games with Whist produced modern Contract Bridge.

Games based on combinations. In this family, which is of older lineage, the object is to acquire combinations of cards that have a prescribed scoring value, a principle seen in ancient Chinese Domino games. The popular example today is Poker. Poker developed from a long line of European games of which the first may have been Primero, a Spanish game that the antiquary Joseph Strutt in *Sports and Pastimes of the People of England* (1801) believed to be the most ancient of the card games played in England. According to Shakespeare, Primero was played by Henry VIII on the night Queen Elizabeth was born. From Primero came the still popular English game of Brag, which was referred to as Brag or Pocher (Ger. *pochen*, "to knock"). It is similar to Poker in that: (1) it is based on groups of cards in sequence or of the same rank, and the best hand, determined by arbitrary rules, wins; (2) players can bet on their chances; (3) if the highest bet is unchallenged, the hands are not exposed; (4) bluffing is therefore an important element. Modern Poker, which first emerged in the United States in the early 19th century, became popular by virtue of its superior opportunities for calculation and psychology.

Poker games

The other widely popular game based on grouping, or melding, cards in combinations is Rummy and its countless variations. Instead of each deal ranking as a separate event as in Poker, play is continuous. Scoring follows the principle that cards not melded (grouped) into scoring combinations when a critical point is reached are counted as penalty cards. One game of this family, Conquian, or Cooncan, entered the United States from Mexico in the early 1900s. In 1949 Canasta, invented in Latin America, spread rapidly to North America and Europe.

Rummy games

Games of both rank and combination. Trick play and melding have often been combined, notably in Piquet, which has a courtly terminology that derives from a lengthy association with aristocrats and serious gamesters, especially in France. For centuries Piquet reigned as the king of games for two, which it remains, although it is now little played. The object is to score points first by melding and then by capturing tricks, so that in the early stages a player tries to acquire cards with both objectives in mind. The game Bezique is based on a similar idea but is played with two packs—sometimes more—and is a test of memory. Games of this type include the Pinochle group, highly popular in the United States in its four-handed versions.

The old English game of Cribbage appears to have evolved quite separately. Though it involves melding and play, both are different from other games.

The Solitaire or Patience games. At least 350 variations of games for one person are known. They are played with either one or two decks. The game usually begins by releasing certain key cards and trying to build the remaining cards upon them in a prescribed order. The disadvantage of most Solitaire games is that success or failure depends largely on the chance initial arrangement of the cards. Some, however, especially those of the two-deck variety, contain an appreciable element of skill.

Children's and party games. The games for children are necessarily simple, as they must appeal to all age groups, and are seldom played in a serious frame of mind. Children enjoy them because they can compete with adults with a chance of winning. Most can be played by any reasonable number, and many games accentuate the element of suspense by giving each player three lives, after losing which he is out. Some games introduce actions, as in Slapjack, in which the player who first slaps a jack when it appears takes all the cards in a common pile. Some have an educational value, such as Casino, which is a foremost children's game because it gives practice in elementary arithmetic and can also be played at a more serious level by adults. Other popular games are Old Maid and Beggar-My-Neighbour.

Older children quickly learn to outshine most adults in such games as Concentration (Memory, Pelmanism) in which, on each turn, the player faces two cards from a complete deck laid out face down. If a pair is formed, the player keeps them; if not, they are returned to their places, again face down. The winner is the player who collects the most cards.

Casino games. The most widely played casino card games in Europe are Baccarat Banque, its more popular variant Chemin de fer or "Chemmy," and Trente et Quarante; in the United States the single most popular casino card game is Blackjack (Twenty-one). All are derived from 15th- and 16th-century European games and have in common extreme simplicity in mechanics of play. The underlying principle is to assemble cards whose value does not exceed a specified number—nine in Baccarat, 21 in Blackjack—and to bet on the probability of the player or the bank being successful.

Caribbean Cultures

The large islands of Cuba, Hispaniola, Jamaica. and Puerto Rico and the smaller Lesser Antilles stretch from near Florida, in the United States, to the Venezuelan coast of South America and form the heartland of Caribbean cultures; but the Bahamas and Bermuda northward in the Atlantic, as well as Guyana, Surinam, and French Guiana, on the South American mainland, and British Honduras, in Central America, must also be considered integral parts of the culture area. Of the 21,000,000 people who live in the Caribbean, more than one half live in Cuba and Haiti. The remainder are divided into more than 50 distinct geographical, political, and cultural entities ranging in size from Guyana (83,000 square miles [210,000 square kilometres] but only 750,000 people) to such minuscule island nations as Barbados (166 square miles), whose population of 253,000 or 1,500 per square mile (580 per square kilometre) is one of the densest on Earth. All the islands together cover only 87,291 square miles, roughly the size of the island of Great Britain, and half of this total area is in Cuba, with 44,218 square miles. Languages are equally diverse and include Spanish; a Spanish Creole spoken in Curaçao and Aruba, called Papiamento; English; Sranan (Taki-Taki), or the English Creole of Surinam; French; French Creole in at least three distinct dialects; Dutch; Hindi-Urdu; and Chinese; and although the aboriginal languages are extinct in the islands, in British Honduras the language known as Island Carib has been kept alive by the so-called Black Caribs forcibly transported there from St. Vincent in 1797, and Mayan, Tupi-Guarani, and other Indian languages are spoken in the mainland countries. Politically, the range is equally great, from the Cuban experiment with Socialism, through military and civilian dictatorships, parliamentary democracies, Puerto Rico's internally independent Commonwealth, and Britain's "special relationship" with the associated states of the Lesser Antilles (Antigua, Dominica, Grenada, St. Kitts-Nevis, Anguilla, St. Lucia, St. Vincent), to three integral *départements* of France (Martinique, Guadeloupe, and French Guiana), a state of Venezuela, and a considerable number of crown colonies, colonies, dependencies, and even dependencies of dependencies.

In spite of the wide divergencies in size, ancestry, language, history, population density, and political organization, the countries of the Caribbean share a common culture, the result of their somewhat parallel experiences as plantation colonies populated by African and Asian labourers dominated by distant European economic and political powers. Cut off from their homelands and in most cases unable to attain the schooling that would have given them entrée into the European ruling class, the Caribbean peoples made a virtue of necessity by combining the disparate elements of their past and their new environment to produce a truly new cultural manifestation that is best called Creole culture. From Portuguese *crioulo*, meaning "locally raised," Creole (Spanish *criollo*) has come to describe the local culture and people of mixed foreign origin. In the same way, linguists use the term to describe languages that have evolved from pidgins used by speakers of mutually unintelligible languages and that have become the first language of the local people. In the Caribbean the French, Spanish, and English Creoles are a blend of these languages with African and aboriginal Indian languages and with each other. In the same way, Creole culture takes pride in the lively cultural scene, the frequent dances, parties, and festivals culminating in carnival, the marvelously diverse foods and drinks, the beauty and generosity of the people of mixed ancestry, and the easygoing but frenetic quality of interpersonal relationships. Today, "real Creoles" may be of any ancestry and class but must be devoted to the local culture in all of its unlikely juxtapositions, and must not look outside at the institutions and gadgetry of industrially more complex societies.

Creole culture

Social organization. *Stratification.* Caribbean societies may be considered to be stratified both vertically by ancestry and horizontally by class. For instance, in Trinidad, possibly the most complex of all Caribbean societies, blacks and mixed Creoles can each be further subdivided on the basis of Catholicism or Protestantism, with a third division for similarly African-derived people

who migrated in recent times from nearby islands, such as Barbados and St. Vincent. Other vertical divisions exist for Hindu, Muslim, and Christian East Indians, foreign-born and locally born whites, the Chinese, Portuguese, and Lebanese merchant communities, Venezuelan immigrants, and several others. Each of these communities has at least a few representatives at the top of the social pyramid and sharply differing percentages of their members at each step farther down the social scale. North American teaching volunteers serving rural areas might, for instance, be the lowest class foreign-born whites, while proportionally more members of each succeeding group are farther down the social scale, with the rural dark Creole plantation labourers and Hindu cane cutters in the largest numbers on the lowest rungs of the scale. As a result, the Trinidadian middle and upper classes are truly international in ancestry, education, and outlook, while the rural proletariat is equally divided between the uneducated and impoverished blacks and East Indians.

In other areas the components are quite different; there are additionally, for instance, the Javanese and American Indians in Surinam, the Latin Catholic mestizos in British Honduras, and the 11 percent local "Conchy Joe" whites of distant British origin in the Bahamas. But the patterns of stratification remain similar from country to country with a largely foreign-educated governmental, business, professional, and landed elite; a relatively small middle class of local traders, landed proprietors, and small businessmen; and a large lower class of landless rural and urban labourers, the underemployed, and the unemployed.

Family and resident patterns. The origins of West Indian family organization have been the subject of considerable controversy among scholars. Although lifelong monogamous unions on the European model and Hindu and Muslim polygynous marriages can be found in the Caribbean, the most common pattern is serial monogamy, wherein each person has two or more mates one after the other in the course of a lifetime. In this context, legal or church marriage is rare and is considered a validation of social position rather than as a statement of cohabitation. Sexual activity usually begins early for both sexes, and illegitimate birth carries no stigma when the overwhelming majority of the population is illegitimate, legally at least, if not functionally. West Indians do frown on conception resulting from casual sexual contact, but a family-sanctioned nonlegal union of even a few weeks duration gives any resulting children a kind of local legitimacy not recognized in official statistics. Young girls welcome children as proof of their attractiveness and fertility, and young men are willing to claim their offspring and contribute to their support as proof of their virility. A number of wealthy men support 50 or more children by many mates, and a few claim to have fathered even more. Because women can earn income as domestics and raise food in kitchen gardens while the market for men's unskilled labour is seasonal and uncertain, many households become "matrifocal," centring around an older woman and her daughters and grandchildren but with no permanent male members. Because such families resemble those of female members of African polygynous marriages and the serial monogamy resembles standard West African marital patterns, an American anthropologist, Melville J. Herskovits, has postulated an African origin for Caribbean family structure. Other authorities have seen these marital types as resulting from slavery wherein the men had been deprived of control over their wives and children. Although the controversy has never been completely resolved, this family system works as well as any in ordering human relations and in caring for offspring, and it may be worth noting that in recent years American and European mating patterns are conforming more and more to those of the islands.

Serial monogamy

West Indian family structure sometimes finds physical expression in the yard, tenement, or barracks, all terms for multiple housing units inhabited by members of a family. Although many West Indian families in rural and urban environments live in individual privately owned or rented houses set on owned or leased lots, a significant number of city dwellers live in clusters of small jerry-built houses around a common yard or in teeming multi-storied rental buildings. The residents are largely blood relatives and their mates, as well as close friends, the children of rural relatives, adopted children, and an occasional crippled, demented, or aged person who has no other place to go. The yard is a cooperative enterprise, supported by those who are working and operated by those who are not. The latter do the cooking and what cleaning and laundry may be necessary and care for the children. Residents are expected to contribute whatever they can, and a person who holds back his salary when working finds little hospitality when unemployed. But if he is pleasant and cooperative and contributes food and cash and judiciously offers gifts when he is working, he can always find food and shelter in the years to come, so that his contributions might be considered a West Indian form of unemployment and retirement insurance. In this context, ties of love and mutual need supersede ties of blood, and it is quite common for a young man to give a substantial portion of his income to the old woman, no kin of his, who fed him when he first left the bush and came to town. Such cooperative enterprises are, of course, a common resort of the very poor in many societies. The clearing and preparing of fields, seeding, weeding, harvesting, pulling in large fishnets, house building, and many other activities are organized in this way. Young men are recruited for the work with promises of food, rum, and prestige, plus firm social pressure, and these otherwise exhausting chores are transformed into social events, with special songs and drum rhythms for each task. (Although family organizations in Africa and Asia were badly disrupted by the experiences of slavery and indenture, it is notable that small communities of runaway slaves, or "maroons," established isolated villages, some of which still exist today, and supported themselves by subsistence agriculture. These sometimes maintained the old ways of life.)

Cooperative enterprise

Economic patterns. Soon after emancipation, which took place in 1834 in British territories but not until 1886 in Cuba, the new freedmen did their best to break away from plantation labour and obtain farmlands through purchase, renting, or sharecropping or simply by squatting on unused lands or deserted plantations. In a few cases, church groups organized cooperative efforts to purchase and divide former sugar estates into family farms, but all too often, especially on the smaller islands, the former slaves had no choice but to stay on the plantations as low-paid wage labourers. In Guyana, Trinidad, and, to a lesser extent, in other areas, the former slaves soon found themselves in competition for the available jobs and land with Chinese, Portuguese, East Indian, and even African indentured labour. As a result of the interplay of these factors with geography, each country developed differently. Some islands, such as Barbados, St. Kitts, Antigua, and Martinique, produce sugar in huge foreign-owned or locally owned private plantations, while in others, such as Grenada, St. Vincent, Guadeloupe, and St. Lucia, new plantation crops such as bananas and long-staple cotton have been introduced, and peasant crops such as nutmegs, arrowroot, cocoa, coconuts, pineapples, and citrus fruit earn income for small landowners. So far, only Cuba has nationalized its sugar estates, not without considerable cost in output per year, but most of the other governments now hold substantial percentages of arable land as well as stock in banana estates, bauxite mines and processing plants, oil wells and refineries, and other large-scale agriculture and industry.

Religious beliefs and arts. Virtually all Caribbean people except the East Indian Hindus and Muslims are members of at least one Christian sect, with Catholicism strongest in the Spanish- and French-speaking areas and Protestantism in the English-speaking areas. But, as they do with so many other borrowed parts of their culture, the West Indians give new content to these alien forms. Alongside virtually every major sect of Christianity, West African cults such as Shango, from Nigeria, and

Blend of religious sects and beliefs in magic

Rada, from Dahomey, have persisted in many areas, and the much-publicized Haitian voodoo represents an amalgam of Christian and African beliefs and practices. Charismatic leaders frequently organize distinctive local variants of Christianity, such as the Baptist sects graphically termed "Shouters" or "Jumpers," or attempt to reproduce the rituals of Islām, the Ethiopian Coptic Church, or Judaism. Although most people are entirely devoted to their own sect, many others continue to search for a faith more suitable to their own needs and desires. It is quite common for a High Church Anglican to consult an African magic practitioner, or obeahman, in search of knowledge of the future, cures for spiritual illnesses and insanity, or protection against the magical machinations of enemies. In Puerto Rico a European spiritualist cult has taken root as orthodox Catholicism increasingly divorces itself from magic practices beyond prayer. Because of the wide choice of sects available and the virtually universal belief in at least the possibility of magic, Caribbean peoples have retained religious concerns at the centre of their consciousness.

African and European traditions have mingled in a particularly spectacular way to produce the music and carnival arts of the Caribbean. Witty and allusive calypso songs, written and sung by professionals, precede the Trinidad carnival, with its huge bands of masked and costumed dancers "jumping up" to music made by beating on tuned steel oil drums. The steel "pan" is made of an upturned oil drum, the flat surface of which has been hammered and incised to make as few as three or as many as 20 convex areas, each tuned differently. These unique musical instruments, typical of the Caribbean in their creative use of discarded alien objects, can be played solo, in unison, or in complicated musical arrangements giving the effect of a giant theatre organ. Afro-Cuban music, some of it, such as the rhumba "La Cumparsita," deriving equally from carnival, has long been an established genre of popular music throughout the world; and in spite of the present overwhelming concern with economic problems, the music remains one of Cuba's most influential ambassadors. Every other area can claim musical or dance forms of international renown—Jamaica's *mentos*, Martinique's beguine, Haiti's merengue, Puerto Rico's *plenas*, Bahamian "Junkanoo," Bermudian Goombay, and the distinctive music of Surinam and Curaçao. Probably no area of comparable size and population on Earth has so many qualified musicians and performers. The other arts have also grown lively in recent years, producing distinguished painters such as Wilfredo Lam, of Cuba, novelists such as Edgar Mittelhölzer, of Guyana, Pierre Marcelin and Jacques Roumain, of Haiti, V.S. Naipaul, of Trinidad, and George Lamming, of Barbados, and poets such as Nicolás Guillén, of Cuba, and Derek Walcott, of St. Lucia. Aimé Césaire is a noted Martiniquais poet, politician, and political philosopher of Negritude.

Tradition and current social change. Throughout a long and cruel history of slavery, colonialism, and exploitation, the peoples of the Caribbean have had to learn to be realistic and adaptable. They learned what they could from the planter aristocrats and *petit blancs* (poor whites) and kept what they could of their African heritage in music, lore, religion, and values. In spite of the innate poverty and isolation of their far-flung rocky islands and infertile tropical lands, they have slowly developed a distinctive and piquant culture, a unique and highly successful blend of many lands and ages plus a great deal of local creation. After Ethiopia, Haiti is the oldest black nation on Earth, and political independence has come to most of the other areas in the past generation. Ties with the former colonizing powers remain close, and their continuing aid is crucial in supporting the fledgling independent governments. More and more, the leaders of the new nations are coming to recognize the similiarity of their problems and aspirations with those of Asia, Africa, and South America.

Problems of inequality

In the present postcolonial world of parliamentary democracies, the Caribbean system of stratification has resulted in political power devolving to the representatives of the majority, usually the blacks in most Caribbean nations, but with economic power left in the hands of foreign investors or local elites. A few families in Martinique, for instance, control most of the productive land, a situation that goes far to explain the strong Communist Party in that French *département*. Even in the original "Black Republic" of Haiti, the relatively light-skinned descendants of the planters control the wealth while the black professionals and army control the government, and the poor blacks eke out a precarious living on their worked-out and eroded hill farms. As a result of these glaring and ever increasing inequalities, the Caribbean nations, whether newly independent or long established, are experiencing increasing revolutionary ferment and governmental instability in the unenviable pattern of South America. Proponents of effective change, such as Juan Bosch in the Dominican Republic, do not remain long in office, being all too often overthrown by military and business interests in defense of their privilege. With little to attract foreign investment on the scale necessary for industrialization and former opportunities for emigration now limited to those trained professionals whom these countries can least afford to lose, the outlook for just and stable governments and equitable distribution of the available resources appears unpromising to most authorities in the Caribbean. Under these circumstances, the graceful and sanguine Creole culture gives meaning to otherwise difficult lives.

BIBLIOGRAPHY. LAMBROS COMITAS, *Carribbeana 1900–1965: A Topical Bibliography* (1968), is the best recent bibliographical source on the area; and the most recent issue of the *Yearbook of the West Indies and the Countries of the Caribbean* is useful for up-to-date facts and statistics. Caribbean Sea

The Caribbean Sea is a suboceanic basin, approximately 1,020,000 square miles (2,640,000 square kilometres) in extent lying between 9° to 22° N and 89° to 60° W. To the south, it is bounded by the coasts of Venezuela, Colombia, and Panama; to the west, by Costa Rica, Nicaragua, Honduras, Guatemala, British Honduras, and the Yucatán Peninsula of Mexico; to the north, by the Greater Antillean islands of Cuba, Hispaniola, Jamaica, and Puerto Rico; and to the east by the Lesser Antillean chain, composed of the island arc, that extends from the Virgin Islands in the northeast to Trinidad, off the Venezuelan coast, in the southeast. Within the boundaries of the Caribbean itself, Jamaica, to the south of Cuba, is the largest of a number of islands. (For articles on localized aspects of the region, see PANAMA CANAL, as well as articles on individual Caribbean countries. For articles

on associated physical features, see ATLANTIC OCEAN, and MEXICO, GULF OF. For historical aspects, see article CENTRAL AMERICAN STATES, HISTORY OF.)

Together with the Gulf of Mexico, the Caribbean Sea has been erroneously termed the American Mediterranean—due to the fact that, like the Mediterranean, it is located between two continental land masses. In both hydrography and climate, however, the Caribbean does not resemble the Mediterranean. The preferred oceanographic term for the Caribbean is the Antillean–Caribbean Sea, which, together with the Gulf of Mexico, forms the Central American Sea. The Caribbean's greatest known depth is Cayman Trench (Bartlett Deep) between Cuba and Jamaica, at approximately 25,216 feet below sea level.

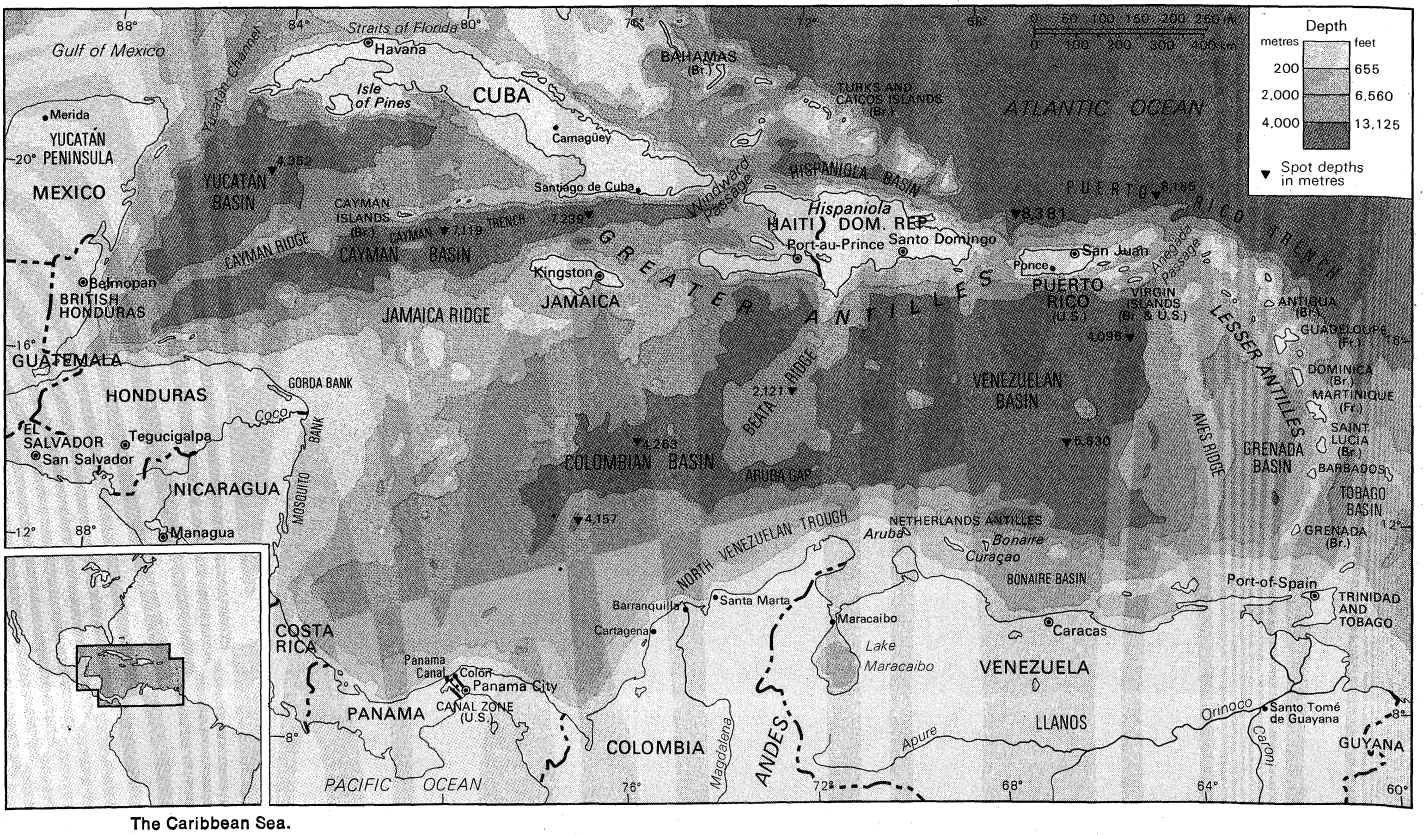
Climate. The climate of the Caribbean is generally tropical, but there are great local variations, depending on mountain altitude, water currents, and the trade winds. Rainfall varies from 350 inches a year in parts of Dominica, to only 10 inches a year on the island of Bonaire off the coast of Venezuela. The northeast trade winds dominate the region with an average velocity of 10 to 20 miles per hour. Tropical storms reaching a hurricane velocity of more than 75 miles per hour are seasonally common in the northern Caribbean as well as in the Gulf of Mexico; they are almost non-existent in the far south. The hurricane season is from June to November, but hurricanes occur most frequently in September. The yearly average is about eight such storms a year. The Caribbean has fewer hurricanes than either the Western Pacific (where these storms are called typhoons) or the Gulf of Mexico. Most hurricanes formed in the Caribbean follow the arclike path of the trade winds into the Gulf of Mexico, although the exact path of any hurricane appears unpredictable. In 1963 Hurricane Flora caused the loss of over 7,000 lives and $528,000,000 of damage in the Caribbean alone. Such storms have also been a major cause of crop failure in the region.

Tropical storms

Physiography and submarine morphology. The Caribbean Sea is divided into five submarine basins, roughly elliptical in shape, which are separated from one another by submerged ridges and rises. These are the Yucatán, Cayman, Colombian, Venezuelan, and Grenada basins. The northernmost of these, the Yucatán Basin, is separated from the Gulf of Mexico by the Yucatán Channel, which runs between Cuba and the Yucatán Peninsula, and has a sill depth of only 5,250 feet. Cayman Basin, to the south, is partially separated from the Yucatan Basin by Cayman Ridge, an incomplete fingerlike ridge that extends from the southern part of Cuba toward Guatemala, rising above the surface at one point to form Cayman Island. Jamaica Ridge, a wide triangular ridge with a sill depth of about 4,000 feet, extends from Honduras to Hispaniola, bearing the island of Jamaica, and separating the Cayman Basin from the Colombian Basin. The Colombian Basin is partly separated from the Venezuelan Basin by the Beata Ridge. The two basins are connected by the submerged Aruba Gap at depths of over 13,000 feet. The Aves Ridge, incomplete at its southern extremity, separates the Venezuelan Basin from the small Grenada Basin, which is bounded to the east by the Antillean arc of islands.

Subsurface water enters the Caribbean Sea across two sills. These sills are located below the Anegada Passage, which runs between the Virgin Islands and the Lesser Antilles, and the Windward Passage, which runs between Cuba and Hispaniola. The sill depth of Anegada Passage is between 6,400 to 7,700 feet (1,950 to 2,350 metres); the sill depth of the Windward Passage is from 5,250 to 5,350 feet (1,600 to 1,625 metres).

Hydrography and currents. North Atlantic Deep Water enters the Caribbean beneath the Windward Passage and is characterized by an oxygen maximum of six millilitres per litre, and a salinity of just under 35 parts per thousand. From there it divides to fill the Yucatan, Cayman, and Colombian Basins at depths near 6,500 feet. This Caribbean Bottom Water also enters the Venezuelan Basin, thus introducing high oxygen water at depths of between 5,900 and 9,800 feet. Subantarctic Intermediate Water (*i.e.*, water differing in several characteristics from the surface and bottom layers of water that it separates) enters the Caribbean below the Anegada Passage at depths of between 1,600 to 3,300 feet. Above this water, the subtropical undercurrent and surface water both enter. The shallow sill depths of the Antillean arc block the entry of Antarctic Bottom Water, so



The Caribbean Sea.

that the bottom temperature of the Caribbean Sea is close to 4° C (39° F), as compared with the Atlantic bottom temperature of less than 2° C (36° F).

Surface currents

Surface currents, bearing both high- and low-salinity water depending on the source, enter the Caribbean mainly through the channels and passages of the southern Antilles. These waters are then forced by the trade winds through the narrow Yucatán Channel into the Gulf of Mexico. The wind-driven surface water piles up in the Yucatán Basin and the Gulf of Mexico, where it results in a higher average sea level than in the Atlantic, forming a hydrostatic head that is believed to constitute the main driving force of the Gulf Stream. Of the 26,000,000 cubic metres of water passing through the Yucatán Channel each second, only 6,000,000 represent the deeper Subantarctic Intermediate Water. The remainder is the surface water that passed over the Antillean arc at depths of less than 2,600 feet.

Geology. The geologic age of the Caribbean is not known with certainty. As part of the Central American Sea, it is presumed to have been connected with the Mediterranean during Paleozoic times (from about 225,000,000 to about 570,000,000 years ago) and then gradually to have separated from it as the Atlantic Ocean was formed. The ancient sediments overlying the sea floor of the Caribbean, as well as of the Gulf of Mexico, are called the Carib beds. They are about one kilometre (0.62 of a mile) in thickness, with the upper strata representing sediments from the Mesozoic–Cenozoic Era, and the lower strata presumably representing sediments of the Paleozoic–Mesozoic Era. Three phases of sedimentation have been identified. During the first phase the basin was free of deformation, as it also was during the second phase, when the Carib beds were deposited. The Central American Sea had apparently become separated from the Atlantic before the end of the first phase. Near the end of the second phase, gentle warping and faulting occurred, forming the Aves and the Beata Ridges. Forces producing the Panamanian isthmus and the Antillean arc were vertical, resulting in no ultimate horizontal movement. The Carib beds tend to arch in the middle of the basins and to dip as land masses are approached. The younger Cenozoic beds (formed during the last 65,000,000 years) are generally horizontal, having been laid down after the deformations occurred. Connections were established with the Pacific Ocean during the Cretaceous Period (which lasted from about 65,000,000 to about 136,000,000 years ago) but were broken when the land bridges that permitted mammals to cross between North and South America were formed in the Miocene and Pliocene epochs.

The existing Cenozoic sediment cover of the seabed consists of red clay in the deep basins and trenches, of globigerina ooze (a calcareous marine deposit) on the rises, and pteropod ooze on the ridges and continental slopes. Clay minerals appear to have been washed down by the Amazon or Orinoco rivers, as well as by the Magdalena River in Colombia. Coral reefs fringe most of the islands.

Vegetation. While the vegetation of the Caribbean region is generally tropical, variations in topography, soils, rainfall, humidity, and soil nutrients have made it diverse. The porous limestone terraces of the islands are generally nutrient poor. Near the seashore, black and red mangroves form dense forests around lagoons and estuaries. Coconut palms typify the sandy vegetation of the littoral. On the dry side of each island, succulents and cactus plants are common. Rain forests prevail on islands having sufficient altitude—such as, for example, Cuba, Jamaica, and Puerto Rico.

The Caribbean region has a diversity of land fauna, which is unevenly distributed. The solenodon, a shrew-like insectivore, is found only in Cuba and Hispaniola. Cuba also has an atelopidid (brightly coloured and poisonous) species of frog, a xanthusid (nocturnal carnivorous) species of lizard, as well as a relict species of cycad (a plant intermediate in appearance between a jem and a palm). Puerto Rico has a species of endemic rodent. The Central American states bordering the sea also have a great diversity of land plants and animals. The three-toed sloth, cats, marsupials, and monkeys abound in the forests, as also do snakes and other reptiles not usually found on the islands. Both the Central American region and the Antillean islands are on the routes of birds migrating to or from North America, so that large seasonal variations occur in the bird populations. Parrots, parakeets, and toucans are typical resident Caribbean birds, while the frigate bird also is seen frequently.

Shallow-water fauna

The shallow-water marine fauna and flora of the Caribbean are far more homogenous than are those of the land. Marine life in the shallows centres around the submerged fringing coral reefs, which attract assemblages of fishes and other forms of marine life. The marine biota as a whole represents a survival—a relict of the warm seas of the Cretaceous Period. Coral reef growth throughout the Antillean region is favoured by uniformly warm temperatures, clear water, and little change in salinity. Submerged fields of turtle grass are found there. Sea turtles of several species, the sea cow, and the Manta (devilfish) ray are also characteristic of the region. The spiny lobster is harvested throughout the Caribbean, being sold mainly in the markets of North America.

Fishes of commerce are the sardine from Yucatan, and the tuna fish. Among common game fish are the bonefishes of the Bahamian reefs, barracuda, dolphin, marlin, and wahoo.

Economic resources. The economic resources of the Caribbean countries are poor. Such industrialization as exists is restricted to one or two countries. Coffee-producing countries include Colombia, El Salvador, Guatemala, Costa Rica, Nicaragua, Honduras, Dominican Republic, Haiti, Cuba, Venezuela, and Trinidad and Tobago. Banana-exporting countries include Honduras, Costa Rica, Panama, Colombia, Martinique, Jamaica, Guatemala, and Guadeloupe; most other Caribbean countries are minor producers. Sugar is exported by Cuba, the Dominican Republic, Jamaica, Colombia, Trinidad and Tobago, Guadeloupe, Barbados, Venezuela, and other countries. These three products between them account for 28 to 72 percent of the total exports of each individual country in the region with the exception of Venezuela. Among the minerals mined are gold in Nicaragua and Colombia; silver and antimony in Honduras; and manganese in Cuba. Venezuela, the richest Caribbean country in terms of natural resources, produces 8 percent of the world's oil. With its iron reserves and hydroelectric potential, it also has prospects for industrialization. Aruba and Trinidad refine and export oil. Jamaica, the Dominican Republic, and Haiti are the sources of about 22 percent of the world's bauxite. Jamaica and the Dominican Republic also produce gypsum. Fish and agricultural products are mostly used for domestic consumption. Much farming is on a subsistence basis.

Tourism

Tourism has become an increasingly important part of the Caribbean economy, serving the huge populations of the United States and Canada to the north, and Brazil and Argentina to the south. Communications by air and sea between the Caribbean and North America are far more developed than is interisland communication. With its sunny climate, and recreational resources, the Caribbean has become one of the world's principal winter vacation resort areas.

Trade and communications. The Caribbean has a complex pattern of trade and communications. The volume of trade per capita is high, but most of this trade is conducted with countries outside the Caribbean. Each Caribbean country tends to trade with countries elsewhere that share a common language. Cuba, an exception, trades with a variety of countries, trade with Communist bloc countries accounting for three-quarters of the total. Intra-Caribbean trade is small, due to limited industrial resources and the monocultural economic pattern. Goods and commodities exchanged within the Caribbean economy are few—rice from Guyana; lumber from British Honduras; refined oil from Trinidad and Curaçao; salt, fertilizer, vegetable oils, and fats from the eastern islands; and a few manufactured products. A

lack of capital and limited natural resources discourage industrial development. Markets for most Caribbean products are in the United States and Canada, which import bananas, sugar, coffee, bauxite, rum, and oil. All of the Atlantic–Pacific shipping using the Panama Canal passes through the Caribbean.

It is anticipated that emergent local nationalisms will lessen prospects for future unions or federations that could foster diversification and industrialization. A continuation of the monocultural economic pattern appears likely for some time to come. Tourism is likely to continue to increase and to result in better prices for local produce, as well as in a strengthening of island economies. Measures to protect such natural resources as unpolluted water, beaches and sand will, however, be necessary if the island countries are to continue to benefit from them.

Caricature, Cartoon, and Comic Strip

Caricature, cartoon (in the satirical sense), and comic strips (including comic books) are related forms. Historically, they arose in the order given, but they all have flourished together. All use the same artistic mediums of drawing and printmaking; caricature and the element of satire is usually present in each.

DEFINITION OF TERMS

Caricature. Caricature is the distorted presentation of a person, type, or action. Commonly, a salient feature is seized upon and exaggerated, or features of animals, birds, or vegetables are substituted for parts of the human being, or analogy is made to animal actions. Generally, one thinks of caricature as being a line drawing and meant for publication to people to whom the original is known; the personal trait is usually present.

Origin of the word caricature

The word caricature derives from the Italian verb *caricare* ("to load," "to surcharge" as with exaggerated detail) and seems to have been used first by Mosini in *Diverse Figure* (1646). The 17th-century sculptor-architect, Gian Lorenzo Bernini, who was a skilled caricaturist, seems to have introduced the word *caricatura* into France when he went there in 1665. There is perhaps, in the choice of the verb *caricare* as a source for the noun, some influence from the idea of *carattere* (Italian: "character") or even from *cara* (Spanish: "face"). At any rate, the face is the point of departure for most caricatures. It is conceivable that underlying the series of overlapping profiles with varieties of extraordinary noses and chins and brows which Leonardo da Vinci and Albrecht Dürer drew independently about 1500 was an observation not only of contemporary human types but of the fact that the heads of rulers on coins and medals, when worn with age, often became ridiculous. A latter-day case is the penny showing Queen Victoria, whose coiffure began to look like an elephant's head when the coin was well worn down.

Caricature, after its spread as idea and practice from Italy and France to Britain in the 18th century, became rather a broad term. In the late 19th century, Gilbert and Sullivan, the English creators of comic operettas, spoke of one of their subheroines as having "a caricature of a face." Perhaps, therefore, it is not surprising that, although cartoons as they are now known developed gradually out of a caricature from the 15th century, cartoon is a 19th-century word.

Satirical deformations and comic analogies in sculpture, the drama, and vase painting are older than purely graphic caricature. The ancient Egyptians represented men as animals; Greek comedy had by-products in burlesqued figures on vases and in terra-cotta statuettes; Romanesque and Gothic sculptors made fun of human failings in stone capitals and wood miserere seat carvings all through the Middle Ages. The marginal flourishes of illuminated manuscripts contain grotesque faces and occasional exaggerated scenes from daily life, or references to the morality plays which have the same relationship to those plays as Greek clay representations have to the stage. All such works verged upon caricature in the narrow personal sense; some were caricature in a broad sense. In the generations since caricature became a clearly defined idea, there have been occasional examples in painting and sculpture alongside the more usual drawing for reproduction.

Cartoon. A cartoon originally was and still is a drawing, a full-size pattern for execution in painting, tapestry, mosaic, or other form. The cartoon was the final stage in the series of drawn preparations for painting in traditional Renaissance studio practice. In the early 1840s, when that studio practice was rapidly decaying, cartoon rather suddenly acquired a new meaning: that of pictorial parody, almost invariably a multiple-reproduced drawing, which by the devices of caricature, analogy, and ludicrous juxtaposition sharpens the public view of a contemporary event, folkway, or political or social trend. It is normally humorous but may be positively savage. Just as the personal caricature was for an audience which knew the original, so the cartoon was and is based on wide acquaintance with the subject. It serves as a capsule version of editorial opinion when it makes political satire, and it is a running commentary on social change, sometimes intended as a corrective to social inertia (for animated cartoons, see ANIMATION). (W.Am.)

Comic strip and comic book. The comic strip consists of a series of adjacent drawn images, usually arranged horizontally, that are designed to be read as a narrative or a chronological sequence. The story is usually original in this form. Words may be introduced within or near each image; they may also be dispensed with altogether. Words should never functionally dominate the image, which then would become merely illustration to a text. The comic strip is essentially a mass-medium, printed in a magazine, newspaper, or book. A comic book is a bound collection of strips, telling a single story or various different stories. Most of the better newspaper strips eventually appear in book form.

Misleading use of "comics"

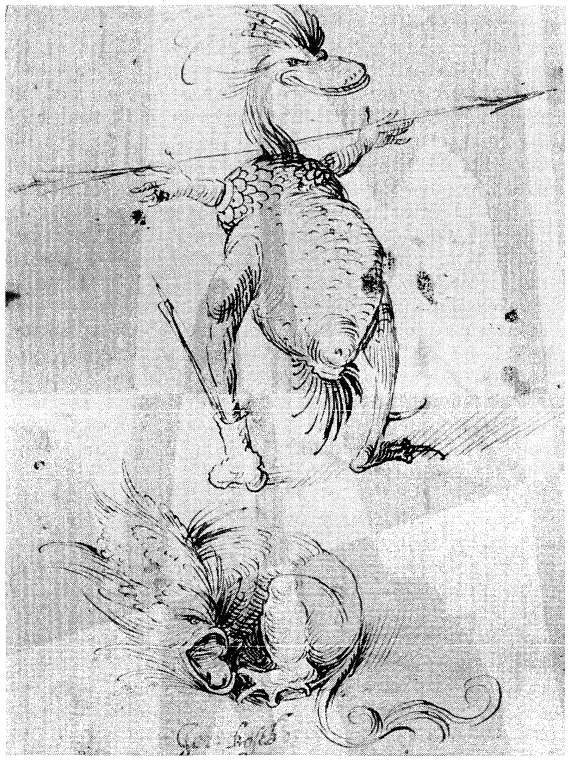
The word comic in connection with these strips is used only in the English language. Although now firmly established, it is misleading, for the early (pre-19th-century) strip was seldom comic either in form or content, and a large proportion of contemporary strips are in no sense primarily humorous. The terms comics and comic strip became established around 1900 in the United States, when all strips were indeed comic. The French term is *bande dessinée* (*i.e.*, "drawn strip," or BD for short). The older German term is *Bildergeschichte* or *Bilderstreifen* ("picture story," "picture strip"), but the Germans now tend to employ the English word. In Italy the term is *fumetto* (meaning literally "little puff of smoke," after the balloon within which most modern strips enclose verbal dialogue). (D.M.Ke.)

ORIGINS OF CARICATURE AND CARTOON

Individual satire. Caricature was a product of the Renaissance and Reformation emphasis on the importance of the individual. If a man was seen officially as an emperor, he was seen unofficially to have feet of clay or to be wearing no clothes. From about the first third of the 16th century the emphasis on decorum was so strong

in Italy and spread so fast northward and westward, reinforced by a still more solemn decorum from Spain, that it produced a reaction. Desiderius Erasmus' *In Praise of Folly* was both a Renaissance effort at satire and a carryover of medieval mockeries; the marginal drawings made in one copy of it by early 16th-century members of the German-Swiss Holbein family are neither caricature nor cartoon in the modern sense, but they are in the same stream of subjective comment on objective observation as the series of exaggerated profiles drawn by Leonardo da Vinci and Albrecht Dürer. In the 16th century the work of the Flemish painter Pieter Brueghel is full of near caricature, as in the familiar drawing of an artist who is troubled at his easel by a nosy peering connoisseur behind his shoulder. In the work of Brueghel and that of his contemporary the Dutch painter Hieronymus Bosch, there are witty and sometimes horrendous dislocations of parts of the body, combinations of human anatomy with fishes, birds, animals, and windmills, and exaggeration of obese or emaciated physical types that are likewise near cartoons.

Staatliche Museen Preussischer Kulturbesitz, Kupferstichkabinett Berlin (West)



"Two Fabulous Animals," pen and brown ink drawing by Hieronymus Bosch (*c.* 1450–c. 1516). In the Staatliche Museen Preussischer Kulturbesitz, Kupferstichkabinett, Berlin. 16.3 × 11.7 cm.

Yet true caricature in the sense of the satirical portrait of an individual is almost impossible to identify before the work of a late 16th-century Bolognese painter, Agostino Carracci. The first caricatures of persons whose names are still known today are by Bernini.

Development of the modern cartoon

Social satire. The less personal and caricature-like features of the modern cartoon developed slowly through the 16th century and up to the last third of the 17th. In part consciously based on Bosch and Brueghel, in part an autonomous protest against the Renaissance belief in order, symmetry, and fixed canons of beauty, there rose a European family of grotesqueries with sources as mixed as its appearance. Its only visible overall characteristic might be said to be that it reacted, from the depth of old folkways, against the novelty of the Renaissance, the New World, and the various hierarchies. Echoes of the dark Gothic forests mixed with fantastic reports of travel (some of them not really new but rehashed from Marco Polo) and with travesties of the Renaissance ornament of such works as Raphael's decorations for the loggias of the Vatican Palace. One result was the double images of faces and landscape or of human figures built of books, fish, or pots and pans by the 16th-century Italian painter Giuseppe Arcimboldo. In a slightly different area lay two types of pictorial comedy. The first type was the conscious satire by professional printmakers, illustrating such works as the *Ship of Fools* (1494), an allegory by the German poet Sebastian Brant, or issued as independent prints. Some of them were tendentious to the point of libel (such were Lucas Cranach's attacks on the papacy, inspired by Martin Luther); others were merely mockery, such as the 16th-century German painter Hans Beham's satirical view of mercenary soldiers and their camp followers. The second type was the unconscious pictorial comedy by comparatively untutored practitioners of woodcut or etching, hastily made and issued as newspaper extras might be issued now. These works were the ancestors of 18th- and 19th-century broadsides.

If caricature deals with the individual and with what makes him individual, cartoons may be said to deal with groups and with their corporate characteristics; both are connected with the Renaissance love of classification and categorizing. Up to the time, in the mid-17th century, when both caricature and cartoon jelled in forms which answer to the modern definition, caricature had been prepared on the whole by knowledgeable artists; and cartoons had been prepared (though often with the assistance of professional artists) at a somewhat lower level. Thereafter, cartoons (in the modern sense of the term) came to be created in response not merely to artistic impulses but to the same sorting-out impulses that were creating the modern state and its society, its science, and its religion. Besides the sublime–ridiculous and the artist–layman dualisms in this field, there is a sort of class dualism that is a result of historical factors rather than of general human disposition. The history of caricature and cartoon is intimately connected with the history of the way in which one class has looked at another. Dürer looked down on the heavy-bodied man whom he called farmerish; yet within two generations Brueghel was draw-

Class distinctions in caricature

"John Calvin," oil caricature by Giuseppe Arcimboldo, 1566. In Gripsholm Castle, Sweden. 64 × 51 cm.

ing peasants in a sympathetic manner. A 16th-century Swiss engraver, Jost Amman, treated trades and professions dispassionately, as did the 17th-century French engraver Abraham Bosse, although Bosse did create some lampoons on unpopular types and callings. Jacques Callot, an early 17th-century French etcher, satirized dandies, beggars, and all classes between, and he even made the generally detested gypsies (who were not yet romantic) almost sympathetic.

A rather comfortable social climate developed in the 17th century: the wars of religion had quieted in France and the Low Countries, though civil war occupied Britain in the middle of the century. But by the time the Restoration had quieted Britain, a general European threat appeared in the form of Louis XIV. Against his absolutism and against his influence through agents in Britain and the Netherlands, the first modern cartoon campaign was made. It was modern in that it was on a large scale—cartoons were published on a fairly regular serial basis, much like that of the modern daily newspaper's editorial cartoon (though the newspaper was still in the letter-and-gazette stage); and it was based on a fairly large and general acquaintance with the persons satirized if not always with the literary analogies used. The cartoons, which as yet made no particular use of personal caricature (that was still on a friendly studio footing), were prints made in Holland by a group of artists of whom Romeyn de Hooghe was the chief, and they were sold cheap. There had been Dutch political cartoons before, but they were laborious and appeared irregularly. The Dutch–English connection in the person of William III, the continuing threat of Louis XIV, and a succession of shattering events in various spheres stimulated a vast production of cartoons from the 1680s on.

Separation of cartoon and caricature

As the cartoon spread—along with its almost indispensable element, caricature—it began to divide; and although the periodical carrying cartoons was not to appear regularly until the third quarter of the 18th century, nor the true comic periodical until early in the 19th century, the divisions were real enough to follow from that time.

"Marquis Spada," pen and ink drawing by Pier Leone Ghezzi (1674–1755). In the Allen R. Hite Art Institute, University of Louisville, Kentucky. 20.3 × 29.2 cm.

PERSONAL AND POLITICAL SATIRE (PURE CARICATURE)

18th century. About 1740 the English printmaker Arthur Pond published together 25 caricatures after original drawings by a number of artists. This collection must have been effective in spreading the idea and the word, for it was an excellent publication. Pier Leone Ghezzi, one of the artists included, was probably the first professional caricaturist, for he made a living with his pen portraits of Romans and visitors to Rome, many of which he engraved. He was a minor master in comparison to his contemporary the Venetian artist Giovanni Battista Tiepolo, yet the caricatures by the latter, delightful though they are, appear to deal with types or at least with anonymous individuals rather than with nameable ones. Tiepolo's pen-and-wash drawings were a small side issue in his enormous production, and they were not engraved or otherwise multiplied in his lifetime. Both artists had an eye for ungainly legs and posture and for odd clothing and the obvious features of the face.

On the heels of Pond's reproductions came the handbill-like personal caricatures circulated from time to time. Apparently begun in the 1760s by the Englishman George Townshend (later Marquess Townshend), these were comic portraits with punning titles or accessories, intended by disingenuous means to avoid being outright libellous. A flood of imitations followed, and it was not long before Townshend's cards became comic illustrations in magazines such as *The London Magazine*, the *Political Register*, and the *Town and Country Magazine*.

Early 19th century. *Great Britain.* Thomas Rowlandson created the comic images of a great many public characters in his day: royal dukes, actresses, auctioneers, hack writers of Grub Street. He was the perfect professional to carry on what the amateur Townshend had begun. Like Tiepolo, he was able to make the person and the costume assume a homogeneously ludicrous or pathetic–bathetic look, with factitious coiffures, wildly

Rowlandson's comic images

frogged uniforms, enormous bosoms and bottoms, and the dejected attitudes of trailing handkerchiefs.

Rowlandson's contemporary James Gillray was less of an artist and more of a professional cartoonist in the modern sense. Coming from the theatre to the political scene, he brought a highly dramatic sense of situation and analogy, but he was peculiarly violent and often scurrilous or scatological. His greatest talent was with patterns and ornaments of costume, which he would allow to take on a luxuriant life of their own. The Swiss-born English painter and teacher Henry Fuseli, though hardly a professional caricaturist, stood halfway between the painted Italianate caricature groups of Sir Joshua Reynolds, an academic English painter, and the Rowlandson–Gillray drawings and etchings; he had something of Gillray's theatrical manner, but his satirical drawings were more often sensual than scatological.

France. The French painter and engraver Philibert-Louis Debucourt might have equalled Rowlandson if he had not been so occupied with the intricacies of colour prints; but he produced a few superb cartoons of the Paris of his day, full of caricatures of fashionable personages.

The whole Napoleonic period gave rise to such passion that, besides the British caricaturists of "Boney," a school of French caricature was generated, the effect of which was to come after the Restoration. Two members of an older generation, Louis-Léopold Boilly and Jean-Baptiste Isabey, really began the work. Boilly, starting where Debucourt left off, satirized the modes and manners of the French. He was not in the direct sense a political caricaturist but frequently used satirical portraits.

Isabey was primarily a portrait painter, but he was in contact with all the great continental political personalities of the first half of the 19th century, and he caricatured many of them privately. Most of the caricatures were not published, but they had an effect among artists, as did the satirical prints of Francisco de Goya.

The tendency of the Restoration to suppress Napoleonic enthusiasms provided another rich ground for cartoon as political complaint. As soon as the first stage was over (in

The cartoon as political complaint

1830), a change of administration was accompanied by the appearance of Charles Philipon's periodical *La Caricature*, the first great vehicle of Honoré Daumier, Henri Monnier, Grandville, and others. The presiding genius had great politico-legal skill and knew exactly how far he and his artists could go. The famous likening of Louis Philippe to a pear, which was both a visual and a verbal pun, was not the least of *La Caricature's* successes. Daumier's colossal gifts included personal caricature, though in his later life he dealt almost entirely in more general social satire. In the early '30s he created for Philipon "Le Ventre legislatif" ("The Legislative Belly"), at once a political indictment, a rogue's gallery of caricatures, and a monumental composition; not to mention a long series of more detailed single antiportraits. Daumier's composite sociopolitical villain, Robert Macaire, and Monnier's Joseph Prudhomme, the sum of bourgeois pettiness, served as butts of satire when censorship caught up with directly personal caricature in Philipon's three or more overlapping papers.

Middle 19th century. *Great Britain.* The specifically cartoon-bearing journal was by this time an established fact. The *Monthly Sheet of Caricatures* had begun publication in London in 1830, lithographed like Philipon's journals. In these and other ventures, the publisher Thomas McLean issued hundreds of political caricatures during a great formative period of modern legislation; his artist, Robert Seymour, was in the Gillray line rather than the later one of John Doyle, who also worked for McLean. John Doyle's son Richard became one of the masters of the mid-century British school of subtler cartooning. The younger Doyle was one of the initial staff of *Punch* when Henry Mayhew started it in 1841.

First caricaturists of *Punch*

Punch began as a fiercely democratic weekly which applied to the young Queen Victoria and her growing family, as a matter of course, the same savage treatment that had been given by caricaturists of the previous hundred years to the Hanoverians. *Punch* was born (1841) in the years when the new Westminster Palace (Houses of Parliament) was under construction. Prince Albert and his team of artistic advisers, wishing to revive fresco painting as a means of decorating the vast wall spaces of the new buildings, opened a competition. When the cartoons (in the original sense of the word) of the proposed compositions were exhibited, it was evident that many of the painters were unfamiliar with work on so heroic a scale, and some of their designs were ludicrous. *Punch* was quick to satirize them in a series of *"Punch*'s Cartoons." One of the reasons for *"Punch*'s Cartoons" on the Westminster hall exhibition was that the unpopular foreign Prince Albert had fomented the competition. But *Punch* was not so much merely antiroyal as it was antihumbug (the novelist W.M. Thackeray, after all, was another of the staff). Though its first few years were marked by some of the worst puns in a punning age, it not only kept up, with its fairly small fixed staff, a remarkable fire of lampoon but soon developed the weekly full-page political cartoon, certainly one of the chief ancestors of the modern editorial cartoon. Nineteenth-century British and general European politics might be briefly comprehended in a few dozen of these. The most famous is probably still that farewell to Otto von Bismarck, "Dropping the Pilot," by Sir John Tenniel.

The woodcut technique used for many decades in *Punch* caused the cartoons on the political page, the largest in scale of the cartoons, to be almost invariably dull in surface. The speed required of the divided-labour teams which produced the cuts from the artists' drawings did not allow for subtleties.

Other countries. The earliest really impressive makers of personal caricature and political cartoon in the United States were David Claypoole Johnston and Thomas Nast. Nast first made his name with American Civil War cartoons in *Harper's Weekly*, which like *Punch* used the woodcut process with an elaborate division of labour in the back shop for the rapid reproduction of cartoons.

The middle and late century produced in Italy the brilliant political caricaturist Virginio, who was to the rise of Italian nationalism what Nast had been to the North in the American Civil War; he worked for *Il Fischietto* of Turin. In 1848 *Kladderadatsch* started in Berlin. Munich had *Fliegende Blätter* and *Punsch*. *Punsch* was more political than the others, which were long-lived comic weeklies in the social-comment style. Schleich's *Punsch* cartoons were a running Bavarian comment on Prussianism.

Late 19th century. *The United States.* In the boom days of the 1870s, Thomas Nast became a master of personal satire; his long practice in dealing with the professional wood engravers gave him at last a style and scale that triumphed over finicky crosshatching and gave full effect to his ruinous attacks on William Marcy "Boss" Tweed and other grafters; he was one of the most fertile of symbol makers outside the personal field and is probably the creator of the donkey of the Democratic Party as well as of the Tammany Hall tiger of the New York Democratic organization.

Nast's personal satire

In 1876 *Puck* was founded. It was soon to develop new artists, notably Joseph Keppler and Bernhard Gillam. They worked in a lithographic style of considerable artis-

"Who Stole the People's Money?—Do Tell. 'Twas Him," by Thomas Nast (1840–1902).
Harper & Row, New York

tic competence, without the force of Nast or the effortless flow of Daumier, but with plenty of clever analogies and with an understanding of the sort of likeness required in caricature.

England. *Punch* meanwhile had settled into its richest period, with Sir John Tenniel and Harry Furniss as political cartoonists. *Vanity Fair* (from 1868) offered some competition, especially at first with its regular coloured lithographic antiportraits. These were signed "Ape" (Carlo Pellegrini) and "Spy" (Leslie Ward, later knighted); they kept up a steady supply of big-headed comic figures against an almost invariably blank background. They also kept up the old device of never quite naming the subject in so many words, but as they were directed at a public which was "in the know," this was part of the fun. These colour caricatures were much loved, and were often framed and hung on private walls. Max Beerbohm (knighted in 1939) devoted himself largely to social and literary satire but almost always on a basis of personal caricature. His deceptively understated outlines and pallid washes, the latter used as local colour for the sake of the overall design, were the perfect means for parodying the good taste of the *fin de siècle*. His symbols for the writers G.K. Chesterton, G.B. Shaw, Joseph Conrad, and W. Somerset Maugham have become almost the standard views of those writers.

Technical developments. Toward the end of the century there was a rebirth of personal satire which accompanied new techniques of reproduction and perfected enrichments of such older techniques as colour lithography. Photomechanical reproduction, especially after the development of halftone, allowed direct reproduction of the artist's drawing without personal interpretation by wood engravers or other technicians. Colour lithography, which had been either limp or turgid on the whole, found a new life. The caricaturists who had been able to draw directly on the stone, as Daumier did, had always had more freedom and better control over results than those who worked with pen and paper; now the latter could depend upon themselves and a photomechanical process.

Influence of photomechanical reproduction

France. Henri de Toulouse-Lautrec produced large-scale posters and, earlier, polychrome lithographs for the Parisian publication *Le Rire* (from 1894) and for independent distribution. He created a new style of informal composition, somewhat influenced by Japanese prints, with bright clear colour, broad, rather casual outlines drawn largely with the brush, a trick of making tone by means of spatter, and a wit which saw through ugliness to a new sort of eloquence. His view of Oscar Wilde was economical and devastating, and his caricatures of theatre and music-hall personalities are unmatched. Another French artist, Caran d'Ache (Emmanuel Poiré), worked on a smaller scale with pen and brush and was one of the most effective continental commentators on the South African War.

Germany. The artists of the Munich satirical publication *Simplicissimus* (from 1896) were all somewhat influenced by Toulouse-Lautrec in their use of white space, spatters, and often random outline; they all commented on those features of German life which were most disliked outside Germany—the didactic professor, the tourist, and the military dandy. Their caricatures in the last field were very thinly veiled; Eduard Thöny, one of this group, was especially popular for the way he conveyed the upper-class boorishness of Prussian officers.

20th century. *The United States.* Charles Dana Gibson was a virtuoso of the pen, using the manner of *Punch*'s Phil May as a point of departure. He used the pen as he pleased, sometimes in a direct descriptive manner, sometimes with colouristic suggestion, sometimes almost anti-graphically. Though he helped to create the caricature types of Theodore Roosevelt and Woodrow Wilson, he was more a social than a personal caricaturist. He is mentioned chiefly because he introduced American physical types called Gibson girls and Gibson men.

A position much like that of *Simplicissimus* was occupied in the years 1911–17 by *The Masses* of New York, which had an editorial policy based on old-fashioned socialist idealism. It was served by a remarkable group of artists whose fine drawing made their often sharp propaganda for reform tolerable in quarters where they might not otherwise have gotten a hearing. John French Sloan, George Bellows, Boardman Robinson, and Art Young were as likely to deal in general social terms as in personal ones, for by this time personal, particularly political, caricature was tending to move into the newspaper editorial cartoon or the pages of theatrical or sporting news.

Role of *The Masses*

Photomechanical reproduction not only allowed greater freedom for comic artists; it made possible the daily newspaper cartoon and later the syndicated editorial cartoon and the comic strip. From about the same time as the new generation of weeklies there was a rise in the use, the autographic character, and the influence of pictorial journalism. John T. McCutcheon of the *Chicago Tribune*, though he used a rather dry and old-fashioned pen technique, was able to range over a world that included politics, the "good old days," the mores of the moment, and sports. His cartoon world, like that of *The Masses*, was almost entirely urban, but he was one of the first of a generally imperturbable type of American cartoonist, whose view is amused rather than aroused. His career ran from before Theodore Roosevelt to after Franklin D. Roosevelt's time. In his line of succession stood such men as Edwin Marcus and S.J. Woolf in the *New York Times*, Oscar Cesare of *The Sun*, Herbert Block ("Herblock") of the *Washington Post*, Daniel Fitzpatrick of the *St. Louis Post-Dispatch*, Rollin Kirby of the *New York World-Telegram*, Bill Mauldin of the *Chicago Sun-Times*, John Fischetti of the *Chicago Daily News*, and others too numerous to list.

England and the Continent. The outstanding political commentator of the first half of the 20th century was David Low, a New Zealander, who worked for the *Sydney Bulletin* before going to Britain. Low was perhaps the best all-round man in the field of caricature since Daumier. His brush drawing was of an Oriental economy, his invention of analogy gleeful without being really outside the classic British educated tradition, and his hatred reserved for a few needful occasions. Like many before him, he employed hackneyed devices (*e.g.*, the heads of a pack of British politicians on dogs' bodies) but by slyness of expression always managed an original twist. There was almost no one in the political field to touch Low except for the Dutchman Louis Raemaekers during World War I, and Raemaekers was bitter where Low was dry and crisp, with footnotes of rumbling laughter. Jean-Jacques Sennep (pen name of J.-J.-C. Pennès) of the Paris *Le Figaro* and Fritz Meinhard of the *Stuttgarter Zeitung* were important French and German caricaturists of the 20th century.

Dominance of David Low

COMEDIES OF MANNERS (THE CARTOON)

Types and groups, rather than politics and the politician or any nameable individuals, are the concern of the co-

"Tricks or Treaties," by Herbert Block.
"Tricks or Treaties,"—from *Straight Herblock* (Simon & Schuster, 1964)

median of manners. He may love mankind for its imperfections or set out to seek improvement, but his method will be much the same. He does not need, as the political cartoonist does, to set up allegories and analogies or to write names on labels, but he may sometimes sharpen his comment by treating human beings as animals (monkeys and apes for obvious reasons have long been the favourites, along with dogs and birds). If the personal caricature is an antiportrait, the cartoon on human foibles is often a sort of anti-sumptuary law or a countergrammar which says, "The exceptions are more fun than the rules."

16th to 18th century. Brueghel and Callot were certainly comedians of manners. Brueghel's picturizing of Flemish proverbs, themselves often comments on foibles, and his prints of the Seven Deadly Sins with satirical examples filling the backgrounds combine a bit of moralizing with the delighted empathy of a participant. Callot is slightly more detached, possibly because of his more conscious style and because he was himself the printmaker (Brueghel drew for professional engravers and woodcutters); but in the catalogs of byplay in his panoramic scenes of fairs and in his trick of making the beggar wear his rags handsomely, he is always balancing and measuring.

Parallel to two-dimensional comment in this vein ran the theatre, notably the commedia dell'arte, puppet theatre, and the performances of the jester and clown. Both appeared in the late 17th and early 18th centuries in the rather courtly comic drawings of the Frenchman Claude Gillot, Antoine Watteau's predecessor. These are not really comedies of manners, for the clowns are used as if they were monkeys aping human ways at a remove toward greater elegance rather than toward apishness. They point the way to a good many 18th-century practices: Gillot and Watteau both made decorations which included monkeys (singerie) just as François Boucher and later artists were to use pseudo-Chinese scenes (chinoiserie) occasionally as ways of commenting on contemporary European life.

Hogarth's cartoons of manners

It is with William Hogarth that the cartoon of manners reached great stature. His series "Marriage à la Mode," "A Rake's Progress," "A Harlot's Progress," the "Four Stages of Cruelty," and the unfinished "Industrious and Idle Apprentices" were loaded with observation not only of human beings but of objects and their ecology, as if he were using his own proliferation of comic images in protest against waste of time, talents, life, and pride. Hogarth, like Sir Joshua Reynolds after him, even painted comic subjects, but he kept to social satire and avoided personal caricature. His pictures of depravity and ferocity are hard to beat, but he could put an expression of by no means unholy delight on a wicked face. In the "Laughing Audience" he gave a full measure of laughter. Hogarth's engravings ran to very large editions and were recut and reissued and then copied at reduced scale for books of the *Complete Works.*

19th century. *Spain.* Francisco de Goya is hard to place in the historical development of the comedy of manners. His "Caprichos" (1796–98), etchings prepared

by some of the most simple and trenchant brush drawings ever made, appeared in the last years of the 18th century and can be called comedies of manners only insofar as they are related to folk sayings and the bittersweet Spanish folk wisdom. Thus, they stand in the line of Bosch and Brueghel, so many of whose paintings were in Habsburg collections in Madrid. The "Proverbios" of 1813–19 are even more monumental transfigurations of various states of the human condition. Like the "Caprichos," they used the caricaturist's means for irony and satire, but there was little of the comic left in them and none at all in the "Desastres de la guerra" (1810–14, "Disasters of War"), which used the Peninsular phase of the Napoleonic Wars as a point of departure. They are closer to universality than even Callot's similarly inspired series and are searching comments on more stages of cruelty than Hogarth covered. In them, Goya was really a political cartoonist using no names; yet he was hardly a public cartoonist in the normal sense because censorship and other factors allowed only a very small circulation of his later work until a sizable edition was printed a generation after his death. The earlier work, which contains elements of comedy, did get abroad and had influence in France and England probably before Goya's death. Artistically, if not politically, his work would have had the same powerful effect whenever "discovered" or circulated.

The folk wisdom of Goya

France. "Paul Gavarni" (Sulpice-Guillaume Chevalier) was more purely a comedian of manners than Daumier, although he was no less perceptive and no less sympathetic with the *petit parisien.* He had a grace derived from his apprenticeship in fashion illustration that produced enchanting jokes on young people in love, dandies, and the theatre and circus. He worked late in life for the *Illustrated London News,* as did Constantin Guys, the French foreign correspondent who reported the Crimean War to the British. Guys, a prolific draftsman who always kept a comic touch, was peculiarly subtle in reporting the great but contrived elegance of Napoleon III's court. He helped both British and French to see themselves as others saw them. "Grandville" (J.I.I. Gérard) was a comic artist on *La Caricature* whose work recalls some of the complicated inventions of Arcimboldo.

Daumier was, of course, the great master of social comedy with or without political content. His series of affectionate if disenchanted comments on married life, the theatre, the courts, concierges, musicians, painters, bluestockings, bathhouses, and children constitute as full a report on Paris in his time as Rembrandt's drawings were for 17th-century Amsterdam. The words were often important, especially when Daumier was indicating in his text the unspoken thoughts of his characters (thus anticipating the 20th-century cartoon in which a thought or vision is indicated as a balloon with cloud-scalloped edges and a picture rather than words inside). His often untidy line and knowingly casual accents of tone produced (at will) sensations of chill weather, of ecstasies of gluttony, of juvenile pride, or of legal craftiness.

England. Rowlandson, as noted earlier, was a political caricaturist part of the time, but above all he was a lampooner of ludicrous and excessive behaviour. He created almost unaided a gallery of types missed by Hogarth, many of which persist in British life—the antiquarian, the old maid, the harried foreign servant, the pleasantly blowzy barmaid, the decent old parson. He was by no means as bawdy as he is supposed to have been, but he liked to push action, like appearance, to an extreme. His Dr. Syntax may be called an ancestor of comic strips.

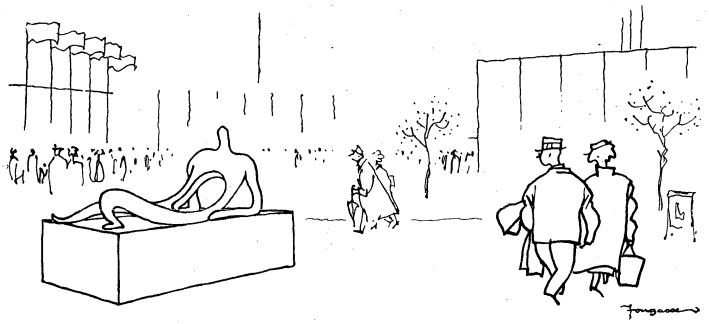
George Cruikshank carried Rowlandson's methods almost beyond extremes in his youth. He used superfantastic costume and sometimes that device of enormous heads which some 17th-century caricaturists used and which is still used by sports-page cartoonists and comic advertising artists.

The longest continuing habit and tradition of humorous comment on the passing world has been made by the English humour magazine *Punch.* Though it began in puns and peevishness, it warmed up during the 19th century with John Leech, Charles Keene, George du Maurier, and in the 20th century with George Belcher, "Fougasse" (Kenneth Bird), H.M. Bateman, Nicolas Bentley, E.H. Shepard, and Osbert Lancaster. Leech was in a sense the pictorial equivalent of Thackeray (Thackeray was an excellent comic draftsman but better at getting the feel of past time with a comic flavour than at considering his contemporaries other than in words). Leech and Keene belong to the era of wood-engraved reproduction; when one sees their original drawings and manuscript captions or dialogue, it is apparent that something was lost in detail and finesse of line but nothing in sense of comedy, in the affectionate tone. The enormous self-confidence of the optimistic Victorians, expressed at first through the violent or bumptious Regency manner of the young George Cruikshank, was tempered by the staff-meeting or meeting-of-minds conduct of *Punch.* The "manners" part of the phrase "comedy of manners" became subjective as well as objective. *Punch* became an upper-class weekly and continued as such for three or four generations, reflecting the large knowledge of all classes which it was possible for its staff to offer its readers, and the large delight of the upper class in seeing its own foibles and those of its servants, tradesmen, lame ducks, and "climbers" exposed. The swing of a crinoline by Leech and the curl of a cabdriver's hat brim by Keene were perfect selective imitation, themselves almost inimitable; the crinoline and the hat are gone with those who knew how to wear them, but the picture in *Punch* remains.

Humorists of *Punch*

Photomechanical reproduction came in during du Maurier's day but hardly affected his generation of artists. Phil May's pen was better served by the camera and the zinc block than Leech's had been by end-grain boxwood and gravers, but the general language was the same. With the generation of George Belcher there was a great change. His own crumbly charcoal or crayon strokes were perfectly adapted to the new process—indeed it was mutual—as were the fat blacks of the Frenchman Jean-Louis Forain and the mid-20th-century cobwebs of Rowland Emett. Fougasse's highly personal little curly stick men, drawn perhaps with a signwriter's pen, could be reproduced by almost any method, but the sharp lines and solid black areas of Bateman (deriving ultimately from Aubrey Beardsley's decorative style) and the thick–thin pen strokes of Shepard (more in the Keene tradition) were well served by modern processes. Shepard was more truly an illustrator than a cartoonist, but Bateman's towering humours and bulging-eyed apoplectic businessmen were in the direct line from Edward Lear to such frantic American cartoonists as Virgil Partch.

Edward Lear practiced as a comic draftsman an economy and geniality that are hard to improve upon, but like Daumier he supposed that his own best gifts lay in an-



"That reminds me, dear—did you remember the sandwiches?" by Fougasse (Kenneth Bird).

Contributions of Edward Lear

other field. Humour had been brought into satire by Hogarth; a truly funny style of drawing was brought into cartooning by Lear. Hitherto, standard drawing techniques had been applied to grotesque shapes and comic situations, but Lear's line went wandering off into a sort of joke on calligraphy. Furthermore, he travelled into areas of fantasy previously barely hinted at.

Aubrey Beardsley used a caricaturist's methods, but little of his work, except perhaps the illustrations to *The Rape of the Lock*, was actually caricature or cartoon. If some of Cranach's prints can be called illustrated libels, some of Beardsley's can be called illustrated yearnings by unfrocked lechers. They are important because their combination of large white spaces, clear lines, and solid or slightly irritated blacks could be reproduced successfully in a choice of dimensions and thus laid down a discipline for illustration, commercial art, and the comic strip.

20th century. The whole tenor of pictorial comedy was shifted by World War I and by the boom times thereafter. Some previously forbidden subjects became admissible. Political caricature during and after the war was excessively partisan, while the cartoons about the war itself tended to alleviate the pain of the struggle. Bruce Bairnsfather's Old Bill and his colleagues in Britain got through it by joking. After it was over, the public for comic publications was greatly enlarged; while the newly rich were standard butts for cartoonists catering to all classes, they were themselves buying comic weeklies.

In the United States the usually monthly comic magazines of universities and colleges had a sudden flowering, to such an extent that an anthology for their cartoons called *College Humor* was published for several years in the 1920s and '30s. The tendency of previously serious weeklies to use small cartoons here and there or to insert a funny page somewhere, created not only new markets for cartoonists but also a temporary decline in the purely humorous magazines, and *Punch, Life*, and *Judge* had difficulty surviving the Depression of the 1930s. The title of *Puck* had already passed to a newspaper chain which used it for a Sunday supplement, and the title of *Life* eventually passed to a periodical of different character. *Simplicissimus* never quite rose between wars to its pre-1914 stature; the effort which went into Dada and Surrealist publications in Germany and France in the '20s, when art itself became an object of social satire, meant a loss to other comic publications. Meanwhile, the public in general gradually became aware of modern art, and its presumed incomprehensibility became almost as routine a subject by 1940 as mothers-in-law or freshly painted park benches.

In the United States an older generation of humorists somewhat of the upper-class *Punch* style lingered briefly after World War I. Of such were Oliver Herford, whose *Alphabet of Celebrities* and other comic verses with pictures were published as small books; Peter Newell, whose highly original *Slant Book, Hole Book*, etc., had a sharp eye to late prewar costume, and Gelett Burgess, whose *Goops* for children were spaghetti-like little figures whose behaviour illustrated a moral.

But to these was now added a new generation of sophisticated but slightly flashier performers, many of them with theatrical connections, many at first employed by the fashion magazine *Vanity Fair* and later by the *New Yorker* (beginning in 1925); Ralph Barton, who did superb roués; Rea Irvin of the thin trembly line, poached eyes, and almost oriental splendour; Gluyas Williams and Ellison Hoover, who satirized business, industrial labour, and other subjects not well-known to the *Punch* tradition; and Alfred Frueh, whose caricatures of theatre people recalled Toulouse-Lautrec. The Depression of the 1930s brought forward a few artists with a genius for social protest, few of whom had any real sense of comedy because tragedy was not to them, as it had been to Daumier, the other side of the same coin. In the United States the Communist *Daily Worker* had the services of William Gropper, a distinguished lithographer and editorial cartoonist who was sometimes able to capture something of the humorous tone of the prewar *The Masses*. And it gradually became known that in the Soviet Union a comic magazine called *Krokodil* was allowed to gibe at the ways of its brothers and even occasionally of its masters.

Cartoons of the Depression years

The two most interesting features of cartoon and caricature in the first half of the 20th century were the rises of the one-line joke and the pictorial joke without words, and the enormous diversity of styles of drawing. The *New Yorker* was probably the inventor or reinventor of the one-line joke and certainly its chief fomenter. Five-decker dialogues with headings were swept away even from *Punch*, and there was a greater unity of words with picture, paralleling the tendency toward tabloid newspapers with large photographic halftones and very pithy text. The joke without words, often in two or more frames, was the extreme of economy of language. One result of this change was that the comedy-of-manners cartoon must convey its comment entirely through costume, setting, and (to a lesser extent) situation, and the emphasis thus tended to fall more on comic situation than on plays on words, class differences, or marked action. The *New Yorker* and magazines whose cartoons had been influenced by it aimed at a sophisticated audience. The *New Yorker* itself, while enjoying in its maturity a position equivalent to that of *Punch* in the 1880s, aimed its advertising and much of its writing at upper-income classes, but its cartoons were aimed at the classes described as highbrow and upper-middle-brow. Such features of the old-fashioned British-style upper class as servants were always treated by *New Yorker* cartoonists (notably Mary Petty) as necessarily comic fossils of an old order and hence in, rather than out of, that old upper class. Whole new areas of social-comedy subject matter arose in this

Drawing by Chas. Addams; copyright © 1949 The New Yorker Magazine, Inc.

"For heaven's sake, can't you do anything right?" by Charles Addams.

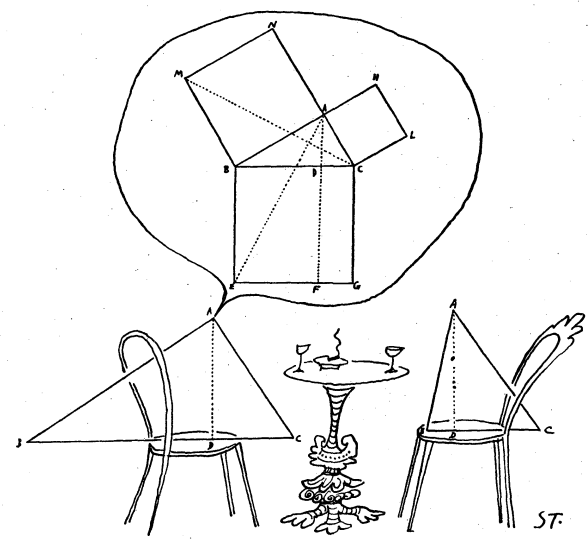
magazine: the life of the Jewish community, the fauna of bars, the managerial class and its flavour, the lighter side of the well-kept woman, commercialized sports, and the imagined life of colonies or races of antisocial beings.

The diversity of styles of drawing reflected the influence of Postimpressionist art quite as much as did the use of modern art as a subject for jokes. The great draftsmen who were on the edges of Impressionism (such as Toulouse-Lautrec) had much influence on caricature and cartoon; while the same photomechanical reproduction that advanced the latter communicated modern painting to a vast public. The loose, almost deliberately ugly method of the Expressionists got into some of the single-cartoon commentators to such an extent that their shorthand was sometimes difficult for those who did not read them daily. The meandering willful line of the 20th-century Swiss painter Paul Klee certainly influenced Saul Steinberg; the Cubists' studies in African sculpture were echoed in cartoons by Miguel Covarrubias and Virgil Partch; the "classical" period of Pablo Picasso in Richard Taylor and others; the curving economical line of Henri Matisse (oddly enough) in Richard Decker. Occasionally, cartoonists parodied one another: Oliver Herford once presented Gibson girls as paper dolls without expression; Al Capp in the comic strip "Li'l Abner" parodied "Dick Tracy" and "Mary Worth." *Mad* magazine parodied everybody: style, subject, everything from politics to pornography.

The cartoon of predicament or situation

The comic strip having taken over the comic presentation of events almost completely, especially since the rise of the one-line joke or picture caption, the modern cartoon became one largely of situation or of predicament that was stated without a solution's being worked out or suggested. The mother of a side-show circus family, confronted with more than she can manage, simply says that after all she has only three hands; a young girl is in ecstasies over a sunset, while behind her a bearded artist-stereotype says, "Too much purple." Meanwhile, the longer sort of comic anecdote retreated to a purely oral–aural life or to the bound volume of jokes, where it sometimes had a vignette-like illustration.

The cartoon of situation was certainly not new, but it predominated in the first half of the 20th century. A Daumier lithograph showing a very fat woman in a crinoline climbing into an omnibus bore no dialogue, but simply the caption, "A mere nothing, and the bus is full." This was a cartoon of predicament. There has tended to be a cluster of these situation subjects: the desert island no larger than a hearthrug, the man who meets a woman walking and imagines her naked (in a scalloped balloon), the flying carpet with novel chauffeur or passenger, the picture gallery with mutual reaction between work of art and viewer, the psychoanalyst's couch, the big-game hunter's trophy room. If the situation was clear, not even one line of joke was required. Such cartoons had a sort of family connection with the earliest caricatures, but they were not merely anti-portraits of types, they were portraits with accessories that created the predicament. So were the tiny single woodcut figures that were inserted as pictorial puns into the text pages of *Punch* in the 1840s. But the latter-day predicament may be highly complicated; in the hands of such a cartoonist as George Price, whose split pen line built up tattered edifices of dowdiness, or Rowland Emett, whose fantastic locomotives and wispy codgers were half infernal and half heavenly, the comedy came from an accumulation of frustrating but ludicrous detail. Frustration, that renowned companion of modern life, was dissolved by laughter. Even the presumably invincible American businessman was often represented in cartoons in frustrating situations, often briskly indicated by the graphic lines on the charts in his office (Whitney Darrow excelled in this genre). André François, who worked for both French and British papers, was a master of the rapidly sketched situation; so was "Anton" of *Punch* (a man and a woman jointly using the name), who kept up the tradition of satire through clothes, being particularly good at pseudo-Edwardian nattiness. Herb Stansbury's "Smart Chart," a one-frame comic for the financial page, satirized stock market graphs. In the drawings of the Romanian-born Saul Steinberg there was almost a parody of the cartoon of situation, for his lines doubled back on themselves and bit their own tails: the hand was indicated as drawing the portrait of which it was a part, or the frustrating details positively engulfed the subject (a wicker chair taken over entirely by its curlicues; tattooing extended beyond the tattooed man; the woman with a lozenge-shaped face, on her lap a baby whose lozenge-shaped face is one-quarter of the larger lozenge).



Captionless cartoon by Saul Steinberg.

Unique style of Steinberg

Yet there were also extraordinarily simple performances; the unassuming little people of Jean Effel (François Lejeune) moved gently through the trials of Adam and Eve; Jacques Faizant's bad children produced hilarious effects by conveying their concentration in a few lines; Otto Soglow's stenographic vocabulary of forms for human bodies (perhaps slightly indebted to Burgess' *Goops*) was so graphic that it could be used in minuscule dimensions with perfect legibility. On the other hand, Peter Arno's large-scale and heavy outlines, despite simple straightforward design, made his beaky and bosomy figures almost jump off the page (for many years one of his near-bawdy cartoons almost invariably occupied a position in the *New Yorker* on the full page immediately after "The Talk of the Town," which suggested that the political cartoon of *Punch* was being ridiculed). Ronald Searle, after a long British career of making spiky and raffish pseudo-Edwardians and fiendish schoolgirls, had a success as an artist for American advertising. A pair of delightful opposite numbers were W. Heath Robinson and the slightly later Rube Goldberg, who on both sides of the Atlantic created wild half-anthropomorphic parodies of intricate machinery. During World War II, Bill Mauldin's disenchanted soldiers were proper descendants of Bairnsfather's. (W.Am.)

COMIC STRIPS AND COMIC BOOKS

Early strips. The comic strip, defined as a mass medium, cannot reasonably be said to exist before the invention of printing. In the early period two principal forms may be observed: the series of small images printed on a single piece of paper (narrative strip proper), and the series composed of several sheets of paper, with one image per page, which when displayed on the wall of a house formed a narrative frieze or picture story. From the outset two basic groups of themes emerge: political morality and private morality.

Early German woodcuts

Surviving pre-1550 strips, most of which are German woodcuts, deal with such subjects as the lives of saints (subdivided in the manner of late medieval painted altarpieces, an arrangement that may be considered a decisive factor on the compartmentalization layout of broad-

sheets); accounts of contemporary miracles; mockery of worldly love; and politically inspired accusations against the Jews. The Reformation and the ensuing wars of religion through the 17th century, particularly in Protestant Germany and the Netherlands, gave rise to many propagandistic and patriotic strips based on contemporary political events. In the course of the 17th century the narrative strip, hitherto an ill-defined and irregular phenomenon, became stabilized and typically took the form of an allegorical centerpiece surrounded by narrative border strips. Although generally crude in style, these strips manage to render accounts of political intrigue and moving descriptions of military terror; the best-known in the latter category is the exquisitely executed and carefully cadenced narrative of the Thirty Years War by the Lorrainer Jacques Callot. Little known, but as powerful in their way, are Romeyn de Hooghe's indictments of Huguenot persecution under Louis XIV. Romeyn, the first named artist to devote himself consistently to the narrative strip, also left colourful, forceful, and elaborate accounts of the accession of William III to power in Holland and England. English engravers, inspired by the Dutch example and led by Francis Barlow, retailed the complex political events of the period in the form of playing cards, which were often sold in uncut broadsheets.

The earliest strips concerning private morality are German and recount particularly atrocious forms of murder and their public punishment, the emphasis shifting progressively from the latter (in the 16th century) to the former (in the 18th century). The crime strip eventually developed into the more or less exaggerated and romanticized life of the famous brigand, which is the precursor of the modern detective strip. Narratives based on a wider spectrum of ideally immoral behaviour took as their point of departure illustrations for the parable of the Prodigal Son, woodcut versions of which, independent of the biblical text, were first produced by Cornelius Teunissen of Amsterdam. The riotous living of the Prodigal, enriched with elements from illustrations for the Seven Deadly Sins and the Ten Commandments, was distilled in various Italian lives of harlots and rakes, the most comprehensive and drastic of which are mid-17th century Venetian. A generation later, the Bolognese artist G.M. Mitelli was giving his narrative and semi-narrative satires almost caricatural moral emphasis. German artists in the 17th century specialized in satirically exposing the tyranny of shrewish wives and proposing violent remedies. The Dutch at this time produced frankly farcical strips of very primitive design, made expressly for children. By mid-18th century the Russians, too, were making satirical strips.

The various social and moral themes that had been crudely treated in different countries and at different times were the raw material for the English artist William Hogarth, who raised the anonymous broadsheet picture story to an aesthetic level which rarely has been surpassed. With a social insight both broad and deep, with an unrivalled sense of satirical counterpoint and topicality of reference, and with exceptional physiognomic finesse, Hogarth dealt with types from all classes of society. His narrative richness is entirely visual, for he dispensed with all the broadsheet paraphernalia of caption–balloon–legend–commentary, permitting only such inscriptions as can be introduced naturalistically into the scene. Hogarth's moral attitude was also new: he depicted the follies and the punishment of his protagonists with a measure of sympathy, reserving the full fire of his satire for those who exploit them. Among Hogarth's many followers, two stand out: the German Daniel Chodowiecki, who reduced the Hogarthian picture story within the compass of almanac illustrations, and the Englishman James Northcote, who tried to combine Hogarthian realism with a Neoclassical sentimentality ("Diligence and Dissipation," 1796).

Hogarth's picture stories

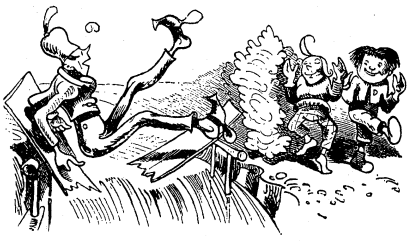
It was the introduction into the broadsheet of the essentially comic mechanism of caricature that established the "comic strip" as basically comic in both form and content. The major exponents of the caricatural strip during the "Great Age" of English caricature around 1800 were minor artists such as Henry Bunbury, George Woodward, and notably Richard Newton, who in his brief career combined elements of Hogarthian satire with the grotesque exaggerations of Rowlandson and Gillray. Economy of line, instantaneousness of comic effect, and visual and verbal wit now became the hallmark of the strip. With the story concentrated on a single page, backgrounds and narrative incident were minimized in favour of striking facial expressions and silhouetted poses.

19th century. The heir to the experiments of the English caricaturists, and the father of the comic strip in its modern sense, was Rodolphe Töpffer, a schoolmaster of Geneva, whose life spanned roughly the first half of the 19th century. Exempt from the personal–political preoccupations of the English caricaturists, Töpffer created a species of absurdist anti-heroes who struggled desperately, fruitlessly, and farcically against the caprices of fate, nature, and an irrational, mechanistic society. The stories (lithographed in little oblong albums containing up to 100 pages) are purposefully purposeless, flow with calculated non sequiturs, and make digression a narrative principle. The pace is sustained by another revolution in draftsmanship, for Töpffer discovered how to turn systematic doodling to account, how to exploit the accident, and how to vary physiognomies experimentally. By abandoning the academic concept of anatomical, three-dimensional drawing, he showed how to render movement for movement's sake. Töpffer's strips are also morally mobile: the normal relationship between cause and effect or crime and punishment, which had underpinned all the older stories, disintegrated.

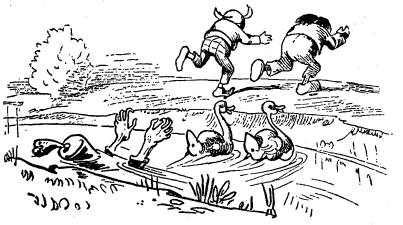
Rodolphe Töpffer

The Töpfferian mode was introduced into the new French satirical periodical journalism by various minor artists. By entering the regular newspaper press, the old broadsheet cartoon exchanged independence for security, and became, for better or worse, subject to editorial control. Cham (pseudonym of Amédée de Noé) published several albums modelled on Töpffer in the 1840s, before settling for a style nearer to that of Daumier. The photographer Nadar, among others, flirted intermittently

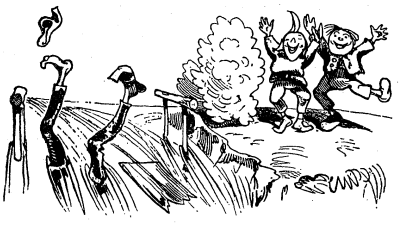
"Profanation of the Host by Jews at Passau 1477." German broadsheet, *c.* 1490.



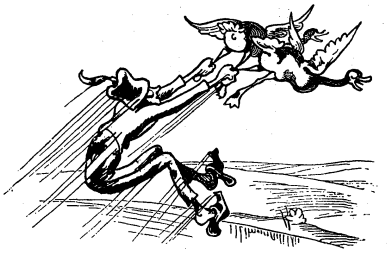
Und schon ist er auf der Brücke,
Kracks! die Brücke bricht in Stücke;



Grad als dieses vorgekommen,
Kommt ein Gänsepaar geschwommen,
Welches Böck in Todeshast
Krampfhaft bei den Beinen faßt.



Wieder tönt es: „Meck, meck, meck!"
Plumps! da ist der Schneider weg!



Beide Gänse in der Hand,
Flattert er auf trocknes Land. —

"Max und Moritz" by Wilhelm Busch.

with the new mode, rendering style and story line more realistic and therefore heavier. Léonce Petit, who had Töpffer's lightness of touch but not his imaginative flair, specialized in rustic farce. A special place is occupied by the illustrator Gustave Doré, who developed a new method owing relatively little to Töpffer (shown in, *e.g.*, *Histoire de la Sainte Russie*, 1854). This was the illustrated chronicle in which a startling hodgepodge of picturesque effects was arranged casually or with deliberate incongruity into a loose chronological sequence.

The contribution of English 19th-century artists is as yet undetermined. George Cruikshank, Cham visiting England in 1847, and thereafter T.H. Nicholson produced Töpfferian variations. Du Maurier around 1869–70 executed some curious animal metamorphoses and wordless gag stories. Among dozens of artists who later tried the comic strip, one may tentatively single out J.F. Sullivan, whose working-class types are drawn in a style that may owe something to Wilhelm Busch and W.G. Baxter, whose Ally Sloper, a proletarian loafer, appeared in *Ally Sloper's Half Holiday* (1884–1923).

Dominance of Wilhelm Busch

The dominant figure of the late 19th century is the German Wilhelm Busch, whose immense popularity in his own day has survived into the late 20th century. At first in periodicals, then in separately published albums, Busch quickly established himself as the first fully professional and truly popular comic-strip artist, appealing to educated and simple, young and old alike. Not being bound to journals, he could, like Töpffer, develop much longer stories than his French contemporaries, whose strips rarely exceeded 50 or so scenes running over three successive issues of a magazine. His graphic and narrative line appears more controlled, more predictable than that of Töpffer; it is comic in an earthier and more rational way. He revived the tradition of realistic social satire, although only two of his stories (*Helen* and *St. Anthony*) have a simply definable satiric butt (religious hypocrisy). Busch appears as a man obsessed with the farcical situation and its potential for physical violence. Happiness appears to lie in the avoidance of the petty annoyances of life and in the repression of instinctual behaviour. His cautionary tales of naughty children and animals may be regarded, on one level, as sophisticated parodies of the didactic juvenile literature of Germany and, on another, as condemnations of the childish sadism that is assumed to lie in everyone. On yet another level, all his work can be viewed as essays on the vulnerability of human dignity. His best known characters, the infant pranksters Max and Moritz, have spawned innumerable progeny down to our own day. Busch's graphic inventiveness was tremendous: his use of patterns of oscillation to represent movement and new conventional signs to express shock, pain, and other emotions constitute a vocabulary that has served the humorous strip cartoonist down to our own times. The rolling rhythm of Busch's graphic line has its counterpart in his facile comic verse, which is both independent and complementary. Variation in the amount of this verse accompanying each picture plays an essential part in the pace of the narrative.

The only German follower of Busch worthy of the name was Adolf Oberländer, a sharp observer of human behaviour. The heir to Busch in France was Caran d'Ache (pseudonym of Emmanuel Poiré), who in supplements to *Le Figaro* in the later 1880s drew the first strips to appear in a general-interest daily newspaper rather than in a weekly satirical magazine of relatively restricted readership. Always witty in a purely graphic sense, he frequently dispensed with captions altogether. In this respect, as in his technique of motif accumulation —his manner of letting a motif or movement snowball or crescendo ad absurdum—he taught much to later cartoonists, especially to H.M. Bateman in the 1920s.

Influence of the *Imagerie d'Épinal*

The influence of Busch on the development of the American newspaper strip was decisive; but European children's illustrated literature derived more from *Imagerie d'Épinal* and from the comic-strip artist Christophe. Throughout the 19th century the common people in France and The Netherlands, especially in rural areas, had subsisted on *Imagerie d'Épinal*, single broadsheets emanating from the town of Épinal, France, and hawked about the countryside. They covered, often in narrative form, such topics of folk interest as religious stories, patriotic histories, and fairy tales. The severe and simple didactic plates had a more or less realistic social emphasis. Some *Imagerie d'Épinal* are comic in content, although not always comic in style, relating, for instance, the folly of certain traditional social stereotypes or satirical characters from folklore and literature like Tyl Eulenspiegel and Baron Munchhausen. It was Christophe (pseudonym of Georges Colomb) who raised this type of popular imagery to the level of the intelligent, urban child, first in the children's periodical, then in various albums published separately. These were originally designed, like Töpffer's, for the children of his own household and the pupils of his school. Christophe's gentle mockery of such types as the naïve bourgeois and the

absent-minded professor is now implanted in French folklore. Christophe established a format for English and French children's comics which survived down to World War II, whereby the text is excluded from the image instead of being incorporated in the balloons of American usage.

20th century. *United States.* The modern newspaper strip was born in the heat of rivalry between giants of the American press. In January 1894 a comic strip filled, for the first time, a full-colour page of Joseph Pulitzer's newspaper the *New York World;* in October 1896 the publisher William Randolph Hearst announced in his rival paper the *Morning Journal* the first regular weekly full-colour comic supplement. This supplement ran to eight pages and included the "Yellow Kid" of Richard Outcault, whom Hearst had enticed away from the *New York World*. The "Yellow Kid" was the first continuous comic character in the U.S. Outcault established earthy, strictly urban farce as the keynote of the early American strip, which thereafter grew in sophistication and sentimentality. The "Yellow Kid" also standardized the speech balloon, which had fallen largely into disuse since the 17th century and its occasional appearance in the English caricatural strip around 1800. In 1897 Rudolph Dirks, at the instigation of Hearst, who had enjoyed the work of Wilhelm Busch as a child, worked up a strip based on "Max und Moritz," called the "Katzenjammer Kids," which proved an instant success. It had, for the first time, the fully developed form of the newspaper strip; *i.e.*, it used balloons, had a continuous cast of characters, and was divided into small regular panels (dispensing with the full panoramic scenes in which the "Yellow Kid" had appeared). The spread of comics to other newspapers was rapid and was aided by the development of newspaper syndication. The aesthetically outstanding strip of the early years was Winsor McCay's "Little Nemo in Slumberland" (first appearance 1906), which created a dreamworld at once gentle, exciting, and humorous. The strip was executed in fairy-tale illustration style, with a conscious display of colouristic effects.

First newspaper strips

The daily strip in black and white, indispensable to all major newspapers since 1915, was inaugurated in 1904 in the Chicago *American* with Claire Briggs' "A. Piker Clerk," in which a character gave tips on horse races. Harry C. "Bud" Fisher's "Mr. A. Mutt" (later "Mutt and Jeff") appeared in 1907. Initially a tip sheet, it soon became a general-interest comic.

During the years 1907–20 most of the major categories of American comics were established, including the first aviation, ethnic-character, and career-girl strips. The most important gag strip was George McManus' "Bringing up Father," dating from 1913. It was the first American strip to achieve international fame. Outstanding among the family-saga or domestic-problem strips that burgeoned during the '20s was Frank King's "Gasoline Alley," which dated from 1919. It strove for realism rather than farcical effects, and had a strict continuity (as opposed to the daily gag), during which, moreover, characters actually grew older. The first career-girl strip (Martin V. Branner's "Winnie Winkle") appeared in 1920. It was followed by the fashion-conscious "Tillie the Toiler" in 1921 by Russ Westover. Another major group of the '20s were fantastic, satirical, and parodistic. Elzie Crisler Segar's "Popeye" (first appearance 1919) still depended upon slapstick, but George Herriman's "Krazy Kat" (1911–44) created a tender world of poetry, at once surreal and humorous. Drawn with the greatest of graphic economy, the absurd interrelationships of a tiny cast of characters (basically three) were presented using the thinnest imaginable plot line. "Krazy Kat" was the first newspaper strip anywhere to be aimed at relatively intellectual adults.

Establishment of subject categories

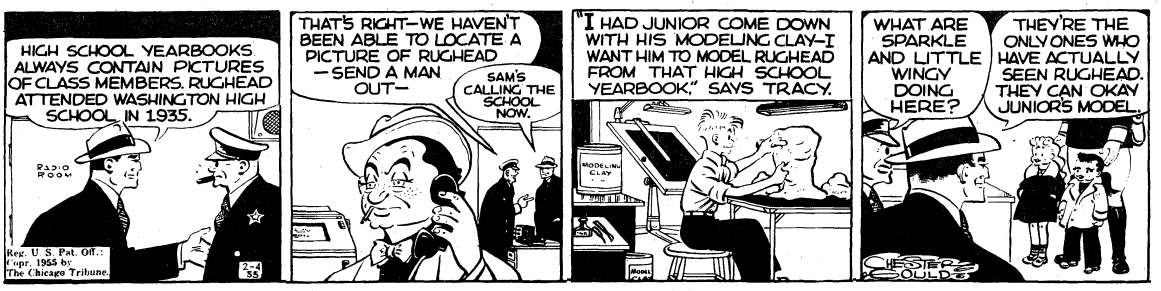
During the '30s the comics page expanded both in quantity of strips and in range of subject matter. Several of the strips created then have survived for more than 40 years. One of these, Chic Young's domestic comedy strip "Blondie" (first appearance 1930), has achieved unparalleled international renown.

A new category of immense significance emerged: the continuous-action adventure strip. This category took many forms: domestic and detective drama, science and space fiction, and, by 1938, war and supermen strips. The earliest adventure strip was "Tarzan" (first appearance 1929) whose creator Harold Foster broke completely with the prevailing caricatural style, adopted cinematic techniques, and sought picturesque, documentary realism. No less concerned with classic aesthetic effects was Alex Raymond, first master of the exotic space strip ("Flash Gordon," first appearance 1933). An aggressively cinematic, adventure strip, meticulously researched, was evolved by Milton Caniff in his "Terry and the Pirates," which appeared in 1934. Caricatural simplifications and grim forms of humour were introduced into the genre by Chester Gould's "Dick Tracy" (first appearance 1931), the detective strip par excellence, which is laced with science-fiction gadgetry and bizarre eroticism. Truly satirical forms of exaggeration returned to the strip with Al Capp's "Li'l Abner" (first appearance 1934).

The comic book

The demand for adventure stories spawned a new and highly lucrative vehicle for the comic strip: the cheap, staple-bound comic book. The first true comic books were marketed in 1933 as give-away advertising premiums. These had a 7½- by 10¼-inch (19- by 26-centimetre) page size, a format that has continued. By 1935 such titles as *Famous Funnies, Tip Top Comics, King Comics,* at first chiefly reprints of newspaper strips, then with original stories, were selling in large quantities. Specialization soon set in: *Detective Comics* (1937) and *Action Comics* (1938). "Superman," which appeared first in *Action Comics,* was the creation of Jerry Siegel (scenario or text) and Joe Shuster (art); it was soon syndicated and transposed to other media. The "Superman" formula of the hero who transcends all physical and social laws to punish the wicked, was widely imitated. The animated cartoon characters of Walt Disney, aimed at younger children, took root in the comic book.

World War II hastened the development of strips and comic books dealing with war and crime, the latter finding a new and avid readership among American soldiers stationed abroad. Being outside the control of newspaper editors, the comic book became increasingly violent and gruesome. The sadism of the American comic became proverbial; the "comic" became equated by Europeans with the "horror comic," and voices of educators were raised against it on both sides of the Atlantic. United States Congressional investigations in 1951 and 1954 blamed rising juvenile deliquency on the pernicious influence of the comic book. The industry responded by



"Dick Tracy," by Chester Gould.

instituting systems of self-censorship, administered by several organizations; the more vicious-looking material was restrained, but, in Europe, some U.S. adventure strips continued to be criticized for their pursuit of violence and for their racist, militarist, and fascist tendencies.

Perhaps as a reaction, there was a parallel, postwar development in newspaper strips devoted to sentimental domestic drama—such as "Rex Morgan, M.D.," "Mary Worth," and "The Heart of Juliet Jones"—and simple-looking, but subtly conceived gag strips—such as "Beetle Bailey," the incorrigible draftee, and "Dennis the Menace," a sophisticated Katzenjammer. "Pogo" (first appearance 1946) by Walt Kelly was generally considered the most humorous and most cerebral. Drawn in a style reminiscent of Walt Disney, the strip transcended Disney's moral simplism, presenting a highly nuanced world populated with an almost Dickensian multitude of comic characters. "Pogo" exuded a tender, nostalgic air, perpetually ruffled by the breezes of sociopolitical allusion. Kelly's dialogue was also much admired, particularly since it appeared at a time when the comic strip was widely criticized for verbal poverty.

Literate strips of the 1950s

The literate strip with philosophical, psychological, and sociological overtones was the principal innovation of the later 1950s. Most successful in this group was Charles Schulz's "Peanuts" (first appearance 1950), a strip in which all the characters were children, dispensing with the adult foil. Of comparable psychological finesse, and imbued with truly satirical flashes, was Johnny Hart's "B.C." (first appearance 1958) and "Wizard of Id" in collaboration with Brant Parker (first appearance 1964), which had prehistoric and medieval settings, respectively. The major strip of political satire, "Feiffer" by Jules Feiffer (first appearance 1956), appeared weekly and was not run on the comics page but on editorial pages of the more liberal or "left" papers. In this strip the dialogue was more important than the drawings, which were deliberately repetitive; the content played upon the logic-twisting rhetoric of politicians and the neurotic relationships between social competitors and lovers.

The most significant innovation since about 1965 has been in the parodistic, erotic, and surrealistic comic. This type emerged in opposition to the newspaper comic strip, in protest as it were against the mass media's saturation with conservative, bourgeois values. Parody and burlesque of the newspaper strip was pioneered by *Mad* magazine (first published in 1952). The erotic, laced with parody, found a home in the liberal periodical press ("Little Annie Fannie" in *Playboy* in 1962 and "Phoebe Zeitgeist" in *Evergreen Review* in 1968). Comic books satirizing a cultural underworld "liberated" by sex and drugs became popular, particularly among college students. These comics were pioneered in San Francisco by Robert Crumb, Rick Griffin, and S. Clay Wilson. The major drug-oriented strip, Gilbert Shelton's "Fabulous Furry Freak Brothers," was in 1970 reaching 100,000 persons weekly in the *Los Angeles Free Press*.

Europe. The first recurrent British comic characters, after Ally Sloper appeared in 1884, were Tom Brown's tramps "Weary Willie and Tired Tim." The strip was sponsored in 1896 by the publisher Alfred Harmsworth and was originally intended for the newly literate and semi-literate masses, but it developed into children's fare.

Strips for young children in Great Britain

Distinctive British contributions were the magazine of strips designed for pre-literate children (*Tiger Tim's Weekly*, first published in 1920, and *Playbox*, which first appeared in 1925); the picture paper based on film comedy (*Film Fun, Kinema Comic*); and the multitude of children's magazines containing both articles and comic strips. The first strip for young children to appear in an adult newspaper was "Rupert, the Adventures of a Little Lost Teddy Bear," created by Mary Tourtel for the *Daily Express* in 1920. The text is fitted in below the balloonless pictures, in order to facilitate reading aloud by adults. The first British adult newspaper strip and after *Krazy Kat* the first daily strip anywhere designed exclusively for adults was the witty "Pop" by John Millar Watt, which first appeared in 1921. "Pop," together with Reginald Smythe's "Andy Capp" (first printed in 1957), were among the very few European strips to be exported to the United States. A notably original strip was Norman Pett's "Jane," published first in the *Daily Mirror* in 1932. It used an artful striptease theme and had great popularity with servicemen during World War II. The mildly satirical strip was pioneered in 1949 in the *Daily Express* by "Flook," a continuing narrative of various kinds of adventure (drawn by Wally Fawkes and written since 1958 by George Melly), and by Frank Dickens' "Bristow," a daily gag strip set in a business office. The outright satirical and political strip flowered in the new satirical magazines such as *Private Eye* (first published in 1961).

Comics in France and Italy

In France, Jean-Pierre Pinchon's "Bécassine" (first appearance 1905), modelled on Christophe, depicted the humorous adventures of a stupid but well-intentioned Breton servant; Louis Forton's "Bande des pieds-nickelés" (first appearance 1908), although ostensibly for

Reprinted courtesy Publishers—Hall Syndicate. © Walt Kelly

"Pogo," by Walt Kelly.

children, had political touches and a mocking tone that appealed to adults as well. The first European strip to be fully developed in the American sense (notably as regards the use of balloons) was Alain de Saint-Ogan's "Zig et Puce" (first appearance 1925), which also was published in an adult newspaper. France had no daily comic strip until 1934. There and in Italy, even more than in England, the market was smothered in the 1930s and '40s by American imports and imitations. An outstanding and hardy domestic product was "Tintin," created by the Belgian Hergé (pseudonym of Georges Rémi), a realistically conceived and relatively didactic adventure strip with a kind of Boy Scout hero. The immense popularity of "Tintin" has (since about 1964) been challenged by a warrior of ancient Gaul called "Astérix," the work of the writer (and comic-strip theorist) René Goscinny and the artist Albert Uderzo. "Astérix," besides being simply humorous and adventurous, indulges in sophisticated puns, witty anachronisms, and satirical flashes. The albums are produced in beautiful, accurately printed colour.

Colour, previously distorted and cheapened on the coarse newsprint of weekend papers and children's magazines, at last began to change the whole aesthetic character of the picture story—and improve it beyond recognition. In the 1960s Italian and French strips for adults by such artists as Guy Peellaert ("Jodelle"), Guido Crepax ("Valentina"), and Nicholas Devil ("Saga de Xam") paved the way for a new era in the comic strip, in which aesthetic expression aligned itself with contemporary art movements such as Pop, Op, and psychedelic art and availed itself of the most advanced printing techniques. The influence worked both ways. American art, particularly the Pop movement, was profoundly affected from about 1963 by comic-strip imagery. In Europe, where leading film makers admitted their debt to the comics, it was predicted that film, graphic art, and the comic strip would fuse into a new medium.

The comics industry. The newspaper strip and comic book have become arguably the largest and most influential iconographic field in history, with an estimated 8,000,000 to 12,000,000 pictures produced between 1900 and 1970. They certainly represent the dominant graphic mythology of the 20th century. Not even the film or television can boast of reaching a third of humanity, as can the comic strip. More than 100,000,000 Americans, young and old, educated and not, read one or more comic strips in their Sunday and daily newspapers. In 1963 there were more than 300 different strips in the United States. "Blondie" is syndicated in 1,200 newspapers all over the world, "Peanuts" in 1,000; "Pogo" reached and "Dick Tracy" reaches more than 50,000,000 readers in 500 newspapers. *Superman* comics circulated in the '50s at the rate of 1,500,000 monthly; in 1943 U.S. comic books totalled 18,000,000 monthly copies, constituting a third of total magazine sales, to a value of $72,000,000.

Dissemination of comics

Not surprisingly, reader participation has reached extraordinary heights; readers truly laugh and suffer with their favourite characters. Chic Young received 400,000 suggestions for a name for Blondie's new baby.

Perhaps in no other form of art has the creator become to such an extent prisoner of his creation, to which he may be locked for his lifetime and which becomes in a real sense independent of his own existence, for the successful strip will almost always be continued by other artists if the original creator should die or lose interest in it. The newspaper strip is also in fief to the syndicates, publishers, and editors who regard it primarily as a circulation booster. It must not offend any conceivable readership or commercial-interest group and therefore must observe strict, conservative codes of morality and decorum. This explains the extent to which the newspaper strip generally has avoided controversial issues of the day. Often enough, a new strip has been conceived by a newspaper proprietor and his art editor according to a pretested formula based on sociological surveys. Regular, efficient production is guaranteed by assembly-line methods: the adventure or soap-opera strip may pass through at least six stages and six different pairs of hands: scenario writing, blocking out, drawing of figures, drawing of background, lettering, colouring, copy editing, etc. Once printed on a crowded page containing up to 20 others, the strip may be "killed" aesthetically; and the small scale, the rigid format, and cheap printing put severe limits on the artist's graphic freedom. It was against such restrictions that the American underground comic and the European *bande dessinée pour adultes* ("adult strip") struck out. (D.M.Ke.)

(1959); "CHAMPFLEURY" (JULES FLEURY), *Histoire de la caricature* (1865) and three expanded subdivisions of this work for the ancient world, the Middle Ages, and the Renaissance; MARION H. SPIELMANN, *The History of Punch* (1895, reprinted 1969); EDUARD FUCHS, *Die Karikatur der europäischen Völker vom Altertum bis zur Neuzeit* (1901), a rather Marxian view; CHARLES R. ASHBEE, *Caricature* (1928); ERNST H.J. GOMBRICH and ERNST KRIS, *Caricature* (1940), which goes to the psychological root of the matter, and "The Principles of Caricature," in ERNST KRIS, *Psychoanalytic Explorations in Art*, pp. 189–203 (1952); WERNER HOFMANN, *Die Karikatur von Leonardo bis Picasso* (1956; Eng. trans., *Caricature from Leonardo to Picasso*, 1957), a purely European view; WILLIAM MURRELL, *A History of American Graphic Humor*, 2 vol. (1934–38, reprinted 1967); ALLAN NEVINS and FRANK WEITENKAMPF, *A Century of Political Cartoons: Caricature in the United States from 1800 to 1900* (1944); DAVID LOW, *A Cartoon History of Our Times* (1939, many reprints); JAMES PARTON, *Caricature and Other Comic Art in All Times and Many Lands* (1969); WILLIAM G. ROGERS, *Mightier Than the Sword: Cartoon, Caricature, Social Comment* (1969); THOMAS WRIGHT, *A History of Caricature and Grotesque in Literature and Art* (1968); RALPH E. SHIKES, *The Indignant Eye: The Artist As Social Critic in Prints and Drawings from the Fifteenth Century to Picasso* (1969); BEVIS HILLIER, *Cartoons and Caricatures* (1970). Ashbee, Hofmann, and Murrell have ample bibliographies. There have been numerous volumes of reprints of well-liked cartoons.

Comic strip: DAVID KUNZLE, *The History of the Comic Strip*, vol. 1, *The Early Comic Strip: Picture Stories and Narrative Strips in the European Broadsheet, ca. 1450–1826* (1973), a recent comprehensive history; COULTON WAUGH, *The Comics* (1947); and STEPHEN BECKER, *Comic Art in America* (1959), two works that form the basic manual—both strong on the origins of major strips, on techniques, and personalities (picturesque description rather than criticism); PIERRE COUPERIE *et al.*, *Bande dessinée et figuration narrative* (1967; Eng. trans., *A History of the Comic Strip*, 1968), the best international history; GEORGE PERRY and ALAN ALDRIDGE, *Penguin Book of Comics* (1967), on American and British comic strips, with a chapter on the cultural overflow; MARTIN SHERIDAN, *Comics and Their Creators: Life Stories of American Cartoonists*, rev. ed. (1944). (*European*): JACQUES MARNY, *Le Monde étonnant des bandes dessinées* (1968); JEROME PEIGNOT, *Les Copains de votre enfance* (1963); MARTEN TOONDER, *Beknopte Striptologie zijnde een poging tot verheldering bij de bestudering van de oudste verhaalvorm die de mensheid kent* (1962), includes a bibliography of Dutch strips; OSCAR MASOTTA, *La historieta en el mundo moderno* (1970), with bibliography; ENRIQUE LIPSZYC, *La historieta mundial* (1958). (*Anthologies*): JACQUES STERNBERG, MICHEL CAEN, and JACQUES LOB, *Les Chefs d'Oeuvre de la bande dessinée* (1967), international, includes some little known examples; JULES FEIFFER, *The Great Comic Book Heroes* (1965), American only; LUIS GASCA, *Los comics en España* (1969). (*Technique*): ROBERT BENAYOUN, *Le Ballon dans la bande dessinée, vroom, tchac, zowie* (1968); MANFRED WELKE, *Die Sprache der Comics* (1958), highly analytical; FRANCIS LACASSIN, *Pour un neuvième art, la bande dessinée* (1971). (*Sociology*): DAVID MANNING WHITE and ROBERT H. ABEL (eds.), *The Funnies: An American Idiom* (1963), articles by critics, creators, and scholars, including sociological statistics of readership and comics content, a comprehensive bibliography of articles in professional, specialized, and general periodicals, and of theses and special studies; FREDERIC WERTHAM, *Seduction of the Innocent* (1954, reprinted 1971), on the theory that the horror comic has contributed to juvenile delinquency; ARIEL DORFMAN and ARMAND MATTELART, *Para leer al Pato Donald* (1972), the Donald Duck comic viewed in Latin America as imperialist, capitalist propaganda.

(W.Am./D.M.Ke.)

Carlyle, Thomas

Scottish essayist and historian, Thomas Carlyle became one of a select group of sages whom the serious-minded Victorian public read avidly, discussed endlessly, and revered deeply. Whether his subject was historical, political or economic, religious or biographical, his aim was always to be a prophet; and though it is possible to challenge his merits as a writer, few would doubt his historical importance.

Carlyle, oil painting by G.F. Watts, 1877.
In the National Portrait Gallery, London.

Early life. Carlyle was born at Ecclefechan, Annandale, in southern Scotland on December 4, 1795. The second son of James Carlyle, Thomas was the eldest child of his second marriage. James Carlyle was a mason by trade and, later, a small farmer, a man of profound Calvinist convictions whose character and way of life had a profound and lasting influence on his son. Carlyle was equally devoted to his mother as well as to his eight brothers and sisters, and his strong affection for his family never diminished.

Calvinist background

After attending the village school at Ecclefechan, Thomas was sent in 1805 to Annan Academy, where he apparently suffered from bullying, and later to University of Edinburgh (1809), where he read widely but followed no precise line of study. His father had intended him to enter the ministry, but Thomas became increasingly doubtful of his vocation. He had an aptitude for mathematics, and in 1814 he obtained a mathematical teaching post at Annan. In 1816 he went to another school, at Kirkcaldy, where the Scottish preacher and mystic Edward Irving was teaching. He became one of the few men to whom Carlyle gave complete admiration and affection. "But for Irving," Carlyle commented sometime later, "I had never known what communion of man with man means." Their friendship continued even after Irving moved to London in 1822 where he became famous as a preacher.

The next years were hard for Carlyle. Teaching did not suit him and he abandoned it. In December 1819 he returned to Edinburgh University to study law, and there he spent three miserable years, lonely, unable to feel certain of any meaning in life, and eventually abandoning the idea of entering the ministry. He did a little coaching and journalism, was poor and isolated, and was conscious of intense spiritual struggles. About 1821 he experienced a kind of conversion, which he described some years later in fictionalized account in *Sartor Resartus*, whose salient feature was that it was negative—hatred of the devil, not love of God, being the dominating idea. Though it may be doubted whether everything was really experienced as he described it, this violence is certainly characteristic of Carlyle's tortured and defiant spirit. In those lean years he began his serious study of German, which always remained the literature he most admired and enjoyed. For Goethe, especially, he had the greatest reverence, and he published a translation of *Wilhelm Meister's Apprenticeship* in 1824. Meanwhile, he led a nomadic life, holding several brief tutorships at Edinburgh, Dunkeld, and elsewhere.

Marriage. On October 17, 1826, Carlyle married Jane Welsh, an intelligent, attractive, and somewhat temperamental daughter of a well-to-do doctor in Haddington. Miss Welsh had been one of Irving's pupils, and she and Carlyle had known one another for five years. The hesitations and financial worries that beset them are recorded in their letters. It is interesting that Carlyle, usually so imperious, often adopted a weak, pleading tone to his future wife during the time of courtship, though this did not prevent him from being a masterful, difficult, and irritable husband; and, in spite of their strong mutual affection, their marriage was full of quarrels and misunderstandings. Those who knew him best believed Carlyle to be impotent.

In the early years of their marriage the Carlyles lived mostly at Craigenputtock, Dumfriesshire, and Carlyle contributed to the *Edinburgh Review* and worked on *Sartor Resartus*. Though this book eventually achieved great popular success, he had at first much difficulty in finding a publisher for it. Written with mingled bitterness and humour, it is a fantastic hotchpotch of autobiography and German philosophy. Its main theme is that the intellectual forms in which men's deepest convictions have been cast are dead and that new ones must be found to fit the time but that the intellectual content of this new religious system is elusive. Its author speaks of "embodying the Divine Spirit of religion in a new Mythus, in a new vehicle and vesture," but he never says very clearly what the new vesture is to be.

Sartor Resartus

London. In 1834, after failing to obtain several posts he had desired, Carlyle moved to London with his wife and settled in Cheyne Row. Though he had not earned anything by his writings for more than a year and was fearful of the day when his savings would be exhausted, he refused to compromise but began an ambitious historical work, *The French Revolution*. The story of how the partially completed manuscript was lent to J.S. Mill and accidentally burned is well known. After the accident Carlyle wrote to Mill in a generous, almost gay, tone, which is truly remarkable when Carlyle's ambition, his complete dependence upon a successful literary career, his poverty, the months of wasted work, and his habitual melancholy and irritability are considered. The truth seems to be that he could bear grand and terrible trials more easily than petty annoyances. His habitual, frustrated melancholy arose, in part, from the fact that his misfortunes were not serious enough to match his tragic view of life; and he sought relief in intensive historical research, choosing subjects in which divine drama, lacking in his own life, seemed most evident. His book on the French Revolution is perhaps his greatest achievement. After the loss of the manuscript he worked furiously at rewriting it. It was finished early in 1837 and soon won both serious acclaim and popular success, besides bringing him many invitations to lecture, thus solving his financial difficulties.

Greatest achievement

True to his idea of history as a "Divine Scripture," Carlyle saw the French Revolution as an inevitable judgment upon the folly and selfishness of the monarchy and nobility. This simple idea was backed with an immense mass of well-documented detail and, at times, a memorable skill in sketching character. The following extract is characteristic of the contorted, fiery, and doom-laden prose, which is alternately colloquial, humorous, and grim:

> . . . an august Assembly spread its pavilion; curtained by the dark infinite of discords; founded on the wavering bottomless of the Abyss; and keeps continual hubbub. Time is around it, and Eternity, and the Inane; and it does what it can, what is given it to do (part 2, book 3, ch. 3).

Though many readers were thrilled by the drama of the narrative, it is not surprising that they were puzzled by Carlyle's prophetic harangues and their relevance to the contemporary situation.

In *Chartism* (1840) he appeared as a bitter opponent of conventional economic theory, but the radical-progressive and the reactionary elements were curiously blurred and mingled. With the publication of *On Heroes, Hero-Worship, and the Heroic in History* (1841) his reverence for strength, particularly when combined with the conviction of a God-given mission, began to emerge. He discussed the hero as divinity (pagan myths), as prophet (Muḥammad), as poet (Dante and Shakespeare), as priest (Luther and Knox), as man of letters (Johnson and Burns), and as king (Cromwell and Napoleon). It is perhaps in his treatment of poets that Carlyle shows to the best advantage. Perverse though he could be, he was never at the mercy of fashion; and he saw much more, particularly in Dante, than others did. Two years later this idea of the hero was elaborated in *Past and Present*, which strove "to penetrate . . . into a somewhat remote century . . . in hope of perhaps illustrating our own poor century thereby." He contrasts the wise and strong rule of a medieval abbot with the muddled softness and chaos of the 19th century, pronouncing in favour of the former, in spite of the fact that he had rejected dogmatic Christianity and had a special aversion to the Roman Catholic Church.

The hero

It was natural that Carlyle should turn to Cromwell as the greatest English example of his ideal man and should produce the bulky *Oliver Cromwell's Letters and Speeches. With Elucidations* in 1845. His next important work was *Latter-Day Pamphlets* (1850), in which the savage side of his nature was particularly prominent. In the essay on model prisons, for instance, he tried to persuade the public that the most brutal and useless sections of the population were being coddled in the new prisons of the 19th century. Though incapable of lying, Carlyle was completely unreliable as an observer, since he invariably saw what he had decided in advance that he ought to see.

In 1857 he embarked on a massive study of another of his heroes, Frederick the Great, and the *History of Friedrich II of Prussia, Called Frederick the Great* appeared between 1858 and 65. Something of his political attitude at this time can be gathered from a letter written in April 1855 to the exiled Russian revolutionary A.I. Herzen, in which he says "I never had, and have now (if it were possible) less than ever, the least hope in 'Universal Suffrage' under any of its modifications" and refers to "the sheer Anarchy (as I reckon it sadly to be) which is got by 'Parliamentary eloquence,' Free Press, and counting of heads" (quoted from E.H. Carr, *The Romantic Exiles*).

Unfortunately, Carlyle was never able to respect ordinary men. Here, perhaps, rather than in any historical doubts about the veracity of the gospels, was the core of his quarrel with Christianity—it set too much value on the weak and sinful. His fierceness of spirit was composed of two elements, a serious Calvinistic desire to denounce evil and a habitual nervous ill temper, for which he often reproached himself but which he never managed to defeat.

Last years. In 1865 he was offered the rectorship of Edinburgh University. The speech that he delivered at his installation in April 1866 was not very remarkable in itself but its tone of high moral exhortation made it an immediate success. It was published in 1866 under the title *On the Choice of Books*. Soon after his triumph in Edinburgh, Mrs. Carlyle died suddenly in London. She was buried in Haddington and an epitaph by her husband was placed in the church. Carlyle never completely recovered from her death. He lived another 15 years, weary, bored, and a partial recluse. A few public causes gained his support: he was active in the defense of Governor E.J. Eyre of Jamaica, who was dismissed for his severity in putting down a Negro uprising in 1865. Carlyle commended him for "saving the West Indies and hanging one incendiary mulatto, well worth gallows, if I can judge." He was excited by the Franco-German War (1870–71), saying "Germany ought to be President of Europe," but such enthusiastic moments soon faded. In these last years he wrote little. His history *The Early Kings of Norway: Also an Essay on the Portraits of John Knox* came out in 1875, and *Reminiscences* was published in 1881. Later he edited his wife's letters, which appeared in 1883 under the title *Letters and Memorials of Jane Welsh Carlyle, Prepared for Publication by Thomas Carlyle.* Carlyle died in London on Feb. 5, 1881, and although Westminster Abbey was offered for burial, he was buried, according to his wish, beside his parents at Ecclefechan.

Rector of Edinburgh University

Carlyle's contribution. It is perhaps difficult to be fair to Carlyle. Those who do not accept him as an inspired prophet find he makes intolerable claims on his readers' patience and on their emotional energy. A sentence, a paragraph can be pithy, but a whole book, on the other hand, is always repetitive and diffuse, and he was invariably biassed.

Though he was a man of many words and wide learning, his religious sense, intense in its way, played always round two grand and simple ideas that many religions have in common: the terror of God's glory and the immortality of the soul. The whole of his life and writings can be seen as an attempt to secularize, to reclothe the Calvinist insights without mitigating them. In the effort to preserve religion while discarding its doctrines, he has affinities with several famous Victorians, particularly Matthew Arnold. But whereas Arnold, working from a moderate Anglican basis, attempted to turn Christianity into sweetness and light, Carlyle preserved to the full and even increased the fierceness, the momentous drama, the seriousness of Calvinism. The idea of the elect and the reprobate, even though transferred into moral and secular terms, was an ever-present reality to him. For an infallible Bible he substituted an infallible History, what he called "the true epic poem and universal Divine Scripture, whose plenary inspiration no man out of Bedlam or in it shall bring in question." He stirred the conscience of his century; he helped thousands to see their experience in a historical and spiritual context and thus to find new meaning in a monotonous existence; and in an age of prolonged physical toil, he inspired thousands with belief in the dignity of their work.

MAJOR WORKS

HISTORY: *The French Revolution*, 3 vol., 1837; *On Heroes, Hero-Worship, and the Heroic in History*, 1841; *Oliver Cromwell's Letters and Speeches. With Elucidations*, 2 vol., 1845; *The History of Friedrich II of Prussia, Called Frederick the Great*, 6 vol., 1858–65; *The Early Kings of Norway: Also an Essay on the Portraits of John Knox*, 1875.

BIOGRAPHY AND CRITICISM: *The Life of Friedrich Schiller*, 1825; *Critical and Miscellaneous Essays*, 4 vol., 1838; *The Life of John Sterling*, 1851; *On the Choice of Books*, 1866 (inaugural address at his installation as rector of Edinburgh University).

SOCIOLOGY: *Sartor Resartus: The Life and Opinions of Herr Teufelsdröckh*, 1836; *Chartism*, 1840; *Past and Present*, 1843; *Latter-Day Pamphlets*, 1850; *Last Words of Thomas Carlyle on Trades-Unions, Promoterism and the Signs of the Times*, 1882.

BIBLIOGRAPHY

Bibliographies: I.W. DYER, *A Bibliography of Thomas Carlyle's Writings and Ana* (1928); C. MOORE, "Thomas Carlyle: A Critical Bibliography" in C.W. and L.H. HOUTCHENS (eds.), *English Romantic Poets and Essayists*, rev. ed. (1966); the *New Cambridge Bibliography of English Literature*, vol. 3 ed. by G. WATSON (1969).

Collections of manuscripts: About 70 percent of the manuscript letters of Carlyle and Jane Welsh Carlyle are in the National Library of Scotland, Edinburgh. Other public institutions with considerable collections of letters include the Victoria and Albert Museum, London; the John Rylands Library, Manchester; Harvard University; Yale University; the Henry E. Huntingdon Library, San Marino, California; and the New York Public Library. For Carlyle's collections, see W.C. LANE, *The Carlyle Collection: A Catalogue of Books on Oliver Cromwell and Frederick the Great, Bequeathed by Thomas Carlyle to Harvard College Library* (1888); M.E. WEAD, *A Catalogue of the Dr. Samuel A. Jones Carlyle Collection* (1919).

Major collected editions and selections: The fullest collected works is the Centenary Edition by H.D. TRAILL, 30 vol.

(1896–99). Selections include: *The Carlyle Anthology*, ed. by E. BARRETT (1876); *The Best of Carlyle*, ed. by T.O. GLENCROSS (1923); *Carlyle: An Anthology*, ed. by G.M. TREVELYAN (1953); *Selected Works, Reminiscences and Letters of Carlyle*, ed. by J. SYMONS (1955); and *Selections from Carlyle*, ed. by A.M.D. HUGHES (1957).

Biographies: J.A. FROUDE, *Thomas Carlyle*, 4 vol. (1882–84), is not only the best life of Carlyle but one of the greatest of English biographies, combining the attitude of an intelligent disciple with penetrating observation and remorseless moral criticism. See also Froude's, *My Relations With Carlyle* (1903), his private account of the writing of the biography, voicing his suspicions that sexual impotence may have been responsible for troubles in Carlyle's marriage. Froude also edited two autobiographical pieces, *T. Carlyle: Reminiscences* (1881), which gives a vivid picture of Carlyle's father and wife, among others; and *Letters and Memorials of Jane Welsh Carlyle: Prepared by T. Carlyle*, 2 vol. (1883), which gives full documentary evidence about Jane's life and character and conveys in notes and comments Carlyle's intense remorse for his shortcomings as a husband. Principal critical works include BASIL WILLEY, *Nineteenth Century Studies* (1949), which places Carlyle judiciously in relation to Samuel Taylor Coleridge, Matthew Arnold, and other leading thinkers; and JOHN HOLLOWAY, *The Victorian Sage* (1953), which provides an admirable account of the philosophical and rhetorical aspects of Carlyle's persuasive methods.

(A.O.J.C.)

Carnap, Rudolf

Rudolf Carnap was one of the originators and eventually the leading figure of the Logical Positivist school of thought. A highly creative and original thinker, he made important contributions to logic, the philosophy of science, and the theory of probability and inductive inference. His many writings, most of which are quite technical, reflect his thorough mathematical and scientific training and pervasive concern for clarity and rigour.

Carnap, 1960.

Education and military service

Early life. Carnap was born on May 18, 1891, at Ronsdorf in northwestern Germany. From 1910 to 1914 he studied mathematics, physics, and philosophy at the universities of Jena and Freiburg im Breisgau. At Jena he attended the lectures of Gottlob Frege, now widely acknowledged as the greatest logician of the 19th century, whose ideas exerted a deep influence on Carnap.

After serving in World War I, Carnap earned his doctorate in 1921 at Jena with a dissertation on the concept of space. He argued that the conflicts among the various theories of space then held by scholars resulted from the fact that those theories actually dealt with quite different subjects; he called them, respectively, formal space, physical space, and intuitive space, and exhibited their principal characteristics and their fundamental differences.

For several years afterward Carnap was engaged in private research in logic and the foundations of physics and wrote a number of essays on problems of space, time, and causality, as well as a textbook in symbolic, or mathematical, logic (*Abriss der Logistik*, 1929; a considerably different later German version appeared in English translation: *Introduction to Symbolic Logic and its Applications*, 1958).

Participation in the Vienna Circle

Career in Vienna and Prague. In 1926 Moritz Schlick, the founder of the Vienna Circle—a small group of philosophers, mathematicians, and other scholars who met regularly to discuss philosophical issues—invited Carnap to join the faculty of the University of Vienna, where he soon became an influential member of the Circle. Out of their discussions developed the initial ideas of Logical Positivism, or Logical Empiricism. This school of thought shared its basic Empiricist orientation with David Hume, a Scottish Empiricist, and Ernst Mach, an Austrian physicist and philosopher. Its leading members, informed and inspired by the methods and theories of contemporary mathematics and science, sought to develop a "scientific world view" by bringing to philosophical inquiry the precision and rigour of the exact sciences. As one means to this end, Carnap made extensive use of the concepts and techniques of symbolic logic in preference to the analytic devices of traditional logic, which are limited and often entirely inadequate.

Carnap and his associates established close connections with like-minded scholars in other countries, among them a group of Empiricists that had formed in Berlin under the leadership of Hans Reichenbach, an eminent philosopher of science. With Reichenbach, Carnap founded a periodical, *Erkenntnis* (1930–40), as a forum for the new "scientific philosophy."

The basic thesis of Empiricism, in a familiar but quite vague formulation, is that all of man's concepts and beliefs concerning the world ultimately derive from his immediate experience. In some of his most important writings, Carnap sought, in effect, to give this idea a clear and precise interpretation. Setting aside, as a psychological rather than a philosophical problem, the question of how human beings arrive at their ideas about the world, he proceeded to construe Empiricism as a systematic–logical thesis about the evidential grounding of empirical knowledge. To this end, he gave the issue a characteristically linguistic turn by asking how the terms and sentences that, in scientific or in everyday language, serve to express assertions about the world are related to those terms and sentences by which the data of immediate experience can be described. The Empiricist thesis, as construed and defended by Carnap, then asserts that the terms and sentences of the first kind are "reducible" to those of the second kind in a clearly specifiable sense. Carnap's conception of the relevant sense of reducibility, which he always stated in precise logical terms, was initially rather narrow but gradually became more liberal.

First works

In his first great work, *Der logische Aufbau der Welt* (1928; Eng. trans.—with a smaller work—*The Logical Structure of the World: Pseudoproblems in Philosophy*, 1967), Carnap developed, with unprecedented rigour, a version of the Empiricist reducibility thesis according to which all terms suited to describe actual or possible empirical facts are fully definable by terms referring exclusively to aspects of immediate experience, so that all empirical statements are fully translatable into statements about immediate experiences.

Prompted by discussions with his associates in Vienna, however, Carnap soon began to develop a more liberal version of Empiricism, which he elaborated while he was professor of natural philosophy at the German University in Prague (1931–35); he eventually presented it in full detail in his important essay "Testability and Meaning" (*Philosophy of Science*, vol. 3 [1936] and 4 [1937]). Here, Carnap argued that the terms of empirical science are not, indeed, all fully definable in purely experiential terms but can at least be partly so defined by means of "reduction sentences," which are a logically much refined version of operational definitions, and by virtue of which an empirical statement implies various consequences in the form of "observation sentences," whose truth can be checked by direct observation and which thus permit an experiential test of the given statement. Carnap stressed that usually such tests cannot provide

strict proof or disproof but only more or less strong "confirmation" for an empirical statement.

Sentences that do not thus yield observational implications and therefore cannot possibly be tested and confirmed by observational findings were said to be empirically meaningless. By reference to this testability criterion of empirical significance, Carnap and other Logical Empiricists rejected various doctrines of speculative metaphysics and of theology, not as being false but as making no significant assertions at all.

Carnap argued that the observational statements by reference to which empirical statements can be tested may be construed as sentences describing directly and publicly observable aspects of physical objects, such as the needle of a measuring instrument turning to a particular point on the scale or a subject in a psychological test showing a change in pulse rate. All such sentences, he noted, can be formulated in terms that are part of the vocabulary of physics. This was the basic idea of his "physicalism," according to which all terms and statements of empirical science—from the physical to the social and historical disciplines—can be reduced to terms and statements in the language of physics.

In later writings, Carnap liberalized his conception of reducibility and of empirical significance even further so as to give a more adequate account of the relation between scientific theories and scientific evidence.

Career in the United States. By the time "Testability and Meaning" appeared in print, Carnap had moved to the United States, mainly because of the growing threat of German National Socialism. From 1936 to 1952 he served on the faculty of the University of Chicago. During the 1940–41 school year, Carnap was a visiting professor at Harvard University and was a very active participant in a discussion group that included Bertrand Russell, Alfred Tarski, and W.V.O. Quine.

Founding of the *International Encyclopedia of Unified Science*

Soon after going to Chicago, Carnap joined with the sociologist Otto Neurath, a former fellow member of the Vienna Circle, and with an academic colleague, the Pragmatist philosopher Charles W. Morris, in founding the *International Encyclopedia of Unified Science*, which was published, beginning in 1938, as a series of monographs on general problems in the philosophy of science and on philosophical issues concerning mathematics or particular branches of empirical science.

Since his Vienna years, Carnap had been much concerned also with problems in logic and in the philosophy of language. He held that philosophical perplexities often arise from a misunderstanding or misuse of language and that the way to resolve them is by "logical analysis of language." On this point, he agreed with the "ordinary language" school of Analytic Philosophy, which had its origins in England. He differed from it, however, in insisting that more technical issues—*e.g.*, those in the philosophy of science or of mathematics—cannot be adequately dealt with by considerations of ordinary linguistic usage but require clarification by reference to artificially constructed languages that are formulated in logical symbolism and that have their structure and interpretation precisely specified by so-called syntactic and semantic rules. Carnap developed these ideas and the theoretical apparatus for their implementation in a series of works, including *Logische Syntax der Sprache* (1934; *The Logical Syntax of Language*, 1937; 2nd ed., 1959) and *Meaning and Necessity* (1947; 2nd enlarged ed., 1956).

Carnap's interest in artificial languages included advocacy of international auxiliary languages such as Esperanto and Interlingua to facilitate scholarly communication and to further international understanding.

Analyticity, induction, and rational decision

One idea in logic and the theory of knowledge that occupied much of Carnap's attention was that of analyticity. In contrast to the 19th-century radical Empiricism of John Stuart Mill, Carnap and other Logical Empiricists held that the statements of logic and mathematics, unlike those of empirical science, are analytic—*i.e.*, true solely by virtue of the meanings of their constituent terms—and that they can therefore be established a priori (without any empirical test). Carnap repeatedly returned to the task of formulating a precise characterization and theory of analyticity. His ideas were met with skepticism by some, however—among them Quine, who argued that the notion of analytic truth is inherently obscure and the attempt to delimit a class of statements that are true a priori should be abandoned as misguided.

From about 1945 onward, Carnap turned his efforts increasingly to problems of inductive reasoning and of rational belief and decision. His principal aim was to construct a formal system of inductive logic; its central concept, corresponding to that of deductive implication, would be that of probabilistic implication—or, more precisely, a concept representing the degree of rational credibility or of probability that a given body of evidence may be said to confer upon a proposed hypothesis. Carnap presented a rigorous theory of this kind in his *Logical Foundations of Probability* (1950).

Carnap spent the years from 1952 to 1954 at the Institute for Advanced Study in Princeton, where he continued his work in probability theory. Subsequently, he accepted a professorship at the University of California at Los Angeles.

During those years and indeed until his death in Santa Monica, California, on September 14, 1970, Carnap was occupied principally with modifications and considerable extensions of his inductive logic.

BIBLIOGRAPHY. NORMAN M. MARTIN'S article on Carnap in the *Encyclopedia of Philosophy*, vol. 2 (1967), gives a lucid survey of Carnap's work and the development of his ideas with extensive bibliography. An especially valuable source is *The Philosophy of Rudolf Carnap*, ed. by P.A. SCHILPP (1963). It includes a far-ranging intellectual autobiography, 26 critical essays by other philosophers on aspects of Carnap's work, his replies to these essays, and a complete bibliography of his publications through 1961. Included in ROGER C. BUCK and ROBERT S. COHEN (eds.), *Boston Studies in the Philosophy of Science*, vol. 8 (1971), are 13 pieces in homage to Carnap; they convey a vivid idea of his qualities as a man, a teacher, and a thinker.

(C.G.H.)

Carnivora

The order Carnivora includes ten families of living mammals: Canidae (dogs, wolves, jackals, and foxes), Ursidae (bears), Procyonidae (raccoons), Mustelidae (skunks, mink, weasels, badgers, and otters), Viverridae (civets and mongooses), Hyaenidae (hyenas), Felidae (cats), Otariidae (eared seals), Odobenidae (walrus), and Phocidae (earless seals). The term carnivore is frequently applied by mammalogists to members of this order and is employed in that sense in the present article. In a more general sense, a carnivore is any animal (or even, occasionally, a plant) that eats the flesh of other animals, as opposed to a "herbivore," which eats plants. Although the Carnivora are basically meat eaters, a substantial number, especially among bears and procyonids, feed extensively on vegetable material.

This article is divided into the following sections:

I. General features
- Importance of the Carnivora
- Form and function
- Distribution and abundance

II. Survey of carnivore families

I. General features

IMPORTANCE OF CARNIVORA

There is probably no other group of animals more familiar to man than mammals belonging to the order Carniv-

ora. The more popular domesticated pets of man, the dog and the cat, are both derived from wild members of this order. The majority of luxurious natural furs (ermine, mink, sable, otter) worn by women of fashion, as well as the furs of utility used by primitive man, come from members of the Carnivora. Many of the animals that attract the largest crowds at circuses and zoos are members of this order. Most of the large, dangerous carnivores are the objects of hunters, who wish to obtain a trophy grizzly bear, polar bear, or tiger. The man stranded in the wild fears the wolf, dhole, bear, tiger, leopard, or jaguar, virtually the only predators capable of injuring him. The stockman is concerned about possible depredations upon his herd by nature's large predators.

The carnivores, the meat eaters, form the apex of the pyramid of life, the food pyramid, and thus are basic to the existence of a "balance of nature" in a world unmolested by man. In today's world, man's world, this precarious balance was first upset by the extermination of many carnivores. Formerly considered undesirable because of their predation on game animals, carnivores are now recognized as necessary elements in natural systems. Far from depressing game numbers, carnivores improve the stability of game populations by keeping numbers within the carrying capacity of the food supply. As a result, individual animals are better fed and less subject to disease. Many of these predators dig dens and provide burrows in which other forms of wildlife can take refuge. Those carnivores best known for their burrow building are the badgers and the skunks. Digging results in the mixing of soils and the reduction of the runoff of water during rains.

Intelligence and training

Carnivores rank high on the scale of intelligence among mammals. The large size of the brain, compared to that of the animal, is an indication of their superior mental powers. For this reason, these animals are among the easiest to train for entertainment purposes, as pets, or as hunting companions. Their highly developed sense of smell supplements the sharper vision of man. Dogs are the most common carnivores trained for hunting, but the cheetah, caracal, and ferret have also been used to some extent. In China the otter is trained to drive fish under a large net, which is then dropped and pulled in. Carnivores, dependent for survival upon their ability to prey upon living animals in a variety of situations, have evolved a relatively high degree of learning ability (see LEARNING, ANIMAL).

Carnivorous mammals tend to establish territories, areas defended against others of the same species; herbivorous ones, which eat vegetation, are less apt to do so. Territories are often exclusive, defended by the residents against other animals of their own kind. Such areas may sometimes be marked by secretions produced by anal or scent glands.

There is a wide range of social patterns among carnivores. Some (bears, raccoon, red and gray foxes, genets, most cats, and most mustelids) are strictly solitary, except during the breeding season. Some remain paired throughout the year (black-backed jackal and lesser panda) or occasionally hunt in pairs (gray fox, crab-eating fox, and kinkajou). Other carnivores, such as the wolf, African hunting dog, dhole, and coatimundi, normally hunt in packs or bands. Still others form sedentary colonies during the breeding season (sea lions, fur seals, and elephant seals), during a somewhat larger part of the year (sea otters), or all year round (meerkats).

FORM AND FUNCTION

The smallest living member of the Carnivora is the least weasel (*Mustela nivalis*), which weighs about two ounces. The largest terrestrial form is the Alaskan grizzly (*Ursus arctos*), weighing up to 780 kilograms (1700 pounds). The largest aquatic form is the elephant seal (*Mirounga leonina*), which may weigh 3,630 kilograms (four tons). Most carnivores weigh between four and eight kilograms (9–18 pounds).

Most members of the order are terrestrial. Some, such as the sea otter, river otter, and polar bear, spend most of their lives in water. The pinnipeds, or seals, are more aquatic than other members of the order. Aquatic or semi-aquatic forms tend to have body specializations such as a streamlined body and webbed feet for this mode of life.

Dentition

Carnivores, like other mammals, have a number of different kinds of teeth: incisors in front, followed by canines, premolars, and molars in the rear. Most carnivores, especially those that feed exclusively on meat, have carnassial, or shearing, teeth that function in slicing meat and cutting tough sinews. The carnassials are usually formed by the fourth upper premolar and the first lower molar, working one against the other with a scissorlike action. Cats, hyenas, and weasels, all highly carnivorous, have well-developed carnassials; while the bear and procyonids, which tend to be omnivorous (eating both plants and animals) and the seals, which eat fish or marine invertebrates, have little or no modification of these teeth for shearing. The teeth behind the carnassials tend to be lost or reduced in size in highly carnivorous species. Most members of the order have six prominent incisors on both the upper and lower jaw, two canines on each jaw, six to eight premolars, and four molars above and four to six molars below. Incisors are adapted for nipping off flesh. The outer-most incisors are usually larger than the inner ones. The strong canines are usually large, pointed, and adapted to aid in the stabbing of prey. The premolars always have sharply pointed cusps, and in some forms (*e.g.*, seals) all the cheek teeth (premolars and molars) have this shape. Except for the carnassials, molars tend to be flat teeth utilized for crushing. Terrestrial carnivores that depend largely on meat, such as weasels, cats, and hyenas, tend to have fewer teeth (30–34), the flat molars having been lost. Omnivorous carnivores, such as raccoon and bear, have more teeth (40–42). Seals have fewer teeth than terrestrial carnivores. In addition, seals exhibit little stability in the numbers of teeth; for example, a walrus may have from 18 to 24 teeth.

Several features of the skull are characteristic of the order Carnivora. The articulating surfaces (condyles) on the lower jaw are transverse, their axis at right angles to that of the head, forming a half-cylindrical hinge that allows the jaw to move only in a vertical plane but with considerable strength. The clavicles (collarbones) are either reduced or absent entirely and, if present, are usually embedded in muscles without articulation with other bones. This allows for a greater flexibility in the shoulder area and prevents breakage of the clavicles when the animal springs on its prey.

The brain is large in relation to the weight of the body and contains complex convolutions characteristic of highly intelligent animals. The stomach is simple, and a blind pouch (cecum) attached to the intestine is usually reduced or absent. Since animal tissues are in general simpler to digest than plant tissues, the carnivore's dependence on a diet with a high proportion of meat has led to less-complex compartmentalization of the stomach and a decrease in the length and folding (surface area) of the intestine. The teats are located on the abdomen along two primitive lines (milk ridges), a characteristic of mammals that lie down when nursing.

DISTRIBUTION AND ABUNDANCE

Carnivores are found worldwide. Terrestrial forms are absent from most oceanic islands, though the coastlines are usually visited by seals (pinnipeds). Except for the dingo (which probably was introduced by aboriginal man), Australia has no native terrestrial members of the Carnivora. Man has taken his pets, as well as a number of wild species, to most islands. For example, a large population of the red fox now inhabits Australia, having been introduced there by fox hunters.

Since carnivores are large and depend on meat, there must be fewer carnivores in the environment than those animals that form their diet. The maintenance of established territories limits the number of predators to the

carrying capacity of prey populations. In general, carnivores have a population density of approximately one per square mile. By comparison, omnivorous mammals average about 20 per square mile, and herbivorous rodents attain densities of up to 100,000 per square mile at peak population. Existing at relatively low densities, carnivores are vulnerable to prey, population fluctuations, habitat disturbance, and predation by man. In some cases the mobility and adaptability of carnivores has enabled species to shift ecological roles and survive the changes brought about by human activities; in other instances less-flexible species have become extinct.

World carnivore population

The world population of aquatic carnivores (pinnipeds) has been estimated to be between 13,000,000 and 27,000,000 animals. Estimates of the total numbers of terrestrial carnivores have not been made. The yearly sale of furs indicates a harvest of at least 6,000,000 pelts of wild carnivores; this is equalled only by the number of mink raised and harvested on fur farms (approximately 8,000,000 annually in the mid-1960s). There are probably around 50,000,000 to 60,000,000 terrestrial members of the Carnivora present today. Some species (many cats, pandas, and bear, some seals) are becoming quite rare and near extinction.

II. Survey of carnivore families

DOGS AND ALLIES (FAMILY CANIDAE)

Natural history. Canids are basically meat eaters, although some vegetable matter is taken. The gray or timber wolf (*Canis lupus*), the African hunting dog (*Lycaon pictus*), and the dhole, or wild dog of India (*Cuon alpinus*), are strictly carnivorous. The various foxes and jackals, coyotes, and the raccoon dog eat whatever food is abundant—small mammals, birds, insects, crustaceans, mollusks, fruits, or berries. The canids that are strictly carnivorous tend to hunt in packs; those that are omnivorous tend to be solitary in their hunting habits. Since the carnivorous forms depend primarily on one or a few prey species, they usually follow the moving herds of caribou or antelope, on which they feed, or move into areas where the prey species are more numerous. African hunting dogs are extremely social, always hunting in packs so intricately organized that some researchers doubt that an individual dog could survive alone. The varied diet of the omnivore reduces the necessity for organized attack on the prey species and for extensive movement.

Canids have the ability to endure a continuous chase pattern with exceptional stamina but are not capable of great bursts of speed. Their senses of smell and hearing are highly developed. Smell is used largely to track prey, and hearing to warn of impending danger. Smell is also used in association with the demarcation of territory, which tends to be outlined by frequent urination at established scent posts. Sight is less well developed, but movement is noted quickly. Canids are highly intelligent, can be trained easily, and form a basis for such sayings of man as "sly as a fox." From a behavioural standpoint wild canids are cunning or crafty, even vicious or treacherous by human standards, but usually cowardly or furtive unless running in a pack.

Reproductive behaviour of canids

Canids give birth in a den in the ground, in a hollow log or tree, in a hidden brushy area, among boulders, or in a crevice of rock. The African hunting dog often dens in old diggings of the aardvark. Usually one litter of from four to six young is produced each year after a gestation period of from 51 to 80 days, depending on the species. The Arctic fox, *Alopex lagopus*, may produce two litters in a season. Most breeding takes place late in the winter, the young being born in middle or late spring. Canids living in the northern regions breed a month or so later than those in the southern regions. Carnivorous animals tend to produce young soon after the peak in the prey reproduction, a time of abundant food availability. Thus the timing of the breeding season and the duration of the gestation period must be coordinated with the season of available food in order that the young be produced when the most food is available for their rapid growth. The eyes of the young usually open in about two weeks, and they nurse for from four to six weeks. Canids of the smaller species can begin production of their own young when only one year old, but the larger forms, such as the wolf, reach sexual maturity at two or three years of age.

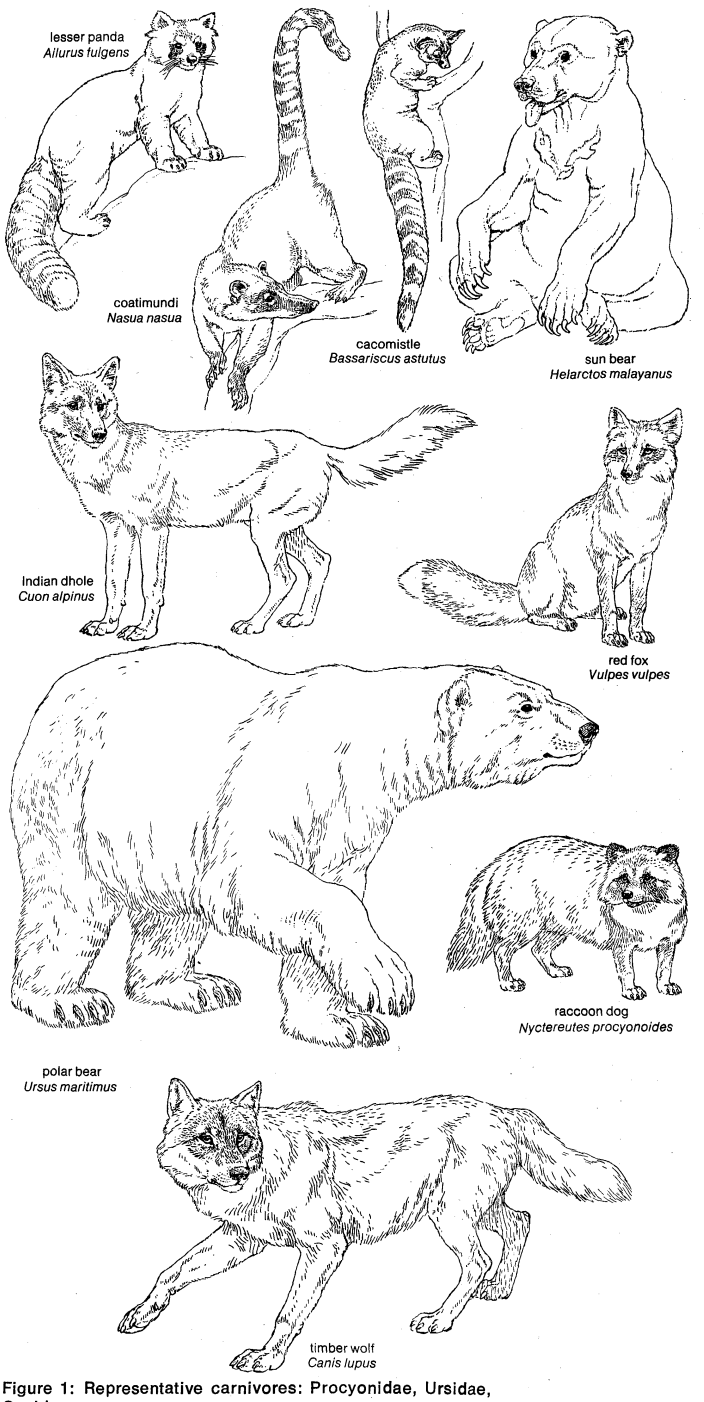

Figure 1: Representative carnivores: Procyonidae, Ursidae, Canidae.
Drawing by R. Keane; Indian dhole based on Zoological Society of London photograph

Canids are basically adapted to running and do so on their toes (a mode of walking or running called digitigrade). They live in a variety of habitats but generally tend to be animals of the open or grassland areas where their prey species are more abundant. Only the rare bush dog (*Speothos venaticus*) confines itself to forested areas. The red fox (*Vulpes vulpes*) tends to be an animal of the forest edge, and the gray fox (*Urocyon cinereoargenteus*) an animal inhabiting wooded areas. Thus, in North America, where both forms exist, these foxes live in slightly different niches. Although basically terrestrial

in habits, the gray fox is not averse to climbing trees. The raccoon dog (*Nyctereutes procyonoides*) often lives in tree hollows if the entrance is close to the ground. The family Canidae is worldwide, being absent only from New Zealand, Antarctica, and most oceanic islands. The Arctic fox is found farther north than any other strictly terrestrial mammal. Every major habitat has some type of canid, from the Arctic tundra, through the desert and grassland, to the tropical forest.

Canid communication

Canids communicate with a variety of sounds. The vocal repertoire, most highly developed in social species, includes howls, yelps, snarls, barks, and growls. These sounds are frequently associated with specialized visual signals involving movements of the ears and tail, raising of certain areas of the fur, and baring of the teeth. Within the social group or pack there is a complex dominance hierarchy, involving age levels, pair bonds, physical condition, and sexual state. Vocal and visual signals serve to minimize aggressive interactions, such as quarrels over food, that might prove injurious to the group as a whole and to the individual members. In solitary species vocalizations serve to advertise the territory, to ward off aggressors, and to communicate with the mate and young.

Importance to man. The domestic dog (*Canis familiaris*) is undoubtedly the canid of the greatest importance economically. Numerous humans are actually employed in raising, selling, doctoring, grooming, training, or providing and manufacturing food for "man's best friend." Dogs probably were the first wild animals to be domesticated; they have been found associated with Neolithic sites dating back some 8,000 years. (For information on domestic dogs, see DOG.)

Some canids are important to the fur trade. At one time a mutant form of the red fox, called the "silver fox," formed a significant part of the fur-farming industry, with a breeding pair bringing as high as $40,000. The raccoon dog is still raised in some regions of the Soviet Union. The more important canids whose fur is utilized are the raccoon dog, red fox, grey fox, Arctic fox, and timber wolf. Coyotes, kit and swift foxes (*Vulpes macrotis* and *V. velox*), jackals (*Canis aureus, C. adustus, C. mesomelas*), Corsac fox (*Vulpes corsac*), hoary fox (*Vulpes cana*), dhole, South African silver fox (*Vulpes chama*), Cape fox (*Octocyon megalotis*), maned wolf (*Chrysocyon brachyurus*), crab-eating fox (*Cerdocyon thous*), and the South American foxes (*Dusicyon* species) are occasionally used by the fur trade. Other canids, especially the red fox, are hunted for sport. Some hunters call or lure foxes up to them by using an imitation of the sound of an injured rabbit to attract the attention of the fox.

Canids also are basically important as a natural control over rodent populations. Livestock is occasionally endangered when not properly protected from the forays of wild canids. Individual foxes learn where an easy meal is located, if the farmer does not have his chickens properly housed. In many cases all individuals of the species are condemned because of the damaging activity of a few. Proper selective control of those individuals actually doing the damage is the only sane conservation practice. Some species also form important natural reservoirs for parasites, causing a number of diseases, especially the virus producing rabies. Not many canids are utilized by man for food, but the American Indian once regarded dog meat as a delicacy to be eaten on special occasions.

Form and function. Canids have unspecialized incisor teeth, and large fanglike canines used to kill their prey by slashing. The premolars are narrow and sharp and the carnassials well developed; the molars form broad surfaces that can crush substantial bones. Most canids have the basic dental formula of terrestrial carnivores, with a total of 42 teeth.

Distinguishing physical features of canids

The possession of a long face or muzzle is characteristic of wild canids. All have a relatively long and obviously bushy tail. The ears are pointed, held erect, and often quite large in desert species. As well as functioning for sound detection, these large ears are believed to act as heat regulators, allowing a greater amount of heat to be dissipated in hot climates. Arctic foxes tend to have small ears, providing less loss of heat in a region where heat conservation is important to survival. Most canids have relatively long legs (especially long in the maned wolf, *Chrysocyon brachyurus*, of South America). The long legs and digitigrade gait are special adaptations for ease of running. Canids have four well-developed toes, plus a dew claw (reduced hind toe) on the front foot (except in the African hunting dog, which lacks the dew claw), and four toes on the rear foot. Each toe is capped by a blunt, nonretractile claw (*i.e.*, with no sheath into which it can be withdrawn). The short claws are not adapted for use as a weapon but do aid the animal during the digging of a den or during pursuit of small prey animals in their burrows. Scent glands are often present at the base of the tail. Most canids have a uniform coloration, although there are some contrasting colours on the gray fox, a raccoon-like mask on the raccoon dog, a blotching of black, yellow, and white colours on the African hunting dog, and a lighter coloured belly in most canids.

BEARS (FAMILY URSIDAE)

Natural history. Members of the Ursidae, except for the carnivorous polar bear (*Ursus maritimus*), are omnivorous, consuming many items that seem small for an animal the size of a bear. Ants, bees, seeds of trees, roots of the skunk-cabbage, nuts, berries, insect larvae such as grubs, and even the dainty dog-toothed violet are eaten. Many bears relish honey, and the sun bear (*Helarctos malayanus*) is sometimes called the "honey bear" because of its preference for this food. Meat items taken by bears include rodents, fish, deer, pigs, and lambs. Grizzlies and Alaskan brown bears (North American subspecies of the widespread *Ursus arctos*) are known for their skillful fishing abilities during the spawning runs of the salmon. The polar bear feeds almost exclusively on seals and is the most carnivorous of all bears, but little vegetation grows within its range, so the carnivorous habit is dictated by the Arctic environment. The sloth bear (*Melursus ursinus*) delights especially in raiding and destroying termite nests, sucking up termites and larvae with its funnel-like lips. Bamboo shoots form the major food of the giant panda (*Ailuropoda melanoleuca*), which has a special bone formation of the forefoot that functions as a sixth digit, opposable to the other five and thus useful in handling bamboo.

Moving slowly about, bears seem to be sluggish and oblivious to much that is going on around them, but once disturbed their reactions may be violent and highly unpredictable. Although clumsy in appearance, a grizzly can move surprisingly fast, even through dense cover that would seriously impede a man or a horse. Their senses of sight and hearing are poorly developed, and most hunting is done by the sense of smell. Thus the smell of bacon kept in camp is an invitation to a bear in search of food. Bears, like many of their canid relatives, are solitary, except during the mating season.

Bears tend to congregate during the mating season and then pair off and mate in seclusion. Males play no role in raising the young, leaving the female soon after mating. The gestation period may vary, the fertilized egg remaining dormant in the uterus (delayed implantation), insuring the birth of young when food is abundant. Ursids breed only once a year. With a breeding season usually in late spring or early summer, and delayed implantation, most young are born in January or February when the female is in the winter den. Newborn grizzlies weigh about one pound and are about nine inches long from the tip of the nose to the tip of the short tail. The Himalayan brown bear (a race of *U. arctos*) have their young later (in April and May) than the North American populations, but the polar bear has the greatest variation of any bear population in the dates when young are born (January to April). Twins are most common in bears, but up to five young may be produced. The cubs nurse for about two months and stay with the female until the next

breeding (about a year and a half after birth). Most young, however, can get along on their own when about six months old. Bears reach breeding condition at three and one-half to four years of age, males usually a few months later than females. Litters are produced every second year after the initial litter.

Winter sleep of bears

Most bears eat large amounts of food before entering a den for a period of deep sleep during the winter. The polar bear digs a den in the snow. Grizzlies build large mounds of dirt in front of their dens. Bears are not true hibernators, since they lack the physiological characteristics (lower heart rate, body temperatures, breathing rate, and blood pressure) exhibited by those animals that do hibernate. A true hibernator is slow to be awakened from its deep sleep, and those who believe bears hibernate need only kick a sleeping bear to become convinced to the contrary. Bears usually are quiet, but they do growl at times when feeding or when being challenged by another bear.

Ursids do not roam over great distances even though they are rather large carnivores. Black bears (*Ursus americanus*) tend to stay within an area of about 14 square miles, grizzlies within an area 10 miles in diameter, or about 80 square miles. A grizzly marks the boundary of its territory each spring by rubbing trees, scratching bark, or even biting large pieces from the trunks of trees. All bears, except the grizzly, Eurasian brown, and probably the polar bear, climb trees. Bears inhabit forested areas and areas that have a minimum of disturbance by man. At one time the grizzly was an animal of the plains and was one of the mammals reported by Lewis and Clark in their journey through eastern Montana in 1804. Polar bears have been noted in the open sea 40 miles from the nearest shore and on ice 200 miles from the nearest land.

Ursids are largely animals of north temperate regions, being found farther north than any other mammal (only the Arctic fox is found as far north on land). Most of the southern continents, Central and South America, Africa, and Australia, lack bears. The bear that formerly occurred in the Atlas Mountains of Morocco (*Ursus crowtheri*) became extinct in the early 19th century. The spectacled bear (*Tremarctos ornatus*) of the Andes is the southernmost form.

Importance to man. If taken when young, the grizzly can be tamed quite easily and is not uncommon in circus acts. Unfortunately, man has come to picture the bear as being quite tame and harmless, with the result that the bear is viewed without the respect that this potentially dangerous creature deserves. The grizzly is the most dangerous of the bears to man, of the most interest economically because of the damage that it can do to livestock, and of the most interest to the big-game hunter as a prized trophy. Some ursids, such as the Asiatic black bear (*Selenarctos thibetanus*), destroy fruits. At times the North American black bear does considerable damage to fruit crops and to corn fields when the corn is in the milk stage, pulling the stalks into a pile from as far as the bear can reach.

Use of bear pelts

The pelts of bears have been used for a number of purposes. Perhaps most popular has been the bearskin rug. Skins also have been used for lap rugs or sledge rugs, hats for the English Guard regiments, trimmings of coats, and for muffs. Skins of the rare giant panda commanded a high price in the early 1900s, but this animal apparently is close to extinction today. Black bears are prized as a food source in China, as is the flesh of the polar bear in the far north. The liver of the polar bear, however, is highly poisonous, due to high levels of vitamin A. The teeth and claws of bears have been favourite ornaments with the Indians and Eskimos for years, and the fat furnishes the "bear grease" of commerce.

Form and function. The teeth of the omnivorous bears are unspecialized. The first three premolars are usually either missing or extremely small. The carnassials are poorly developed, and the molars have broad, flat crowns. Except for variability as to the presence of premolars, the ursid dental formula is that of the Carnivora generally. The sloth bear lacks one pair of upper incisors. The jaw of the bear is controlled at the hinge by a powerful set of muscles.

Bears have an elongate skull that is especially heavy in the back portion. These plantigrade animals (plantigrades walk on the sole and heel of the foot) are powerful in build and have relatively short, massive legs with five toes on each foot. The toes end in enlarged, nonretractile claws that are especially well developed in the sloth bear and to some extent in the grizzly. The claws on the front feet are usually better developed than those on the rear and are especially adapted for digging out marmots or other small rodents. Bears, however, seldom use the claws to construct burrows. They generally have naked soles, but those of the polar bear are covered with hair, enabling the animal to walk on ice with a firm footing. In swimming, the polar bear uses only its front limbs, an aquatic adaptation found in no other four-legged mammal. Bears lack a clavicle but have a baculum (penis bone). Their lips, which are not attached to the gums, are protrusible and mobile. Ursids have a short (7 to 13 centimetres), stubby tail and are the largest living terrestrial members of the Carnivora. The Alaskan grizzly may weigh as much as 780 kilograms (1,700 pounds), and the smallest bear, the sun bear, weighs approximately 27 kilograms (60 pounds). In most species the two sexes are about the same size, but the male tends to be larger in the grizzly and polar bear. Bears of the genus *Ursus* tend to be of a uniform colour, ranging from white to brown, blue gray, and black. Unlike the majority of carnivores, ursids are often black or mostly black. The North American black bear occurs in a number of colour variants or phases; in addition to the typical black phase, there is a tan-brown phase (called the cinnamon bear) and a bluish-black phase (called the glacier bear). The spectacled bear and the several specialized Asian bears are black with white or tan markings. The giant panda is strikingly black and white, and the remaining genera largely black, with areas of white or orange on the chest, neck, or face. The fur is coarse, long, and shaggy in most northern forms.

RACCOONS AND ALLIES (FAMILY PROCYONIDAE)

Natural history. The family Procyonidae includes raccoons, coatis or coatimundis, olingos, and the ringtailed cat, kinkajou, and lesser panda. Procyonids, like bears, are omnivorous, eating numerous types of insects, crayfish, crabs, fishes, amphibians, reptiles, birds, small mammals, and a variety of fruits, nuts, roots, and young plants. A characteristic of most omnivorous animals is that they take whatever foods are available, varying their food habits with the season, the locality, and the abundance or population levels of the food items from one year to the next. The ringtailed cat (*Bassariscus astutus*) tends to be more carnivorous than the raccoon (*Procyon lotor*). The lesser panda (*Ailurus fulgens*) is the most vegetarian of the group.

The various senses of procyonids do not seem to be especially well developed, but the raccoons and lesser panda appear to be above average in intelligence and are often described as being cunning. Raccoons are well known for their insatiable curiosity and ability to use their "hands" in performing feats such as opening doors and getting into mischief when kept as pets. This curiosity of raccoons is well known by trappers, who have used bright objects placed on the treadle of a trap to attract them. The sense of touch probably is of the greatest importance to the raccoon in its food-gathering activities. Most procyonids, except perhaps the coatis (*Nasua* species), are more active in the twilight and evening hours than in the daylight. Procyonids tend to be solitary, although families often move and feed as a group. Coatis travel in bands, some individuals moving through the trees as others follow on the ground. Olingos (*Bassaricyon* species) also move about in small bands. All procyonids are arboreal and move around in trees with agility. On the ground, the raccoon resembles a small bear as it ambles along.

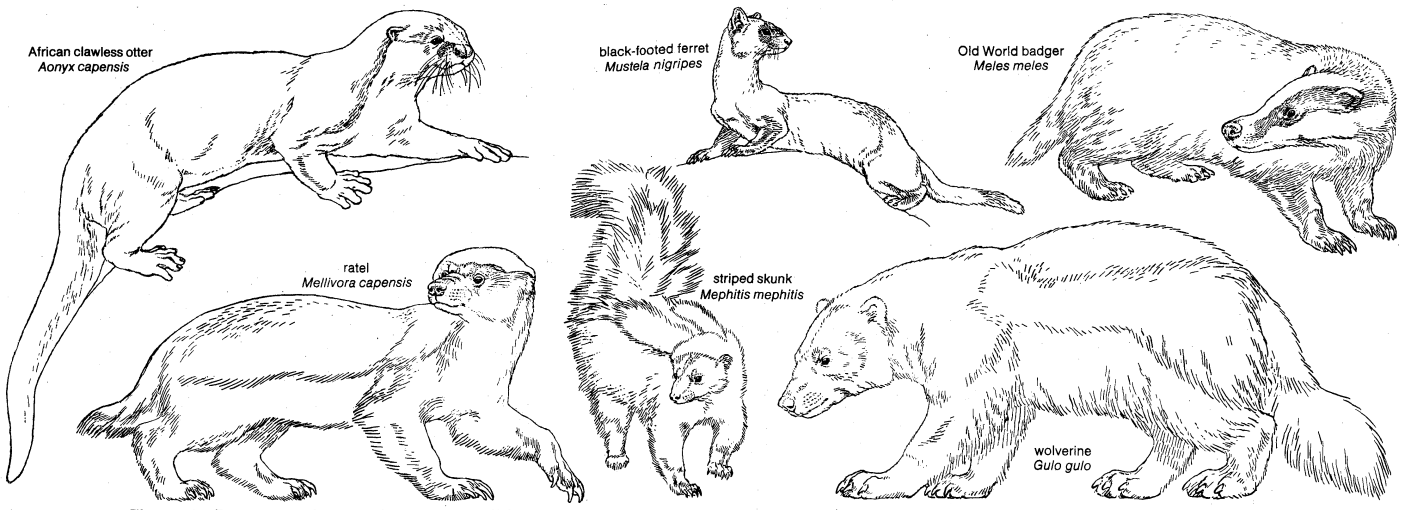

Figure 2: Representative carnivores: Mustelidae.
Drawing by R. Keane; striped skunk based on E. P.Walker, *Mammals of the World*

Procyonid breeding habits

Procyonids breed in late winter or early spring. During copulation, the female raccoon makes sharp rattling cries. After a gestation period of about two months (for the raccoons 54 to 66 days, for lesser panda 90 days), two to six young are produced. One litter a year is usual. Young raccoons "twitter" like young birds when disturbed in the nest, and the young of other procyonids also produce high-pitched calls. Most adult procyonids produce a variety of snarls, growls, whines, screams, and barks. Most of these calls have little carrying power. Young raccoons are dependent on the female for the first ten weeks but may nurse until approximately 20 weeks of age (ringtails to about four months) and may stay in the family group into winter. Being mainly arboreal, young procyonids are born in tree dens. Raccoons use old buildings or dens in the ground if tree dens are scarce. Ringtails use crevices in rocks.

Except for the lesser panda, which is found in the southeastern Himalayas of Asia at elevations from 6,500 to 12,000 feet, procyonids are found naturally only in the New World. They are largely mammals of the lower elevations of temperate and tropical regions, in areas well supplied with water and trees. Raccoons have been introduced successfully into many parts of Europe (Germany, White Russia, the Ukraine) and Asia (Lake Balkhash, Siberia).

Importance to man. The raccoon is the only procyonid of major economic significance. Raccoon hunting is a sport of substantial importance in the United States, and in some parts of the United States many people own dogs trained to hunt raccoons. The coatimundi also is hunted with dogs and its flesh is also eaten. Meat of the raccoon is in more demand as food than that of any other carnivore. The meat is roasted, fried, stewed, barbecued, fricasseed, and made into patties. The "coonskin" cap has become part of American legend. The fur of the raccoon is one of the staple items of the fur trade in the United States today, as it has been over many of the past 100 years. Also used are the furs of the ringtailed cat, kinkajou (*Potos flavus*), and the lesser panda.

Raccoons at times do damage to fields of corn and to abandoned buildings, which they frequently inhabit when natural dens are scarce. In certain regions, raccoons become a problem to nesting waterfowl, especially wood ducks and goldeneye, which, like the raccoons, raise their young in hollow trees.

Most procyonids make interesting pets. Raccoons, kinkajous, and coatis are frequently sold as house pets, but their inquisitive nature and climbing ability make them troublesome if allowed to run loose indoors.

Form and function. The unspecialized teeth of procyonids are adapted for an omnivorous diet. The elongate canines are oblong in cross section, and the premolars are small, narrow, and pointed. As in bears, the carnassials are poorly developed and the molars are broad. Procyonids have the basic dental formula of the Carnivora, except that there is one less lower molar.

Procyonids are plantigrade or semiplantigrade, with legs of moderate length and five flexible toes with nonretractile or (in the ringtail cat and lesser panda) semiretractile claws. The tail is well developed (20 to 70 centimetres long), bushy, and in all forms except the kinkajou ringed by light and dark bands. In the kinkajou, it is prehensile, gripping a branch like a fifth limb. The anal scent glands of the kinkajou and lesser panda produce a musky odour when the animal becomes excited. The snout is extremely flexible in the coati and somewhat movable in other procyonids. The members of this family are medium in size, ranging from 0.8 to 22 kilograms in weight (the record weight of a raccoon is 66 pounds, 6 ounces). There is no difference in size between males and females. In coloration the procyonids range from gray or brown to the rich, reddish brown of the lesser panda.

MUSTELIDS (FAMILY MUSTELIDAE)

Natural history. The family Mustelidae contains a variety of animals unmatched by any other family in the Carnivora except the civets (Viverridae). The family includes the weasels, ferrets, mink, marten, fisher, skunks, wolverine, otters, badgers, and a number of less well-known animals, a total of about 70 species in 25 genera. The weasels, mink, and polecats (*Mustela* species) are fierce predators, feeding exclusively on small mammals and birds, hunting and trailing their prey with a keen sense of smell. At times, bird eggs, salamanders, snakes, and insects are taken. The smallest mustelid, the least weasel (*M. nivalis*), consumes a third to half its body weight per day, killing the prey by biting at the base of the skull. Weasels often store food in underground caches. The Asiatic polecat (*M. eversmanni*) and the North American black-footed ferret (*M. nigripes*) feed almost exclusively on the animals whose colonies they inhabit, the polecat on marmots and ground squirrels, the ferret on prairie dogs. Both of these animals occasionally feed on insects. Mink (*M. vison* and *M. lutreola*) feed largely on aquatic animals (muskrats, crayfish, mollusks, and fish) as well as on organisms inhabiting the banks of bodies of water.

Feeding habits of mustelids

The fisher (*Martes pennanti*) feeds mainly on mammals, but a few nuts, birds and eggs, fish, and seeds are taken. This animal is noted for its ability to kill and eat porcupines. Small terrestrial mammals make up over 90 percent of the food of the American marten (*M. americana*). The Eurasian pine marten (*M. martes*) and the stone or beech marten (*M. foina*) feed largely on small mammals but in the autumn may turn to wild berries and fruit. The yellow-throated marten (*M. flavigula*) of Asia is one of the largest martens and feeds on the

young of larger mammals such as musk deer, wild boars, roe deer, spotted deer, and raccoon dogs, as well as on squirrels, rabbits, and the smaller rodents. These large mustelids also take a variety of other food items: mollusks, grasshoppers, spawning fish, birds and their eggs, cedar nuts, grapes, and berries.

Badgers are quite variable in their diet. About 50 percent of the diet of the American badger (*Taxidea taxus*) is composed of ground squirrels, which are captured in their burrows. Badgers can dig with remarkable speed and can overtake the rodent when the latter has taken refuge in a blind tunnel. The remainder of their food is made up of small rodents, rabbits, birds and their eggs, snakes, turtle eggs, and insects. Insects, in fact, form a staple food of the young badger. The Eurasian badger (*Meles meles*) and the ferret badgers (*Melogale* species) are more omnivorous than the American badger and prefer insects (especially bees) and their larvae (grubs). Earthworms, mollusks, crustaceans, frogs, lizards, birds, eggs, as well as vegetable matter, such as berries, nuts, grains, fruits, bulbs, and green vegetation, are also taken. Ratels or honey badgers (*Mellivora capensis*) eat small mammals, lizards and snakes, insects, fruit, and especially honey. An interesting association exists between the African honeyguide (a piciform bird) and the honey badger. When the bird finds honey it gives a special call, which attracts the badger. The latter breaks open the hive with its long, sharp claws, exposing enough honey for both bird and mammal. If the bird does not succeed initially in attracting a honey badger, it seeks one out and, using the "honey" call, which the badger recognizes, leads it to the bee tree.

Skunks (*Mephitis, Spilogale, Conepatus*) are omnivorous mustelids, with small mammals forming an important part of the diet. Skunks may be becoming scarce in some parts of North America due to poisons gradually accumulated through extensive feeding on insects poisoned in agricultural control programs.

Otter feed largely on the invertebrates and vertebrates (especially fish) found in their aquatic environment. The oriental small-clawed otter (*Aonyx cinerea*) and the clawless otter (*Aonyx capensis*) feed to a greater extent on invertebrates (clams, snails, crabs) than do the river otter (*Lutra* species). *Lutra canadensis* at times take large numbers of crayfish. The African small-clawed otter (*Aonyx* species) are believed to feed on small mammals, the eggs of birds, and amphibians more than on fish. The sea otter (*Enhydra lutris*) is perhaps known best for its habit of breaking open sea urchins and clams on a rock held on its chest while it floats on its back. Seaweed, cuttlefish, and small fishes also are eaten.

Sharp senses of mustelids

Smell apparently is the most important sense to mustelids hunting on land. Black-footed ferrets have been noted to stop repeatedly and sniff the air while hunting. Hearing is also well developed and seems to be utilized as a means of detecting danger. Sight is less developed and, in the ferret at least, of little importance beyond about 300 feet. Of most importance to otters, living in an aquatic environment, is an acute sense of touch, through their very sensitive whiskers, which they use as an aid to guide them through the water. Most mustelids are silent, seldom making more than a squeak, whistle, or bark. Many will snarl or growl when annoyed. The giant otter (*Pteronura brasiliensis*) of South America is perhaps the most vocal, with its high-pitched whistle. Yellow-throated martens give a harsh cry when excited and often chuckle in a low tone.

Almost all mustelids are active both day and night, although most of their activity is nocturnal. Only the Old World badgers (*Meles meles*), ferret badgers (*Melogale* species), spotted skunks (*Spilogale* species), and hog-nosed skunks (*Conepatus* species) seem to be almost strictly nocturnal. The giant otter and sea otter seem to be more diurnal than other mustelids.

Except when travelling with young in a family group, most adult mustelids are solitary in habits. Sea otters seem to be more or less gregarious, as are Old World badgers. Badgers build a labyrinth of underground passages that some call "badger cities," because of the extent of the burrows and number of badgers that inhabit them. Female skunks (*Mephitis* species) often den together in large groups during the winter. Grisons (*Galictis* species) and yellow-throated martens often travel in groups of five or six individuals. Tayras (*Eira barbara*) and ratels tend to travel in pairs.

Since a great variation exists in the habits of mustelids, a great diversity would be expected in the habitats in which they live. Most mustelids, however, are terrestrial, living in forested or brushy areas. Many species can survive in a variety of habitats, from forest to desert. Some, like the marten and fisher, are strongly arboreal. Others, like the otter, are largely aquatic. The New World skunks and the North African spotted weasel (*Poecilictis libyca*) tend to inhabit areas farmed by man. The ferrets, American badger, and Eurasian polecats live mainly in grassland or semi-arid areas. Wolverines live in the more northern areas of taiga and forested tundras.

The locomotion of mustelids also varies. Most small mustelids scamper across the ground, making intermittent bounds as they move along. The larger forms sometimes lumber slowly. During their travels, mustelids tend to stop, sit up on their haunches, and look over the area. Some are extremely agile in trees; others are excellent swimmers.

Delayed implantation is perhaps more characteristic of the mustelids than any other group of the Carnivora. Members of the genus *Mustela* have gestation periods (determined from the date of fertilization) ranging from as much as 220 to 337 days (long-tailed weasel, *M. longicauda*) or as little as 36–42 days (ferrets). In the genus *Martes* the period is highly variable, between 220 and 297 days. The gestation period of badgers (*Taxidea, Mellivora, Meles*) ranges from six to eight months and that of otter from eight months to a little more than a year. Skunks (*Mephitis* species) do not have delayed implantation and apparently have the least variation in the period of gestation (62 to 72 days). Mink (*Mustela vison*) usually produce young in 45 to 50 days, with extremes from 38 to 76 days. On mink ranches, the later in the year that mink are bred, the shorter the gestation period.

Mustelid reproduction

The breeding season usually is in the late winter or early spring (mink, skunks, polecats, otters) or in the summer (weasels, marten, wolverine, sables, European and American badgers). Some mustelids breed at almost any time of the year (least weasel, river and sea otters). Those with exceptionally long gestation periods breed soon after the litter is born or in the following year. Some forms have two litters a year (striped skunk, least weasel, ratel), but in most only one litter is produced. Average litter size varies from one young in the sea otter to between 8 and 12 young (up to 18) in the Asiatic polecat. Most mustelids have between three and five young in a litter. The young of mustelids are born in ground dens, in rock crevices, under the roots of trees, under haystacks or buildings, or in hollow trees (the pine and American martens). The young of most species are weaned when between six and ten weeks of age, but young river otters nurse for about four months. Wolverine young are allowed to remain with the female for two years before establishing their own territories. In most species, however, the family disperses near the end of the summer or early fall. Mustelids are found worldwide, except for most oceanic islands, Australia, and Madagascar. Introductions have been made on some of the larger islands, such as New Zealand. Mustelids, like bears, generally are more abundant in the more northern continents.

Importance to man. Of all mammalian families, the Mustelidae contains the greatest variety of valuable mammals utilized by the fur trade. Fur coats that command the highest prices are usually those made from these luxuriant furbearers, especially mink, ermine (short-tailed weasel), and sable (a name applied by the fur trade to several species of *Martes*, especially the Eurasian *M. zibellina*, but also the American *M. americana*). Excellent skins are produced by the marten, fisher, skunk, and otter. In fact, the durability of all furs, including those

from other mammalian orders, is based on the river otter, which has been given the top rank of 100. Pelts of the ermine and sea otter have been the furs of royalty for hundreds of years. More than $100,000,000 worth of ranch-mink skins alone are produced yearly, and some breeds (like the Kojah mink) brought $2,700 per skin in the late 1960s. During the 18th and 19th centuries a collar made from the sea otter was regarded by some as the highest of status symbols, equivalent to owning a Rolls Royce or private yacht today. In 1968, at the first sale of sea-otter skins in 55 years, the better quality skins brought $2,300 apiece.

The pelt of the wolverine is prized highly by the Eskimos and others in Arctic areas because, when used for the lining of a parka, it can be cleared of frost from breath by a sweep of the hand. Moisture does not freeze to wolverine hair as it does to other furs. Badger hair has been utilized in the past to manufacture shaving brushes. Hair from the tails of many species is in high demand for paint brushes. Among the Chinese, the tail of the kolinsky or China mink (*Mustela sibirica*) is used for making delicate paint and artists brushes and is in more demand than is the rest of the pelt. The tails are removed from the skins and sold by the pound. Hairs from the tail of the sable also make excellent brushes, since the taper of the individual hairs causes the brush to form a sharp point when wet (see also FURS).

Importance in the food chain

Being largely carnivorous, the mustelids form an important link in the biological food chain. Rodents are kept at a reasonable level by this natural control. The spotted skunk, ferret badger, long-tailed weasel, Patagonian weasel, zorille (*Ictonyx striatus*), and sometimes the striped skunk (*Mephitis mephitis*) have been encouraged to live in or near the habitations of man because of their ability to keep the rodent and pest insect populations under control. Systematic destruction of these valuable predators can be a costly mistake to farmers.

Being carnivorous, mustelids sometimes become pests, especially around poultry—particularly when the poultry farmer is lax in his sanitation. Weasels, marbled polecats, and striped skunks are the common offenders. Considerable exaggeration of the prowess and deliberate maliciousness of the wolverine exists in literature. The behaviour of this animal has led many trappers to regard it as a true "demon of the north." A wolverine travels a trapline because it learns that a ready source of food is being held captive. In many cases the wolverine will follow the trapline back to the trapper's cabin and ransack the area in its search for food. The largest of the mustelids (around 25 pounds), this animal can do extensive damage.

Those mustelids that are proficient diggers (*e.g.*, badgers) sometimes become a hazard to horses (and riders), which stumble when stepping into a burrow. Other mustelids, such as the North American skunk, tend to be one of the more common wild mammals that serve as a reservoir for rabies. Meat of the Malayan stink badger (*Mydaus javanensis*), and sometimes the skunk (*Mephitis mephitis*), is eaten in some areas of the world. The obnoxious scent glands of mustelids discourage man from eating most of these animals, however. On the other hand, the scent from these glands was used in the past as a base for perfumes. Grisons and the ferret (*Mustela putorius*) have been trained by man to enter the burrows of other animals and drive them out; the grison to flush chinchillas, and the ferret, rabbits and rats. In China Oriental clawed otter and river otter are trained to catch fish or to chase them under nets which are then dropped, securing the catch. In some areas the bones or various parts of the tayra, African striped weasel, Malayan stink badger, hog-nosed skunks, and the African small-clawed otter are believed to possess medicinal value.

Form and function. Being highly carnivorous, mustelids have well-developed carnassials and a reduced number of premolar and molar teeth, the total number of teeth being between 30 and 38 (average, 34). With such a reduction in tooth number, the facial area of these animals is shortened. In the wolverine and American badger the bone of the lower jaw has a projection, the postglenoid process, that curves over the jaw articulation (glenoid fossa), resulting in a condition in which the mandible can be locked in place.

Mustelids are either digitigrade or plantigrade, and they have five toes on each foot. Most mustelids have short legs and many tend to have an elongate, slender body. They are quiet, agile, and graceful in their movements. There is a great variation in the tails of mustelids: flattened and elongate in the otter; stubby in the stink badgers; short in some of the weasels and badgers, long and thin in other weasels; long and bushy in marten; and especially elongate, with long hairs, in the skunks. The ears are small and rounded. Colours are usually brown or black. Some weasels change colour, becoming white in the winter, thus protecting the animal or, perhaps more probably, hiding it from its prey and making capture easier. Such white weasels are called ermine in the fur trade. Most mustelids have well-developed anal scent glands. The skunks, zorille, and the marbled polecat (*Vormela peregusna*), and to some extent the stink badger and ratel, can forcibly eject the vile-smelling material as a spray or fluid. All mustelids that possess powerful, controllable scent glands (except the stink badger) are marked in obvious contrasting colours, usually black and white. Such a striking colour combination may serve as a warning to potential predators, minimizing the likelihood that the animal will be attacked. After a single encounter with an adult mustelid, a predator avoids all animals so marked, including the less formidable young of the mustelid.

Repellent scent of mustelids

The smallest member of the Carnivora, the least weasel, belongs to the family Mustelidae and weighs 30 to 70 grams (1 to 2.5 ounces). The largest mustelid is the sea otter, which may weigh 41 kilograms (90 pounds). In most mustelids the males are larger than the females.

CIVETS AND ALLIES (FAMILY VIVERRIDAE)

Natural history. Viverrids are more numerous than the mustelids in terms of living genera (about 36) and species (about 75).

They are largely omnivorous in food habits, eating a variety of small mammals, birds, reptiles, eggs of birds and reptiles, amphibians, fishes, crustaceans, insects and their grubs, and earthworms, as well as vegetation such as fruits, nuts, bulbs or roots, and other plant material. A few, such as the palm civets (*Nandinia, Arctogalidia, Paradoxurus, Macrogalidia*), tend to be mostly vegetarian but at times take small mammals, birds, and insects. The binturong (*Arctictis binturong*), the largest member of the family, feeds mainly on fruit, although carrion is sometimes eaten. Although the suricates or slender-tailed meerkats (*Suricata suricatta*) tend toward an omnivorous diet, bulbous roots constitute most of their food. Approximately half of the genera of viverrids are composed of species that tend to be more carnivorous than herbivorous; the remaining genera are truly omnivorous. Some species tend to feed on one type of food: the ruddy mongoose (*Herpestes smithi*) on large snails, the Indian mongoose (*H. edwardsi*) on carrion remaining from the feasts of the large predators, the water mongoose (*Atilax paludinosus*) on crocodile eggs, the striped-necked mongoose (*H. vitticollis*) and the Congo water civet (*Osbornictis piscivora*) on fish. The banded palm civet (*Hemigalus derbyanus*) and Owston's civet are sometimes known to eat significant amounts of earthworms.

A number of viverrids (*Herpestes, Atilax, Mungos, Helogale*) are noted for their peculiar habit of opening eggs, as well as other food items with hard shells (crabs, mollusks, nuts). The animal stands on its hindlegs and hits the egg against the ground. Sometimes it carries the egg to a rock and, standing with its back to the rock, throws the egg between its legs and against the rock until the shell is broken. (Early reports of this behaviour met with skepticism but have been verified by other observers.) The Madagascar narrow-striped mongoose (*Mungotictis lineatus*) exhibits the same behaviour but lies on its side and uses all four feet to toss the egg. Viverrids are per-

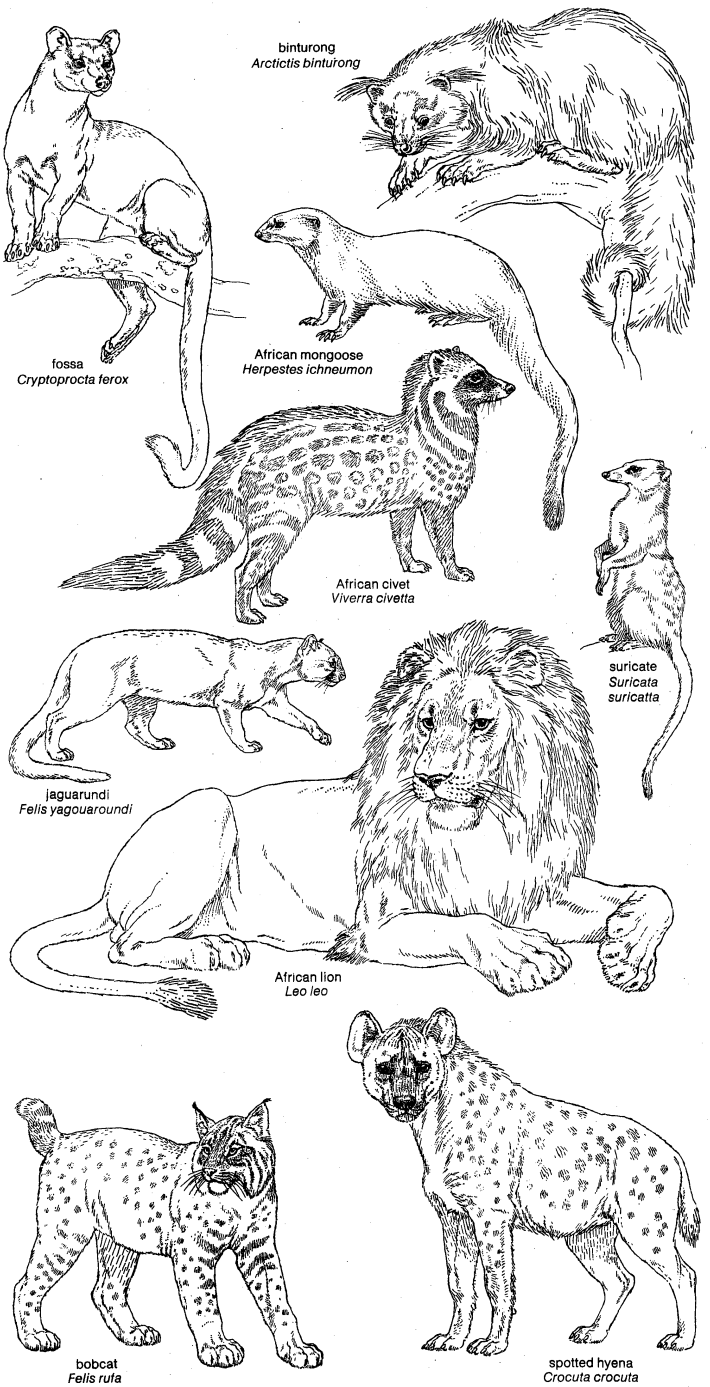

Figure 3: Representative carnivores: Viverridae, Felidae, Hyaenidae.
Drawing by R. Keane

Viverrids as snake-killers

haps best known for their ability to kill poisonous snakes, especially cobras, which are slow in striking and apparently unable to strike when at close quarters. The mongoose can dart within the outer striking range of the snake and grab and break the lower jaw. The mongoose is much less successful against a viper such as a rattlesnake, which has a very rapid strike and return to the pre-strike defensive position. The white-tailed mongoose (*Ichneumia albicauda*) has the unusual habit of feeding on the tree hyrax, which it follows and kills in the tops of trees.

Viverrids are highly variable in hunting and social behaviour. Some species are solitary; others hunt in groups, ranging from a single pair to a family group or a wandering band of more than 20 individuals. Two species, the meerkats (*Suricata suricatta* and *Cynictis penicillata*), live in colonies. Colonial organization is unusual for animals that are largely carnivorous but is found also in the European badger. An interesting relationship exists between the type of association and the time of day that viverrids are active. The viverrids that travel singly or hunt in pairs comprise the majority of species, and all are nocturnal. All those viverrids that hunt in bands or live in colonies are diurnal. The only exceptions are the mongooses of the genus *Herpestes*, which may hunt singly or in bands and may be either nocturnal or diurnal depending on the species involved.

The senses for seeing, hearing, and smelling are well developed in viverrids. Predatory birds apparently are recognized almost instantly and at considerable distances. Viverrids, like mustelids, tend to be silent, but such sounds as purring, grunting, chirping, low-pitched coughing, growling, hissing, whining, twittering, and barking have been described. More elaborate or complex "language" usually is found in gregarious forms. Specific warning or danger cries, signifying the approach of either a ground or aerial predator, are known in the social meerkats. The noisiest viverrid, however, is the nocturnal, arboreal binturong, which growls, hisses, and, at times, howls loudly. Also extremely noisy are the cusimanses (*Crossarchus* species), which travel in large groups grunting, chattering, and twittering.

Viverrid habitats

Most viverrids are terrestrial, but at least ten genera have forms that inhabit trees to a considerable extent. Mostly arboreal are the African palm civet (*Nandinia binotata*), the small-toothed palm civet (*Arctogalidia trivirgata*), the musang (*Paradoxurus* species), the masked palm civet (*Paguma larvata*), the binturong, the fossa (*Cryptoprocta ferox*), and the slender mongoose (*Herpestes sanguineus*). The linsangs (*Prionodon* species), although spending some time on the ground, are good climbers and live in the hollows of trees. Palm civets (subfamily Paradoxurinae), a few other civets, and genets also spend considerable time in trees. Mongooses, however, seldom climb and are unable to move about easily in trees. This inability is evident when they descend from trees. An efficient well-adapted climber comes down a tree head first. Of the mongooses, only the slender mongoose, and perhaps the Indian gray mongoose, have been observed descending head first. All other mongooses back down. Although most viverrids can swim if need be, three genera have semi-aquatic members: the Congo water civet, the African civet (*Viverra civetta*), and at least three species of mongooses of the genus *Herpestes* (*H. brachyurus*, *H. urva*, and *H. vitticollis*). The otter civet (*Cynogale bennetti*) has slightly webbed feet and is aquatic. An even more aquatic viverrid, or at least more agile one, is the water mongoose, which dives and swims like an otter, although, unlike the otter, its feet are not webbed.

Some mongooses exhibit curious antics to attract their prey. The white-tailed mongoose may dance outside of chicken pens and bite off the heads of chickens that curiously stick their heads through the netting. The banded mongoose is said to stand upright and fall over on its side, using such antics to attract curious guinea fowl close enough for capture. An interesting habit found in the meerkat plays a role in heat regulation. The belly of this animal has little hair, much less than the back. In the winter or during cold weather, the meerkat basks in the sun, standing on its hind feet with the ventral surface directed toward the heat source. When the temperatures are high, the animal seeks out cool surfaces, on which it lies on its stomach. It may even dig out an area to expose the cool subsurface layers of earth before lying down.

The fossa walks on the soles of its feet and thus is plantigrade or semiplantigrade, but most other viverrids walk on their toes (digitigrade).

Information concerning reproduction in viverrids is sketchy. In most species studied there are two litters a year (usually one in spring and one in fall), although breeding can occur throughout the year. The gestation period is usually between 49 and 64 days, but in various mongooses of the genus *Herpestes* it ranges from 32 to 49 days. Most litters consist of three or four young, but the

black-legged mongooses (*Bdeogale* species) may have only a single young. Most female viverrids have two pairs of abdominal nipples, thus perhaps restricting the litter size to four, but some females of the genus *Herpestes* have three pairs. The young are born in burrows, in a nest of grass on the ground, or in hollow trees.

Viverrids are found in the Old World tropics and subtropics, throughout Africa, southern Asia, Madagascar, and southeastern Europe. Only the genet (*Genetta genetta*) occurs naturally in Europe. Although restricted to southern France and Spain today, it was at one time found as far north and east as Belgium and Germany. Various mongooses (*Herpestes* species) have been introduced into the West Indies, Hawaii, and New Zealand, as well as the countries of Italy and Yugoslavia. Viverrids are most abundant in Southeast Asia (India and the Malay Peninsula). In habits and habitat they fill the niches of the mustelids and procyonids found more abundantly in the northern regions or in the New World. Viverrids are the only members of the Carnivora to reach Madagascar, where they have flourished and undergone adaptive radiation. About a sixth of the known genera of viverrids are restricted in distribution to this large island.

Importance to man. Probably of most significance economically is the musk, called civet, produced by the anal gland in members of the viverrid group known as "civet cats." Civet is a yellowish substance with the consistency of butter and is of great importance as a base for perfumes. It is produced by the anal scent glands and stored in a sac near the genital region. The Oriental and African civets (*Viverra* species) and the lesser Oriental civet, or rasse (*Viverricula indica*), are kept in captivity so that this musky secretion can be collected several times weekly. The secretion is obtained by scraping the sac with a wooden spatula. As much as four grams of civet can be obtained in one week. Long, narrow cages are used to prevent the animal from turning and biting while the secretion is being collected. This musk has been in great demand for many years, and at the beginning of the 20th century brought as much as ten dollars an ounce. Civet is used as a base for perfume extracts, and in India the product of the lesser Oriental civet has been used to flavour tobacco. In some areas, parts from viverrids are believed to have various medicinal values (the binturong and the linsang, *Poiana richardsoni*).

Viverrids as the source of musk

The only civets of value to the fur trade are certain members of the subfamily Viverrinae. Of these the large Indian, or "Chinese," civet (*Viverra zibetha*) is the only one to be utilized to any great extent. Fur of the small Indian civet and the genet is used for trimming. Some members of tribes in Madagascar use the tails of civets for ornaments. The meat of both the large and small Indian civets has been described as delicious.

The genet, white-tailed mongoose, and fossa often become pests in areas where poultry is raised. Most viverrids are efficient rat catchers, and some, such as the binturong, suricate, cusimanse, and certain mongooses, are domesticated because of their affectionate nature and their ability to eliminate mice, rats, and cockroaches from the residence of the owner. In some areas, Greece and southern Italy for example, genets have been kept as house pets, and this animal may have been the "cat" of the ancient Greeks. In other areas, the binturong is tamed to follow its master like a dog.

Form and function. Viverrids have from 36 to 42 teeth. The canines are slender and elongate and the carnassials well developed.

Viverrids have short legs with five toes on each foot, except for the meerkats; *Suricata* has four toes on each foot and *Cynictis* four on the hindfoot. The pollex ("thumb") and hallux ("big toe") are functionless and do not touch the ground. Each toe is capped with semiretractile claws that are more retractile in digitigrade species than in those that are semiplantigrade. Most viverrids have a long slim body and a long, bushy tail. Except for some marsupials, the binturong is the only Old World mammal with a prehensile tail. The elongate head ends in a pointed, foxlike muzzle. Coloration in the civets can be quite variable in pattern, from uniform to spotted, blotched, or striped, and ranges from black and gray through various shades of brown to rufus and yellow. The stripes may run longitudinally (*Mungotictis, Galidictis*) or vertically (*Mungos, Chrotogale, Hemigalus*). Some forms (especially *Bdeogale, Ichneumia*) have black legs.

Viverrids range in size from the dwarf mongoose (*Helogale parvula*) with a weight of about 500 grams (about one pound) and a total length of 300 millimetres (12 inches) to the binturong with a weight of up to 1,400 grams (about 3.5 pounds) and a length of 1,800 millimetres (72 inches).

HYENAS (FAMILY HYAENIDAE)

Natural history. Hyenas form a relatively homogenous family that includes two basic types: the true hyenas (two species of *Hyaena* and one of *Crocuta*) and the aardwolf (*Proteles cristatus*). Hyenas are noted for their scavenger feeding and bone-crushing habits, although at times they take live animals. Their food consists largely of the remains of artiodactyls, such as the antelope, left by the large cats. Vultures and jackals often feed on such kills after the cats and before the hyenas move in. The spotted hyena (*Crocuta crocuta*) eats large amounts of bone and skin, seeming to prefer them to meat. This, of course, is the type of remains left after the predator has had its fill. Spotted hyenas hunt in aggressive packs and at times attack and kill larger animals, even as large as a young rhino. If the animal attacked puts up a fight, the hyenas stop the attack and move away. In addition to carrion, brown hyenas (*Hyaena brunnea*) feed on small mammals, young or new-born larger mammals, reptiles, eggs, insects, fruits, and berries. On the coast they may feed on dead crabs, whales, and other sea life washed up on shore. The brown hyena is less apt to attack living animals than is the spotted hyena. The striped hyena (*Hyaena hyaena*) has food habits similar to those of the brown hyena. The aardwolf feeds almost exclusively on termites but eats a few other insects, such as beetles. A large quantity of soil and grass is usually eaten accidentally while feeding at termite mounds.

Feeding habits of hyenas

Since carrion produces a distinctive odour, hyenas depend on the sense of smell to a great degree. Most of their food probably is located by this sense alone, sight and hearing being less important. Sight is poorly developed in hyenas.

Hyena scavenging

The well-known howl of the "laughing hyena" is the call of the spotted hyena. The other species are not as noisy.

In areas undisturbed by man, hyenas hunt during the day. Members of this family inhabit open areas of plains and brushland but at times may be found in open forested areas. Hyenas form packs and are tireless trotters and runners, at times wandering great distances.

Spotted hyenas breed during the dry months, from April to July; the aardwolf breeds in the fall (October–November). The gestation period is approximately three months (95 to 110 days in the spotted hyena). Hyenas usually have three or four young. Dens may be located in abandoned burrows, caves, dense brushy areas, or among rocks. Some hyenas use the burrows of the aardvark for nesting spots, as does the African hunting dog.

The Hyaenidae have a distribution similar to, but more restricted than that of the viverrids, being found throughout Africa and southern Asia, east to eastern India.

Importance to man. The scavenger habits of most of the members of the Hyaenidae make them of considerable benefit to the ecosystem as a whole and often directly to man. They perform the service of eliminating the remnants left by the large predators and thus fit into a niche unused by most mammals. In some parts of Africa the natives allow the hyenas to roam their villages, cleaning up garbage. In some areas natives place their dead out in the open to be removed by these inexpensive "natural undertakers."

Hyenas at times will attack and kill livestock and sometimes even man, usually sleeping persons or young children. Being cowardly, they seldom fight if the individual

puts up any type of defense. When hungry, they may raid camps and carry off various items made of leather. In attacking large livestock or antelope, they usually approach from the rear and kill their prey by tearing open the abdomen.

Form and function. Hyenas have a total of 34 teeth, fewer than the generalized number found in other carnivores. The aardwolf has fewer upper and lower premolars and molars, resulting in from 28 to 32 teeth. The incisors are unspecialized in all members of the Hyaenidae, with the third incisor being the largest. The canines are well-developed, sharp, and elongate. Premolars of hyenas have well-developed crowns, useful in bone crushing, and tend to be conical. In the aardwolf the premolars are small, widely spaced, and, along with the small molars, tend to be vestigial. The lack of development of the cheek teeth is related to its insect-food diet, which does not require a powerful dentition. The molars of the hyenas are large and powerful, aiding in bone crushing, as do the jaws, the most powerful found in any mammal of comparable size. The head tends to be massive, with a broad muzzle, not long-nosed as in the canids or short-faced as in the cats. Anal glands are present in most forms and are well developed in the aardwolf, which can eject an obnoxious fluid when threatened.

All hyenas have a characteristic stance. The front legs are longer than the hindlegs, causing the back to slope conspicuously from a high point at the shoulders to a low point at the hindquarters. Hyenas walk on their toes and run well. There are four toes on each foot, capped by blunt, nonretractile claws. *Proteles* has five toes on the front foot. Most members of the family have a well-developed mane on the neck, which may extend down the midline of the back. This mane often is more noticeable in the young hyenas, although well developed in all age classes of the aardwolf. All have large, rounded ears. These animals are grayish or brownish in colour, marked with spots (*Crocuta*), stripes (*Proteles, Hyaena hyaena*), or uniform with bars on the legs (*Hyaena brunnea*). The tail is medium in size, bushy at the base, and pointed at the end.

CATS (FAMILY FELIDAE)

Natural history. Almost all cats are strictly carnivorous and feed on small mammals and birds or on the larger herbivorous artiodactyls like deer and various types of antelope. The fishing cat (*Felis viverrina*) feeds largely on fishes and clams or snails and thus fits into a slightly different niche from that of most cats. The flat-headed cat (*Felis planiceps*) is the only felid known to feed to any extent on vegetation, with fruit and items like sweet potatoes being preferred when available. The large cats sometimes drag the kill into a tree or place it under a bush after the initial gorging. Cats live on a feast-or-famine routine, gorging themselves when a kill is made and then fasting several days between kills.

Cats have good senses of sight and hearing. Long, sensitive whiskers on the face aid the cat during the stalking of the prey by brushing against any obstacle in a path and enabling the cat to avoid making excessive noise as it stalks its prey. The easiest, most open path can be followed through vegetation, even at night. Smell apparently is not as well developed as in some other carnivores, such as the dogs. Cats are nocturnal in habits. The cheetah is an exception to this rule, hunting predominantly by day. Their large eyes are especially adapted for seeing at night, when the amount of light is low. The cat stalks its prey to a point as close as allowed by available cover, then closes the final distance by a leap or a short dash. A chase may ensue, with the predator relying on superior speed and reflexes to overtake the dodging prey, which often has greater endurance. Although the endurance of most felids is sufficient for a chase of only a few hundred metres at most, the cheetah may pursue its prey for much greater distances, up to about 5,500 metres (about three miles). If overtaken, the prey is thrown down and dispatched with a deep bite, usually in the neck. Almost all hunting by these animals is done alone and quietly. The major exception to the solitary habit is the lion (*Leo leo*), in which the group, or pride, may number as many as 30 individuals. Cheetahs sometimes are found travelling in small groups but stalk and chase their prey individually.

Hunting method of cats

The gestation period of most smaller cats is approximately two months (50 to 68 days), and that of the large cats is three or three and a half months (88 to 113 days). Two or three kittens make up the usual litter. The jaguar (*Leo onca*) tends to have only one kitten. The domestic cat (*Felis catus*) sometimes has more than six kittens. Female cats may have from four to eight nipples. The breeding season usually is in the late winter or early spring. In smaller species those females that have early litters may produce a second litter in late summer or early fall. Some cats are capable of breeding at any time during the year (lion, tiger, and leopard). The size of the animal does not seem to determine the litter size, number of litters, or the time of the breeding season. In the larger cats, however, the age of initial breeding is greater; the females may be three or four years of age and males as much as five or six years old. Smaller cats may breed when less than a year old. Most litters are born in places seldom disturbed by man, such as in a rocky cavern, under a fallen tree, or in a dense thicket. The serval (*Felis serval*) uses an old porcupine or aardvark burrow. In most species the male does not aid in the care and raising of the young, and in fact, the female may have to guard against his attacks on the kittens. The male jaguar and ocelot (*Felis pardalis*) do help in raising the young.

Vocalizations of cats

Cats are noted for their purring when apparently content and for their snarling, howling, or spitting when in conflict with another member of their kind. The larger forms, especially the lion, often roar, growl, or shriek. Usually, however, cats are silent. Many cats have "clawing trees," upon which they leave the marks of their claws as they stand and drag their front feet downward with the claws extended. House cats are well known for this habit, and an owner may supply an artificial tree to save damage to furniture. Whether such behaviour is for the purpose of cleaning or sharpening the claws is debatable, but the behaviour is innate; kittens raised in isolation soon begin to claw objects. Other characteristics of cats are the constant movement of the tail when stalking, the habit of washing the face, and the habit of digging a hole in which to bury the fecal material and urine.

Almost every area on earth has some type of native cat. Australia is the only continental area that has no native felids, though the family also is absent from Madagascar and a number of oceanic islands. Cats are found in most habitats, from the forest to the desert, although they are typically animals of wooded environments. Many are in danger of extinction because of their incompatability with the activities of man or because of their combined value to zoos and the fur trade.

Importance to man. The cat, like the dog, was originally taken into the home of man as a pet. Unlike the dog, the cat has not been trained to hunt or to serve as a guardian. Cats may perform the function of "mouse catcher" in those areas where mice become a problem, but most urban house cats do not have the opportunity to perform this unless garbage and trash are allowed to accumulate. On farms, where storage of grain is common and rodents become numerous, cats help to hold their numbers in check. (For information on domestic cats, see CAT).

The fur of cats is sometimes in great demand, especially when high fashion calls for "fun furs," those with contrasting colours involving spots or stripes of the type found on the pelts of many cats. The demand is such that numerous kinds of cats are in danger of becoming extinct. In some regions of the world, catskins have been in great demand for many years. In parts of Africa the royal furs are usually those of a cat, as those in Eurasia are from the ermine or the sea otter. Chiefs and other high dignitaries of some native tribes use the pelt of the serval as a sleeveless cloak thrown over the shoulders.

Man-eaters

The larger cats are strong, fierce, and extremely danger-

ous when hungry. Should one of these animals learn that the flesh of man is edible, it must be eliminated. In many, if not most, cases the "man-eater" is an old cat no longer able to kill native wild prey. Although tigers and leopards are most famous for man-eating activities, lions and jaguars also may become dangerous. The American lion or puma (*Felis concolor*) tends to avoid contact with man and most records of its attacking man, except when cornered, are questionable. Similarly, if a large cat learns that a ready meal is available in the form of fenced or domesticated livestock, the rancher will have problems until the predator is eliminated. As in the case of the man-eater, the problem is caused by one animal and not all the individuals should be condemned.

Cats are intelligent and can be trained. Many kinds of cats can be tamed as pets, but some, especially the larger species, really can never be trusted when they become older or when they are sexually active. Most wild animals, to be trustworthy, must be fed by bottle before their eyes open, in which case the cat apparently will regard the human as its actual mother. The domestic cat, when liberated in the wild or allowed to roam in the field, may become a more serious and damaging predator on wildlife than the native predators in the region.

Form and function. Cats have a reduced number of premolar and molar teeth; the typical dental formula includes only 30 teeth. The incisors are small and chiselike and the canines long and pointed. The premolars are sharp, and occasionally an upper premolar may be lacking. The lower molar is elongate and sharp, the upper molar rudimentary. Because of the reduction in the number and size of the cheek teeth, a space remains between the canines and premolars in all cats except the cheetah. Felids form the most carnivorous group in the order, and the highly developed carnassial teeth reflect this specialized food habit. There is little if any specialization in the teeth for grinding or chewing. The strong masseter (chewing) muscles of the jaw restrict the amount of lateral movement and primarily permit vertical movements of the jaw, for holding the prey in a viselike grip and for slicing off pieces of meat with the carnassials. Thus meat is cut off and swallowed in relatively unchewed chunks that are broken down by strong enzymes and acids in the digestive tract. Cats use the rasplike tongue to remove the flesh from the bone.

Because of the reduction in the number of teeth, cats have a short face and a rounded, compact head. The ears tend to be short or, in some forms, tufted with hair. Most forms, except the lynxes (*Felis lynx*, *Felis rufa*), have an elongate tail that comprises about a third of the total length. The agility of a cat is evident in its anatomy. The clavicle, or collarbone, is much reduced in size. It does not connect with other bones but is buried in the muscles of the shoulder region. This type of construction allows the animal to spring on its prey without danger of a supporting or connecting structure, like the clavicle, being broken. The hindlegs are well developed, with powerful muscles that propel the animal in its spring toward or onto the prey animal. In addition to the power of the hindlegs, the animal uses strong back muscles to straighten the spinal column and provide extra force in springing and running. Most of the skin covering the body of the cat is loose, allowing for even more freedom of movement as well as providing some protection during a fight.

Anatomical basis of feline agility

The legs of the jaguarundi (*Felis yagouaroundi*) are rather short, and those of the cheetah elongate. All cats, except the cheetah, have retractile claws. Such claws can be drawn back into a sheath when the animal is walking, rendering the footsteps noiseless and keeping the claws sharp; or they can be extended as an aid in pulling down and holding the prey when the animal is attacking or in protecting the cat when attacked. The sharp, strongly curved claws are also utilized when the cat climbs trees. There are five toes on the front foot and four on the rear. The first toe and its pad on the front foot are raised so that only four toes register in a track.

Cats are usually some tone of brown in colour. Some, like the American mountain lion and jaguarundi, are uniform in coloration, but most are marked with spots, stripes, or rosettes. The young of the mountain lion are spotted, which may indicate a spotted ancestor. Characteristic of all cats is a dark stripe extending laterally from the external corner of the eye. This stripe tends to exaggerate the expression on the animal's face toward one of meanness but probably serves to conceal the face by breaking the roundness of the eyes. Many of the colour patterns are repeated again and again in the different species of cats, from the largest to the smallest. Several species have black or nearly black colour phases mixed into normally coloured populations. The only cat with a well-developed mane or long hair on the back and chest, or both, is the male African lion, which is also the only terrestrial member of the order Carnivora that shows obvious sexual dimorphism. In many felids the male is larger than the female, but this sexual difference is not easy to distinguish, because the difference in size is slight.

WALRUS AND SEALS (FAMILIES OTARIIDAE, ODOBENIDAE, AND PHOCIDAE)

Natural history. Members of the families Otariidae (eared seals), Odobenidae (walrus), and Phocidae (earless seals), commonly called pinnipeds, are strictly carnivorous and mostly marine. A few venture up freshwater rivers, and two forms (*Pusa* species) are landlocked on inland lakes. In actuality, pinnipeds are amphibious, being aquatic as to food habits but terrestrial for mating, bearing young, and resting. The diet of pinnipeds consists mainly of fishes, cuttlefishes, octopuses, and crustaceans. Most of the fishes fed upon by seals are those which school. A few pinnipeds are specialized for feeding on krill (macroscopic pelagic plankton, primarily small shrimplike euphausians). Seals known to feed largely on krill are the ringed seal (*Pusa hispida*), harp seal (*Pagophilus groenlandicus*), and the crabeater seal (*Lobodon carcinophagus*); all take fishes, as well. The crabeater seal is misnamed, as it is not known to feed on crabs. Some seals, such as the leopard seal (*Hydrurga leptonyx*), are quite predatory, feeding on penguins, other birds that land on water, and other seals. The Australian sea lion (*Neophoca cinerea*) feeds largely on penguins. Such predators take advantage of the surface light at night and probably feed by visual discrimination from below. The bearded seal (*Erignathus barbatus*) and walrus (*Odobenus rosmarus*) are bottom feeders, taking largely sessile organisms such as mollusks. The walrus occasionally feeds on small whales, narwhals, and seals.

Pinniped feeding

Generally, the senses of hearing and smell are poorly developed in the pinnipeds, although smell is fair in the phocids. Both the ears and the nostrils are closed when the animal is underwater. Sight is good and is adapted for use underwater and at night. All pinnipeds have well-developed facial whiskers and a well-developed system of nerves in the facial area. Seals probably have an excellent sense of touch in the whiskers, which aids in locating their prey or warns the animal of a possible collision with a submerged object. Young walrus have such well-developed whiskers that these appear as a brushlike mustache. The walrus and bearded seal utilize these whiskers to filtre food organisms found on the bottom and as a tactile organ. Phocid seals have patches of elongate hairs above the inside corners of the eyes. There is no evidence that seals use echolocation (reflected pulses of sound) in their movements or food-seeking activities, as has sometimes been postulated.

Pinnipeds may be solitary at certain times of the year but are usually gregarious, much more so than terrestrial carnivores. During the breeding season more than a million individuals may congregate on an island. Each male sets up a territory and gathers as many females as he can. The territory is maintained by frequent loud vocalization, a threat stance with neck outstretched, rushing at an approaching rival, and possibly through the use of olfactory odours thought to be produced in the mouth. Although the term harem is usually used to describe the large number of females in the territory of a male, this concept is misleading, since the females can move from one group

Territoriality in pinnipeds

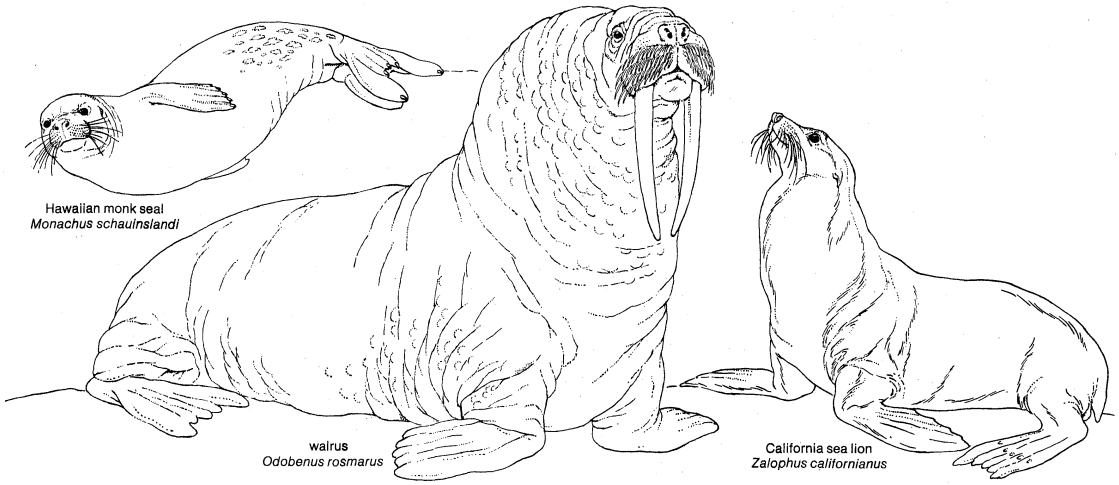

Figure 4: Representative carnivores: Pinnipedia.
Drawing by R. Keane; Hawaiian monk seal based on San Diego Zoological Garden photograph

to another. The groups are a result of the females staying clear of the males as the latter patrol their territories. Once the territory is established the male remains to protect it, going as long as two months without eating (sea lions and fur seals). Eared seals (the otarids) and walrus tend to gather harems, while the earless seals (the phocids) are mostly monogamous (one male, one female) in their breeding activities. The gathering of harems forces the mating activity to be terrestrial rather than aquatic. In many, if not most, of the northern species of seals the breeding season is restricted in many ways by the environment. In most areas only four months exist with a climate favourable for the production of young.

Pinnipeds have a fairly long gestation period, ranging from eight months in the leopard seal to 12 months in fur seals and sea lions. Breeding often takes place soon after the birth of the young (five days in the fur seal) or, as in the leopard seal, four months after the young are born. Copulation is usually on land, but some phocids mate in the water. Most seals, except the walrus and perhaps the crabeater seals, exhibit delayed implantation in embryonic development. The young are born on land or on ice. Usually there is but one young born, although most females have two pairs of mammary glands (some phocids have one pair). The mother goes out to sea to feed soon after the young is born. Since she must search to find her young when she returns, there has probably been a selection against the production of more than one young, at least in highly gregarious forms, for the time spent searching for the second pup would be at the expense of the first. It is evolutionarily better to produce one vigorous offspring than two weak ones. Nursing usually takes place on land. At birth the newborn pup can travel on land and swim, although young otarids are several weeks old before they develop enough blubber to keep them floating and insulated against the cold water. The young of the earless seals nurse for only three to six weeks, and the females remain near the young throughout this period. Pinniped milk is low in water content and high in fat. Such high fat content results in the rapid growth of the young, but perhaps of more importance is the low water content, of benefit to the mother in a habitat where water conservation is so important.

Female pinnipeds are sexually mature when two to eight years of age, usually at the age of three or four years. Males, at least in the polygamous species (those which gather a "harem"), may not be allowed to mate for several years after reaching sexual maturity. In these species the younger males are driven by the old males to a bachelor group located outside of the breeding group and restricted to a given area. After the breeding season, pinnipeds are largely pelagic (open-sea dwellers), travelling long distances either singly or in small groups.

A number of animals prey on seals: large sharks, killer whales, polar bears, and other seals, such as the leopard seal and walrus. Seals, especially the young, spend a good deal of time playing. They resemble the river otter in this regard.

Seal barking

Pinnipeds produce a number of different types of sounds. Barking by male seals may be related to social dominance and territorial defense, as the polygamous species are extremely vocal and the monogamous forms extremely quiet. The "barking" of the circus seal (the California sea lion, *Zalophus californianus*) is familiar to most people. The study of underwater communication in seals is difficult and in its infancy, but a variety of sounds have been recorded. These sounds may play a role in navigation, social behaviour, and foraging. Seals also roar or bellow, honk, chirp, bleat, grunt, or cough.

These aquatic, carnivorous animals are found throughout most of the coastal regions of the world. They are especially abundant in the cold polar waters. The walrus and phocids are well distributed throughout the northern coastal and ice-front areas. The otarids do not extend as far north, southern Alaska and Kamchatka being the most northern points, and are absent from the mid-Atlantic and North Atlantic Ocean areas. Pinnipeds are absent from the region of the Indian Ocean, southern Asia and northern Australia, the coastal regions of Central America and northern South America, and most of the coastline of central Africa. A few seals are landlocked on the Caspian Sea (*Pusa caspica*) and Lake Baikal (*Pusa sibirica*), where they subsist mainly on fish.

Importance to man. The seal is of significant importance to the survival of the Eskimos and other inhabitants of the north, who use almost every part of the animal: the meat is eaten; bones used for implements; tendons for sewing; hides for leather to make footwear, boats, shelters, bags, clothing, and ornaments; and the oil and fat for fuel, lubrication, and tanning. The ivory tusks of the walrus are carved into statues and knife handles. Seals also are taken commercially for their oil, for meat that can be used for food or fertilizer and for their hides that are used as leather.

A few seals are of importance to the fur trade. Of special interest are the true fur seals, *Callorhinus ursinus* in the northern regions of the Pacific Ocean and *Arctocephalus* species in the southern regions off the coasts of South America, Africa, and Australia. Most of the species utilized by the fur trade are members of the family Otariidae, which have dense underfur. The young of members of the Odobenidae and Phocidae have an insulating coat of short, dense, woollike hair at birth. Skins of these young animals are of some interest to the fur trade but are used mostly for novelties. Adult phocids have skins with stiff hair; the underfur is reduced to the point that the hide appears naked. However, some of the extremely striking phocids were in demand for furs in the late 1960s.

California sea lions are trained to entertain at circuses

and zoos. Some seals become pests to commercial fisheries and may gather during salmon or herring runs, sometimes being killed in large numbers by fisherman.

Form and function. Basically, the difference in the tooth pattern of pinnipeds, in comparison to the dentition of terrestrial carnivores, reflects an adaptation toward grasping and tearing rather than chewing. Thus there is less variation in the form of the different teeth (commonly said to be homodont, or "similar teeth"), and there tends to be a reduction in the number of teeth. There are, generally, two or three pairs of upper incisors and one or two pairs of lowers. There is a pair of conical canines that form elongate tusks in the walrus. The premolars and molars are conical and so similar that they are difficult to differentiate and are usually referred to as postcanines. There are no carnassial teeth. Usually there are ten postcanine teeth each in the upper and lower jaws, but the exact number can vary so greatly, even within one species, that the total number of teeth may range from 26 to 38. In the walrus the tooth number is reduced even further, the usual number being two upper incisors, no lower incisors, four canines, and twelve postcanines, a total of only 18 teeth. This number is variable, with some individuals having as many as 24 teeth. Weddell's seals have canines and incisors adapted for cutting holes in the ice so that areas are available for breathing when the water freezes over. The upper incisors extend forward and contact the ice before the canines.

Adaptations for aquatic life

Pinnipeds have a number of aquatic adaptations that separate them from the terrestrial carnivores. The body is streamlined, allowing the animal to pass through the water with the least amount of friction. External ears are reduced or absent, also aiding in making the pattern of the body more streamlined. Adaptive features of the skull include an overlapping of the bones, a feature even more exaggerated in the whales, and a flattening of the head, an advantage during diving. The neck is thickened by increased musculature but is more flexible (at least in the eared seals) than in the terrestrial carnivores, allowing the animal to capture its prey in the water with greater ease. In most pinnipeds the face is short, with the cranial part of the skull longer than the facial region. The eyes are large, located forward, close together, and imbedded in a cushion of fat. The iris of the eye is contracted when out of water, dilated and almost circular when diving. This type of eye can accommodate rapidly when the animal moves from dim to bright light. The ears and nostrils can be closed while diving. The pelvic girdle is more nearly parallel to the vertebral column than in terrestrial forms. Such a change in the location of the pelvis enables the hindlimbs to be held in more of a trailing position and to be more efficient in propulsion through the water. The limbs are enclosed within the body skin to or beyond the elbows and knees. This enclosure also streamlines and results in a more efficient passage through the water. The extremities of the limbs are flattened to form paddles used to steer or propel the animal through its environment. Each paddle contains five toes, extending from bones in the palm and sole (metapodials), elongated to increase the surface area of the paddles. The first digit on both forefeet and hindfeet is more elongate than the other four. The tail is short and rudimentary, a condition approached by the sea otter but quite unlike the paddle-like tail of the freshwater otter. Mammary teats and external reproductive organs are so constructed that they can be withdrawn beneath the skin to aid in preserving the smooth outline of the body. The skin, adapted to a water environment, is tough and thick and contains a thick layer of subcutaneous fat or blubber. The blubber provides a source of energy that can be used during lactation or at times of fasting. Such fasting is characteristic of pinnipeds. This layer also provides the animal with more buoyancy, so that sinking in the water is less apt to occur. In addition, the blubber insulates the body so that the body temperature remains nearly constant. A pinniped living in cold water may be exposed to a surface temperature of about 0° C and yet have a body temperature of 37° C, requiring an efficient system of heat production and insulation. In warm waters, and especially in warm air, the animal cannot get rid of excess body heat rapidly enough to prevent overheating. The flippers, so useful for swimming, can be used on land as radiators to get rid of excess body heat. One of the most obvious behavioural features of a colony of seals on land is the waving or extension of the naked flippers.

Physiological adaptations for diving

There are a number of physiological adaptations to life in the sea. Being air breathers, seals must be able to carry as much oxygen as possible with them in diving and to conserve what they do take. This adjustment is obtained by the increased volume of blood (very large for an animal their size) and the decreased rate in the use of oxygen by the body (decreased metabolism). The heart rate decreases in the elephant seal from about 85 beats per minute when the animal is on the surface to approximately 12 per minute during a dive. This drop in heartbeat rate conserves oxygen in terms of the amount being carried in the blood. There cannot, however, be a decrease in the amount of oxygen being carried to some parts of the body. The heart and brain, for example, must have a constant and sufficient supply, or the cells in these organs will be damaged. This problem is alleviated by closing down the small arteries in the tail and flippers, while the larger arteries to the head and brain remain unchanged. The muscles function without free oxygen during submergence; the energy is obtained by partly breaking down the blood sugars and without expending the limited supply of oxygen. Most dives last less than 15 minutes, and upon return to the surface there is a greater exchange of oxygen and carbon dioxide than is found in terrestrial mammals. The amount of tidal air in one respiratory cycle may be as much as 90 percent, compared to 20 percent in man. Most dives are deep vertical dives rather than extensive horizontal dives because of the problems of orientation toward the breathing hole in the ice when horizontal directions are taken. Since there is no exchange of gases with the environment while submerged, seals have the additional problem of an accumulation of carbon dioxide. They seem to be less sensitive than terrestrial animals to increased amounts of this gas. The body temperature is lowered, a result of the decreased rate of metabolism. Seals are also adapted to withstand the great pressures during their dives. Weddell's seal (*Leptonychotes weddelli*), for example, dives as deep as 1,100 feet, more than four times the distance that man can go in a diving suit. The longest known dive by a Weddell's seal lasted 43 minutes and 20 seconds (to 350 metres), with one elderly bull reaching a depth of 600 metres (2,000 feet) but remaining down a shorter time. Exactly how these animals can accomplish such feats is unknown. The anatomy of the seal reveals part of the answer. Many structures in the body are built to yield to such pressures, not to resist them. Some of these adaptations are smaller lungs; elimination of most air from the lungs before the dive; a thorax that permits the lungs to collapse; incomplete rings of cartilage in trachea, permitting complete collapse; driving air out of the middle ear by partly filling the ear cavity with blood; and redistribution of blood in general. The phocids are more efficient divers than the otarids, and, of the phocids, those living in the Antarctic dive the deepest.

The clavicle or collarbone is absent, allowing more flexibility in the shoulder. The kidneys, unlike those of most mammals, are composed of numerous lobes resembling a bunch of grapes, a condition also found in the terrestrial bear and otter.

Members of the families Otariidae and Odobenidae can walk on their limbs when on land. Phocids must move by undulations of the body as the limbs cannot be turned in a position to support the body. This does not mean that the phocids are helpless on land; the crabeater seal, a phocid, is probably the fastest moving seal on land, being difficult for even a running man to catch.

III. Evolution and paleontology

Opinion is divided as to whether the order Carnivora arose from the ancient creodonts or had a separate and

independent origin from the order Insectivora. Most paleontologists now favour the latter view. The Cretaceous insectivore *Procerberus* seems to be morphologically close to the most primitive carnivores (miacids), the creodonts, and the primitive hoofed mammals (ungulates). *Procerberus* was an unspecialized rat-sized predator. The order seems to be a separate and distinct line that includes the modern Fissipedia (terrestrial forms) as well as Pinnipedia (marine and aquatic forms), while also including the more ancient and extinct family Miacidae.

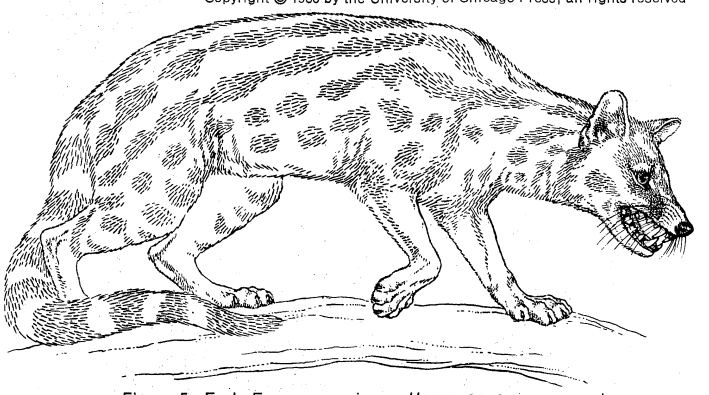

Figure 5: Early Eocene carnivore, *Hesperocyon*, an ancestor of the dogs.

The extinct Miacids

Although not much is known about them, the miacids were probably arboreal forest dwellers of the tropics. Animals from this type of habitat are rarely preserved as fossils, which accounts for our incomplete knowledge of the group. These primitive carnivores may have resembled our modern weasels, with elongate bodies, short limbs, and long tails. Miacids possessed several creodont features, such as an unossified tympanic bulla (a large bubble of bone or cartilage surrounding the internal ear) and lack of fusion of the carpal (wrist) bones. Miacids differed from the creodonts in having a larger brain capacity, toe sections that were not grooved, and well-developed carnassial teeth. The carnassials, as in modern carnivores, involved the fourth upper premolar and first lower molar.

In the late Eocene and early Oligocene these primitive miacids underwent an adaptive radiation; *i.e.*, they produced diverse lines that seem to have been the beginnings of the present-day families of the Carnivora. The changes needed to convert a miacid into a modern terrestrial carnivore are minor: fusion of the separate bones of the carpus and ossification of the tympanic bulla. Carnivores that began to resemble the modern weasels, dogs, and civets were in evidence in the Oligocene, but these early carnivores were still quite similar to each other and had not differentiated to the extent of representing different families.

Two major lines within the Carnivora were distinct by the late Eocene. One, the Feloidea (or Aeluroidea), today contains cats, viverrids, and hyenas; the other, the Arctoidea (or Canoidea), contains the mustelids, dogs, bears, and raccoons. Some fossils are intermediate between the two lines, but most show definite relationships to one or the other.

Feloids had the tympanic bulla made up of an external (tympanic) and an internal (endotympanic) bone, each being a separate ossification. In many forms the claws were retractile. The transition between the miacids and viverrids (civets) was so gradual that some authorities have placed the miacids in the family Viverridae. Because of the similarities to the miacids, the viverrids are considered to form the basal stock of the feloid line. Hyenas appear to be a more recent line, having evolved from the viverrids in the early Miocene. *Ictitherium*, a mid-Miocene viverrid, had characteristics intermediate between the viverrids and hyenas, but apparently was more like the "true" hyenas. Other fossil viverrids also showed similarities to the hyenas. Although the cats seem to have evolved "suddenly," the resemblance of certain catlike viverrids (such as the Oligocene *Stenoplesictis* and the modern *Cryptoprocta* of Madagascar) to the recognized felids is regarded by some authorities as indicating the close relationship of the felids to the viverrids. In the late Eocene and early Oligocene, the felids were quite distinct, with a number of highly specialized cats already present. Of particular interest are the sabre-toothed cats such as *Hoplophoneus* and the false sabre-tooth *Dinictis*, which had large upper canines fitting into a flange on the lower jaw. The Pleistocene *Smilodon*, a more recent genus, is probably the best-known sabre-toothed cat. The genus *Felis* dates back to the early Pliocene, by which time its members had features similar to those of the modern cat.

In contrast to the feloids, the arctoids almost never had retractile claws; the tympanic bulla was made up of the tympanic bone alone; and there was a canal below the bulla, through which the carotid artery passed, supplying blood to the brain. Some of the earlier miacids are difficult to separate from the mustelids, which were distinct as early as the late Eocene. They probably were one of the first arctoid lines to differentiate. By the close of the Miocene, several general types of mustelids were evident: the weasels, badgers, skunks, and otters. Another ancient arctoid line included the dogs. Oligocene canids, represented by the genera *Cynodictis* and *Hesperocyon*, resembled elongate, short-legged weasels and civets. Both genera, although considered to be primitive dogs, were generalized enough to be ancestral to many carnivores. Genera that were more typically canid appeared in the early Oligocene. These were running animals, with four well-developed toes and reduced hindtoes (hallux and pollex), each ending in a blunt claw. More than 50 genera of doglike forms are known, but the main line of evolution seems to have passed through forms like *Temnocyon* (upper Oligocene) and *Cynodesmus* (lower Miocene) to the modern genera *Canis* (first seen in the lower Pliocene deposits), *Vulpes* (perhaps in the upper Miocene), and *Urocyon* (Pleistocene). Two lines of extinct canids are the hyena-like dogs and the bear dogs, neither of which has any relationship to the living hyenas or bears. Because of the close relationships of the bears, dogs, and raccoons, various taxonomists have disagreed on the placement of intermediate genera. For example, *Dinocyon*, *Hemicyon*, and *Cephalogale* were once considered to have been canids but are now placed with the bears and regarded as perhaps part of the ancestral lineage that diverged from the canid line in the late Oligocene or early Miocene. *Phlaocyon* and *Aletocyon* were once considered to be primitive procyonids because of their teeth, but the skull and ear structures are more reminiscent of the dogs. A recent form, the giant panda (*Ailuropoda*), considered by some to be a bear and by others to be a procyonid, probably diverged from primitive ursid stock when the ancestor of the bear and raccoon lines still had features common to both. Procyonids (raccoons) are poorly represented in the fossil record, perhaps because of their arboreal habits. They appear to have diverged from the canid line in the late Oligocene.

The preponderance of carnivorous and carrion-eating fishes and mammals in the open sea, along with the buoyant characteristics of the bodies of the pinnipeds, results in the almost immediate destruction of any seal that dies. Dead pinnipeds seldom settle intact and become buried (the first steps toward becoming a fossil) and so are poorly represented in the fossil record. Relationships must be inferred through studies of recent forms. Although there is no fossil record of pinnipeds prior to the Miocene, it is probable that the ancestors of the pinnipeds evolved during the adaptive radiation of the miacids in the Eocene. There are two rather distinct evolutionary lines in the animals called pinnipeds. One includes the two rather closely related families Otariidae and Odobenidae. This line may have become distinct in the early Miocene or late Oligocene, evolving from a form closely related to the canid ancestor of the bears. The other line

Evolution of pinnipeds

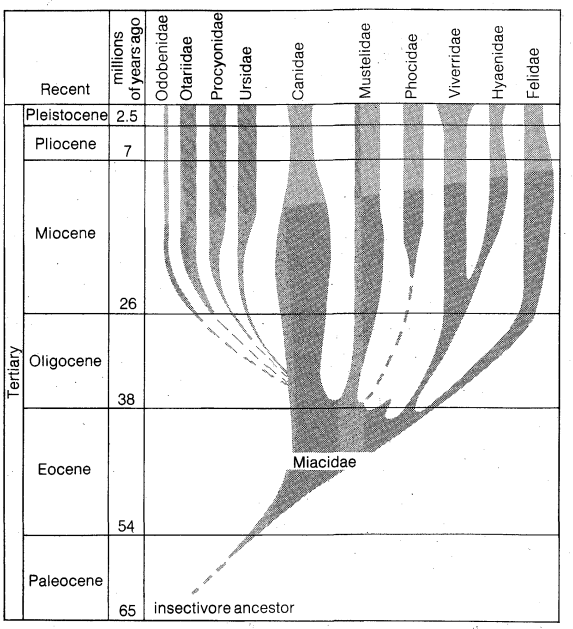

Figure 6: Phyletic dendrogram of Carnivora.

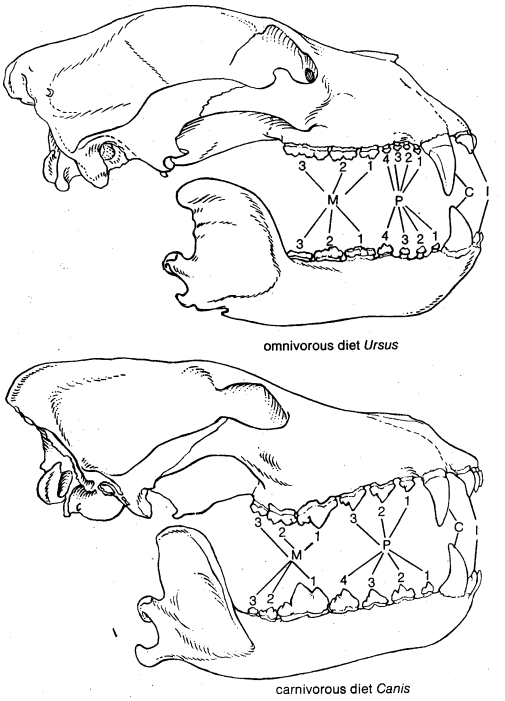

Figure 7: Tooth patterns in omnivorous and carnivorous members of Carnivora. Side view of lower mandible and cranium.

From Hall and Kelson, *The Mammals of North America*, vol. II, copyright © 1959; The Ronald Press Company, New York

led to the modern phocids, which are quite different from the otarid–odobenid group. Their affinity to any other group of the Carnivora has not been shown, although the mustelids have more frequently been suggested as related to the phocids than any other group. *Semantor*, an aquatic carnivore from the lower Pliocene, was once considered to belong to a separate pinniped family, but is now considered a mustelid. The separation of the phocid and otarid–odobenid lines must have occurred at an extremely early date, if the two lines ever had a common pinniped ancestor. Some paleontologists postulate a separation in the early Miocene or late Oligocene. Possibly the two lines never evolved from a single aquatic group but had separate origins within the miacids, sometime in the late or even mid-Eocene. Or perhaps the otarids stemmed from an ancestral ursid type in the early Oligocene. Such an early separation, or lack of any real ancestral association, could have produced the dissimilarity of the two types of pinnipeds, as well as the difficulty in associating the phocids with any other family of the Carnivora.

IV. Classification

DISTINGUISHING TAXONOMIC FEATURES

If one groups the seals with the terrestrial carnivores, the number of characteristics common to all members of the order Carnivora is small.

The characteristics used to separate the Carnivora from other mammalian orders and to define the subdivisions of the Carnivora are primarily structural. Of great importance are certain features of the skull (the type of jaw articulation and the shape of the paroccipital process), of the feet (the number of toes, lack of opposability of the hindtoe, type of claws, and fusion of the scaphoid and lunar bones), and of the teeth (both the overall tooth pattern and the shape of the individual tooth). The dentition is especially important in determining the relationships of fossil forms. Also useful in the taxonomy of modern carnivores are the convolutions (irregular ridges) around the lateral or sylvian fissure of the brain, the relative weights of the adrenal and thyroid glands, the type of uterus and placenta, and the position of the nipples.

ANNOTATED CLASSIFICATION

Although the terrestrial and marine carnivores are grouped together in the following classification, many authors separate them into two orders. In this article the split is indicated by erecting two suborders, the Fissipedia and Pinnipedia, based largely on the degree of specialization undergone by the members as they evolved and adapted to radically different environments. Basically the taxonomy presented combines the classifications by G.G. Simpson and A.S. Romer, North American paleontologists.

Numerical dental formulas are used below to indicate the number of each type of tooth in the right or left half of the upper and lower jaws and the total number of teeth in the mouth. 4 tooth types are indicated in the following manner:

Upper jaw: incisors . canines . premolars . molars
Lower jaw: incisors . canines . premolars . molars
= total number of teeth

ORDER CARNIVORA

Medium- to large-sized terrestrial or aquatic meat eaters distributed worldwide; composed of 10 extant families, about 115 living genera, and 274 living species.

Suborder Fissipedia

Terrestrial (except otters and polar bear); usually 3 pairs of incisors above and below, adapted for biting off flesh; premolars vary in number from the usual 4 on each half of each jaw (4/4) to 4 above and 2 below (4/2); molars vary from 2/3 to 1/2; carnassial teeth well developed and formed by the 4th upper premolar and 1st lower molar; usual dental formula: $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 3} = 42$ teeth; all-inclusive dental formula: $\frac{3 \cdot 1 \cdot (2\text{–}4) \cdot (1\text{–}4)}{(2\text{–}3) \cdot 1 \cdot (1\text{–}4) \cdot (1\text{–}5)} = 28\text{–}50$ teeth; facial part of skull usually elongate; tympanic bullae large; alisphenoid canal (a perforation in the skull for a branch of the carotid artery) usually present; lacrimal duct present; pelvis at distinct angle from vertebral column; femur (thigh bone) straight, moderately slender, with small head; fibula (minor lower bone of hindlimb) much smaller than tibia (shinbone); 1st metatarsal and bones of phalanges with epiphyses only at proximal ends; metapodials never elongate; vertebrae with interlocking processes; external ears (pinnae) well developed; large intestine short (6 to 8 times length of body in dog); kidneys simple, not lobulate except in otters and young bears.

Superfamily Miacoidea

All extinct generalized carnivores with carnassial teeth. Middle Paleocene to upper Eocene. There is one family, Miacidae, about 13 genera.

Superfamily Feloidea (cats, civets, and hyenas)

Tympanic bullae divided, composed of external tympanic and internal endotympanic bones; paroccipital process in

close contact with bullae; most have retractile or semiretractile claws; cecum small; baculum (bone of penis) present or absent; usually polyestrous; upper Eocene to Recent; 42 living genera and 115 species.

Family Viverridae (civets and mongooses). Upper Eocene to Recent. Distributed throughout most of the southern regions of the Old World (Asia, Europe, Malay Peninsula, most of Africa, Madagascar, and associated southern oceanic islands) but most abundant in the India–Malay region; introduced on New Zealand, Hawaii, and the West Indies. Small to medium sized (0.7 to 14 kg). Well-developed carnassials; upper carnassials usually lack an anterior lobe and the lower carnassials have a well-developed talonid process; middle incisor on each side located farther inward than the outer 2; incisors broad; 4 small premolars, with 1st minute or absent; molars 2/2 or in some cases 1/2 (*Prionodon*), 2/1 (*Salanoia*), or 1/1 (*Cryptoprocta*); molars large, especially the 1st; dental formula usually $\frac{3 \cdot 1 \cdot (3\text{–}4) \cdot 2}{3 \cdot 1 \cdot (3\text{–}4) \cdot 2} = 36\text{–}40$ teeth. Alisphenoid canal usually present (absent in *Eupleres* and most members of subfamily Galidiinae); entepicondylar foramen of humerus usually present; auditory bulla externally constricted and divided by septum. Baculum well developed. Intestinal cecum small, sometimes absent. Elongate body, short legs; digitigrade or semiplantigrade gait; 5 toes usually present, with semiretractile claws (retractile in *Cryptoprocta*); pollex and hallux located on side of foot above other toes. Ears small and rounded; tail usually long (12–90 cm) and bushy or tapering to a point from a bushy base. Scent glands often well developed, producing secretion called "civet." Usually uniform in coloration but some spotted or striped.

Subfamily Viverrinae (true civets, genets, and linsangs). Mainly African; approximately 7 living genera and 15 species.

Subfamily Paradoxurinae (palm civets). Mainly Asian, 6 living genera and 8 species.

Subfamily Hemigalinae (banded palm civets, web-footed civets). Asia or Madagascar, 5 living genera and 7 species.

Subfamily Galidiinae (striped and ring-tailed mongooses). Restricted to Madagascar, 4 living genera and 7 species.

Subfamily Herpestinae (true mongooses and meerkats). All African, 13 living genera and approximately 37 species.

Subfamily Cryptoproctinae (fossa). Monotypic. *Cryptoprocta ferox*, found only in Madagascar.

Subfamily Stenoplesictinae. Fossil. Upper Oligocene to middle Miocene of Europe.

Family Hyaenidae (hyenas and aardwolves). Middle Miocene to Recent. Found today throughout most of Africa and southern Asia (Turkey to eastern India). Medium-sized (10 to 80 kg) carrion feeders; teeth specialized for crushing bones; incisors unspecialized, outer (3rd) larger than other 2; canines powerful; premolars strong and conical; molars strong and large; carnassials well developed (hyenas); long, slender canines in aardwolf (*Proteles*) with small and widely spaced premolars, small molars, and no development of carnassials. Dental formula $\frac{3 \cdot 1 \cdot 4 \cdot 1}{3 \cdot 1 \cdot 3 \cdot 1} = 34$ teeth for hyenas; premolars 3/(2–1), molars 1/(1–2) = 28–32 for aardwolf. Alisphenoid canal absent; auditory bullae partially divided by a rudimentary septum in hyenas, divided in aardwolf; front legs longer than rear legs; digitigrade; 4 toes (5 on forefoot in aardwolf); claws blunt and nonretractile; entepicondylar foramen absent; baculum absent; more thoracic vertebrae (15) than any other feloid: tail of medium length (20 to 33 cm) and bushy. Preanal scent glands absent. Cecum 15 to 23 cm long. Short mane usually present. Ears large and rounded.

Subfamily Protelinae (aardwolf). African. 1 species. *Proteles cristatus.*

Subfamily Hyaeninae (hyenas). Africa and southwest Asia; 2 living genera, 3 species.

Subfamily Ictitheriinae. Fossil. Miocene–Pliocene. 1 Old World genus.

Family Felidae (cats). Upper Eocene to Recent. Now worldwide except for Antarctica, Australia, Madagascar, and some oceanic islands. Size medium to large (2.5 to 275 kg). Highly carnivorous; well-developed carnassials. Total number of teeth reduced from primitive carnivore condition; dental formula typically $\frac{3 \cdot 1 \cdot 3 \cdot 1}{3 \cdot 1 \cdot 2 \cdot 1} = 30$ teeth; alisphenoid canal absent; auditory bullae not constricted externally; posterior palatine foramina on maxillopalatine suture instead of on maxilla. Elongate body with relatively short legs; digitigrade; 5 toes on front, 4 on rear feet, capped with sharp, curved, retractile claws. Entepicondylar foramen present; baculum absent or vestigial; cecum small; tail short (lynx) to long (up to a third of total length). Preanal scent glands absent; tongue covered with horny papillae.

Subfamily Felinae (lynxes, typical cats, lions, tigers, leopards). Worldwide except Antarctica, Australia, Madagascar, and most oceanic islands. 2 living genera, 35 species.

Subfamily Acinonychinae (cheetah). Africa and southwest Asia. 1 species, *Acinonyx jubatus.*

Subfamilies Proailurinae, Nimravinae, Machairondontinae, Hyainailourinae. All fossil. About 39 genera.

Superfamily Canoidea (dogs, bears, raccoons, and weasels)

Tympanic bulla formed from tympanic bone only; not divided into 2 chambers; long canal beneath bulla; paroccipital process prominent and independent of bullae. Claws nonretractile. Cecum present or absent; baculum well developed; usually monestrous (1 litter of young per year). Eocene to Recent; 53 living genera and 133 species.

Family Canidae (dogs, foxes, jackals). Eocene to Recent. Now worldwide except Antarctica and most oceanic islands. Size medium (1.5 to 80 kg). Carnivorous or omnivorous; well-developed carnassials; dental formula typically $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 3} = 42$; bush dog (*Speothos*) with (1–2)/2 molars (1 upper molar is sometimes minute or absent) = 38 to 40 teeth; Cape fox (*Otocyon*) with (3–4)/(4–5) molars = 46 to 50 teeth. Facial part of skull elongate; alisphenoid canal present; legs long and semirigid; digitigrade with 5 toes on front (1 dew claw) and 4 on rear foot; claws blunt and nearly straight. Entepicondylar foramen absent; baculum well developed and grooved. Cecum always present, short and simple or long and characteristically folded. Tail relatively long (up to about a third of total length) and bushy; scent glands often on dorsal part of base of tail. Ears pointed, erect, and large.

Subfamily Caninae (dogs, jackals, and foxes). Worldwide except Antarctica and most oceanic islands; dingo probably introduced on Australia in prehistoric times; wild dogs of New Guinea probably derived from domestic dogs. 11 living genera and approximately 37 species.

Subfamily Simocyoninae (dhole, hunting dog, bush dog). Asia, Africa south of the Sahara, and northern South America. 3 living monotypic genera: *Cuon alpinus, Lycaon pictus, Speothos venaticus.*

Subfamily Otocyoninae (big-eared fox). Eastern and southern Africa; monotypic, *Otocyon megalotis.*

Subfamilies Amphicynodontinae, Amphicyoninae, Borophaginae. Fossil only. Total genera about 34.

Family Ursidae (bear and giant panda). Middle Oligocene to Recent. Restricted to larger land masses of world, ice floes of Arctic, and in South America to Andes; bear of Atlas Mountains of northwest Africa now extinct. Size medium to large (27 to 780 kg); usually omnivorous; carnassials poorly developed; dental formula variable, but typically $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 3} = 42$ teeth. Skull elongate; alisphenoid canal present. Legs short, large, and powerful; plantigrade; 5 toes on each foot, capped by elongate, powerful, nonretractile claws. Entepicondylar foramen of humerus usually absent; lacrimal bone of skull, clavicle, and cecum absent; tail short, practically absent; ears small and rounded; lips mobile and free from gum. 6 genera and 8 living species.

Family Procyonidae (raccoons, coatis, lesser panda). Upper Eocene (probably) to Recent. Fossils through Pleistocene in Europe. Except for the lesser panda (*Ailurus*) of the southeastern Himalaya region of Asia, family is restricted to northern South America, Central America, and southern North America. Size medium (0.8 to 22 kg); omnivorous; carnassials poorly developed; dental formula usually $\frac{3 \cdot 1 \cdot 4 \cdot 2}{3 \cdot 1 \cdot 4 \cdot 2} = 40$, with some variation in number of premolars (kinkajou 3/3, lesser panda 3/4); alisphenoid canal absent except in *Ailurus;* legs of medium length; semiplantigrade to plantigrade; 5 flexible toes on each foot capped by nonretractile or semiretractile claws; entepicondylar foramen sometimes present; baculum well developed and, except for *Ailurus*, bilobed and hooked at distal end; cecum absent; clavicle vestigial; tail long (20 to 70 cm), often ringed, prehensile in *Potos;* ears small to medium in size and rounded. 7 living genera and approximately 14 species.

Family Mustelidae (weasels, badgers, skunks, otters). Eocene to Recent. Now worldwide except Madagascar, Australia, and most oceanic islands; introduced into New Zealand; more common in Northern Hemisphere. Size from smallest of carnivores (35 gm) to medium; mainly carnivorous; carnassials usually well developed; dental formula usually $\frac{3 \cdot 1 \cdot 3 \cdot 1}{3 \cdot 1 \cdot 3 \cdot 2} = 34$ teeth but may range from 30 to 38 teeth, with variation in incisors (3/2 in sea otter), molars (1/1 in ratel and African striped weasel), but especially premolars (2/3 in the African striped weasel, 4/2 in the river otter, 4/4 in American bad-

ger); alisphenoid canal absent; legs short in relation to elongate body; plantigrade to digitigrade; 5 toes on each foot, capped with nonretractile claws; entepicondylar foramen present or absent; tail usually long (up to 1/3 of total length); ears small and rounded; anal scent glands well developed.

Subfamily Mustelinae (weasels and Old World polecats). Subfamily with widest distribution and most kinds. There are 11 genera and 33 recent species.

Subfamily Mellivorinae (ratel or honey badger). African and southern Asia. There is 1 species, *Mellivora capensis.*

Subfamily Melinae (badgers). North America, Europe, Asia, with most forms found in Southeast Asia. There are 6 genera and 8 recent species.

Subfamily Mephitinae (skunks). New World only. There are 3 living genera and 11 species.

Subfamily Lutrinae (otters). Worldwide. There are 5 living genera and 19 species.

Subfamily Leptarctinae. Fossil. Miocene and Pliocene. New World. 3 genera.

Suborder Pinnipedia

Aquatic; teeth nearly homodont (uniform) and adapted for grasping and tearing, not chewing; 2 pairs of incisors below; postcanines (premolars and molars) similar, never more than 2-rooted, and usually 5 on each jaw (varies from 3 to 7); carnassials absent; usual dental formula $\frac{3 \cdot 1 \cdot 5 \text{ (postcanines)}}{2 \cdot 1 \cdot 5 \text{ (postcanines)}}$ = 34 teeth; all inclusive dental formula $\frac{1\text{–}3 \cdot 1 \cdot (3\text{–}7)}{0\text{–}2 \cdot 1 \cdot (3\text{–}6)}$ = 18–38 teeth; cranial part of skull longer in proportion to facial part than in most fissipeds; face profusely innervated by extremely large trigeminal nerve; brain more spherical and with greater development of convolutions than fissipeds. Tympanic bullae small in some; alisphenoid canal present or absent; lacrimal duct absent; basioccipital and sphenoid relatively large as compared with fissipeds; pelvis small and nearly parallel to vertebral column; femur broad, flattened, with globular head on short neck; fibula almost as large as tibia; metatarsals and all bones of phalanges with epiphyses at both ends of shaft; metapodials elongate; 5 well-developed digits on each limb; 1 digit on manus and 1st and 5th digits of pes usually longer than other digits; feet fully webbed; nails small to absent; baculum massive. Fusiform-shaped body; external ears (pinnae) reduced or absent; tail short or vestigial (5 to 20 cm long) with 8 to 15 caudal vertebrae. Intestine long; cecum short; kidneys lobulate. Thick layer of subcutaneous fat (blubber). One large, precocial young.

Family Otariidae (eared seals). Lower Miocene to Recent. Coastlines of Pacific, South Atlantic, and Indian oceans. Hindlimbs useful for support on land; nails well developed on middle 3 digits, rudimentary on outer ones. Small external pinnae of ears. 2 pairs of lower incisors; upper incisors of 1st pair notched transversely; usually 20 to 22 postcanine teeth; dental formula $\frac{3 \cdot 1 \cdot 4 \cdot (1\text{–}3)}{2 \cdot 1 \cdot 4 \cdot 1}$ = 34 to 38 teeth. Males are 2 to 4 times as large as females (males 120 to 1,000 kg; females 60 to 270 kg); testes suspended in distinct external scrotum; small but distinct tail; obvious neck; skin whitish or light gray.

Subfamily Otariinae (sea lions). Coastal regions of northern and eastern Pacific Ocean, southern Australia and southwestern New Zealand; coastal regions off eastern coast of South America. There are 4 living genera and 5 species.

Subfamily Arctocephalinae (Pacific and southern fur seals). Southern coastal areas of all southern continents; north Pacific region. There are 2 living genera, 7 species.

Family Odobenidae (walrus). Upper Miocene to Recent. Circumpolar holarctic distribution, seldom south of about 58° north latitude. Hindlimbs useful for support on land. External pinnae absent; postorbital process absent; alisphenoid canal present. Lower incisors absent in adult; upper canines of both sexes form tusks; usually 12 postcanine teeth; dental formula $\frac{(1\text{–}2) \cdot 1 \cdot (3\text{–}4) \cdot 0}{0 \cdot 1 \cdot (3\text{–}4) \cdot 0}$ = 18–24 teeth; males larger (up to 1,270 kg) than females (up to 860 kg). Testes abdominal (internal). No free tail. Skin whitish or light gray. Monotypic, *Odobenus rosmarus.*

Family Phocidae (earless seals). Middle Miocene of Europe and North America; Pliocene of Asia; lower Pleistocene of Africa; Recent along northern and southern coastal areas, sporadic in tropical and southern regions. Hindlimbs useless on land (cannot be placed forward under body); nails equally well developed on all digits; external pinnae absent; postorbital process rudimentary or absent; alisphenoid canal absent; 2 to 4 lower incisors; usually 16 to 20 postcanine teeth; dental formula $\frac{(3\text{–}2) \cdot 1 \cdot 4 \cdot (0\text{–}2)}{(1\text{–}2) \cdot 1 \cdot 4 \cdot (0\text{–}2)}$ = 26 to 36 teeth; males may be much larger than females (elephant seal, hooded seal), slightly larger (some members of subfamily Phocinae), equal in size (some Phocinae and some Monachinae), or females may be larger than males (some Monachinae); olfactory apparatus reduced; testes abdominal; stubby tail; no visible neck; skin brown or black.

Subfamily Phocinae (northern seals). Northern temperate to Arctic waters; 7 living genera and 9 species.

Subfamily Monachinae (southern seals). Tropical and Southern Hemisphere waters; 6 living genera and 9 species.

CRITICAL APPRAISAL

The taxonomy of the major categories of major groups placed in the Carnivora has been in a state of flux for at least 100 years, and these categories do not seem to be stabilizing, even today. Most mammalogists at present regard the seals and terrestrial carnivores as belonging to different orders, the Pinnipedia and Carnivora. There are, in reality, only a few features common to the seals and their terrestrial relatives because of the extensive and numerous adaptations the aquatic forms have undergone to make them efficient carnivores of the sea. Mammalogists who have studied seals intensively now realize that there is no anatomical structure unmodified by the extensive aquatic adaptations; every organ and tissue examined has been found to be different in some way from its counterpart in terrestrial forms. In many, if not most, ways there is more difference between seals and terrestrial carnivores than between the bats and the insectivores, and few mammalogists would place the bats and insectivores in the same order. Other mammalogists, tending toward conservative taxonomy, feel the relationship of the terrestrial and aquatic carnivores can be best expressed by retaining them in two suborders, the Fissipedia and Pinnipedia, of the single order Carnivora. The conservative attitude is retained in this article.

Of the ten living families recognized in the Carnivora, two have separated from their lines most recently and are most easily associated with other existing families: the Odobenidae with the Otariidae and the Hyaenidae with the Viverridae. The family Procyonidae has perhaps the greatest number of taxonomic problems. It appears to be a collection of primitive forms whose relationships are not yet clear. Most of the living genera have at one time been placed in distinct families or subfamilies (Nasuidae, Bassariscidae, Ailuridae, Bassaricyonidae, Procyoninae, Potosinae). In most other families there are also genera sufficiently different from other members of their family that they have been given separate families (the canids *Lycaon* and *Otocyon;* the giant panda *Ailuropoda;* the otters; the viverrid fossa *Cryptoprocta;* and the aardwolf *Proteles*).

The arrangement of the ten families into two distinct superfamilies, Canoidea and Feloidea (or Aeluroidea), appears to be a natural arrangement dating back to the works of W.H. Flower and H. Winge in the late 1800s. In the Canoidea, as revealed by studies in comparative anatomy and the fossil record, the families Canidae, Ursidae, and Procyonidae seem to be most closely related. Also placed in the Canoidea is the family Mustelidae, although some of the more primitive members show resemblances to the primitive viverrids as well as the canids. In the Feloidea, the families Viverridae and Hyaenidae seem most closely related, the Felidae being the most aberrant.

Those families that contain rather diverse lines have been subdivided into subfamilies; the number of subfamilies in each family indicating the amount of evolutionary divergence that has occurred. The groups that have probably been distinct the greatest length of time have the most subfamilies; the Viverridae with six and the Mustelidae with five. Within the viverrids some of the subfamilies are distinct, a few less distinct. Most distinct are the subfamilies Herpestinae and Cryptoproctinae. The Cryptoproctinae seems to be an ancient group with the genus *Cryptoprocta* retaining characteristics of the felids as well as the viverrids, so much so that some taxonomists, have placed *Cryptoprocta* in the felids, although most mammalogists regard them to be more similar to the

viverrids. The remaining four subfamilies have been combined and split in a number of ways. Usually retained, along with the two above subfamilies, are the subfamilies Viverrinae and Galidiinae. Each of the five mustelid subfamilies seems to be distinct from the others. Some authorities feel that the skunks and badgers may be close enough to place them in the same subfamily. Of the five subfamilies, the most diverse is the Mustelinae with 11 distinct genera.

What much of the discussion above means, in terms of critical taxonomic appraisal, is that a system of classification is in some ways an artificial system set up for the convenience of man. Ideally, the system reflects real evolutionary relationships, but these must be inferred from a scanty fossil record and from comparisons of modern species. Since there are differences of opinion among specialists as to which taxonomic characters should be given the most weight, there are certain to be alternate classifications, the acceptability of which depends on new information continually being discovered. Just as the animals have evolved, so does the taxonomic system.

BIBLIOGRAPHY. For general information on the biology of the carnivores, see E.P. WALKER *et al.*, *Mammals of the World*, 3 vol. (1964), in which each genus is described and illustrated, along with a brief summation of its biology. The taxonomy of carnivores is discussed in G.G. SIMPSON, "Principles of Classification and a Classification of Mammals," *Bull. Am. Mus. Nat. Hist.*, vol. 85 (1945), a classic work on classification, followed by most recent mammalogists; and H.J. STAINS, "Carnivores and Pinnipeds," in S. ANDERSON and J.K. JONES, JR. (eds.), *Recent Mammals of the World: A Synopsis of Families* (1967). F.E. BEDDARD, *Mammalia* (1902), is a definitive early work on mammalian anatomy. The paleontology of the Carnivora is summarized in two works by A.S. ROMER: *Vertebrate Paleontology*, 3rd ed. (1966), basic to an understanding of fossil forms, and *Notes and Comments on Vertebrate Paleontology* (1968), containing additional information not found in the general text. Books devoted to particular subgroups of the carnivores include: A. DENIS, *Cats of the World* (1964), an excellent summary of the status of all members of the Felidae; C.J. HARRIS, *Otters* (1968), a fine summary of the status of the otters of the world; H.E. HINTON and A.M.S. DUNN, *Mongooses: Their Natural History and Behavior* (1967), which contains much interesting information difficult to find, except in scattered literature; R.J. HARRISON *et al.* (eds.), *The Behavior and Physiology of Pinnipeds* (1968), an excellent summation of recent knowledge of these aquatic carnivores; and V.B. SCHEFFER, *Seals, Sea Lions, and Walruses: A Review of the Pinnipedia* (1958), a major work on the taxonomy of the Pinnipedia.

(H.J.S.)

Carnot, Lazare

Lazare Carnot, the French military engineer and politician known to French history as "the Organizer of Victory" for his role in the Revolutionary Wars of the early 1790s, was born at Nolay in Burgundy on May 13, 1753, the son of a lawyer. Carnot studied at the Collège d'Autun and subsequently at the small seminary in the same town. After attending the artillery and engineering preparatory school in Paris from 1769 to 1771, he graduated from the Mézières school of engineering, in January 1773, with the rank of lieutenant. Thus he began the life of a garrison officer, going from one provincial town to another, moving in literary circles wherever he was stationed. In 1780 he was admitted to a distinguished literary society and in 1784 became known for a eulogy of Sébastian Le Prestre de Vauban, the French military engineer, which received an award from the Dijon Academy. In 1787 he was elected a member of the Arras Academy, the director of which at that time was Robespierre, who was to be a leading figure in the Revolution.

When the Revolution broke out in 1789, Carnot was still a captain, a rank he had received in 1784. In 1791 he was elected deputy from Pas-de-Calais to the Legislative Assembly. As a member of the diplomatic and public education committees, Carnot did not distinguish himself; but on August 11, 1792, the day after the attack on the royal palace of the Tuileries in Paris, he was sent to the Army of the Rhine to report what had occurred.

Lazare Carnot, lithograph by Ambroise Tardieu (1788–1841), after an engraving by C.A. Forestier.
By courtesy of the Bibliotheque Nationale, Paris

In September 1792, Carnot was elected representative from Pas-de-Calais to the National Convention—the assembly elected under the influence of the fall of the monarchy—and at the end of the month was sent, with two other representatives, on a mission to Bayonne to organize the defense against a possible attack from Spain.

Since he was absent from Paris until the beginning of January 1793, Carnot did not take part in debates accompanying Louis XVI's trial. He did, however, take part in the decisive votes, in which he voted against an appeal to the people and in favour of the King's death. He thus indicated that he had been won over to the position of the Jacobins—the radicals—even though by temperament and inclination he was a man of the independents of the centre.

As a member of the Committee of War, Carnot was assigned to the Committee for General Defense, a predecessor of the Committee of Public Safety, which was to act as the executive branch throughout the republic. In this capacity Carnot presented various reports to the Convention, particularly one on March 9, 1793, which resulted in the dispatch of 82 representatives into the provincial *départements* to expedite the conscription of 300,000 men. Carnot himself was sent into the *départements* of the Nord and of Pas-de-Calais and at the end of March to the Army of the North. He remained with the Army of the North until August 1793, establishing his mastery in military operations as well as in the command of men. He reorganized the army, re-established discipline, and took part, musket in hand, in the attack and capture of Furnes.

On August 14, 1793, the Convention appointed Carnot a member of the Committee of Public Safety. Shortly after, he set out again for the Army of the North, while the enemy besieged Maubeuge. This mission ended in the victory of Wattignies on October 16, 1793 and in the raising of the siege of Maubeuge. Once again Carnot, at the side of the generals, led the attack and entered the recaptured town alongside them. At the end of the month, he resumed his seat on the Committee of Public Safety.

From then on, Carnot devoted himself to the immense task of the Committee, concentrating on the conduct of military operations, although he did not entirely divorce himself from general policy. From the very start Carnot demanded that the ancient tactic of line combat be abandoned, advocating instead attack by masses concentrated at decisive points; eventually his views were adopted by the entire Committee. Carnot took a dominant part in the development of campaign plans, which were discussed by the entire Committee; Robespierre and Saint-Just, one of Robespierre's chief aides, concerned themselves particularly with strategy.

Beginning in May 1794, dissensions arose within the

Committee of Public Safety between Carnot and Robespierre and Saint-Just, all of whom were of equally authoritarian and unyielding temperament. Carnot, basically a conservative, did not approve of the egalitarian aims of the social policy of Robespierre and his followers. If he did not play a decisive role during the coup of 9 Thermidor, year II (July 27, 1794), which overthrew Robespierre and marked the end of the Reign of Terror, Carnot must at least have approved of the fall of Robespierre.

Subsequently, however, Carnot's role began to diminish. He continued to occupy himself with directing military operations for another few months, but he soon had to defend himself against attacks by the executors of the Thermidorian coup, aimed without distinction against all former members of the Committee of Public Safety. Thus, in March 1795, in an attempt to dissociate himself from his former colleagues, he claimed that each of them was responsible only for the duty with which he was charged and that the signatures to decrees regarded as reprehensible were only a formality. Yet Carnot did not succeed in silencing the charges. In May 1795, when an obscure deputy demanded the arrest of all the members of the former committees and named Carnot, he was saved by another deputy who shouted "He organized the victory."

Carnot was elected to the Directory, the French government from 1795 to 1799, the executive branch of which consisted of five directors; and he became even more conservative than before. When the elections of the spring of 1797 brought in a royalist majority, Carnot bowed to the results, so that during the coup d'état of 18 Fructidor, year V (September 4, 1797), which quashed the elections, he had to flee in order to escape arrest. He crossed into Germany and settled in Nürnberg.

Return under Napoleon

After the coup d'état of 18 Brumaire, year VII (November 9, 1799), which brought Napoleon Bonaparte to power as first consul of France, Carnot returned. He was minister of war for a few months in 1800 but resigned. Appointed in 1802 a member of the Tribunat, a body chosen by the Senate to debate legislation, he fought the authoritarian development of the consular regime, opposed the institution of the Legion of Honour, voted against bestowing on Napoleon the consulate for life, and courageously opposed the establishment of the Empire under Napoleon. He continued, however, to hold a seat on the Tribunat until that assembly was suppressed in 1807, when he withdrew from public life.

The allied invasion of 1814 forced him out of retirement. Napoleon appointed him governor of the town of Antwerp, where he remained until after the fall of the Empire. Carnot sided with the Restoration under Louis XVIII, but in July 1814 he published his *Mémoire au roi en juillet 1814*, in which he denounced the excesses of the reaction under the Bourbon king. During the Hundred Days, when Napoleon attempted to reestablish his power, Carnot served as minister of the interior, and after Napoleon's defeat at Waterloo, Carnot encouraged him to resist, but in vain. The Second Restoration marked the end of Carnot's political career.

In July 1815, Carnot was exiled from France. He left Paris in October and settled at Warsaw in January 1816. In August 1816, Carnot left Warsaw for Magdeburg, where he died on August 2, 1823.

Assessment

The Third Republic, eager to acquire ancestors, exalted Carnot's memory, consecrating him as "the Organizer of Victory." When his grandson, Sadi Carnot, was president of the republic, the ashes of Lazare Carnot were placed in the Panthéon in Paris. Carnot was indeed "the Organizer of Victory" but only in collaboration with the other members of the Committee of Public Safety, with whom he shared responsibility for the Terror as well. For although the Committee of Public Safety was able to raise, equip, arm, and feed 14 armies and lead them to victory, it succeeded only by means of a mass levy, mass requisitions, and nationalization of military production—measures based on the revolutionary government's use of force, that is, an authority relying on the Terror. The characterization of Carnot as "the Organizer of Victory" is a legend created by the victors of the Thermidor coup, who, holding those vanquished in the coup responsible for the Terror, surrounded the survivors with all the brilliance of the victory.

BIBLIOGRAPHY. P.F. TISSOT, *Mémoires historiques et militaires sur Carnot, rédigés d'après ses manuscrits, sa correspondance inédité et ses écrits* (1824). The greater part of these *Mémoires* were drafted by Carnot himself; the rest were collected from his notes, writings, and papers. MARCEL REINHARD, *Le Grand Carnot*, vol. 1, *De L'Ingénieur au conventionnel, 1753–1792* (1950), vol. 2, *L'Organisateur de la victoire, 1792–1823* (1952), the best biography of Carnot currently available, gives a favourable interpretation of its subject. An English-language treatment may be found in R.R. PALMER, *Twelve Who Ruled* (1958).

Carnot, Sadi

Sadi Carnot, French army engineer and physicist, is remembered chiefly for his study of the so-called heat cycle, which greatly contributed to the modern science of thermodynamics. In 1824 he examined the basic problems of the operation of the steam engine: the amount of heat supplied as compared with the work produced, the maximum amount of work that can be produced, the suitability of water as the best medium of power. He identified the ideal conditions in which mechanical energy is produced from heat in a steam engine and in heat engines in general. In spite of his intentions, Carnot's work had no practical effect on the design of engines, but its greatest impact was on pure science, particularly on the study of the thermal properties of matter.

Sadi Carnot, engraving after a painting by A. Bailly, 1813.

Early years

Born in Paris on June 1, 1796, Carnot was named for a medieval Persian poet and philosopher, Sa'dī of Shīrāz, whose writings were then enjoying a minor vogue in Paris. His father, Lazare Carnot, was a member of the five-man Directory that governed France between the Revolution and the rise of Napoleon. In this period of unrest, the family suffered many changes of fortune. His father fled into exile a few months after Sadi's birth; three years later he returned to be appointed Napoleon's minister of war but was soon forced to retire. A writer on mathematics and mechanics as well as military and political matters, the elder Carnot now had the leisure to direct his son's early education.

Sadi entered the École Polytechnique in 1812, an institution providing an exceptionally fine education, with a faculty of famous scientists aware of the latest developments in physics and chemistry, which they based on a rigorous mathematics. By the time Sadi graduated in 1814, Napoleon's empire was being rolled back, and European armies were invading France. Soon Paris itself was besieged, and the students, Sadi among them, fought a skirmish on the outskirts of the city.

During Napoleon's brief return to power in 1815, La-

zare Carnot was minister of the interior, but, following the Emperor's final abdication, he fled to Germany, never to return to France.

Army career

Sadi remained an army officer for most of his life, despite disputes about his seniority, denial of promotion, and the refusal to employ him in the job for which he had been trained. In 1819 he transferred to the recently formed General Staff but quickly retired on half pay, living in Paris on call for army duty. Friends described him as reserved, almost taciturn, but insatiably curious about music, science, and technical processes.

The mature, creative period of his life now began. Sadi attended public lectures on physics and chemistry provided for workingmen. He was also inspired by long discussions with the prominent physicist and successful industrialist Nicolas Clément-Desormes, whose theories he further clarified by his insight and ability to generalize.

The problem occupying Carnot was how to design good steam engines. Steam power already had many uses—draining water from mines, excavating ports and rivers, forging iron, grinding grain, and spinning and weaving cloth—but it was inefficient. The import into France of advanced engines after the war with Britain showed Carnot how far French design had fallen behind. It irked him particularly that the British had progressed so far through the genius of a few engineers who lacked formal scientific education. British engineers had also accumulated and published reliable data about the efficiency of many types of engines under actual running conditions; and they vigorously argued the merits of low- and high-pressure engines, and of single-cylinder and multicylinder engines.

Work on the heat cycle

Convinced that France's inadequate utilization of steam was a factor in its downfall, Carnot began to write a nontechnical work on the efficiency of steam engines. Other workers before him had examined the question of improving the efficiency of steam engines by comparing the expansion and compression of steam with the production of work and consumption of fuel. In his book, *Reflections on the Motive Power of Fire*, published in 1824, Carnot tackled the essence of the process, not concerning himself as others had done with its mechanical details.

He saw that, in a steam engine, motive power is produced when heat "drops" from the higher temperature of the boiler to the lower temperature of the condenser, just as water, when falling, provides power in a waterwheel. He worked within the framework of the caloric theory of heat, assuming that heat was a gas which could be neither created nor destroyed. Though the assumption was incorrect and Carnot himself had doubts about it even while he was writing, many of his results were nevertheless true, notably the prediction that the efficiency of an idealized engine depends only on the temperature of its hottest and coldest parts and not on the substance (steam or any other fluid) which drives the mechanism.

Although formally presented to the Academy of Sciences and given an excellent review in the press, the work was completely ignored until 1834, when Émile Clapeyron, a railroad engineer, quoted and extended Carnot's results. Several factors might account for this; the number of copies printed was limited and the dissemination of scientific literature was slower, and such a work was hardly expected to come from France when the leadership in steam technology had been centred in England for a century. Eventually Carnot's views were incorporated by the thermodynamic theory as it was developed by Rudolf Clausius in Germany (1850) and William Thomson (later Lord Kelvin) in Britain (1851).

Little is known of Carnot's subsequent activities. In 1828 he described himself as a "constructor of steam engines, in Paris." When the Revolution of 1830 in France seemed to promise a more liberal regime, there was a suggestion that Carnot be given a government position, but nothing came of it. He was also interested in improving public education. When absolutist monarchy was restored, he returned to scientific work, which he continued until his death on August 24, 1832, in the cholera epidemic in Paris.

BIBLIOGRAPHY. E. MENDOZA (ed.), *Reflections on the Motive Power of Fire, by Sadi Carnot, and Other Papers . . .* (1960), contains translations of Carnot's memoir and two important articles by E. CLAPEYRON and R. CLAUSIUS. The introduction gives biographical details of Carnot's life and a technical discussion of the physics background of his work. The primary source of Carnot's biography is *Réflexions sur la puissance motrice du feu et sur les machines propres à développer cette puissance* (1878), which includes a biography by his brother, HIPPOLYTE CARNOT. A few more fragments are included in E. MENDOZA, "Contributions to the Study of Sadi Carnot and His Work," *Arch. Int. Hist. Sci.*, 12:377–396 (1959). The engineering background is discussed from a technical point of view in two papers: MILTON KERKER, "Sadi Carnot and the Steam Engine Engineers," *Isis*, 51:257–270 (1960); and ROBERT FOX, "Watt's Expansive Principle in the Work of Sadi Carnot and Nicolas Clément," *Notes Rec. R. Soc. Lond.*, 24:233–253 (1969).

(E.M.)

Carpathian Mountains

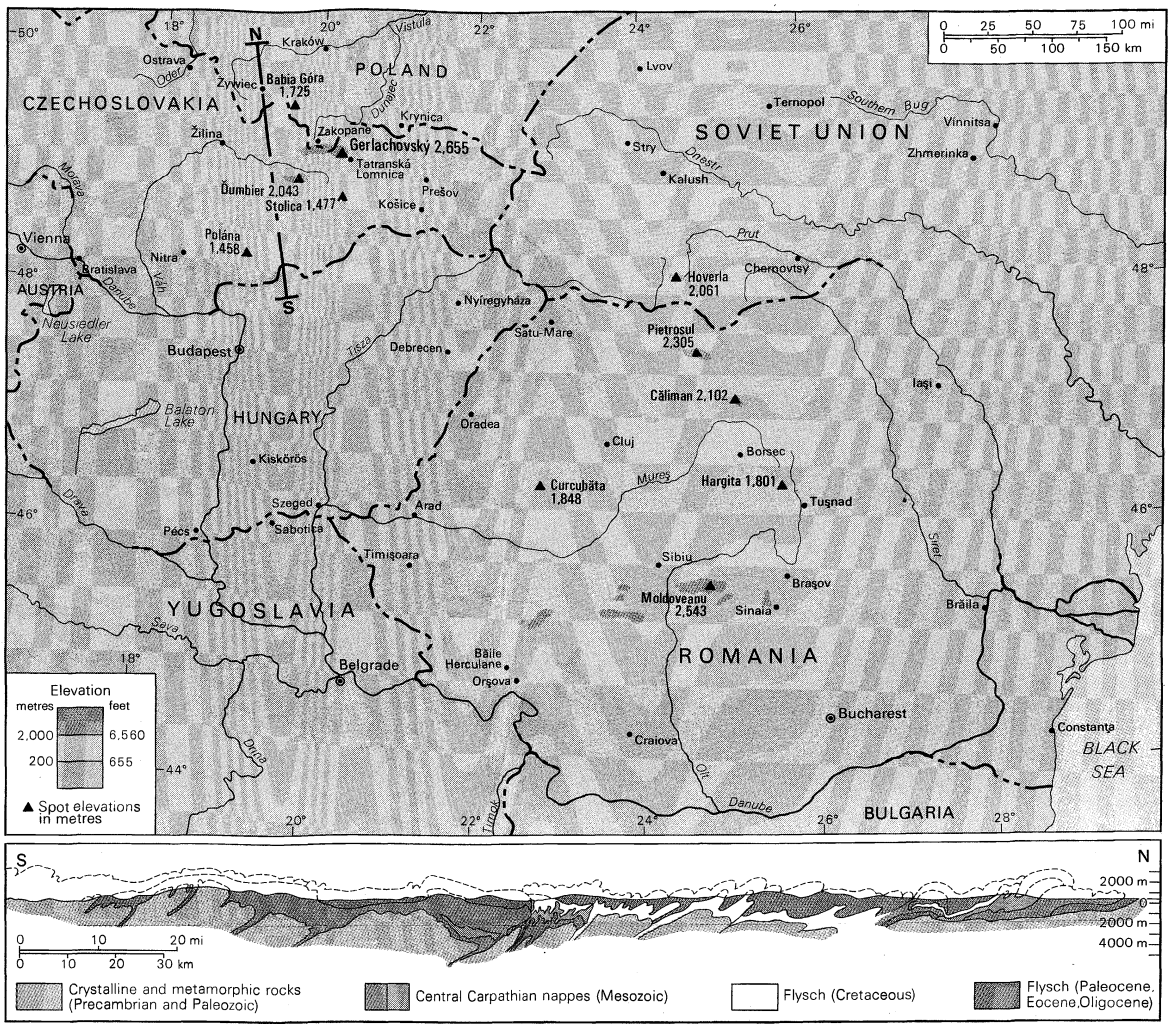
The Carpathians are a young European mountain chain forming the eastward continuation of the Alps. From the Danube Gap, near Bratislava, Czechoslovakia, they swing in a wide arc, some 900 miles (1,450 kilometres) long to near Orşova, Romania, at the portion of the Danube Valley called the Iron Gate. These are the conventional boundaries of these arcuate ranges, although, in fact, certain structural units of the Carpathians extend southward across the Danube at both sites mentioned. The true geological limits of the Carpathians are, in the west, the Vienna Basin and the structural hollow of the Leitha Gate in Austria and, to the south, the structural depression of the Timok River in Yugoslavia. To the northwest, north, northeast, and south, the geological structures of the Carpathians are surrounded by the sub-Carpathian structural depression separating the range from other basic geological elements of Europe, such as the old Bohemian Massif and the East European Platform. Within the arc formed by the Carpathians are found the depressed Pannonian Basin, composed of the Little and the Great Hungarian Plain, and also the relatively lower mountain and hill zone of Transdanubia, which separates these two plains. Thus defined, the Carpathians cover some 80,000 square miles (200,000 square kilometres).

Although a counterpart of the Alps, the Carpathians differ considerably from them. Their structure is less compact, and they are split up into a number of mountain blocks separated by basins. The highest peaks, Mt. Gerlach in the Carpathians (8,711 feet [2,655 metres]) and Mont Blanc in the Alps (15,771 feet [4,807 metres]), differ greatly in altitude, and in average elevation the Carpathian mountain chains are also very much lower than those of the Alps. Structural elements also differ. The sandstone–shale band known as flysch, which flanks the northern margin of the Alps in a narrow strip, widens considerably in the Carpathians, forming the main component of their central zone, whereas the limestone rocks that form a wide band in the Alps are of secondary importance in the Carpathians. On the other hand, crystalline and metamorphic (heat-altered) rocks, which represent powerfully developed chains in the central part of the Alps, appear in the Carpathians as isolated blocks of smaller size surrounded by depressed areas. In addition to these features, the Carpathians contain a rugged chain of volcanic rocks.

Similar differences can be observed in the relief of these two mountain systems, notably in the way that the destructive processes of erosion have occurred. The relief forms of the Alps today result for the most part from the glaciations of the last Ice Age. These affected practically all mountain valleys and gave them their specific relief character. In the Carpathians glaciation affected only the highest peaks, and the relief forms of today have been shaped by the action of running water.

HISTORY OF SCIENTIFIC STUDY

Many nationalities are in contact with each other in the Carpathians, and this has had its effect on the develop-



Regional division of the Carpathian Mountains and a geological cross section of the Western Carpathians. The location of the cross section is shown by the line N-S on the map.

ment of scientific research in the region. From the end of the 18th century until World War I, most of the Carpathians were within the boundaries of Austria-Hungary; and throughout this long period the Carpathians were readily accessible to all scientists of this multinational empire, the work of Polish scientists, together with that of Germans and Hungarians, being most noteworthy. In the late 19th century the Austrian general staff published the first comprehensive topographic map of the region. A century later, each of the countries whose territory covered part of the Carpathians—Czechoslovakia, Poland, Romania, Hungary, and the Soviet Union—had at hand

Mapping

new topographic maps drawn to a scale of 1:50,000 and 1:200,000—compiled on the basis of a coordinated geodetic system and in a mutually correlated sheet pattern.

As for geological maps, the first paper dealing with the geology of the Carpathians as a whole was published in 1815. Today, each of the Carpathian countries has its own general geological maps, and there is also abundant regional geological literature. In 1922 the International Geological Congress created an association of Carpathian geologists, which met every three years thereafter. Regional research in physical geography is also well advanced, and in 1963 a geomorphological committee for the Carpathians and the Balkans was established.

Studies in human geography

Research is somewhat less advanced in climatology and biogeography, although a number of papers began to appear in the second half of the 20th century. In human geography much attention has been given to the problems of pastoral life and associated population movements. By 1970 no synthetic survey of the economic geography of the whole Carpathians had appeared as economic problems were being studied separately in each of the countries involved. Indeed, the only comprehensive geographic account of the Carpathians as a whole remains that published in 1895 by the Polish geographer Antoni Rehman.

By the 1970s the Carpathians had become the object of research by a number of scientific centres in the countries involved, with the geographic institutes of the several national academies of sciences and the geographic and natural history institutes of various universities playing a leading role. National geological institutes and institutes of hydrology and meteorology also amassed a considerable body of information.

STRUCTURE AND RELIEF

The Carpathians extend in a geological system of parallel structural ranges. The Outer Carpathians—whose rocks are composed of flysch—run from near Vienna, through Moravia, along the Polish-Czechoslovak frontier, and through the Western Ukraine into Romania, ending in an abrupt bend of the Carpathian arc north of Bucharest. In this segment of the mountains, a number of large structural units of nappe character (vast masses of rock thrust and folded over each other) may be distinguished. In the eastern part of the outer Carpathians, this fringe is formed by the Skole Nappe, and in the western part it is formed by the Silesian Nappe, both of which are split by the longitudinal central Carpathian depression. Overthrust on the Silesian Nappe is the Magura Nappe, the counterparts of which in the east are the Čorna Hora and the Tarcău nappes.

The Inner Carpathians consist of a number of separate blocks. In the west lies the Central Slovakian Block; in the southeast lie the East Carpathian Block and the

South Carpathian Block, including the Banat and the East Serbian Block. The isolated Bihor Massif occupies the centre of the Carpathian arc. Among the formations building these blocks are ancient crystalline and metamorphic cores onto which younger sedimentary rocks—for the most part limestones and dolomites of the Mesozoic Era (about 70,000,000–185,000,000 years ago)—have been overthrust.

The third and innermost range is built of young Tertiary volcanic rocks formed less than 50,000,000 years ago, differing in extent in the western and eastern sections of the Carpathians. In the former they extend in the shape of an arc enclosing, to the south and east, the Central Slovakian Block; in the latter, they run in a practically straight line from northwest to southeast, following the line of a tectonic dislocation, or zone of shattering in the earth's crust, parallel with this part of the mountains. Between this volcanic range and the South Carpathian Block, the Transylvanian Basin spreads out, filled with loose rock formations of young Tertiary age.

The Central Slovakian Block is dismembered by a number of minor basins into separate mountain groups built of older rocks, whereas the basins have been filled with younger Tertiary rocks.

In Romania, orogenic, or earth-building, movements took place along the outer flank of the Carpathians until the end of the Tertiary Period (less than 10,000,000 years ago), producing foldings and upheaval of the sedimentary rocks of the sub-Carpathian depression; the result was the formation of a relatively lower range called the sub-Carpathians adjoining the true Carpathians.

Relief forms

The relief forms of the Carpathians have, in the main, developed during young Tertiary times. In the inner Carpathians, where the folding movements ended in the Upper Cretaceous Period (about 70,000,000–100,000,000 years ago), local traces of older Tertiary landforms have survived. Later earth-building movements have repeatedly heaved up this folded mountain chain, leaving a legacy of fragmentary flat-topped relief forms situated at different altitudes and deeply incised gap valleys, which often dissect the mountain ranges. In this way, for example, the gap sections of the Danube and of some of its tributaries—the Váh, the Hernad, and the Olt—developed.

The last Ice Age affected only the highest parts of the Carpathians, and glaciers were never more than a few miles long, with a maximum of up to 9 miles (14 kilometres) in the Tatras, where the line of eternal snow ran at 5,000 feet above sea level.

HYDROLOGY

The water runoff from the Carpathians escapes for the most part into the Black Sea. The great curve of the mountain chain abuts in the south upon the Danube; in the east it is flanked by a tributary of the Danube, the Prut River, and farther on by the Dnestr River tributary to the Black Sea. Only the northern slope of the Carpathians, mostly in Poland but partly in Czechoslovakia, is linked to the Baltic Sea by the drainage basins of the Vistula and (in part) Oder rivers. Thus, some 90 percent of the surface of the Carpathians drains to the Black Sea and only about 10 percent to the Baltic. Larger rivers originating in the Carpathians include the Vistula and the Dnestr and the following Danube tributaries: Váh, Tisa, Olt, Seret, Prut. The Carpathian rivers are characterized by a rain–snow regime; high-water periods occur in the spring (March–April) and in summer (June–July), with the latter usually more powerful. Often these floods

Flood peril

assume catastrophic dimensions caused by the poor ground retention of the rainfall. There has been an urgent need for the construction of storage basins, work on which was initiated on a large scale in the decades following World War II. None of the contemporary Carpathian storage basins are of great size. Among the largest are a basin in the Bistrita Valley in Romania, dam 416 feet high, capacity about 35,320,000,000 cubic feet; a basin in the San Valley in Poland, dam 262 feet high, capacity 17,660,000,000 cubic feet; and a basin in the Orava Valley in Czechoslovakia of 12,362,000,000-cubic-foot capacity. Altogether there are some 50 storage basins in the Carpathians. Natural mountain lakes are relatively rare, and all of them are small. Although there are some 200 lakes, their total surface is barely 1.5 square miles. The high-mountain lakes are mainly of glacial origin.

CLIMATE

The situation of the Carpathians, on the boundary line between western and eastern Europe, is reflected in the features of their climate, which in winter is governed by the inflow of polar–continental air masses arriving from the east and northeast, while during other seasons oceanic air masses from the west predominate. The distance from the Atlantic Ocean (from 620 to 1,240 miles) and the influence of the intervening masses of the Alps, the Dinarian Mountains, and the Bohemian Massif cause diminished precipitation in the Carpathians. The Carpathians thus possess certain features of a continental climate, although from the viewpoint of relief they constitute a sort of island amid the surrounding plains, where the climate is much drier. The continentality of the climate is clearly seen in the intermontane depressions, however, as well as on the lower parts of the southern mountain slopes. In winter, temperature inversion, or the retention of very cold air in low depressions while the mountaintops show relatively high temperatures, is a common occurrence throughout the Carpathians. In some depressed areas, notably in the Transylvanian Basin, the total annual precipitation is below 24 inches (600 millimetres), while precipitation in the mountains at 2,600 feet (800 metres) above sea level is about 47 inches (1,200 millimetres) and on the highest massifs it reaches 63 to 71 inches (1,600–1,800 millimetres). The mean annual and monthly air temperatures vary according to altitude above sea level, but by no means at constant rates.

For the Polish part of the Carpathians, a series of climatic types and stages has been distinguished; and with slight modification, these may be applied to the whole Carpathian mountain range (see Table 1).

Table 1: Climatic Stages of the Western Carpathians

type	stage	mean annual temperature °F	mean annual temperature °C	average altitude limits (above sea level) ft	average altitude limits (above sea level) m
Nival	cold	25	−4	8,710	2,655
Nival-pluvial	temperate cold	28	−2	6,070	1,850 (1,670)*
	very cool	32	0	5,080	1,550 (1,400)*
	cool	36	2	3,600	1,100
Pluvial-nival	temperate cool	39	4	2,300	700
	temperate warm	43	6	820	250
	mountain foreland	46	8	under 820	under 250

*The figures in parentheses refer to the Outer Carpathians.

VEGETATION AND ANIMAL LIFE

Different vegetation stages may also be distinguished for the various altitudinal zones of the Carpathians. These are given in detail in Table 2. The alpine stage is characterized by high mountain pastures, the subalpine by dwarf-pine growth, the upper forest stage by spruce, and the lower forest stage by beech. The foreland stage is noted for oaks and elms. The natural vegetation stages are matched by stages of economic land use: the foreland by rye and potato growing, the lower forest stage by oats and potato growing (up to 3,280 feet), and the upper forest stage and the subalpine stages by pastoral life.

The plant life of the Carpathians contains many unique species, especially in the southeastern part of the mountains where the effect of Quaternary climatic cooling was less marked. Forests have been best preserved in the eastern part of the Carpathians, and here the animal life includes bears, wolves, lynx, deer, boars, and, in the highest parts (in the Tatras), chamois and marmots.

REGIONAL DIVISIONS

Taking into consideration surface relief, geological structure, climate, and vegetation as noted above, regional divisions of the Carpathians may be discerned.

Table 2: Vegetation Stages of the Carpathians
(feet [metres])

stages	Western Carpathians		Eastern Carpathians	Southern Carpathians
	Outer	Inner		
Nival	—	up to 8,710 (2,655)	—	—
Alpine	up to 5,660 (1,725)	up to 7,200 (2,200)	up to 6,600 (2,000)	up to 8,344 (2,544)
Subalpine	up to 5,480 (1,670)	up to 5,900 (1,800)	up to 6,070 (1,850)	up to 7,200 (2,200)
Upper forest	up to 4,600 (1,400)	up to 5,080 (1,550)	up to 5,080 (1,550)	up to 5,900 (1,800)
Lower forest	up to 3,770 (1,150)	up to 4,100 (1,250)	up to 4,100 (1,250)	up to 4,900 (1,500)
Foreland	up to 1,800 (550)	up to 2,300 (700)	up to 2,000 (600)	up to 2,800 (850)

Generally speaking, the Carpathians have been divided into the Western and the Eastern Carpathians, the latter also called—probably more accurately—the Southeastern Carpathians. There are marked differences between these parts. The Western Carpathians show a clearly marked zoning in geological structure and relief forms, and the highest elevations occur in the central part of this province, in the Tatras and the Lower Tatras. The geological structure of the inner part of the Western Carpathians is marked by a break running from the east and the south along a line of dislocation in the earth's crust. Along this line, masses of volcanic rocks have been piled up surrounding the Central Western Carpathian Block in a wide arc, with its convex side turned eastward. The boundary between the Western and the Southeastern Carpathians occurs at the narrowest part of the mountain range, marked by the valley of the River San to the north, the Łupków Pass (2,100 feet) and the Laborec Valley to the south. Here the Carpathians are only some 75–80 miles wide, while in the west they are 170 miles and in the east as much as 220–250 miles across.

The Southeastern Carpathians are formed by a triangular block of mountains surrounding a basin. The three mountain formations concerned differ in origin and structure. The Eastern Carpathians, running in a northwest to southeast direction, include the flysch band, which represents the continuation of the Outer Western Carpathians, and also an inner band of crystalline and volcanic rocks. In contrast, the Southern Carpathians, running in an east–northeast to west–southwest direction, consist, in the main, of metamorphic rocks. The Bihor (Apuseni) Massif is also of metamorphic rock but is covered with older sediments.

The extent of these Carpathian regions and their subdivisions are as given in Table 3. The Outer Western Carpathians are generally of low altitude; the highest elevation is Babia Góra (5,658 feet [1,725 metres]) in the Beskid Range, straddling the borders of Poland and Czechoslovakia. On the Polish side, a national park has been established. A considerable part of the Outer Western Carpathians lacks a truly mountainous landscape and rather resembles a hilly plateau elevated to 1,300–1,600 feet above sea level.

Table 3: Subdivisions of the Carpathians

	approximate area	
	sq km	sq mi
Western Carpathians	68,000	26,000
Outer Western Carpathians	27,500	10,500
Central Western Carpathians	15,500	6,000
Inner Western Carpathians	25,000	9,500
Southeastern Carpathians	131,000	50,500
Outer Eastern Carpathians	35,500	13,500
Inner Eastern Carpathians	21,250	8,000
Southern Carpathians	28,250	11,000
Transylvanian Plateau	28,500	11,000
Bihor Massif (Apuseni Mountains)	17,500	7,000

The Tatras

The Central Western Carpathians consist of a series of isolated mountain ranges separated by structural depressions. Highest among them are the Tatras (Gerlach, 8,711 feet [2,655 metres]), exhibiting a typical high-mountain glacial relief with ice-scoured (cirque) lakes and waterfalls. This highest Carpathian massif is built of crystalline (granite) and metamorphic rocks, but the northern part contains, upthrust from the south, several series of limestone rocks with associated karst, or water-incised, relief forms. On both the Polish and Slovakian side national parks have been established. South of the Tatras, separated by the Liptov and Spiš basins, run the parallel Lower Tatras, similar in geological structure but lower (Ďumbier Peak, 6,703 feet [2,043 metres]) and with a less conspicuous glacial relief. Along the boundary line between the Outer and the Central Western Carpathians extends a narrow strip of klippen (limestone) rocks, which, north of the Tatras, has developed into the small but very picturesque Pieniny mountain group. Here, a narrow and sharply winding gap valley has been incised by the Dunajec River, a tributary of the Vistula.

The Inner Western Carpathians are lower and more broken. The principal mountain groups here are the Slovak Ore Mountains (Slovenské Rudohorie), with Stolica (4,846 feet [1,477 metres]) as the highest peak; they are built of metamorphic rocks and of sedimentaries of the Paleozoic Era more than 250,000,000 years old. Also found here are tableland areas of Mesozoic limestones, about 150,000,000 years old, which contain such large caves as the Domica-Aggtelek Cave on the Slovak–Hungarian boundary, which is 13 miles long. Mountain groups of volcanic origin are important in this part of the Carpathians; the largest among them is Polána, 4,783 feet (1,458 metres).

Compared with the Outer Western Carpathians, the Outer Eastern Carpathians, which are their continuation, are higher and show a more compact banded structure. The highest mountain group is Czarnohora (Čorna Hora) on the Ukrainian side, with Hoverla (6,762 feet [2,061 metres]) as the highest peak. The Inner Eastern Carpathians attain their highest altitude in the Rodnei Mountains in Romania; they are built of crystalline rocks and reach a peak in Pietrosul (7,562 feet [2,305 metres]). In this range, some 248 miles long, extinct volcanoes have, to some extent, kept their original conical shape. The highest peaks of these mountains are Călimăn (6,896 feet [2,102 metres]) and Hargita (5,909 feet [1,801 metres]). Fringing the true Eastern Carpathians runs a rather narrow zone called the sub-Carpathians which is made up of folded young Tertiary rocks superimposed on the sub-Carpathian structural depression.

The Southern Carpathians culminate in the Făgăraş Mountains (highest point Moldoveanu, 8,343 feet [2,543 metres]), which show Alpine-type relief forms. The western part of the Southern Carpathians, that is, the Banat Mountains and the mountains of east Serbia (which, at the Iron Gate, are split apart by the gap valley of the Danube), do not exceed an altitude of 5,000 feet.

The Bihor Massif (the Apuseni Mountains), which occupies an isolated position inside the Carpathian arc, features widespread flat summit plains bordered by narrow, deep-cut valleys. The highest peak is Curcubăta (6,063 feet [1,848 metres]).

Finally, mention should be made of the Transylvanian Plateau. This is made up of poorly resistant young Tertiary rocks and characterized by a forestless hilly landscape with elevations of 1,500 to 2,300 feet above sea level; the valleys are cut to depths of 325 and 650 feet.

HUMAN GEOGRAPHY

The Carpathians are inhabited by some 13,000,000–14,000,000 people and have an average population density

of about 180 per square mile. The distribution of this population depends on natural land features and on socio-economic conditions; hence it is very much diversified. In the valleys between the mountains, and again on the northern slopes of the Western Carpathians, the population density locally exceeds 520 per square mile, while close by practically uninhabited mountain massifs are to be found. On the whole, the Southeastern Carpathians are less densely settled than the Western Carpathians, but here also marked aggregations of people occur in the valleys.

Nationalities

The western slope of the Western Carpathians is inhabited by Czechs, the northern slope by Poles, the entire central part of the Western Carpathians by Slovaks, and the southern portion by Hungarians. The northern part of the Eastern Carpathians, both its outer and inner sectors, is occupied by Ukrainians; but south of 47° latitude, a Romanian population predominates. Inside the arc of the Eastern Carpathians, and also partly on the Transylvanian Plateau, lives a compact island of Hungarian population, also some remnants of German colonists dating back from the Middle Ages. Finally, the southwestern margin of the Carpathians, beyond the Danube gap, is occupied by Serbs. Generally speaking, the greater part of the Western Carpathians and the northern part of the Eastern Carpathians is inhabited by a Slav population, and the southern part of both these Carpathian provinces, with the exception of the mountains of east Serbia, by Romanians and Hungarians.

In the 13th and 14th centuries Romanian shepherds, wandering with their flocks, moved along the Carpathians into what is today Ukrainian, Slovakian, and Polish territory, and traces of this penetration have survived in geographic nomenclature and in economic methods and also in types of buildings, garments, and customs, although by the second half of the 20th century many of the latter were gradually disappearing. In general outlines, but by no means in detail, the diversity in nationality coincides with today's pattern of the political boundaries.

Economic development

From an economic point of view, the Carpathians are a region of agriculture and forestry, with industry in an early stage of development. Agriculture flourishes on the Transylvanian Plateau, in intramontane basins, and on lower parts of the mountains, up to some 3,000 feet elevation. On the northern slope rye, oats, and potatoes predominate; on the southern slopes maize, sugar beets, grapes, and tobacco are grown. Above 3,000 feet elevation forestry and pastoral life are the rule. Natural gas, found mainly on the Transylvanian Plateau, is important among natural resources. Oil is also significant; the richest deposits lie in the Romanian sub-Carpathians, with an annual production by the 1970s of 12,000,000–14,000,000 tons. Brown coal is found in low-lying areas of the Western Carpathians in Czechoslovakia and Hungary, and some bituminous coal is mined in the Romanian Southern Carpathians. Also noteworthy are the rock salt beds of the Transylvanian Plateau, the Romanian sub-Carpathians, and the base of the Polish Carpathians, and the potassium salts found at the base of the Ukrainian Carpathians. Iron ores, ores of non-iron metals, and gold and silver ores were intensively mined in the Middle Ages in the Bihor Massif and in the Slovakian Western Carpathians, but today all these deposits are of minor importance.

Larger industrial centres are Bratislava, the capital of the Slovak Republic, with a 1970 census population of 283,539 and a thriving machinery and a petro-chemical industry; and Košice, the principal town of eastern Slovakia, with a population of 145,027 and a modern steel mill. Prominent in Romania are Cluj, which, with some 170,000 people, is the principal town of the Transylvanian Plateau, concentrating on machinery making and chemical and food products; Braşov, situated in a basin near the boundary between the Western and Southern Carpathians, a town of over 140,000 people where machine production predominates; and Sibiu, about 100,000 in population, lying between the Transylvanian Plateau and the Southern Carpathians. In none of the remaining towns, however, did the population exceed 50,000 by the early 1970s.

TRANSPORT

The historical legacy

The railway network of the Carpathians came into existence in the latter half of the 19th century and the beginning of the 20th, at a time when most of the mountains were in Austria-Hungary. In this period the nodal point was Budapest, situated in the centre of the Carpathian arc. The principal railway lines were laid out radially from Budapest across the various mountain passes and were tied in with the important longitudinal west–east railway track running along the northern flank of the Carpathians—the link between Vienna (by way of Ostrava, Kraków, and Lvov)—with Chernovtsy, which then was also situated in Austria. This northern trunk line had its continuation in the sub-Carpathian Romanian railway line running toward Bucharest, and, farther on, by way of Craiova to Orşova, which, in turn, was linked by a Hungarian railway section with Budapest and thus with Vienna also. After the Austro-Hungarian Empire had collapsed, this system lost much of its economic and strategic importance. Within its boundaries the new state of Czechoslovakia started to build longitudinal west–east railway lines. For Romania, on the other hand, which had been allotted Carpathian Transylvania, the previously neglected lines became highly important. To some extent, a change in this pattern came about after World War II, when the northern part of the Eastern Carpathians and Trans-Carpathian Ukraine became part of the Soviet Union. The railway lines crossing this part of the Carpathians became arteries linking the Soviet Union, Czechoslovakia, and Hungary. Although the lines between Poland and Slovakia lost most of their importance in passenger and freight transport, truck routes, utilizing the Dukla (1,640 feet [500 metres]), Jablonka, and other passes, became significant in freight traffic between Poland and the countries south of the Carpathians.

The Ukrainian Carpathians are crossed by railway lines utilizing the Užok Pass (2,916 feet [889 metres]) and the Lavochne and Woronienka passes, while in the Romanian Carpathians the railways run through passes at Ghimeş, Oituz, Predeal (3,390 feet [1,033 metres])—the gap valley of the river Olt—and by the low pass of "Porta Orientalis."

By the early 1970s the most important Carpathian railway lines had been electrified, although the Budapest–Vienna line was electrified before World War II.

TOURISM

The Carpathians play an important role in fulfilling the needs of tourism and recreation, especially for the people of Poland, Czechoslovakia, Hungary, and Romania. By the 1970s, international tourist travel was less developed, although there were a number of regions and sites attractive to visitors from abroad. Most important among these were Zakopane, a centre of sport activities, tourism, and recreation, situated in Poland north of the Tatras. On the Slovak side of the Tatras, a similar role is played by a number of localities, notably Tatranská Lomnica, Smokovec, and Štrbské Pleso. Based on a tourist travel agreement between both countries, passes valid for both sides facilitate access by citizens of both countries to the entire Tatra Massif. In Romania the outstanding centre for winter sport and tourism is Sinaia, situated in the Prahova Valley, at the dividing line between the Eastern and Southern Carpathians.

The Carpathians are noted for their abundance of watering places with mineral springs of high therapeutic value. Among the best known Carpathian health resorts, which are also of international repute, are Krynica in Poland, Piešťany in Czechoslovakia, and Borsec, Băile Herculane, and Tuşnad in Romania.

Carpentaria, Gulf of

The Gulf of Carpentaria is a shallow, rectangular embayment of some 120,000 square miles (310,800 square kilometres) on the northeast coast of Australia. During the 1960s and early 1970s, following centuries of existence as a vast but unimportant backwater, the gulf suddenly became of international significance with exploitation of its aluminum, manganese, and prawn (shrimp) resources; its shore-living population increased from a mere handful to some thousands, and revolution was taking place in the communications with Australia and the world.

Boundaries

The gulf floor is made up of the continental shelf common to Australia and New Guinea. The greatest water depth (230 feet [70 metres]) is found in the northeast of the gulf, although, in the same region, a ridge with water depths of less than ten metres extends across Torres Strait, separating the floor of the gulf from the Coral Sea of the Pacific Ocean. To the northwest, a ridge extending northward from Wessel Island, with water depths of less than 182 feet (55 metres), separates the floor of the gulf from that of the Banda Basin of the Arafura Sea. The gulf-floor gradient is very low; north of 21° S latitude the great western plains of Queensland drain north or northwestward, across the shore and well out into the gulf, in a very gentle fall of only one foot per mile. As the plains approach the sea, they merge into a belt of salt flats, which reach their widest extent—some 20 miles (32 kilometres) across—just west of the Flinders River. About 20 rivers drain into the gulf; they wind profusely in their lower courses and have extensive deltas.

Historical and scientific associations. The eastern side of the gulf was first explored by the Dutch, between 1605 and 1628, and the southern and western coasts were discovered by the explorer Abel Tasman in 1644. The gulf was named after Pieter Carpenter, who visited the area in 1628. The first chart was prepared by Matthew Flinders in 1802, and supplementary data were added by Captain J.L. Stokes in HMS "Beagle" in 1841. In the later stages of the 20th century, there was remarkable activity in the exploration of the bauxite and manganese deposits on the shores and islands of the gulf, and also of its prawn resources. A search for petroleum had not achieved success by the early 1970s. The Royal Australian Navy hydrographic survey ship HMAS "Moresby" completed a detailed survey of the gulf in 1969.

Geological background. The gulf lies on the northern, central, and western half of the Carpentaria Basin—itself a northern subbasin of the Great Artesian Basin—of the Mesozoic Era (about 200,000,000 years ago). The Mesozoic sedimentary rocks, which lie on a basement of very old Precambrian rocks, are some 5,000 feet (1,500 metres) thick. They are made up of rock layers of both terrestrial and marine origin and thicken gradually toward the middle of the gulf. A substantial period of uplift and erosion followed the withdrawal of the sea at the beginning of the Upper Cretaceous Period, about 130,000,000 years ago, and the 1,968 feet (600 metres) of sediments subsequently deposited are again terrestrial. These later rock layers, about 50,000,000 years old, have, at least on the shores of the gulf, given rise to layers of bauxite up to 33 feet (10 metres) thick. Overlying these deposits, on the Wellesley and Sir Edward Pellew islands, are beds of sandstone that may represent a higher stand of sea level than that of today. The latest sediments below the waters of the gulf are at most 15 feet (4.5 metres) thick. A white clay is found solely in the western portion, but there and elsewhere layers of a younger, dark-gray to chocolate-coloured clay and fine silt are overlain by a green marine mud. The latter may have been deposited since the rise in sea level at the end of the Pleistocene Epoch, which initiated the gulf as a marine feature.

Mineral deposits

The huge manganese deposits, which, by the 1970s, were being developed by Broken Hill Proprietary Limited on Groote Eylandt, in the west of the gulf, appear to have been formed along an irregular shoreline of an ancestral gulf. Equally vast bauxite deposits also were being exploited at Weipa, on the Cape York Peninsula, and at Gove Peninsula, in Arnhem Land.

Hydrology and water composition. The salt pans of the southeastern gulf shores are the result of complexly interacting factors. In the extreme north, the tides are resolved into one normal and one very small tide each day; farther south the small tide diminishes until, around two-thirds of the Queensland shores, there is in effect only one tide a day, with a rise for most of the year of from four to six feet. In summer there are three very important changes; the monsoonal rains come (between December and March, with a 40-inch fall at the coast), the winds change from southeasterly offshore to northwesterly onshore, and the tidal amplitude increases to an average of 18 feet. With these conditions of very flat land drainage, monsoonal rain, onshore piling up of the sea by wind, and magnified amplitude of the tide, the salt pan area is submerged by the sea, and behind it the land area is submerged by the drainage water backing up the blocked estuaries. The junction of saltwater and freshwater floods is marked by the transition from bare salt pan to vegetated plains.

The composition of the waters of the gulf, at any one time, is governed by the relative proportions of three major water masses. The first mass is of low salinity, low nitrate and phosphate content, and relatively high temperature (79° F [26° C]). It is formed during summer monsoonal conditions off the western coast of New Guinea, to the north. By March and April this drifts into the northern gulf region but is driven back out again by August by the southeast trade winds. The second water mass is of high salinity, low nitrate and phosphate content, and high temperature (77.9° F [25.5° C]). This originates in the Coral Sea, to the east, and moves through the Torres Strait into the gulf after May. Spreading south along the eastern side, it evaporates and cools, displacing the first mass and mixing with it as it spreads westward. The third mass is of medium salinity, but high nitrate and phosphate content, and is made up of relatively cooler water (68°–72° F [20°–22° C]), with oxygen saturation less than 50 percent. This derives from the northwest, specifically from the subsurface (330–495 feet [100–150 metres]) waters of the Banda Sea, but during its spreading eastward increases considerably in nutrient content, while decreasing in oxygen. Upwelling of the water at the surface of the gulf probably occurs only in restricted areas, where the shelf depth is less than about 16 feet.

Marine life and resource development. By the early 1970s, prawn fishing had developed rapidly. Processing is done in specially equipped ships and, on shore, at Karumba Groote Eylandt and Thursday Island. Banana prawns are the major catch. Because of their habit of coming together in large schools known as prawn boils, in which the bottom mud is churned up, banana prawns can be easily located from the air or by echo sounders. Catches have fluctuated during the few years of operation, and the scientific work necessary before the industry can be regulated is now being done by the Council for Scientific and Industrial Research, Department of Fisheries and Oceanography.

As a result of these important economic developments, settlement increased on the shores and islands surrounding the gulf, and a start was made in improving the transport and communication links with the rest of Australia and with the world economy (see also QUEENSLAND).

(D.Hi.)

Carpentry

Carpentry is the art and trade of cutting, working, and joining timber. This term includes both structural timberwork in framing and items such as doors, windows, and staircases. The working of wood in buildings is an ancient craft and still comprises one of the most important activities in construction work.

In the past, when buildings were often wholly constructed of timber framing, the carpenter played a considerable part in building construction; along with the mason he was the principal building worker. The scope of the carpenter's work has altered, however, with the passage of time. Increasing use of concrete and steel construction, especially for floors and roofs, means that the carpenter plays a smaller part in making the framework of buildings, except for houses and small structures. On the other hand, in the construction of temporary formwork and shuttering for concrete building, the carpenter's work has greatly increased.

Nature of wood

Wood (see also WOOD AND WOOD PRODUCTS), being a natural material, is not uniform in quality. Furthermore, whereas most building materials are subject to slight and fairly predictable changes in form caused by moisture and heat, timber, because of the large quantity of natural moisture present after its conversion into wood, is particularly vulnerable in this respect. Thus, the jointing and framing of wooden members in building work must be done carefully in anticipation of considerable and variable movements that may follow either absorption or loss of moisture.

Because wood is widely distributed throughout the world, it has been used as a building material for centuries; many of the tools and techniques of carpentry, perfected after the Middle Ages, have changed little since that time. On the other hand, world supplies of wood are shrinking, and the increasing cost of obtaining, finishing, and distributing timber has brought continuing revision in traditional practices. Further, because much traditional construction wastes wood, engineering calculation has supplanted empirical and rule-of-thumb methods. Stress grading of timber and mechanical joints (*i.e.*, grading materials in terms of the stresses they are capable of withstanding; see MATERIALS TESTING) and the development of laminated timbers such as plywood have also simplified and lowered the cost of carpentry.

CARPENTERS' TOOLS

Nonpowered hand tools. Many of the nonpowered hand tools have been used in virtually the same form for centuries by carpenters, modified only by the improvement modern steel can give to cutting edges (see also HAND TOOLS).

Planes. Used for smoothing rough surfaces and for reducing wood to size, planes are made of wood or iron (the blade is steel) in a wide variety of sizes. Special plow, or grooving, planes are used for forming channels and grooves; a wide variety of planes was used for cutting special moldings in the past, but this work is now done entirely by machine, and special hand planes are used only to repair existing work.

Saws. Handsaws cut wood either with or across the grain. Tenon and dovetail saws are used for fine, accurate work, whereas the bow saw, keyhole saw, and pad saw cut curved surfaces or are used to form holes.

Chisels. For removing surplus wood or cutting special shapes, a wide variety of chisels is available. Although most chisels have flat blades, the gouge, with a semicircular blade, is used to hollow out rounded grooves.

Other nonpowered hand tools. Hammers, mallets, screwdrivers, bradawls, gimlets, pincers, and pliers are small tools used for making holes, fixing screws, and for driving and extracting nails. There exists also a large group of tools utilized to set out work and check it for truth and alignment. Included are the trisquare, for testing the right angle between adjacent surfaces; the bevel, for testing angles other than right angles and for marking lines inclined to the surface of the material; and gauges, for marking lines parallel to the surfaces of materials.

Powered hand tools. The principal advantage of powered hand tools is portability. Many tasks that would be cumbersome or time-consuming if performed on the site with ordinary hand tools or inconvenient to move to a workshop can be quickly and economically carried out with powered hand tools.

Electric hand drills. Probably the most versatile of all powered hand tools, the electric hand drill can be used for all kinds of drilling and forms a power unit that can be fitted to perform other tasks, such as sanding, polishing, rebating (cutting grooves), and molding. Most drills can be fitted to a bench so that work can be taken to them.

Portable saws. Circular in shape, these tools are powered handsaws. Their chief use is for making straight cuts, ripping (cutting with the grain), and crosscutting against the grain of wood at any angle. The portable saw has advantages not only on the job but also in the workshop, where it takes up less space than the fixed bench saw. Portable saws are equipped with a device called a fence to enable parallel cuts to be made. In the interests of both safety and accuracy, the wood is held securely during cutting. For circular and internal cutting the narrow-bladed jigsaw is used.

The router. Used for recessing, grooving, molding, and general shaping, the router can be used freehand or fixed with a jig, which controls the timber. The router works at very high speed and cuts the fibres cleanly, either with or against the grain. A high-speed circular tool of this kind requires careful control, however, to prevent drifting.

Automated power tools

Fixed power tools. Fixed woodworking machines have sped up output and reduced costs. Automated machines linked in series permit continuous operation for the reduction of large lumber to manufactured components. They are also used to produce furniture.

Circular bench saw. The vertical circular saw is mounted on a frame in a flat metal table. The blade runs in a slot in the table and is used for general cutting purposes, such as sawing planks and small scantlings (pieces of lumber used in frameworks), and for ripping, edging, and crosscutting. A fence mounted parallel to the saw is adjusted to keep the wood at the correct distance from the saw. Held against the fence and fed toward the revolving saw, the wood is kept under pressure until the cut is complete. A riving knife behind the saw keeps the cut open during sawing.

Band saw. Sometimes known as the band resaw, this device performs a wide variety of tasks in cutting lumber. Instead of a circular saw, the band saw employs a continuous flexible steel blade that passes over two pulleys placed one above the other. The diameter of the pulleys varies: for heavy work it is likely to be not less than 36 inches (90 centimetres) and may be 42 or 48 inches (105 or 120 centimetres) for exceptionally heavy work. The saw blade varies in width up to about one and one-half inches (38 millimetres) for the 36-inch pulley and up to two and one-half inches for the heaviest saws. The saw passes through a slot in a steel table about three by three feet (one by one metre) and is hand-fed.

Surface planer and thicknesser. Used to reduce timber to parallel thickness and to plane its surfaces, this device usually operates in one of two ways. Fixed-knife planing follows the principle of the hand plane, except that the wood is passed over the knife. Cutter-block, or rotary, planing is accomplished by passing the wood over a revolving block into which a number of cutters have been fixed.

Mortising machines. A mortise is a cavity, usually rectangular in shape, cut into a piece of timber to receive a tenon, or projection, from another piece of wood, to make a joint. The hollow mortise chisel consists of a hollow square chisel with the four sides sharpened at the cutting edge. An auger, or screw-shaped boring tool, re-

The mortise

volves through the length of the chisel and cuts away all but the corners of the mortise; these are removed by the sharp edges of the chisel. Another mortising machine is the chain cutter, in which the cutters are the links of an endless chain that is brought down onto the material and removes the wood from the mortise in a circular motion. Many machines are equipped for both methods and are operated by a hand lever.

Molding machines. To make trim and molding, sections of wood are passed over blades that cut out unwanted material. Such machines often employ more than one cutter for complicated molding, and thus, most have more than one set of cutter blocks. A spindle molder is used to form moldings on both straight and curved members and for such processes as planing, edging, and recessing. Dovetailing can also be carried out on spindle machines.

Sanders. The finishing of planed surfaces to high standards is done by sanding machines using sandpaper that revolves on a drum, belt, or disk over the surface to be smoothed.

JOINING

Types of joints. The object of a carpentry joint is to fix two pieces of wood together as strongly and unobtrusively as possible. There are a large number of joints in use; long experience with wood as a building material and with certain types of joints has tended to produce accepted patterns for the most commonly used items (see Figure 1). Practically all are based on handwork, for with few exceptions machine-made joints follow the traditional patterns. For their strength, most joints rely upon a combination of mechanical fit and glue, though some are solely dependent upon wedging or pinning and a few on gluing alone.

A joint is made in a thick portion of a member and should be easy to fabricate. If the joint relies on glue, the areas available for gluing are made as extensive as possible. If used out of doors, the joint is designed to resist dampness. Junctions are made as unobtrusive as possible so that, if shrinkage occurs because of moisture, the gap is not easily seen. Allowance is made for movement and tightening of the joint. For the sake of economy, joints are also designed to avoid wasting wood and to minimize the number of operations required for fabrication and assembly. Animal glue, applied hot, is widely used, but, because animal glue is brittle and is not waterproof, glues made of either casein or synthetic resins have been developed for greater strength and weather resistance.

Mortise and tenon joint. Used to join a horizontal with the vertical member of a frame, the mortise and tenon is one of the most common type of joints (see Figure 1A–C). A rectangular projection (tenon), usually a third of the total thickness of the member, is fitted into a rectangular cavity (the mortise) cut out of the other member, so there is enough timber at the top and bottom to enable wedges to be driven in to tighten the joint. A pin, dowel, or bolt may be used to secure the joint (Figure 1D). Where the vertical member (stile) does not continue past the horizontal member (rail) as in the top and bottom members of a doorframe, the tenon must be "haunched" (Figure 1A) to leave enough timber at the top of the stile for wedging. In cabinetwork and highly finished joinery, foxtail wedging, in which the end of the mortise is expanded to prevent withdrawal, may be used (Figure 1A). Here the wedging is "secret," or hidden; it is expensive and requires considerable skill in assembly, for, once the joint is made, it cannot be taken apart.

The tenon

In thick sections, as in heavy doors and frames, tenons are often doubled; in wide members, twin tenons may also be used. The principle is the same as for a single tenon, but the reduction in the size of the tenons offers more opportunities for wedging and less danger of twisting due to shrinkage. An alternative form of mortise and tenon, the dowelled joint (Figure 1E), is commonly used in factory made joinery and mass-produced fittings, such as built-in cabinets for houses.

Other types of joints. The dovetail joint (Figure 1F, G) is used to join two flat members together at right angles, as in drawer construction or at the corners of a bookcase. It may be cut by hand or machine. The rebated joint (Figure 1H) is easily made but not very strong. It is suitable for light construction: wooden boxes, for receiving the backing to fittings, and in small drawers. The housed joint (Figure 1I) is widely used in furniture and fitment construction; for example, to make the shelves in a bookcase. It is not mechanically strong, but it conceals the end grain of the housed member and provides support for light loads. For joining flat boards to form tabletops or similar large areas, edge-to-edge or butt joints are often used. These rely solely on the adhesion of the glue; to make the joint stronger, tongue (loose) or tongue-and-groove boards are used.

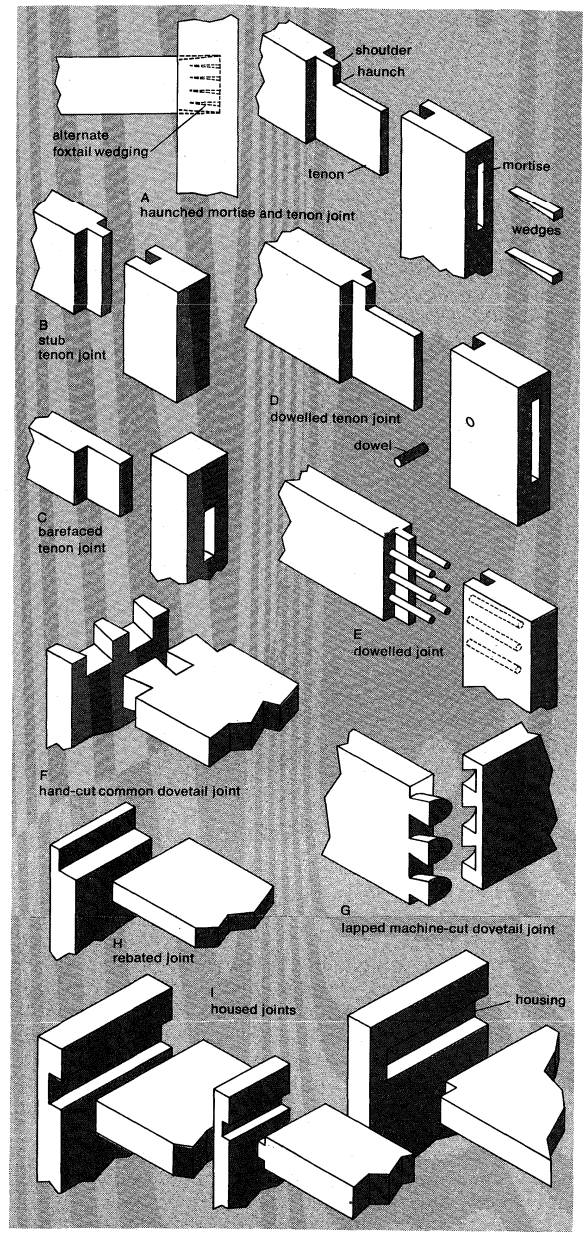

Figure 1: Basic timber joints (see text).

Preparation and assembly. A strong permanent framework must possess individual members of necessary strength joined together so that the inherent disadvantages of wood are minimized. Design is further complicated by the fact that, for the sake of stability, most frameworks are composed of many small members, each of which must be joined.

The frame and flat areas

In making a framework such as a door or a shelf, both the frame and the flat areas are considered. Four pieces of wood are joined to make a frame so that it will remain square with as little shrinkage as possible. Some-

times the corners are reinforced with screwed joints in slots to permit one member to move relative to another. Many flat areas, such as shelves, are small enough to be obtained from a single piece of wood. When two or more pieces are joined to make large flat areas, it is done so that each individual piece may move on its own, or the large area moves as one piece. The invention of laminated boards and plywood has greatly simplified the making of large flat areas because they minimize warping and shrinking.

Doors. The door is one of the most common joinery items. It may be made in several ways, all of which illustrate the main principles followed in framing (see Figure 2). The ledged and braced door (Figure 2A) is

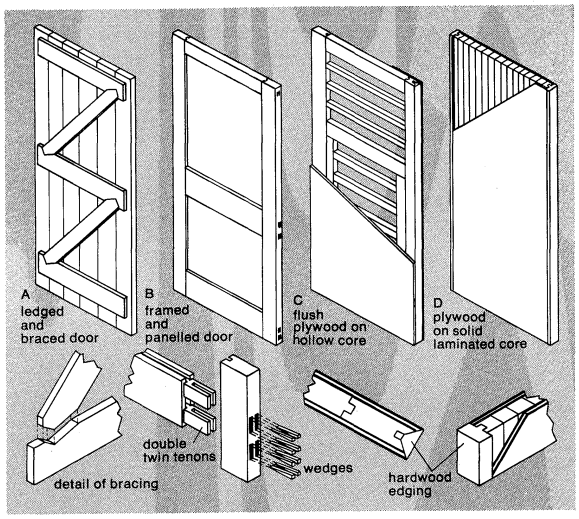

Figure 2: Door types, with details of construction (see text).

the simplest form, the covering usually being tongued-and-grooved boarding nailed to horizontal ledges. Braces keep the shape and prevent sagging. The framed and panelled door (Figure 2B) is the simplest form employing a framed construction. Its vertical members have tenons at each end to receive the horizontal rails, and they may be elaborated in various ways by addition of extra rails and panels. The latter may be filled with wood, glass, or other material.

The factory-produced flush door (Figure 2C, D) is usually made in two ways: a light frame is covered with a plywood skin, or a solid core is built up of narrow strips of softwood with a plywood covering. Both sides of a flush door form a continuous plane; *i.e.*, they are flat. Glass may be provided, as well as fixings for locks and handles. The edges of flush doors of either type are usually lipped with a hardwood strip.

Windows. Most windows consist of a fixed frame set into the wall of the building, within which are placed sashes that hold glass and may open as required, by side hinging, pivoting, or sliding up and down. Vertical sliding sashes must either be counterbalanced by weights or fitted with helical spring balances so they may be opened to a desired amount. The frame is jointed with either pinned or wedged mortise and tenon joints; damp-resistant glues are also employed. The usual fixing for the opening sash is by side hanging, but pivot hanging may be used, and the sash is then hinged at either side at its centre and can rotate horizontally. Windows are particularly vulnerable to changes in weather conditions because they are usually exposed to considerable variation in temperature and moisture on either face. Thus, weather checks (groove-shaped cuttings) are incorporated in the bottom rails of sashes and beneath sills to keep them from warping.

Staircases. Whether simple or elaborate, staircase design illustrates the principles of framing, especially in the precautions taken to resist the inevitable movement that occurs in the framing from the load and movement of persons ascending and descending. Steps are placed between strings, which are members inclined to the angle of the stairs that carry the main weight of the flight. The strings are framed into newel posts, vertical members of which also support a handrail. Each step consists of a tread (the horizontal member) and a riser (the vertical member). The horizontal distance travelled is known technically as the going and the vertical distance the rise. The string is trenched to receive the treads and risers, which are secured and tightened in the trenches by long wedges driven from the underside during assembly of the staircase. The wedging ensures that the treads and risers are securely held in the parallel strings. The risers are also housed into the treads and further secured by means of glued blocks in the angle between tread and riser. The handrail, spanning the newel posts, is supported on balusters, which may be of square or turned sections. Flush or panelled balustrades are also used.

OTHER CARPENTRY FUNCTIONS

Framing of buildings. The principal task of the carpenter at the building site is to cut and fix the timbers with such jointing as is necessary. Joints are made in different ways according to the use to which they are to be put and the stresses they must resist. Though specially designed timber connectors have replaced nails, especially in roof framing, wire nailing is still widely employed.

Platform and balloon framing. Timber-framed buildings are of two main types: platform (or Western) framing (Figure 3) and balloon framing. In platform

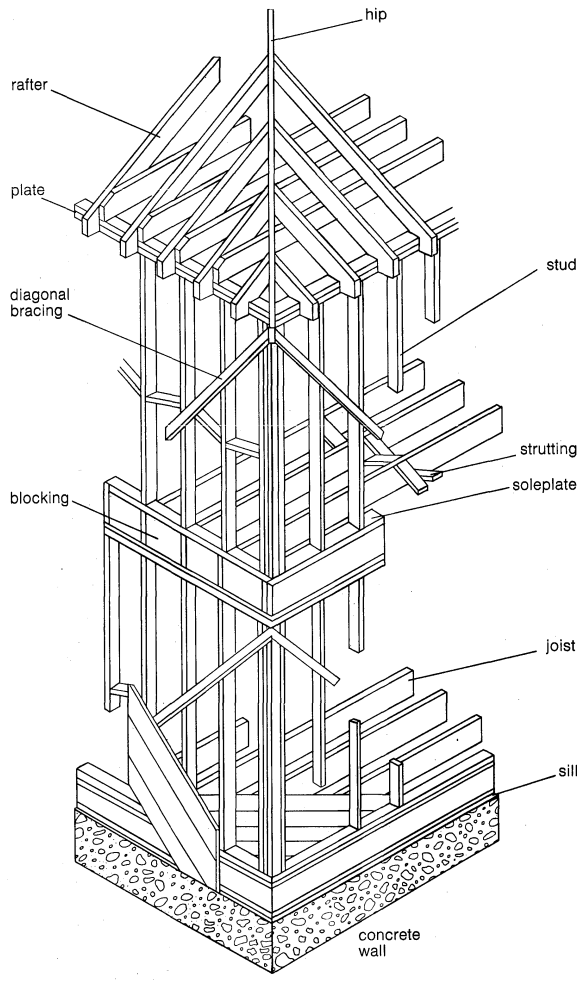

Figure 3: Western (platform) framing.

framing, floors are framed separately, story by story, then raised into place. Such construction provides fire stops for walls and partitions at each floor level. Each finished floor provides a working platform for construc-

tion of the next. In balloon framing, by contrast, the studs (vertical members) extend the full height of the building (usually two stories) from foundation plate to rafter plate.

The roof. The traditional pitched roof with various coverings (tiles, slates, shingles) still remains the most common method of covering small buildings. The framework for the roof is influenced in its design both by the weight and type of covering used and by the space covered. The weight of the roof covering is transmitted to the common rafters, key members in the design of the framing. Common rafters, usually placed about 16 inches (40 centimetres) apart from the eaves to the ridge of the roof, are generally timber of small cross section, either two by three or two by four inches (50 by 75 or 50 by 100 millimetres). In small roofs only the common rafter may be required, but as the length of the rafter increases it is necessary to provide support to prevent sagging. If suitable support can be found (on the cross wall or above partitions, for example), a support (purlin), running horizontally and at right angles to the rafters, is introduced at the midpoint of the rafter span. Light ceiling joists are also required; these span from wall to wall and are secured to the feet of the rafters.

The truss

Where no walls or partitions are available to give support to purlins or where a large clear span is required (as in a hall, for example), it is necessary to use a truss, which is an independent framed unit spanning from wall to wall on which the purlins can be carried. Traditional trusses use a large amount of timber and in consequence are very heavy. For these reasons, they are rarely used today, having been displaced by timber that is graded with respect to its ability to withstand given measured stresses. In consequence, much smaller members are now being used. Standard designs have been developed for various spans and slopes; the trussed rafter roof and the trussed purlin roof have entirely displaced the older and heavier trusses. By using specially laminated and formed beams and portal frames, it is possible to construct timber roofs of virtually any span. Such work, however, is outside the scope of what is normally understood by the term carpentry.

Timber-joisted upper floors. This familiar construction is used for light loads and small spans and, like the suspended ground floor, mainly for buildings of domestic scale and in conjunction with load-bearing brick walls. Joists (see Figure 3) are usually spaced 16 inches (40 centimetres) apart, and depth is selected according to the span, the joists being two inches (five centimetres) in thickness. Three-inch- (75-millimetre-) thick joists are used to carry extra loads. The joists are covered with hardwood or softwood planks and lined underneath with plaster, boarding, or other suitable finish. An ordinary timber floor of this type with three-fourths inch (19 millimetres) of plaster forming the ceiling is rated as fire-resisting for one-half hour. A longer fire-resistance rating, such as the two hours normally demanded for public buildings, will require a concrete floor of some kind. Published tables of joist sizes related both to span and spacing exist; these offer some economy in the amount of timber used. Alternatively, the floor may be designed in accordance with normal engineering practice for its special conditions and loadings. As the depth of a joist increases (with the span), cost of timber rises; it is not generally economical to increase the depth of timber joists over about nine inches (225 millimetres).

Joist sizes

If a span requires more than nine inches depth and will be covered with a timber-joisted floor, it is necessary to introduce an intermediate support in the form of a strengthened steel beam, thus reducing the size of the common joists. Herringbone strutting (bridging) is used to steady the joists against lateral movement whenever the length of the joist exceeds 50 times the thickness.

The joists in upper floors constructed of timber may be supported at the wall by means of pressed steel hangers, spiked to or notched over timber plates. Joists may also be built into the brickwork, in which case it is customary to rest them on a steel strip. Because upper floors are not normally ventilated, built-in timber is treated with a suitable preservative. Where chimneys pass through timber floors, a trimmed opening is formed to keep timber a safe distance from the flues.

Pipes and conduits. For convenience, water and gas pipes and electrical conduits are often run through the first floor; braces may be provided between the joists to support them. Wherever possible, pipes and conduits run parallel with the joists. If it becomes necessary to carry them through a joist, this is generally accomplished by boring through the centre of the joist.

Framed partitions. Framed timber partitions for subdivision of rooms have been in use for centuries, especially in houses. Partitions traditionally consisted of oak posts secured at the foot and head and plastered on both sides. This arrangement is still used today, except that the framing is normally of softer timber.

Usually constructed of light members, the timber frame consists of uprights or studs fixed by spiking, screwing, or mortise joints to headplates and soleplates. Intermediate horizontal members, called noggings, are also inserted for stiffening, for special fixings such as baseboards, or for carrying cupboards or fittings.

Determined by the nature of the job and by the dimensions of the covering to be used, spacing between the studs is likely to be about 18 inches (45 centimetres). In addition to lath and plaster or plasterboard covering, insulating fibreboards, plywood, hardboards, veneered boards, or plastic-impregnated sheeting may be used.

Siding materials

A number of materials are available for exterior wall covering (siding) of timber-framed buildings. The chief categories include wood, laid either horizontally or vertically; wood shingles and tiles; and plywood panels especially treated for external use. Fibreboard, hardboard, and particle board, usually covered with a laminated vinyl surface coating for protection and decoration, can also be employed.

Constructing concrete forms. Formwork is the term applied to all wooden molds used for the casting of concrete; its construction is a specialized branch of carpentry. Work may range from simple house slabs or walls to complicated structures such as reinforced-concrete framing for high-rise buildings, dams, silos, and engineering projects. Formwork must be designed to give adequate support to the weight not only of the concrete but also of the men placing it and the load of hand or mechanical ramming. In addition, formwork must be designed so that it can be erected, taken down, and if necessary reused during the progress of the work. The broad surfaces of forms are usually either plywood sheets or timber boards. These are kept apart the required distance by ties and stiffened by vertical members (studs or walings). Because forms must withstand considerable pressure from the wet concrete, adequate stiffening and bracing are essential to prevent distortion. For special work, formwork is erected on site, which is an expensive process because of the building time involved and because only a small proportion can easily be reused.

Standardized formwork

Today, modular panels of standard size are built and reused as much as possible from one site to another. When constructing formwork for horizontal concrete beams, it is customary to arrange the formwork so that the panels at the sides can be removed without disturbing those supporting the underside. This is done because it is safe to remove the side members as soon as the concrete has set (a matter of a day or two). The entire beam, however, is not ready to support considerable weight for several weeks. The formwork for a long lintel (horizontal member above an opening) is similar in principle to that used for beams.

Building custom-made furniture. Many buildings today, particularly houses, have cabinets and furniture built in. These are generally supplied by specialist firms and delivered complete for installation by the carpenter on the job. The largest area of this special equipment is certainly in the kitchen. Extensive ranges of factory-made cabinets are available, which usually comprise base units with work tops and wall cupboards for general storage but include housings for built-in ovens and sinks. In bedrooms, wardrobes, chests of drawers, and other

storage fitments are increasingly found. The principal materials used for making these fittings are blockboard or plywood on lighter timber framing.

Finishing woodwork. The surface of wood is treated for protection and decoration (see also PAINTS, VARNISHES, AND ALLIED PRODUCTS). Traditionally, for both external and internal finishes, the two main treatments have been staining and polishing or painting with oil paint. Staining and polishing tend to increase the inherent interest of the wood itself by emphasizing the natural colour and grain pattern; this is often enhanced by the use of coloured stains. Oil paint, being opaque, disguises the character of the wood but enables a wide variety of colour to be used on wooden fittings and trim. In recent years the range of possible wood-surface treatments has increased considerably to include an extensive range of sealants and treatments, such as sandblasting. Most modern surface finishes, usually polyurethane sealers, are clear and are intended not only to protect but also to bring out the grain, structure, and colour of the wood. Prefinished plywoods are increasingly employed for internal panelling; these boards are faced with veneers of birch, walnut, oak, mahogany, and other woods having decorative grains, prefinished by sanding and staining to colour, then heat-treated with a vinyl sealer. After filling with a synthetic resin filler, the boards are further treated with thermosetting epoxy or synthetic polymer lacquer and again heat cured. In this way a highly polished and very durable finish is produced. It is also possible to simulate the grain of expensive veneers by photographic methods and by a synthetic polymer coating cured by heat treatment to make this available on cheaper boards.

Staining wood

Timbering and centring. The carpenter is frequently called upon to erect temporary timberwork for the assistance of other construction tradesmen. Examples of such work include timbering for demolition and excavation work and centring for the construction of arches and vaults in brick or stone.

Excavation. Where trenches are excavated on a building site for foundations, drains, or basements, it is usually necessary to support the sides of the excavation by timbering to prevent collapse of the earth and to safeguard those working below. The arrangement and the amount of timberwork required depends on various factors—the depth, the condition of the ground, and the width of the trench. Vertical boards called poling boards, which may be spaced at intervals in firm ground or set closely butted if the ground is loose or waterlogged, are set in contact with the earth. The poling boards are held in place by horizontal timbers called walings, and struts are then driven tight between the walings across the trench.

Arches. For simple brick arches of a flat, segmental, or cambered outline, the centre is formed by cutting a piece of wood to the required curvature; when made in this way the centre is called a turning piece. It is supported in the opening on props with folding wedges that allow not only easy adjustment but also the removal of the centre after the arch has been completed. For wider arches the centre is constructed with two or more ribs set parallel to each other.

The main consideration in the design and construction of a centre is that it shall remain rigid and not alter in shape during the building of the arch. The tendency, especially in wide arches, is that, as the building of the arch proceeds, the weight of the superimposed masonry tends to compress the centre at the haunches (sides) and, in so doing, forces down the crown (top). The reverse tendency is experienced when the weight is put on the crown as the arch nears completion.

ECONOMIC IMPACT

The tendency in the construction industry of the early 1970s was to concentrate an increasing amount of carpenter's work in the manufacture of large components in the workshop and factory and the erection of these items on site by means of mechanical plant, particularly cranes. Though factory manufacture is customary for components such as doors, windows, staircases, and roof trusses, this is being extended to the production of large-scale floor and wall panels. Though there are a number of reasons for this development, the most important single factor is probably the desire to reduce site labour. The ease of assembly and the rapid enclosure of the building against inclement weather speeds up erection time. Improved thermal and sound insulation can be achieved, and the total weight of timber construction, being far less than that of brick, masonry, or concrete, gives a consequent saving on foundation costs or, alternatively, makes it possible to use sites where the ground conditions would not otherwise be satisfactory.

Factory-produced building components

BIBLIOGRAPHY. The published books on carpentry and woodworking practice are, for the most part, written for the practicing designer or manufacturer, and therefore tend to assume some professional acquaintance with the subject. In most cases, however, they are readily understood by the layman because they are usually well illustrated and describe processes in stages with both practical hints and descriptions as well as the underlying theory. Among informative, well-illustrated works explaining basic skills and processes are C.H. HAYWARD, *Carpentry for Beginners* (1960), *Woodwork Joints* (1949), and *Tools for Woodwork* (1963); L.P. MCDONNELL, *Hand Woodworking Tools* (1962); and F. HILTON, *Craft Technology for Carpenters and Joiners* (1968). Definitive texts on English and American practice include W.E. DURBAHN and E.W. SUNDBERG, *Fundamentals of Carpentry*, vol. 2, *Practical Construction*, 4th ed. rev. (1969), a comprehensive statement of American construction practice with extensive practical hints and illustrations; a useful supplement to this book is N.L. BURBANK and O. SHAFTEL, *House Construction Details*, 5th ed. (1959). J. EASTWICK-FIELD and J. STILLMAN, *Design and Practice of Joinery*, 3rd rev. ed. (1966), though written from the point of view of the architect and designer of woodwork, is also an informative and instructive book on woodwork for the general reader, with clear illustrations. D.W. EGELSTAFF and D. HARRIS, *A Designer's Approach to Woodwork* (1970), also sets out to explain the underlying principles in the design and manufacture of woodwork.

For the advanced student of carpentry, there are a number of comprehensive works to cover the whole field of practice and to illustrate current methods of construction of timber details in building. These include R. BAYLISS, *Carpentry and Joinery*, 2nd ed., 3 vol. (1969); A.B. EMARY, *Advanced Carpentry and Joinery for Craftsmen* (1967); C.H. GRONEMAN and E.R. GLAZENER, *Technical Woodworking* (1966); F. HILTON, *Advanced Carpentry and Joinery*, 2nd ed. (1969); and F. KEELING, *Carpentry and Joinery: Advanced Examples*, 2nd ed. (1963).

Two books intended for the student of architecture and building that are well illustrated in detail are W.B. MCKAY, *Carpentry*, 4th ed. (1969), and *Joinery*, 2nd ed. (1965).

For information on woodworking machinery, see F.L. DUNSMORE, *The Technique of Woodworking Machinery*, 2 vol. (1965), a comprehensive manual of machine practice. H.J. FULKER, *Foundations of Machine Woodworking* (1965); and T. HESP, *Principles of Woodcutting Machinists' Work*, 2nd ed. (1965), are smaller books dealing with essentially practical points for the craftsman. Light machinery and portable tools are covered in C.H. HAYWARD, *Light Machines for Woodwork* (1963); and L.P. MCDONNELL, *Portable Power Tools* (1962).

(A.Re.)

Carpini, Giovanni da Pian del

Giovanni da Pian del Carpini, a Franciscan friar, was the first noteworthy European traveller in the Mongol Empire and also the author of the earliest important Western work on Central Asia.

Born in Umbria (*c.* 1180), probably at Piano della Magione (formerly Pian di Carpini) near Perugia, Carpini was a contemporary and disciple of St. Francis of Assisi. By 1220 he was a member of the Franciscan order and subsequently became a leading Franciscan teacher in northern Europe; he held successively the offices of custos ("warden") in Saxony and of minister ("subordinate officer") in Germany and afterward in Spain (perhaps also in Barbary and Cologne). He was in Cologne at the time of the great Mongol invasion of eastern Europe and of the disastrous Battle of Liegnitz (April 9, 1241).

Fear of the Mongols had not abated when four years later Pope Innocent IV dispatched the first formal Catholic mission to them, partly to protest against their in-

vasion of Christian territory and partly to gain reliable information about their numbers and their plans; there may also have been the hope of alliance with a power that might be invaluable against Islām. At the head of the mission, the pope placed Friar Giovanni, then already more than 60 years of age.

Mission to the Mongol Empire

On Easter day, 1245, Carpini set out. He was accompanied by Stephen of Bohemia, another friar, who was subsequently to be left behind at Kiev. After seeking counsel of Wenceslaus, king of Bohemia, the friars were joined at Breslau (now Wrocław) by Benedict the Pole, another Franciscan appointed to act as interpreter. The mission entered the Mongol posts at Kanev and thereafter crossed the Dnepr, the Don, and the Volga. On the Volga stood the *ordu*, or "camp," of Batu, the supreme commander on the western frontiers of the Mongol Empire and the conqueror of eastern Europe. Carpini and his companions, with their presents, had to pass between two fires before being presented to Batu at the beginning of April 1246. Batu ordered them to proceed to the court of the supreme khan in Mongolia, and accordingly, on Easter day, April 8, 1246, they began the second and more formidable part of their journey. Their bodies were tightly bandaged to enable them to endure the excessive fatigue of their great ride through Central Asia. Their route was across the Ural (Yaik) River and north of the Caspian Sea and the Aral Sea to the Syr Darya (Jaxartes) and the Muslim cities, which then stood on its banks, then along the shores of the Dzungarian lakes and thence to the imperial camp of Sira Ordu (*i.e.*, the "yellow pavilion") near Karakorum and the Orkhon River. They reached their destination on July 22, after a ride of about 3,000 miles in just over 106 days.

On arriving at Sira Ordu, the Franciscans found that the interregnum that had followed the death of Ögödei, the supreme khan or imperial ruler, had ended. His eldest son, Güyük (Kuyuk), had been designated to the throne; his formal election in a great *kuriltai*, or general assembly of shamans, was witnessed by the friars along with more than 3,000 envoys and deputies from all parts of the Mongol Empire. On August 24 they were present at the formal enthronement at the nearby camp of the "Golden" Ordu and were presented to the supreme khan. They were detained until November and were then dismissed with a letter for the pope; this letter, written in Mongol, Arabic, and Latin, was little more than a brief imperious assertion of the khan's role as the scourge of God. The friars suffered greatly on their long winter journey homeward and not until June 9, 1247, did they reach Kiev, where they were welcomed by the Slavic Christians as risen from the dead. Subsequently they delivered the khan's letter and made their report to the pope, who was still at Lyons.

Major work

Immediately after his return, Carpini recorded his observations in a large work variously styled in the manuscripts extant as *Historia Mongalorum quos nos Tartaros appellamus* and *Liber Tartarorum*, or *Tatarorum*. He divided his treatise into eight chapters on the country of the Mongols, their climate, customs, religion, character, history, policy and tactics, and on the best way of resisting them; in a ninth chapter he described the regions traversed. He added four name lists: of the peoples conquered by the Mongols, of those who had successfully to his time (1245–47) remained unconquered, of the Mongol princes, and of witnesses to the truth of his *Historia*, including several merchants trading in Kiev. His *Historia* discredited the many fables concerning the Mongols current in Western Christendom. Its account of Mongol customs and history is probably the best treatment of the subject by any medieval Christian writer, and only on geographical and personal detail is it inferior to one written a few years later by the papal envoy to the Mongols William of Rubruquis, or Rubrouck. Carpini's companion, Benedict the Pole, also left a brief account of the mission, taken down from his dictation. Not long after his return, Carpini was installed as archbishop of Antivari in Dalmatia and was sent as legate to Louis IX. He died on August 1, 1252.

For a long time the *Historia* was only partially known through an abstract in the great compendium of Vincent of Beauvais (*Speculum historiale*), made a generation after Carpini's own and first printed in 1473. R. Hakluyt (1598) and P. Bergeron (1634) published portions of the text, but the complete work was not printed until 1839: M.A.P. d'Avezac (ed.) in *Recueil de voyages et de mémoires*, vol. 4, Geographical Society of Paris.

BIBLIOGRAPHY. C.R. BEAZLEY (ed.), *The Texts and Versions of John de Plano Carpini . . .* (1903, reprinted 1967), remains a standard work. Carpini's possible connection with the *Tartar Relation*, "an independent primary source on the Carpini Mission to Central Asia in 1245–47," is discussed in R.A. SKELTON, T.E. MARSTON, and G.D. PAINTER, *The Vinland Map and the Tartar Relation* (1965). Other useful works are *Fra Giovanni da Pian di Carpine nel vii centenario della sua morte, 1252–1952* (1952); CHRISTOPHER DAWSON (ed.), *The Mongol Missions* (1955); and F. RISCH (ed. and trans.), *Johann de Plano Carpini: Geschichte der Mongolen* (1930).

(E.M.J.C.)

Carracci

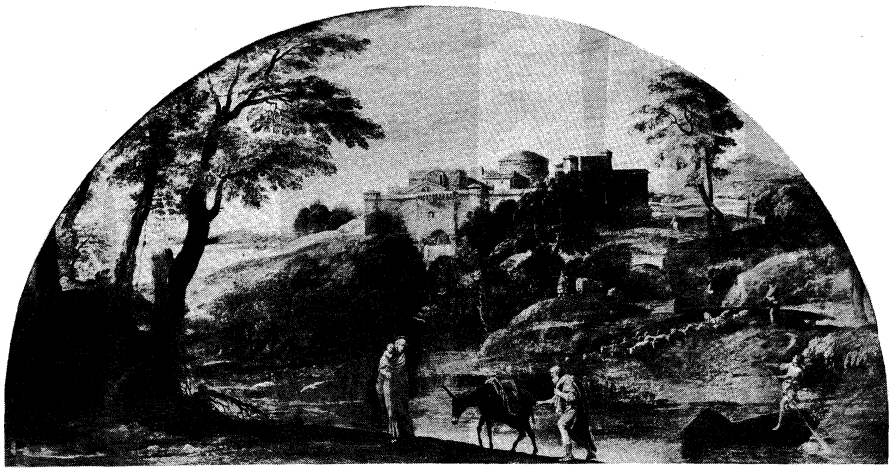
In late 16th-century Italy, three painters of the Carracci family were a major influence in diverting the course of art from the excesses and exaggerations of Mannerism toward a return to the strength and style of the masters of the High Renaissance. The Mannerist style was marked by a certain distortion in dealing with figures that was sometimes bizarre and by an emphasis on virtuosity for its own sake. Much of the influence of the Carracci was exercised through the academy they established in 1582 in their native Bologna, in which many of the leading artists of the next generation were trained. Their influence was felt long and far afield; on 17th-century art in Flanders, particularly through the active admiration of Rubens; and, through the policy of the French Academy in Rome, on young French artists until the end of the 18th century. In addition, each of the three Carracci—the brothers Agostino and Annibale and their cousin Lodovico—developed a distinctive artistic personality in his own right. Annibale was the truest artist of the three and the greatest; Agostino, the most cerebral, was a natural court painter; whereas Lodovico, the eldest and the leader of the family at first, conveyed a deep feeling of religious mystery in his early paintings. All three were also graphic artists of importance.

Births and backgrounds

The Carracci were born in Bologna, in modest circumstances: Agostino, born in 1557 (baptized August 16), and his brother Annibale, born November 3, 1560, were tailor's sons; and their cousin Lodovico, who was born in 1555 (baptized April 21), was the son of a butcher. Early in their careers, Annibale would paint "The Butcher's Shop," and also a smaller version of that subject, to remind the socially ambitious Agostino of their humble origins.

Lodovico in Bologna became the pupil of a fashionable painter, Prospero Fontana. Later he went to Florence and then to Parma; and he visited Venice with the intention of working under a great master, Jacopo Tintoretto. Mannerist influences persisted less in the styles of the two younger Carracci, although Agostino was influenced by a Flemish Mannerist painter, Denis Calvaert, who established an academy in Bologna that was a forerunner of the Carracci's. The precocious talents of the two brothers were developed in tours of northern Italy, their visits to Venice and Parma (1580s) being of special significance. Agostino was first to imbibe 16th-century Venetian art, notably that of Tintoretto and Paolo Veronese, both still active then; and his "Adoration of the Shepherds" for Sta. Maria della Pioggia (1584) demonstrates this influence. Annibale is reported to have lodged in Venice with Jacopo Bassano, by whose style of painting he was for a time affected. Annibale may be credited with the rediscovery of an early 16th-century genius, Correggio, who had been effectively forgotten outside Parma for a generation; Annibale's "Baptism of Christ" for S. Gregorio, Bologna (1585), is a brilliant tribute to this Parmese master.

Lodovico surpassed both his cousins in the mystery of



"Flight into Egypt," oil on canvas by Annibale Carracci, *c.* 1604. In the Galleria Doria-Pamphili, Rome. 1.2 m × 2.3 m.
Anderson—Alinari

Lodovico's sensibility in figure composition

his earlier devotional works, such as "The Vision of St. Anthony of Padua," and in the aristocratic sentiment of his portraits. His first signed and dated painting, the altarpiece for the Bargellini family (1588), demonstrates his peculiar sensibility in figure composition and, in particular, his justly praised rendering of hands. Of the three Carracci, he alone really comprehended the tender feelings conveyed by the deeply religious art of the Urbino master Federico Barocci, and he alone mastered the poetry of night. The illumination and characterization of his "Madonna and Child with St. Francis, St. Joseph and Donors" (1591) was to be a formative experience for the youthful Guercino, one of the most important painters of the next generation; and the treatment of landscape in his early works, inducing mood rather than locality, was to be of importance for Bartolomé Esteban Murillo, the most popular Spanish painter of the Counter-reformation. Lodovico's imaginative approach to religious sentiment in his "Martyrdom of S. Angelo" anticipates another Spanish painter, Francisco de Zurbarán.

For more than 20 years Lodovico was to lead the Carracci's school, the Accademia degli Incamminati. As an informal and progressive institution, it proved to be the most attractive centre of modern art in Italy and a training ground for many distinguished artists who sought, more or less consciously, to free themselves of Mannerism. They include Guido Reni, ultimately Lodovico's successor in Bologna, Francesco Albani, Domenichino, and Alessandro Algardi.

Early in their careers, each of the Carracci, by painting a monumental altarpiece for an Emilian church, evinced a distinctive claim to individual consideration. Annibale's "Enthroned Madonna with St. Matthew" (1588) for S. Prospero, Reggio, glowing with Venetian colours, manifests two persistent characteristics of his genius combined: the noble, classicizing strain in the angel seated in the foreground, which is reminiscent of Correggio, and the genial and bucolic in the simulated stone enrichment of the Madonna's plinth, a swag of fruits, and a harpy. These last elements, although painted in tones of grey, convey sensations of warmth and colour that would radiate from his later successes—the decorations of palace rooms. Lodovico's "Preaching of the Baptist" (1592), in S. Gerolamo della Certosa, Bologna, hung opposite Agostino's almost contemporaneous masterpiece, "The Communion of St. Jerome," which was to inspire further masterpieces on similar themes by Domenichino in Rome and by Rubens in Antwerp.

The three Carracci worked in concert on frescoes in three noble houses in Bologna—two friezes in Palazzo Fava (1584), a frieze in Palazzo Magnani (modern, Palazzo Salem) (1588–92), and decorations in Palazzo Sampieri (1593–94). The "Story of Jason" in the first of these palaces is their earliest public work of that kind. In the great salon of Palazzo Magnani, the cycle of scenes from the "Story of Romulus" initiates for European painting ordered and airy landscape as a principal subject; it was designed by Annibale, who was by this time the leading master in this exceptionally talented family. In the subsequent evolution of heroic landscape in Rome, Domenichino and Nicolas Poussin were to become Annibale's heirs. His lunette-shaped paintings, set high on the walls of the chapel of the Palazzo Aldobrandini, especially the "Flight into Egypt" and the "Entombment" (1604), are of supreme beauty and consequence.

Annibale's ascendancy

In the summer of 1595, leaving his stupendous "St. Roch Giving Arms" for Reggio to be finished by Lodovico, Annibale obeyed the summons south of the rich young cardinal Odoardo Farnese. Cardinal Farnese was determined to decorate with fresco and stucco some rooms on the principal floor of the palace that he had inherited, the most splendid in Rome. In Rome the 35-year-old painter turned eagerly to the study of Michelangelo, Raphael, and ancient Greek and Roman art in order to invest with sonority and grandeur the style he had formed in the artistic centres of North Italy.

Having decorated the Camerino (study) in Palazzo Farnese, Annibale was joined (1597) by Agostino in the chief enterprise of his career—painting the frescoes of the coved ceiling of the Galleria (1597–1603/4) with love fables from Ovid. This decoration, interweaving various illusions of reality in a way that was more complex even than Raphael's famous paintings in the Vatican Loggia, was a triumph of classicism tempered with humanity. Surprisingly, in view of its pagan and erotic subjects, it was acceptable from the first to churchmen as well as laymen. The biographer Bellori described the theme as "human love governed by celestial love." It quickly became and remained a virtually indispensable study for painters until well into the 18th century—the Roman equivalent to what Masaccio's frescoes in the Brancacci Chapel in Florence had meant to the 16th century. A long succession of visitors to Rome made copies of it, and Annibale's prolific preparatory drawings for it became collector's items from the second decade of the 17th century. It was to be an especially rich feeding ground for the Baroque imaginations of Rubens, Bernini, and many others. Bernini called it the best secular decoration in Rome since Raphael; and he expressed his disgust that the largest commission available in the metropolis, the decoration of the Sala Clementina in the Vatican, had not been entrusted to Annibale.

Influence of Galleria frescoes

Annibale's long and highly concentrated efforts had been dismally underpaid by Cardinal Farnese, and he never fully recovered from the ingratitude of his patron. By the summer of 1605 he had quit the Farnese palace forever. His team of loyal young assistants in Rome, which included Albani and Domenichino, could not rally him thereafter to complete any major undertaking unaided. It required a full year of their efforts to induce him to bring a "Nativity" for the Duke of Modena beyond the design stage.

Agostino Carracci had parted company with Annibale in 1600, leaving him to finish the Galleria, in order to work for Odoardo Farnese's brother Ranuccio in Parma. Agostino had already painted at least two portraits of Duke Ranuccio; and he was by nature more apt than either his brother or his cousin to be a court painter. He was proud also of his skill in both music and letters, being aware of the prestige to be gained thereby. In the Duke's service, he died at Parma on February 23, 1602, without completing his own major endeavour in fresco, the decoration with mythologies of a small room in the Palazzo del Giardino.

After Agostino's death, the Duke sent his most promising Parmese pupils, Lanfranco and Sisto Badalocchio, to complete their education by assisting Annibale in Rome. Misinterpretation of the oration delivered in Bologna by Lucio Faberio, secretary of the academy, at Agostino's funeral occasioned the long-continuing legend that the Carracci advocated an eclectic program of copying elements of the style of various masters. Their brilliant renewal of art was made possible by frequent observation of nature, study and revision of poses from life, and boldness of scale in drawing figures with chalk. Such procedures enabled them to profit by the visual knowledge they had gained through drawing and making prints of the works of past masters.

Lodovico published in 1604 an elegant print of the Madonna, but copper engraving was scarcely as important an activity for him as it was for Agostino, who had begun his artistic training as an engraver. Engraving formed a major part of his total output from 1580, when he engraved a "Christ and the Samaritan." The circulation of his prints after Barocci, after Tintoretto—*e.g.*, the large "Calvary" (1589)—and after Titian was of outstanding significance. Annibale's prints of "The Holy Family" (1590) and "Jupiter and Antiope" (Venus and Satyr"; 1592) were evidently appreciated by Rembrandt; and his two engravings on silver, the "Christ of Caprarola" (1598) and the "Drunken Silenus" (for the Farnese dish), rank among the most beautiful and influential designs of their period. As late as 1606 Annibale was able to produce the superb, and justly famous, engraving on copper, "La Madonna della Scodella." He was responsible also, at a much more mundane level, for recording the everyday look of the various tradesmen in his native city by a series of prints, published as the "Arti di Bologna." His gift of humorous perception, exercised in the streets and inns and studios, made him the first caricaturist of note. But that gift was scarcely used in the intermittent production of his last four years of melancholic sickness in Rome. He was smitten in 1605 with a kind of paralysis, which caused temporary amnesia and even loss of speech. Yet he continued to make dutiful efforts to attend meetings of the Academy of St. Luke, the artists' academy, as well as to guide the training and practice of his considerable workshop. In 1607 Albani failed as his chief assistant in frescoing the Herrera Chapel of S. Giacomo degli Spagnuoli; the next year, Annibale made it plain that his mantle was to fall on Domenichino, whose "St. Andrew" fresco in S. Gregorio Magno he preferred to Reni's. On July 15, 1609, Annibale died in Rome. For a decade thereafter, Lodovico remained active in Bologna. There he painted a succession of altarpieces in an increasingly grandiose and heavily mannered style until his own death on November 3, 1619, after painting his "St. Bernard Saving Carpi." Although his hugest undertaking was in the choir and presbytery of Piacenza Cathedral (1606–09), his finest achievement was in his own city of Bologna: it was his illustrations in the cloister of S. Michele in Bosco to the story of St. Benedict, founder of the Olivetan Order, which he frescoed during the summers of 1604 and 1605. This work shows how admirably he had profited by study of the great Venetian and Parmese masters of the 16th century, as well as Raphael and Michelangelo. Its significance in his production corresponds to that of the Galleria Farnese in Annibale's.

Annibale's last four years

Annibale Carracci, self-portrait; in the Uffizi, Florence.

MAJOR WORKS

LODOVICO CARRACCI: "St. Francis Adoring the Crucifix" (1583–84; Capitoline Museum, Rome); "Portrait of a Youth" (*c.* 1583; Capitoline Museum, Rome); "Mystical Marriage of a Saint" (*c.* 1583; Beretta Collection, Bologna); "The Baptism of Christ" (*c.* 1583; Alte Pinakothek, Munich); "The Annunciation" (*c.* 1585; Pinacoteca Nazionale, Bologna); "The Vision of St. Anthony of Padua" (*c.* 1585; Rijksmuseum, Amsterdam); "The Conversion of St. Paul" (*c.* 1587–88; Pinacoteca Nazionale, Bologna); "Madonna dei Bargellini" (1588; Pinacoteca Nazionale, Bologna); "History of Rome" (fresco, 1588–92; Palazzo Salem, Bologna); "Madonna and Child with St. Francis, St. Joseph and Donors" (1591; Pinacoteca Civica e Galleria d'Arte Moderna, Cento, Italy); "Supper in the House of Simon" (1592; Pinacoteca Nazionale, Bologna); "The Martyrdom of St. Ursula" (1592; Pinacoteca Nazionale, Bologna); "The Preaching of the Baptist" (1592; Pinacoteca Nazionale, Bologna); "Flora" (1592–93; Galleria e Museo Estense, Modena); "La Dea Opi" (1592–93; Galleria e Museo Estense, Modena); "Martyrdom of S. Angelo (*c.* 1598; Pinacoteca Nazionale, Bologna); "The Martyrdom of St. Ursula" (1600; SS. Nicola e Domenico, Imola); "The Assumption" (1601; Corpus Domini, Bologna); "The Divine Providence" (*c.* 1604–05; Capitoline Museum, Rome); "Apostles at the Tomb of the Virgin" (1606–09; Galleria Nazionale, Parma); "Funeral of the Virgin" (1606–09; Galleria Nazionale, Parma); "St. Peter Repenting" (1617; S. Pietro, Bologna).

ANNIBALE CARRACCI: "The Crucifixion and Saints" (1583; Sta. Maria della Carità, Bologna); "The Butcher's Shop" (*c.* 1583; Christ Church, Oxford); "The Baptism of Christ" (1585; S. Gregorio, Bologna); "The Triumph of Truth" (1585; Hamptom Court Palace, Middlesex); "Deposition" (1585; Galleria Nazionale, Parma); "The Assumption" (1587; Gemäldegalerie, Dresden); "Self-Portrait and Portrait of the Father and Nephew Antonio" (1587–88; Brera, Milan); "Enthroned Madonna with St. Matthew" (1588; Gemäldegalerie, Dresden); "St. Roch Giving Alms" (1588–95; Gemäldegalerie, Dresden); "Madonna with SS. Luke and Catherine" (1592; Louvre, Paris); "The Assumption of the Virgin" (1592; Pinacoteca Nazionale, Bologna); "Christ at the Tomb" (1593; Louvre, Paris); "Hercules at the Crossroad" (1595; Museo e Gallerie Nazionali di Capodimonte, Naples); frescoes (1597 to 1603–04; Palazzo Farnese, Rome); "The Assumption" (1600–01; Sta. Maria del Popolo, Rome); "Christ Appearing to St. Peter on the Appian Way" ("Domine, Quo Vadis?"; *c.* 1601; National Gallery, London); "Pietà" (*c.* 1603; Kunsthistorisches Museum, Vienna); "The Dead Christ Mourned" ("The Three Maries"; *c.* 1603; National Gallery, London); "Martyrdom of St. Stephen" (*c.* 1604; Louvre, Paris); "Flight into Egypt" (*c.* 1604; Galleria Doria-Pamphili, Rome); "Entombment" (*c.* 1604; Galleria Doria-Pamphili, Rome); "Christ and the Samaritan at the Well" (*c.* 1604–05; Kunsthistorisches Museum, Vienna); "Pietà" (*c.* 1607; Louvre, Paris).

AGOSTINO CARRACCI: "Communion of St. Francis" (1582–83; Dulwich College Picture Gallery, London); "Bacchus and Ariadne" (1584–85; Pinacoteca Nazionale, Bologna); "Adoration of the Shepherds" (1584; Sta. Maria Della Pioggia); "Madonna with Child and Saints" (1586; Galleria Nazionale, Parma); "The Communion of St. Jerome" (1591–93; Pinacoteca Nazionale, Bologna); "Assumption of the Virgin" (1591–93; Pinacoteca Nazionale, Bologna); "Pluto" (1592; Galleria e Museo Estense, Modena); "Christ and the Adultress" (*c.* 1594; Brera, Milan); "Portrait of Giovanna Parolini-

Guicciardini" (1598; Staatliche Museen Preussischer Kulturbesitz, Berlin).

BIBLIOGRAPHY. The earliest considerable source from the first quarter of the 17th century, but then unpublished, is GIULIO MANCINI, *Considerazioni sulla pittura*, ed. by ADRIANA MARUCCHI and LUIGI SALERNO, 2 vol. (1956–57). The earliest published lives of the Carracci, on which all subsequent accounts depend, are in G.P. BELLORI, *Le vite de pittori . . .* (1672); and C.C. MALVASIA, *Felsina Pittrice*, 2 vol. (1678). HEINRICH BODMER, *Ludovico Carracci* (1939), is the first modern monograph (in German) on this artist. DENIS MAHON, *Studies in Seicento Art and Theory* (1947, reprinted 1971), contains the most brilliant critical rehabilitation of the Carracci. FRANCESCO ARCANGELI, "Sugli inizi dei Carracci," *Paragone*, 7:17–48 (1956), deals imaginatively with this special problem. The *Catalogo critico della mostra dei Carracci* (1956), with complete bibliography to that date, established a massive basis for fresh investigations. MICHAEL JAFFE, "Some Drawings by Annibale, and by Agostino Carracci," *Paragone*, 7:12–16 (1956), drew further attention to the problems raised by the drawing section of the 1956 exhibition. See also L. DURRAND, *Les Estampes composant le lascivie du graveur Agostino Carracci* (1957). DENNIS MAHON, "Afterthoughts of the Carracci Exhibition," *Gazette des Beaux-Arts*, 49:193–207 (1957), is a significant addendum by one of the scholars chiefly responsible for the exhibition the previous year. J.R. MARTIN, *The Farnese Gallery* (1965), is a richly illustrated book, devoted to the principal enterprise of Annibale, and especially to its iconography. DONALD POSNER, *Annibale Carracci*, 2 vol. (1971), is the first full-scale treatment of Bellori's hero since Bellori.

(M.J.)

Carriage of Goods, Law of

Until the development of railroads, the most prominent mode of transport was by water. Overland transportation of goods was relatively slow, costly, and perilous. For this reason, the law governing carriage of goods by sea developed much earlier than that governing inland transportation. The preclassical Greek city-states had well-developed laws dealing with the carriage of goods by sea, along with specialized commercial courts to settle disputes among carriers, shippers, and consignees. The sea laws of the island of Rhodes achieved such prominence that a part of them was carried, many centuries later, into the legislation of Justinian.

In Roman law the contract of carriage did not achieve the status of a distinct contractual form; jurisconsults (legal advisers) dealt with it in the framework of the contractual forms known to them, such as deposit and hire of services or of goods. There was special regulation only insofar as the responsibility of the carrier was concerned: shipowners (*nautae*), along with innkeepers and stable keepers, were liable without fault for destruction of or damage to the goods of passengers. Nevertheless, they could be relieved of responsibility by proving that the loss was attributable to irresistible force.

Early developments in common law

In English common law the principles applying to the relationship between the carrier and his customers go back to a time when neither railways nor canals existed. Whether influenced by Roman law or derived quite independently, early English decisions imposed on carriers the obligation not only to carry goods but to carry them safely and to deliver them intact to the owner or his agent. The carrier was always liable for the loss of the goods and also liable for any damage to the goods, unless he could prove that the loss or damage had resulted from an excepted cause. This duty of the carrier to deliver the goods safely was considered to exist quite apart from any contract. It was imposed upon him by the law because he had been put in possession of another's goods. In legal language, this meant that the carrier was considered to be a bailee, who, in certain circumstances, was liable to the bailor if he failed to deliver the goods intact. This law of bailment developed in England long before the law of contract. The contractual element of bailment was not stressed until after the 17th century. Today, in common-law countries, the rights and liabilities of shippers, consignees, and carriers are in the large majority of cases based on a contract of carriage, whether express or tacit. The mere fact that, in the ordinary course of his business, a carrier accepts goods for carriage and delivery implies the making of a contract of carriage. The right of the carrier to claim the freight depends on this contract, and this contract is also the foundation of his duty to carry the goods to their destination. But there remain vestiges of bailment in the law of carriage of goods. Thus, the owner of the goods, though not a party to the contract of carriage between the shipper and the carrier, may sue the carrier for loss of or damage to his goods.

Early developments in civil law

In civil-law countries, the contract of carriage first achieved distinct form in the early 19th century. The French Civil Code of 1804, following the Romanist tradition, still dealt with the contract of carriage as a species of the contract for the hire of services and further subjected carriers to the same obligations as depositaries; but the French Commercial Code of 1807 established a special legal regime for professional carriers, making the contract of carriage a distinct contractual form. Subsequent civil and commercial legislation in civil-law countries gave expression to the same idea. Today, in the civil-law world, the contract of carriage may be regarded as a variation of the contract for the hire of services, namely, a contract whereby one of the parties engages to do something for the other party in consideration of a price agreed upon between them. Specifically, the contract of carriage of goods may be defined as the contract whereby a professional carrier engages to carry goods in accordance with a determined mode of transport and within a reasonable time, with the understanding that the carriage of the goods is the principal object of the contract.

In France and in a great number of countries following the French system, a contract of carriage requires the presence of three indispensable elements: carriage, control of the operation by the carrier, and a professional carrier. If any of these elements is missing, the contract is one for the hire of services rather than a special contract of carriage. The classification of a contract as a contract of carriage involves significant legal consequences. Exculpatory clauses in a contract of carriage are ordinarily null and void; receipt of the goods by the consignee and payment of the freight without protest within a designated period of time exclude all actions against the carrier; actions that may be brought against the carrier are subject to a short period of limitation, that is, one year; the carrier has a privilege, which corresponds to a common-law lien, on the things carried for the payment of the freight; and, finally, either party to a contract of carriage may demand that experts determine the condition of the things carried or intended to be carried.

LIABILITIES OF CARRIERS FOR PUBLIC HIRE

Common carriers

In English and American law, common carriers are distinguished from other carriers. A common carrier is one who holds himself out as being ready to carry goods for the public at large for hire or reward. In England carriers of goods by land that are not classified as common carriers are termed private carriers; carriers of goods by sea or by inland water that are not classified as common carriers may be public carriers, namely, professional carriers who do not hold themselves out as ready to serve the general public or persons who carry goods incidentally to their main business or for one consignor only. In the United States distinction is made among common carriers, contract carriers, and private carriers. A person who engages to carry the goods of particular individuals rather than of the general public is a contract carrier; a person who carries his own goods is a private carrier. Both a common carrier and a contract carrier are engaged in transportation as a business. The basic difference between them is that a common carrier holds himself out to the general public to engage in transportation, whereas a contract carrier does not hold himself out to serve the general public. The exact boundary between common carriage and contract carriage is not always clear.

A person may be a common carrier, although he limits the kinds of goods that he is ready to carry for the public, the mode of transport, or the route over which he is

prepared to carry. He is a common carrier only to the extent that he holds himself out as ready to carry goods for the public. It is indispensable for the classification of a person as common carrier that he accepts reward for the carriage and that his principal undertaking is the carriage of goods. Ancillary carriage for purposes of warehousing does not make one a common carrier. Unless the law provides otherwise, a carrier may cease at any time to be a common carrier by giving notice that he is no longer ready to carry goods for the public at large.

The distinction between common carriers and carriers that are not classified as common carriers, such as private carriers or contract carriers, involves significant legal consequences in the light of both common law and legislation. Common carriers are everywhere subject to strict economic regulation. Thus, a common carrier is forbidden in the United States to charge unreasonably high rates or to engage in unjust discrimination, whereas a contract carrier may charge rates as high as he pleases and may discriminate among his customers, provided that none of his discriminatory rates in motor and domestic water transportation is unreasonably low. In both England and the United States, a common carrier must serve everyone who makes a lawful request for the services he offers, but a private or contract carrier may select his customers; a common carrier is liable for any loss or damage to the goods during carriage, unless the damage or loss is attributable to certain excepted causes, whereas a contract carrier or private carrier is only liable for damage or loss through his negligence; contractual clauses relieving the carrier from liability may have different effects depending on the status of the carrier as common carrier or private carrier; and, finally, the common carrier has a common-law lien on the goods, whereas other carriers may have none in the absence of contractual provision or may have a less extensive lien than that of the common carrier.

The civil-law counterpart of the common carrier

The concept of common carrier has no exact equivalent in civil-law systems. But, if one looks to substance rather than form or terminology, one may conclude that the concept of public carrier in civil-law systems is a functional equivalent of the concept of common carrier. A public carrier is a professional carrier of goods or passengers; he is distinguished from a private carrier who either carries his own goods exclusively or carries goods incidentally to his other business. Generally, the scope of private carriage is narrowly defined so that most carriage operations fall under the rubric of public carriage; this ensures maximum application of rules designed to safeguard the public interest in the carriage of goods. Public carriers, like common carriers in common-law countries, are subject to strict economic regulation and are under the supervision and control of administrative agencies. When a public carrier is also a professional merchant, normally an individual or a private corporation, he assumes all the duties, obligations, and liabilities attaching to merchants under applicable commercial codes or special legislation. Like a common carrier, a public carrier must accept the goods lawfully delivered to him for carriage, either because he is held to a permanent offer made to the public or because he is under obligation to carry by virtue of public legislation or administrative regulations. Unlike common carriers, public carriers are not liable for loss or damage to the goods without fault; this difference is more apparent than real, because carriers in civil-law systems are presumed to be liable, unless they prove that the loss or damage occurred without their fault.

Duties to carry. Common carriers and public carriers are under duty to carry goods lawfully delivered to them for carriage. The duty to carry does not prevent carriers from refusing to transport goods that they do not purport to carry generally. Carriers may indeed restrict the commodities that they will carry. Further, everywhere, carriers may refuse to carry dangerous goods, improperly packed goods, and goods that they are unable to carry on account of size, legal prohibition, or lack of facilities.

Liability for safety of the goods. Everywhere, carriers incur a measure of liability for the safety of the goods. In common-law countries carriers are liable for any damage or for the loss of the goods that are in their possession as carriers, unless they prove that the damage or loss is attributable to certain excepted causes. The excepted causes at common law include acts of God, acts of enemies of the crown, fault of the shipper, inherent vices of the goods, and fraud of the shipper. In maritime carriage perils of the sea and particularly jettison are added to the list of excepted causes. All these terms have technical meanings. An act of God is an operation of natural forces so unexpected that no human foresight or skill may be reasonably expected to anticipate it. Acts of enemies of the crown are acts of enemy soldiers in time of war or acts of rebels against the crown in civil war; violent acts of strikers or rioters are not an excepted cause. Fault of the shipper as an excepted cause is any negligent act or omission that has caused damage or loss—for example, faulty packing. Inherent vice is some default or defect latent in the thing itself, which, by its development, tends to the injury or destruction of the thing carried. Fraud of the shipper is an untrue statement as to the nature or value of the goods. And jettison in maritime transport is an intentional sacrifice of goods to preserve the safety of the ship and cargo.

Excepted causes of loss

When goods are damaged or lost as a result of an excepted cause, the carrier is still liable if he has contributed to the loss by his negligence or intentional misconduct. In this case, however, the burden of proof of the carrier's fault rests on the plaintiff.

In civil-law countries the carrier under a contract of carriage is ordinarily bound as a warrantor for any damage to or loss of the goods carried, unless he proves that the damage or loss has resulted from irresistible force (*force majeure*), the inherent vice of the goods, or from the fault of the shipper or of the consignee. This contractual liability of the carrier under the general law is frequently modified by special legislation or by international conventions. In addition to his contractual liability, the carrier may, of course, incur liabilities that arise without contract. The carrier's contractual liability is often termed an "obligation of result," because the carrier, or a warrantor, is bound to make full restitution, unless he manages to exculpate himself in part or in whole.

Limitations of liability. In the absence of contrary legislation or decisions, carriers in common-law jurisdictions have been traditionally free to exclude or limit their liabilities by contract. In civil-law jurisdictions, as a rule, contractual clauses tending to limit liability for negligence or for willful misconduct have been considered null and void. Today, in most countries, municipal legislation and international conventions ordinarily limit the liability of certain carriers to a specified amount per weight, package, or unit of the goods carried. In this way, the liability of certain carriers has largely become standardized, at least in international carriage of goods. Parties are free to stipulate that the carrier shall be liable in excess of any statutory limitation, but clauses designed to reduce the liability of the carrier below statutory limits are ordinarily null and void. Statutory limitations cover both direct and indirect losses incurred by shippers or consignees. In most legal systems, the benefit of statutory limitation of liability is unavailable if the goods have been delivered to the wrong person or if the carrier is guilty of intentional misconduct or gross negligence.

International conventions limiting liability

The liability of a maritime carrier for loss or damage to goods carried under a bill of lading is limited in most countries to a specified amount per package or unit by application of the provisions of the Brussels Convention of 1924 or by municipal legislation containing rules similar to those of the convention. The liability of air carriers for loss or damage to goods carried in international trade is almost everywhere controlled by the provisions of the Warsaw Convention of 1929, as amended by the Hague Protocol of 1955. Air carriage in domestic trade is subject either to the rules of the international convention or to municipal legislation patterned after the model of the convention. In most countries the liability of railroad carriers is limited by legislation or administrative regulations that regularly become part of the contract of car-

riage. International carriage of goods by railroad is largely subject to the various Berne Conventions, the first of which was adopted in 1890. Most European nations, including Great Britain, Northern Ireland, and Communist countries with the exception of the U.S.S.R., have adhered to these conventions.

SCOPE OF THE LAW

The law of carriage of goods covers a variety of matters.

Goods in transit

Delay and misdelivery. In all legal systems, carriers incur liability for delay in delivering the goods to the consignee. Statutes, international conventions, administrative regulations, or even contractual agreements may fix the period of transportation with reference to the applicable means of carriage and determine the consequences of the delay. Under the law of contracts, failure of the carrier to deliver the goods within the prescribed period of time will be treated as a breach of contract.

In common-law jurisdictions, if the delay is caused by a deviation, the carrier is ordinarily answerable for damages. A deviation takes place when the carrier leaves the route that he has expressly or impliedly agreed to follow or when he goes past his destination. In civil-law jurisdictions carriers are not bound to follow any particular route in the absence of special legislation or contractual agreement. Thus, a deviation from the normal route does not itself constitute a fault of the carrier; if the deviation causes a delay, the carrier will be liable only if he is at fault.

Like delay, misdelivery engages the responsibility of the carrier. Misdelivery is the delivery of the goods by the carrier to the wrong person or to the wrong place.

Diversion and reconsignment; stoppage in transit. The terms diversion and reconsignment are used interchangeably to refer to a change in the destination or billing of a shipment before or after it reaches its original destination. Reconsignment is of considerable importance to the commercial world, because goods may be shipped from a distant source of supply toward a certain destination and then diverted to the most favourable market. Carriers are generally permitted to make a charge for the exercise of a diversion or reconsignment privilege. The number of diversions is generally limited in order to prevent the use of means of transport as places of storage.

The owner of the goods may, in all legal systems, change the carrier's instructions as to the place of destination or as to the person entitled to take delivery. The carrier must comply with this order, provided that he has satisfied himself that the person designating a new place of delivery or a new recipient is the owner of the goods at the time the order is given. In civil-law jurisdictions the person in possession of the title of transport, be it a bill of lading or other document, is ordinarily entitled to change the destination of the goods. This rule has been largely followed in international conventions, including the Warsaw Convention of 1929. At common law, in the absence of other provision, the consignee is regarded as the owner of the goods while they are in transit; therefore, it is ordinarily the consignee who is entitled to change the destination of the shipment.

Stoppage in transit is technically the right of an unpaid seller of goods to change their destination before they are delivered to the consignee. The seller has this right by virtue of directly applicable legislation even if he has not reserved the ownership of the goods in his transaction with the buyer. Indicatively, the British Sale of Goods Act of 1893, which codified the common-law rules, declares that the unpaid vendor may resume possession of the goods as long as they are in the course of transit and may retain them until payment or tender of the price. There are analogous provisions in civil-law jurisdiction.

Dangerous goods. Dangerous goods are those that, from their nature, are liable to cause damage to persons, to means of transport, or to other goods. In all legal systems, the carriage of dangerous goods has given rise to distinct problems and to the development of special rules.

In civil-law countries legislation or administrative regulations define categories of goods considered to be dangerous and either exclude their shipment by public carriers or determine the conditions under which they may be shipped. In common-law jurisdictions the shipper is liable to the carrier for all damage caused by dangerous goods delivered for shipment, unless he has declared the dangerous nature of the goods at the time of delivery, and the carrier has accepted them with knowledge of their nature.

Carriage by two or more carriers. Goods frequently reach their destination after they have passed through the hands of two or more carriers. This may happen when the shipper has contracted with several carriers, when the shipper has authorized one of the carriers to act as his agent with other carriers, or when the carrier, without authority, delivers the goods to another carrier.

If the carrier, without authority, delivers the goods to another carrier, he is liable to the shipper for any misdelivery by the second carrier and for any loss or damage suffered by the owner of the goods while the goods were in the possession of the second carrier. This means that the carrier cannot relieve himself from liability by performing the contract through the services of an agent. Moreover, delivery of the goods to another carrier may be a breach of contract by virtue of an implied or express condition that the carriage shall be effected by the vehicles of the carrier. Such a condition is implied in maritime transports.

The carrier's assurance of payment

Carrier's liens. The law strives everywhere to secure payment of the freight to a carrier who has carried the goods to their destination. In common-law jurisdictions the carrier may have to this effect a common-law lien, a statutory lien, or even a contractual lien. In civil-law jurisdictions the carrier has, ordinarily, a privilege on the things carried.

A common carrier in common-law jurisdictions has a common-law lien under which he is entitled to retain possession of the goods until earned freight is paid to him. The carrier is not entitled to sell the goods or to use them; parties, however, may agree that the carrier shall have an active lien, namely, that he shall have the right to sell the goods. Thus, in maritime carriage in the United States, the shipowner is clearly entitled to seize and sell the goods carried by him in case of nonpayment of the freight. Parties may agree that the carrier shall have no lien at all or that he shall have a general lien on the goods carried, namely, a lien covering debts other than the pending freight. After the lien is exercised, the carrier has the rights and duties of a bailee. He may thus be liable for loss or damage occasioned by his negligence, and he may be entitled to recover expenses that were reasonably necessary for the preservation of the goods.

Carriers in civil-law jurisdictions ordinarily have a privilege on the goods carried by them for the payment of the freight and of incidental expenses. In France and in systems following the French model, this privilege is available only to professional carriers who carry goods by contract of carriage. The civil-law privilege differs from a common-law lien in that it confers on the carrier power and authority to sell the goods for the satisfaction of his claims. The privilege covers the whole shipment as determined by the documents of transport and is extinguished upon delivery of the goods to the consignee. Quite apart from the privilege, the carrier in civil-law jurisdictions may be entitled, under the general law of obligations, to refuse delivery of the goods until payment of the freight; moreover, he may secure payment of the freight by a variety of contractual arrangements.

The carrier's role as a warehouseman and bailee. In all legal systems, the peculiar liabilities imposed on carriers extend only for the duration of the carriage, that is, from the time the goods are delivered to the carrier for shipment until the carrier has taken all reasonable steps to deliver them to the consignee. This means that the carrier is not under his liability as a carrier for the whole time during which the goods may be in his possession. Indeed, goods may be delivered to a carrier for safekeeping before the carriage begins or after it terminates in accordance with the terms of a special contract that may qualify as bailment in common-law jurisdictions and as

a deposit in civil-law countries. Further, goods may be in the possession of the carrier because the consignee has unjustifiedly refused to take delivery, in which case the carrier may occupy the position of an involuntary bailee or depositary.

Goods not in transit

Generally, a carrier who is in possession of the goods before the beginning or after the end of the carriage is a warehouseman, and he is liable accordingly. In common-law jurisdictions the liability of a warehouseman is that of an ordinary bailee. In most cases a bailee, namely, a person entrusted with the goods of another, is not liable for the loss of or damage to the goods in his possession, unless the prejudice was caused by his intentional misconduct or negligence. In civil-law jurisdictions, if the parties agree that the carrier shall be in possession of the goods as a warehouseman before the beginning or after the end of the carriage, they form in effect a contract of deposit for reward, which is distinguishable from a contract of carriage. The elements of the contract of deposit and the rights and liabilities of the parties are dealt with in civil codes; exoneration clauses are valid under the conditions of the general law, and the period of limitation of actions is longer than one year. The depositary for reward is generally liable for intentional misconduct and negligence.

Measure of damages. Damages for the breach or nonperformance of a contract of carriage ordinarily are determined by application of the general rules of the law of contracts. Exceptional provisions applicable in case of breach of a contract of carriage are rare; they are mostly encountered in international conventions.

Bills of lading. Many shipments are made under bills of lading, issued by the carrier to the shipper upon delivery of the goods for shipment. The shipper is entitled to demand issuance of a bill of lading, unless his right is excluded by the contract of carriage. The bill of lading is, in the first place, an acknowledgment by a carrier that he has received the goods for shipment. Secondly, the bill of lading is either a contract of carriage or evidence of a contract of carriage. Thirdly, if the bill of lading is negotiable, as usually happens in carriage by sea, it controls possession of the goods and is one of the indispensable documents in financing the movement of commodities and merchandise throughout the world.

The bill of lading usually states the quantity, weight, measurements, and other pertinent information concerning the goods shipped. It frequently contains the statement that the goods have been shipped in apparent good order and condition. In this case, the carrier is not allowed to contradict the statement as to defects that were reasonably ascertainable at the time of delivery against an endorsee of the bill who relied on the statement. The bill of lading may be signed by the master or by a broker as agent of the carrier. As a receipt, the bill of lading is prima facie evidence that the goods have been delivered to the carrier; the burden of proof of nondelivery thus rests on the carrier.

In some jurisdictions the bill of lading is regarded as the contract of carriage itself. In other jurisdictions it is regarded merely as evidence of the contract of carriage; hence, oral testimony may be admissible to vary the terms of the contract evidenced by the bill of lading. When goods are shipped under a charter party or other document and a bill of lading is issued to cover the same goods, the bill of lading may ordinarily be regarded as a mere receipt. The terms of the contract are embodied in the charter party or other document, unless the parties intended to vary the terms of the agreement by the issuance of a bill of lading. A bill of lading that has been endorsed is ordinarily considered to contain the terms of the contract between the carrier and the endorsee.

Negotiable bills

At common law, a bill of lading functions as a semi-negotiable instrument. Delivery of the bill of lading to a transferee for valuable consideration transfers the ownership of the goods to the transferee, but the transferee cannot acquire a better title than that of the transferor. Under statutes, however, and under international conventions, bills of lading are in all legal systems fully negotiable instruments, unless they show on their face that they are not negotiable. When a bill of lading is negotiable, it confers a privileged status on the good faith purchaser, known as the holder in due course. A carrier who has issued a nonnegotiable bill of lading normally discharges his duty by delivering the goods to the named consignee; the consignee need not produce the bill or even be in possession of it. But a carrier who has issued a negotiable bill of lading will be discharged only by delivery to the holder of the bill, because, in a way, the goods are locked up in the bill of lading. The carrier who delivers goods without the bill of lading remains liable in common-law jurisdictions to anyone who has purchased the bill for value and in good faith, before or after the improper delivery. In civil-law jurisdictions, in case of an improper delivery, the carrier may remain liable to the endorsee of the bill of lading, even if the endorsee is himself not the legal owner of the bill but merely a finder or a thief.

Freight or forwarding agents. Shippers frequently engage the services of freight or forwarding agents, namely, persons who undertake for a reward to have the goods carried and delivered at their destination. The services of these persons are ordinarily engaged when the carriage of the goods involves successive carriers or use of successive means of transport.

A forwarding agent makes contracts of carriage for his principal. He may be a carrier or he may be merely a forwarding agent. When a carrier enters into a contract with the shipper by which he undertakes to carry goods in circumstances that involve an obligation on his part to hand over the goods to another carrier, he may be regarded as acting to some extent in the capacity of a forwarding agent. Conversely, when a forwarding agent carries the goods himself, he is to that extent a carrier and incurs the liabilities of a carrier.

Responsibilities of forwarding agents

In common-law jurisdictions a forwarding agent who is not a carrier is not responsible for what happens to the goods once they are handed over to a carrier with whom the forwarding agent has made a contract for his principal. By his transaction with the carrier, the forwarding agent establishes a direct contractual relationship between his principal and the carrier. Under the principles of the law of agency, the forwarding agent is under obligation toward his principal to conclude the contract on the usual terms. He is under no obligations, in the absence of an express contractual provision, to insure the goods. If, exceptionally, a forwarding agent acts as a carrier throughout the journey and uses other carriers on his own account, he is liable to the owner for any loss or damage to the goods during carriage. The extent of his liability depends on whether he is a common carrier or a contract carrier. If he is a common carrier, his liability to the owner of the goods may be heavier than the liabilities he can enforce against the carriers he has engaged.

In civil-law jurisdictions forwarding agents are clearly distinguished from carriers, and the contracts they make are clearly distinguishable from contracts of carriage. The profession of a forwarding agent, however, is not exclusive; thus, most frequently, carriers qualify as forwarding agents and vice versa. A forwarding agent has ordinarily a privilege on the goods under his control that is much broader and more effective than the privilege of the carrier. He has, in the absence of contrary contractual provision, freedom of choice of the means of transport and of particular carriers. His main obligation is to have the goods carried to their destination and delivered to the consignee. In the discharge of this obligation, he is generally entitled to engage the services of another forwarding agent. The forwarding agent is liable to his principal for any violation of his obligations resulting from negligence or intentional misconduct. He is relieved from liability if he proves that the loss or damage was occasioned by irresistible force. The liability of the forwarding agent for negligence may be excluded by contractual stipulations but not his liability for grave fault and intentional misconduct. A forwarding agent is considered as a carrier to the extent that he carries the goods himself, and to that extent he incurs the liabilities of a carrier. In contrast with the rule in common-law juris-

dictions, the forwarding agent in civil-law countries is fully responsible for loss or damage suffered by the goods in the hands of carriers that the forwarding agent has engaged for the performance of the contract with his principal, unless the services of the particular carrier were requested by the principal. The liability of the forwarding agent does not exceed that of the carrier he has engaged, and, if the carrier is exonerated by virtue of an excepted cause, so is the forwarding agent.

Mixed-carrier transportation. The expression mixed-carrier transportation refers to situations in which goods are carried to their final destination by two or more means of transport, such as road and sea or rail, sea, and air. There are at least two possibilities. The successive carriers may have no common juridical link, as when the shipper has contracted with each carrier independently or when the shipper has contracted with a forwarding agent. In these cases, each carrier is subject to his own regime and has his own rights and duties toward the shipper or forwarding agent. A second possibility is that the successive carriers may be bound by a common juridical link toward the shipper or owner of the goods by virtue of directly applicable legal or contractual provisions or by virtue of the fact that the goods travel under a single document of transport, as a through bill of lading. In these cases, municipal laws in civil-law jurisdictions tend toward the irreconcilable aims of subjecting each carrier to his own regime and, at the same time, holding all carriers solidarily liable. In domestic carriage in common-law jurisdictions, the liability of each carrier is ordinarily determined by application of the rules governing carriage by two or more carriers.

The through bill of lading

Mixed-carrier transportation in international commerce under a through bill of lading or similar document has been dealt with in international conventions. A through bill of lading covers carriage of goods by two or more successive carriers or by two or more means of transport. It is issued by the first carrier and constitutes a single title to the goods. Under a purely maritime through bill of lading, successive carriers are equally bound, unless the contrary has been stipulated. Solutions differ, however, when carriage is effected by two or more means of transport. Under the Berne Railroad Conventions for the carriage of goods, carriage by rail and sea may be subject to the rules governing railroad carriage at the option of the contracting states, unless reservation has been made by them for application of certain rules of maritime law to the portion of sea carriage. Since these conventions may be entirely inapplicable to the portion of sea carriage, interested carriers and international organizations have concluded agreements for a uniform, legal regime of rail and sea carriage. In fact, accords have been concluded among United States and Canadian railway and ocean-shipping companies for application of the rules of the Brussels Convention of 1924 to goods carried under through bills of lading by rail and sea. The rules of the Warsaw Convention for carriage of goods by air apply always to the portion of air carriage and to that portion only, but the International Air Transport Association and the International Union of Railways have concluded agreements for carriage by rail and air under a single document. Only the Geneva Convention of 1956 has undertaken to establish rules applicable to all means of transport under a single document. The convention provides, however, that, if damage has been incurred in a portion of the journey other than road carriage, the carrier shall be subject to his proper law. This convention may conflict with the Berne Conventions and does conflict with the Warsaw Convention to the extent that carriage by air is subjected to the Brussels rather than the Warsaw Convention.

Transportation by official carrier. In the Western world, the transport of goods is divided between public and private enterprise. The basis of the legal relationship between a carrier and his customer is the same whether the carrier is a public corporation, a local authority, or a private corporation or individual. The law of carriage of goods governs the rights and duties of the shipper, carrier, and consignee.

PRINCIPAL LEGISLATIVE APPROACHES

In all legal systems the law of carriage has been influenced by the idea that carriers enjoy a factual monopoly. The services that a customer may demand and the remuneration that a carrier may exact are generally regulated by legislation or administrative regulations. The growth of competition among carriers and means of transport in the Western world has led to a reduction in the scope of municipal legislation in a number of countries, but international conventions and administrative regulations have proliferated. The right to carry on a transport business is still everywhere regulated through elaborate licensing systems, and the operations of transport are subject to continuous supervision and control by appropriate agencies. The legal relation between the carrier and his customer is affected by this intervention of the public authorities, and public as well as private laws form the body of the law of carriage.

U.S. and British regulatory laws

Roads, railways, and inland waterways. Since the 19th century, legislation has been enacted in most countries to safeguard the public interest in the movement of goods by road, railway, and inland waterway. In the United States a decisive step toward regulation of transportation was taken with the Act to Regulate Commerce of 1887. This act was made applicable to all common carriers by railroads engaged in interstate or foreign commerce and to common carriers transporting goods in part by railroad and in part by inland water when both were used under a common control, management, or arrangement for a continuous carriage. The act created the Interstate Commerce Commission, which today has wide powers to hear complaints against carriers concerning alleged violations of law, to investigate matters in dispute, to order carriers to cease and desist from unlawful practices, and to determine the amount of damages suffered as a result of violations. The commission also possesses rate-making power.

Since the time the 1887 act was adopted, new forms of transport have arisen, and older ones have been improved. The Interstate Commerce Commission now has jurisdiction over railroads, pipelines, motor carriers, and certain carriers by water. Other federal agencies that have been charged with regulation of transportation are the Civil Aeronautics Board and the Federal Maritime Commission.

In England the Carriers Act of 1830 was the first legislative intervention in the field of carriage of goods. The act originally applied to all common carriers by land, including both road and railway carriage. The Railways Act of 1921, however, made special provisions with regard to the railways, and the Transport Act of 1962 enacted that the Railways Board shall not be regarded as a common carrier. Consequently, carriage by railways is now regulated by the contract between the Railway Board and the shipper or other contracting party, as laid down in the Book of the Rules of British Railways. The Carriers Act has never been applicable to private carriers and to common carriers by sea or by inland waterway. If part of the carriage is by sea or inland water and part by road, the act applies to the land part only.

The Berne Conventions

For many decades the law governing the international carriage of goods by railway has been codified in a number of international conventions. These are frequently referred to as the Berne Conventions. The first international convention concerning the carriage of goods by rail was concluded in Berne in 1890 and came into operation in 1893; after World War I it was replaced by a new convention concluded in 1924, which was again amended by a convention signed in Rome in 1933. This in turn was replaced after World War II by the Berne Convention of 1952. A new convention was signed in Berne in 1961 and came into operation in 1965. The conventions apply whenever goods have been consigned under a through consignment note for carriage over the territories of at least two of the contracting states and on certain specified lines. They regulate mostly the form and conditions of the contract of carriage; its performance, including delivery and payment of the charges; its modifications; the liability of the carrier for delay, loss, or

damage; and the enforcement of the contract by actions. Further, the conventions establish the obligation of the railways to carry goods and the rights and obligations of the various railway authorities of the contracting states. Most contracting states have incorporated into their municipal laws rules similar to those of the conventions for the regulation of the domestic carriage of goods by railway.

The Treaty of Rome of March 25, 1957, which created the European Economic Community, contains a number of provisions concerning matters of transport. Members of the Community are specifically bound to develop a common policy in matters of transport. The provisions of the treaty have been largely implemented by a number of international agreements. Since all members of the Common Market are members of the Berne Conventions, the mandate for uniformity of rules governing carriage of goods has been largely achieved as to carriage by railway.

Conflicts of laws

Sea carriage. Until the emergence of modern national states, the law governing maritime commerce had been largely uniform in the Western world. In the 18th and 19th centuries, however, legislative enactments and judicial decisions in pursuit of narrowly conceived national interests gradually displaced in various countries the venerable and uniform law of the sea and gave rise to sharp conflicts of laws. The movement of goods from country to country was thus hampered at a time when advancing technology and the spreading Industrial Revolution were about to lead to an expansion of maritime commerce on a world scale. Beginning with the last decades of the 19th century, it has become increasingly apparent that these conflicts of laws might be overcome by means of international conventions. The law of merchant shipping was quite naturally one of the first branches of private law to attract attention for possible international regulation.

The movement for uniformity culminated in the signing in 1924 of the International Convention for the Unification of Certain Rules of Law Relating to Bills of Lading. The convention was merely intended to unify certain rules of law relating to bills of lading and only with regard to damages occurring to hull cargo other than live animals. All bills of lading covered by the convention are subject to certain standard clauses defining the risks assumed by the carrier, which are absolute and cannot be altered by contrary agreement, and the immunities the carrier can enjoy, unless the parties agree otherwise. In general, clauses relieving the carrier from liability for negligence in loading, handling, stowing, keeping, carrying, and discharging the goods or that diminish his obligation to furnish a seaworthy vessel are declared null and void. The carrier, however, is relieved from liability for negligence in navigation or in the management of the vessel and from the absolute warranty of seaworthiness. The convention was originally intended to apply to all bills of lading issued in any one of the contracting states.

Most maritime nations, including the U.S.S.R., have ratified or adhered to the convention, and others, such as Greece and Indonesia, have enacted domestic legislation incorporating the rules agreed upon in Brussels. Some adhering nations, including Germany, Belgium, Turkey, and The Netherlands, have incorporated the rules of the convention into their commercial codes. Others, including the United States, Japan, Great Britain, and most members of the British Commonwealth, have enacted the rules in the form of special statutes known as Carriage of Goods by Sea Acts. Still others, including France, Italy, Egypt, and Switzerland, have given the convention itself the force of law and in addition have enacted domestic legislation modelled on the convention. The substantive standards governing bills of lading in maritime carriage have become largely uniform in most of the civilized world.

Carriage by air. The Warsaw Convention of 1929, as amended by the Hague Protocol of 1955, exemplifies still another legislative approach to problems raised by the carriage of goods. It constitutes a major step toward international unification of the rules governing carriage of goods by air. The convention applies to international carriage of persons, luggage, and goods for reward, as well as to gratuitous carriage performed by an air-transport undertaking. It applies whether the aircraft is owned by private persons or by public bodies; but, as to aircraft owned by a state directly, application of the convention may be excluded by appropriate reservation. According to the convention, there is an international carriage when the points of departure and destination are located within different contracting states or within the same contracting state but stopping has been agreed upon in another state, even if that state is not a member of the convention. The convention applies during the time the goods are in the charge of the carrier in any aircraft, airfield, or other facility. It does not apply when goods are carried by a land, sea, or inland-water carrier. Most nations, including the United States, Great Britain, and the U.S.S.R., are members of the convention. Only a few nations in South and Central America and in the Middle East have remained outside the convention. Although the convention applies to international carriage only, a great number of contracting states, including France and Great Britain, have made its rules applicable to domestic carriage of goods as well.

The Warsaw Convention

The air carrier is liable under the convention for delay and for the loss of or damage to the goods, provided that the occurrence that caused the prejudice took place during the carriage by air. The carrier is relieved from liability if he proves that he had taken all the necessary measures to avoid the damage or that it was impossible for him to take such measures. Unlike carriers by land and by water, the air carrier is not bound to prove the actual cause of the damage and that the damage was not attributable to his fault. If the cause of the damage remains unknown, there is no recovery. Contractual provisions tending to relieve the carrier from liability are null and void, except those concerning limitation of liability for loss or damage attributed to the inherent vice of the goods. Provisions tending to increase the liability of the carrier, however, are valid.

The convention contains provisions as to the jurisdiction of courts in case action is brought against the carrier and establishes a two-year period of limitation for the bringing of actions. No provision is made for liability of the carrier in case of deviation, for a carrier's lien, or for stoppage in transit, as this term is understood at common law. Accordingly, these matters are governed by the municipal law of the contracting states.

Other international agreements. The international movement of goods may be regulated in certain countries by international agreements other than the Berne Conventions, the Brussels Convention of 1924, or the Warsaw Convention of 1929. The Communist countries in eastern Europe, including the U.S.S.R., have established a uniform regime for the movement of goods by railway that is comparable to that of the Berne Conventions. Since these nations, with the exception of the U.S.S.R., belong to the Berne Conventions as well, it is possible that conflicts may arise as to the scope of application of each convention.

Other agreements in the field include the Geneva Convention of 1956 for the carriage of goods by road. The convention became operative in 1961, and its original membership includes France, Austria, Italy, The Netherlands, and Yugoslavia. It applies to international carriage of goods by road for reward, with the exception of certain items, such as mail. Carriage is international if it involves two countries, one of which is a member of the convention. An original feature of the Geneva Convention is that it covers mixed-carrier transportation. It applies for the whole journey, even if the road vehicle has been carried, without being unloaded, by another means of transport, unless there is proof that the damage occurred in a portion of the journey other than that of carriage by road.

Carroll, Lewis

An English mathematician and logician, whose real name was Charles Lutwidge Dodgson, Lewis Carroll is the author of two outstanding children's books, *Alice's Adventures in Wonderland* and *Through the Looking-Glass*, which are among the most quoted books in English and are almost alone of their kind in being read and enjoyed as much by adults as by children. They and a pendant, a narrative poem called *The Hunting of the Snark*, carry the art of "nonsense literature" to its highest levels.

Lewis Carroll, shown holding a camera lens; photograph by Oscar G. Rejlander, 1863.

Charles Dodgson was the eldest son and third child in a family of seven girls and four boys born to Frances Jane Lutwidge, the wife of the Rev. Charles Dodgson. He was born on January 27, 1832, in the old parsonage at Daresbury, Cheshire. His father was perpetual curate there from 1827 until 1843, when he became rector of Croft in Yorkshire—a post he held for the rest of his life (though later he became also archdeacon of Richmond and a canon of Ripon Cathedral).

Daresbury, in the mid-19th century, was a small country village isolated from the industrial development that was beginning to spread over southern Lancashire. The Dodgson children had few friends outside the family but, like many other families in similar circumstances, found little difficulty in entertaining themselves. Charles from the first showed a great aptitude for inventing games to amuse them. With the move to Croft when he was 12 came the beginning of the "Rectory Magazines," manuscript compilations to which all the family were supposed to contribute. In fact, Charles wrote nearly all of those that survive, beginning with *Useful and Instructive Poetry* (1845; published 1954) and following with *The Rectory Magazine* (*c.* 1850, mostly unpublished), *The Rectory Umbrella* (1850–53), and *Mischmasch* (1853–62; published with *The Rectory Umbrella* in 1932). All are interesting, but only the last two contain items worthy of comparison with the mature works of Lewis Carroll.

Meanwhile, young Dodgson attended Richmond School, Yorkshire (1844–45), and then proceeded to Rugby School (1846–50). He disliked his four years at public school, principally because of his innate shyness, although he was also subjected to a certain amount of bullying; he also endured several illnesses, one of which left him deaf in one ear. After Rugby he spent a further year being tutored by his father, during which time he matriculated at Christ Church, Oxford (May 23, 1850). He went into residence as an undergraduate there on January 24, 1851.

Academic career

Dodgson's academic career was all that could be desired. He excelled in his mathematical and classical studies in 1852; on the strength of his performance in examinations, he was nominated to a studentship (called a scholarship in other colleges). In 1854 he gained a first in mathematical Finals—coming out at the head of the class—and proceeded to a bachelor of arts degree in December of the same year. He was made a "Master of the House" and a senior student (called a fellow in other colleges) the following year and was appointed lecturer in mathematics (the equivalent of today's tutor), a post that he held until he resigned it in 1881. He held his studentship until the end of his life.

As was the case with all fellowships at that time, the studentship at Christ Church was dependent upon his remaining unmarried, and, by the terms of this particular endowment, proceeding to holy orders. Dodgson was ordained a deacon in the Church of England on December 22, 1861. Had he gone on to become a priest he could have married and would then have been appointed to a parish by the college. But he felt himself unsuited for parish work and, though he considered the possibility of marriage, decided that he was perfectly content to remain a bachelor.

Dodgson's child friends

Dodgson's association with children grew naturally enough out of his position as an eldest son with eight younger brothers and sisters. He also suffered from a bad stammer (which he never wholly overcame, although he was able to preach with considerable success in later life) and, like many others who suffer from the disability, found that he was able to speak naturally and easily to children. It is therefore not surprising that he should begin to entertain the children of Henry George Liddell, dean of Christ Church. Alice Liddell and her sisters Lorina and Edith were not, of course, the first of Dodgson's child friends. They had been preceded or were overlapped by the children of the writer George MacDonald, the sons of the poet Alfred, Lord Tennyson, and various other chance acquaintances. But the Liddell children undoubtedly held an especially high place in his affections—partly because they were the only children in Christ Church, since only heads of houses were free both to marry and to continue in residence.

Properly chaperoned by their governess, Miss Prickett (nicknamed "Pricks"—"one of the thorny kind," and so the prototype of the Red Queen in *Through the Looking-Glass*), the three little girls paid many visits to the young mathematics lecturer in his college rooms. As Alice remembered in 1932, they

> used to sit on the big sofa on each side of him, while he told us stories, illustrating them by pencil or ink drawings as he went along. . . . He seemed to have an endless store of these fantastical tales, which he made up as he told them, drawing

busily on a large sheet of paper all the time. They were not always entirely new. Sometimes they were new versions of old stories; sometimes they started on the old basis, but grew into new tales owing to the frequent interruptions which opened up fresh and undreamed-of possibilities.

On July 4, 1862, Dodgson and his friend Robinson Duckworth, fellow of Trinity, rowed the three children up the Thames from Oxford to Godstow, picnicked on the bank, and returned to Christ Church late in the evening: "On which occasion," wrote Dodgson in his diary, "I told them the fairy-tale of *Alice's Adventures Underground*, which I undertook to write out for Alice." Much of the story was based on a picnic a couple of weeks earlier when they had all been caught in the rain; for some reason, this inspired Dodgson to tell so much better a story than usual that both Duckworth and Alice noticed the difference, and Alice went so far as to cry, when they parted at the door of the deanery, "Oh, Mr. Dodgson, I wish you would write out Alice's adventures for me!" Dodgson himself recollected in 1887

> how, in a desperate attempt to strike out some new line of fairy-lore, I had sent my heroine straight down a rabbit-hole, to begin with, without the least idea what was to happen afterwards.

The first version of *Alice*

Dodgson was able to write down the story more or less as told and added to it several extra adventures that had been told on other occasions. He illustrated it with his own crude but distinctive drawings and gave the finished product to Alice Liddell, with no thought of hearing of it again. But the novelist Henry Kingsley, while visiting the deanery, chanced to pick it up from the drawing-room table, read it, and urged Mrs. Liddell to persuade the author to publish it. Dodgson, honestly surprised, consulted his friend George MacDonald, author of some of the best children's stories of the period. MacDonald took it home to be read to his children, and his son Greville, aged six, declared that he "wished there were 60,000 volumes of it."

Accordingly, Dodgson revised it for publication. He cut out the more particular references to the previous picnic (they may be found in the facsimile of the original manuscript, later published by him as *Alice's Adventures Underground* in 1886) and added some additional stories, told to the Liddells at other times, to make up a volume of the desired length. At Duckworth's suggestion he got an introduction to John Tenniel, the *Punch* magazine cartoonist, whom he commissioned to make illustrations to his specification. The book was published as *Alice's Adventures in Wonderland* in 1865. (The first edition was withdrawn because of bad printing, and only about 21 copies survive—one of the rarest books of the 19th century—and the reprint was ready for publication by Christmas of the same year, though dated 1866.)

The book was a slow but steadily increasing success, and by the following year Dodgson was already considering a sequel to it, based on further stories told to the Liddells. The result was *Through the Looking-Glass and What Alice Found There* (dated 1872; actually published December 1871), a work as good—or better—than its predecessor.

By the time of Dodgson's death, *Alice* (taking the two volumes as a single artistic triumph) had become the most popular children's book in England: by the time of his centenary in 1932 it was one of the most popular and perhaps the most famous in the world.

There is no answer to the mystery of *Alice*'s success. Many explanations have been suggested, but, like the Mad Hatter's riddle ("The riddle, as originally invented, had no answer at all"), they are no more than afterthoughts. The book is not an allegory; it has no hidden meaning or message, either religious, political, or psychological, as some have tried to prove; and its only undertones are some touches of gentle satire—on education for the children's special benefit and on familiar university types, whom the Liddells may or may not have recognized. Various attempts have been made to solve the "riddle of Lewis Carroll" himself; these include the efforts to prove that his friendships with little girls were some sort of subconscious substitute for a married life, that he showed symptoms of jealousy when his favourites came to tell him that they were engaged to be married, that he contemplated marriage with some of them—notably with Alice Liddell. But there is little or no evidence to back up such theorizing. He in fact dropped the acquaintance of Alice Liddell when she was 12, as he did with most of his young friends. In the case of the Liddells, his friendship with the younger children, Rhoda and Violet, was cut short at the time of his skits on some of Dean Liddell's Christ Church "reforms." For besides children's stories, Dodgson also produced humorous pamphlets on university affairs, which still make good reading. The best of these were collected by him as *Notes by an Oxford Chiel* (1874).

Photographic portraits

Besides writing for them, Dodgson is also to be remembered as a fine photographer of children and of adults as well (notable portraits of the actress Ellen Terry, the poet Alfred, Lord Tennyson, the poet-painter Dante Gabriel Rossetti, and many others survive and have been often reproduced). Dodgson had an early ambition to be an artist: failing in this, he turned to photography. He photographed children in every possible costume and situation, finally making nude studies of them. But in 1880 Dodgson abandoned his hobby altogether, feeling that it was taking up too much time that might be better spent. Suggestions that this sudden decision was reached because of an impurity of motive for his nude studies have been made, but again without any evidence.

Before he had told the original tale of *Alice's Adventures*, Dodgson had, in fact, published a number of humorous items in verse and prose and a few inferior serious poems. The earliest of these appeared anonymously; but in March 1856, a poem called "Solitude" was published over the pseudonym Lewis Carroll. Dodgson arrived at this pen name by taking his own names Charles Lutwidge, translating them into Latin as Carolus Ludovicus, then reversing and retranslating them into English. He used the name afterward for all his nonacademic works. As Charles L. Dodgson, he was the author of a fair number of books on mathematics, none of enduring importance, although *Euclid and His Modern Rivals* (1879) is of some historical interest.

His humorous and other verses were collected in 1869 as *Phantasmagoria and Other Poems* and later separated (with additions) as *Rhyme? and Reason?* (1883) and *Three Sunsets and Other Poems* (published posthumously, 1898). The 1883 volume also contained *The Hunting of the Snark* (first published 1876), a narrative nonsense poem that is rivalled only by the best of Edward Lear. Dodgson died at Guildford, Surrey, on January 14, 1898.

Later in life, Dodgson had attempted a return to the *Alice* vein but only produced *Sylvie and Bruno* (1889) and its second volume *Sylvie and Bruno Concluded* (1893), which has been described aptly as "one of the most interesting failures in English literature." This elaborate combination of fairy-tale, social novel, and collection of ethical discussions is unduly neglected and ridiculed. It presents the truest available portrait of the man. *Alice*, the perfect creation of the logical and mathematical mind applied to the pure and unadulterated amusement of children, was struck out of him as if by chance; while making full use of his specialized knowledge, it transcends his weaknesses and remains unique.

MAJOR WORKS

CHILDREN'S BOOKS: *Alice's Adventures in Wonderland* (1865); *Through the Looking-Glass and What Alice Found There* (1872).

VERSE: *Phantasmagoria and Other Poems* (1869); *The Hunting of the Snark* (1876); *Rhyme? and Reason?* (1883); *The Collected Verse* (1929).

MATHEMATICAL BOOKS: *A Syllabus of Plane Algebraical Geometry* (1860); *Euclid and His Modern Rivals* (1879); *Curiosa Mathematica* (1888–93).

OTHER WORKS: *Sylvie and Bruno*, 2 vol. (1889–93), novel.

BIBLIOGRAPHY. The primary sources are *The Life and Letters of Lewis Carroll*, by his nephew STUART DODGSON COLLINGWOOD (1898); *The Diaries of Lewis Carroll*, 2 vol., ed. and augmented by ROGER LANCELYN GREEN (1953); and *The Letters of Lewis Carroll*, ed. by MORTON N. COHEN and ROGER

LANCELYN GREEN (1973). The best of recent biographies is DEREK HUDSON, *Lewis Carroll* (1954); and the fullest is FLORENCE BECKER LENNON'S, published in 1945 as *Victoria Through the Looking-Glass*, and in a revised edition in 1962 as *The Life of Lewis Carroll*. Other studies of importance include HELMUT GERNSHEIM, *Lewis Carroll: Photographer* (1949); ALEXANDER L. TAYLOR, *The White Knight: A Study of C.L. Dodgson* (1952); ROGER LANCELYN GREEN'S "Bodley Head Monograph," *Lewis Carroll* (1960); and JEAN GATTEGNO, *Lewis Carroll* (1970), in French.

For bibliography, see *The Lewis Carroll Handbook*, by S.H. WILLIAMS and FALCONER MADAN (1931 and rev. by ROGER LANCELYN GREEN in 1962); and for collections of his works, the so-called *Complete Works of Lewis Carroll*, ed. by ALEXANDER WOOLLCOTT (1937); and the fuller, but still not complete, *The Works of Lewis Carroll*, ed. by ROGER LANCELYN GREEN (1965). For special editions of the two *Alice* books, see *The Annotated Alice*, ed. by MARTIN GARDNER (1960); and *Alice*, in the "Oxford English Novels Series," ed. by ROGER LANCELYN GREEN (1971). The manuscript of *Alice's Adventures Underground*, originally given to Alice Liddell, is now in the British Museum; so also are the surviving volumes of his *Diary*. No other major work seems to be extant in manuscript, but the four family magazines and miscellaneous juvenalia and mathematical and logical items are scattered among various collections, mainly in the United States.

(R.L.G.)

Cartesianism

In its broadest sense, Cartesianism is a set of philosophical traditions and scientific attitudes derived from the writings of René Descartes (1596–1650), the father of modern philosophy. The primary doctrine of Cartesianism is the division of reality between mind, the essence of which is thinking, and matter, the essence of which is extension in three dimensions. The ideas of these two substances, plus that of God, whose essence is necessary existence, are innate. Careful examination of these ideas provides a complete Rationalistic metaphysics, or theory of the ultimate nature of Being. The division between mind and matter gives rise, however, to two serious problems in Cartesian metaphysics: how can active, unextended mind interact with passive, extended body? and how can mind contact and thus know matter when the two substances are essentially unlike one another? The various lines of Cartesian philosophy are developed from different answers to these questions.

Descartes's *cogito* and mechanism

Nature of Cartesianism. Descartes is best known for his *cogito:* "I think, therefore I am." This indubitable proposition was the intuitive result of a course of methodic doubt in which the supposed truths of tradition, the senses, and reason were subjected to skeptical attack with the precise goal of refuting Skepticism. The search for certainty in both philosophy and science thus rested on a psychologistic foundation. Ideas—or propositions—that are as clear and distinct as the *cogito* were used to prove the existence of God, to establish the reality of the external world, and to elaborate the sciences of mind and matter.

Descartes denied the intelligibility of Scholastic (medieval Aristotelian philosophical) explanations of physical phenomena that depend on the effects of occult forces and powers, such as those attributing the white colour of objects to an activating quality of whiteness. He also was opposed to any notion of action over a distance, and so denied the existence of a vacuum. Thus, the Cartesians not only opposed the Aristotelians but also the Atomism of Pierre Gassendi, a French Epicurean, and the mitigated Skepticism of the New Scientists—the leaders of the 17th-century scientific revolution—who were satisfied with probabilities.

The present article, however, is concerned not with the philosophy of Descartes (*q.v.*) but with that of his followers.

Cartesian physiologists and physicists followed Descartes by explaining the behaviour of both living and inanimate bodies exclusively in terms of contiguous parts of corpuscular matter in motion. All bodies operate according to mechanistic principles, and all animal bodies —including those of men—are machines. Thus, Cartesianism provided a rationale for experimentation in physics, for vivisection in physiology, and for intensive psychological speculation about man—for man alone in the animal kingdom was said to possess a self-conscious mind in control of a living body.

The first Cartesians were physicists and physicians who applied Descartes's principles to the working out of mechanistic explanations. In Holland, this endeavour led to such vicious disputes as that between the Cartesian physician Regius (Henri de Roy) and the Aristotelian Gisbertus Voetius, a Reformed theologian. In France, the lectures of the Empiricist Pierre-Sylvain Régis on Cartesian physics attracted such attention that Louis XIV forbade them on the ground that civil disturbance could arise from any such general criticism of traditional authority. Throughout Europe, the question of animal machines was debated in a large popular literature; and in England, one of the most widely read expositions of Isaac Newton's physics was a translation of the French dualist Jacques Rohault's treatise on Cartesian physics corrected and annotated with footnotes by the Newtonian moralist Samuel Clarke.

Historical development of Cartesianism. Cartesianism has Neoplatonic roots in the psychologistic philosophy of St. Augustine, who prefigured the aforementioned *cogito*, and in the views of the mathematical physicist Galileo, who made the crucial distinction between the real, quantitative properties of bodies—the so-called primary qualities, such as size, shape, and position—and the sensible properties—the so-called secondary qualities, such as colour, taste, and odour, said to exist only in the perceiving mind. The movement began as a well-orchestrated development. Descartes's philosophical method, and particularly his discoveries in mathematics and his approach in physiology, had been current many years before the publication of his *Meditations* (1641), which was arranged by one of his champions, the influential Rev. Marin Mersenne, to be a century-shaking event. This work was accompanied by seven sets of objections by such distinguished critics as the Materialist Thomas Hobbes, Pierre Gassendi, the Jansenist theologian Antoine Arnauld, and Mersenne himself. These objections, which, together with Descartes's replies, are five times as long as the *Meditations*, set the stage for most further Cartesian controversies. Cartesian writings, letters, and controversies continued to be published long after the master's death.

Malebranche and occasionalism

Mind–matter dualism. The most important philosophical work stemming directly from Descartes's writings is that of Nicolas Malebranche, known as an occasionalist because he held that on the occasion of every perception and motion each such event occurs by God's action. Malebranche denied, however, that he was a Cartesian on several grounds: Descartes taught that the mind is better known than the body, whereas Malebranche claimed (like the Scottish Skeptic David Hume after him) that introspection provides no direct contact with the mind. Descartes also believed that ideas—both notions and sensations—are caused by bodily actions on the mind exerted through the mediation of the pineal gland, near the middle of the brain. Malebranche, on the other hand, being convinced of the objection—urged against the Cartesians most insistently by the Skeptical chaplain Simon Foucher—that Cartesian mind and matter cannot interact, developed a system of occasionalism. This is the view—suggested by Descartes and adopted also in part by Arnold Geulincx, a Flemish convert to Calvinism, and by Géraud de Cordemoy, a Parisian historian and philosopher—that mind and body do not interact but that, on every occasion of their appearing to interact, God causes the appropriate responses in both mind and body. If causal interaction is ruled out, however, so also is the possibility of the mind's knowing bodily properties directly. Because external objects are known for Cartesians only mediately by way of ideas, the Skeptical problem arises of how one can know that ideas are true of their objects. Indeed, Descartes himself raised the spectre of a demon that might cause one to have such ideas even in the absence of an external world. To this last, Malebranche said tersely that the existence of the material world is assured by the first chapter of Genesis.

As for the truth of ideas, Malebranche offered the Platonic view that all ideas actually reside in the mind of God: on the proper occasions, God illuminates these ideas for human observation; thus we see all things in God and rest assured in his goodness.

Orthodox Cartesians followed Malebranche's lead in accepting the dualism of mind and body, but, unlike Malebranche, they continued to insist on the interaction between the two. Régis gave a typical answer to the problem by saying simply that God could make it so, even if the philosopher cannot understand how—a ploy that was taken by his critics as an abdication of philosophy in favour of mysticism. A similar answer was given to the question of how mind could know matter. Accepting Foucher's analysis that the mental representation of an object depends on a resemblance between idea and object and his criticism charging that Cartesian mental ideas cannot resemble material objects, Rohault spoke for orthodox Cartesians in saying that it is simply the nature of ideas to represent their objects: God has made it so that mental ideas represent material objects; thus, no resemblance between the two or any further explanation is necessary.

Applications in religion

Though Thomistic philosophers (followers of St. Thomas Aquinas) had said that the soul or mind is the form of the human body, all Cartesian philosophers emphatically denied this formulation, presenting man as a compound substance formed by the union of mind and body. Beyond the problems of interaction discussed above, this raised the problem of the ultimate nature of man. The French physician Louis de la Forge and several other Cartesians came to the logical conclusion that at death the mind is completely severed from all knowledge of individual bodies; sensations are but confused ideas issuing from this union and are available neither in memory nor in experience when that union is broken. What the soul knows of matter after death is, in this view, only the general disposition of intelligible extension—*e.g.*, the axioms and theorems of solid geometry. Like the notion that animals are mere machines, however, the Cartesian conclusion that the sensible manifestations of this life will be neither continued nor remembered in the next was quite generally unpopular in the 17th century.

Though Descartes explicitly denied any concern with theology, he did offer physical explanations of the Christian doctrine of transubstantiation. It was Rohault, however, who gave the clearest exposition of the mechanistic view that, in the miracle of the Eucharist, the bread and wine are replaced point by point with the flesh and blood of Christ. In the Cartesian view, sensations are produced merely by the configurations of material objects in motion against the sense organs. Flesh and blood, if organized in the configurations of bread and wine, would cause one to have sensations of bread and wine. In this explanation, Thomistic substantial forms that persist despite the absence of underlying substances are unnecessary. Nevertheless, the church was not pleased with this and other Cartesian attacks upon Thomistic-Aristotelian dogma and so banned Descartes's works and forbade the teaching of Cartesianism.

Cartesianism was popularized in England by Antoine Le Grand, a French Franciscan. Though, like Rohault and Régis, he was primarily interested in physics, he attempted to provide expositions of the complete Cartesian philosophy. In response to critics who said that the essence of mind cannot be thinking because it is sometimes thoughtless, he taught, for example, that the mind is always thinking, even when in deep sleep, though these thoughts are not often remembered.

Mechanistic physics. As an example of the mechanistic Cartesian explanations given by Le Grand and others, that of light and colour is typically ingenious. Light was said to consist of tiny globes of highly elastic, subtle matter. In proportion to the speed and spin of the globes, the light is seen in various colours. Moreover, they bounce like tennis balls exactly along lines consistent with mathematical optics. On a grand scale, the entire physical universe consists. in this view, of a plenum of matter of differing degrees of subtlety, whirling at different speeds in vortices as great as that in which the planets sweep around the sun or as small as those of single globes of light. God set this great system going by imparting to it a given quantity of motion that is maintained through all transformations within the universe. The conservation of motion is thus the key to Cartesian-Rationalistic physics: Cartesians recognized the need for experimentation but believed that, if the speeds or amounts of motion and the positions of all portions of matter in the universe were once described for any given time, then simple deductions with reference to the laws of motion would lead to the description of their positions and configurations for any other time. Obviously, only the great mathematical physicist, God, is in a position to make these calculations. The primary cause in this universe is God; secondary causes may not be entirely understood, but they can be adequately described as bumpings among bodies. Thus, whereas Cartesian Rationalism in philosophy depends on the clarity and distinctness of the innate ideas of God, mind, and matter, Cartesian-Rationalistic physics depends on simple mechanistic laws operating in a material world where the quantity of motion is constant.

Vortices and motion

Deterministic ethics. Descartes's moral precepts consisted mostly of prudent advice to adhere to the laws and customs of one's country, station, and religion. Geulincx, however, developed a strict Cartesian ethics based on the deterministic will of God. Although a man can do only what God wills, he is free to accept this willingly or unwillingly. For Geulincx, virtue consists in the humble, diligent, and obedient acceptance of the justice of God's will in the light of reason; sin and evil result from man's egotistic (and futile) stand against God. Human freedom and happiness reside not in action but in the understanding of necessity. Cartesian ethics is thus as deterministic as Cartesian physics.

As a total system, traditional Cartesian philosophy and science were more or less refuted by the end of the 17th century. Cartesian-Rationalistic physics was exceeded in ingenuity and explanatory power by more skeptical empirical physicists. But more than that, Descartes's laws of motion proved to be just wrong, and even Cartesians were forced to admit that the principle of the conservation of motion must be replaced by the Newtonian conservation of energy. The Cartesian metaphysical system was doomed by its failure to solve the problems of its dualism. On more popular grounds, Cartesianism was ridiculed because of its doctrine that animals are machines. And finally, neither theologians nor laymen were satisfied with Cartesian claims to have faith in the doctrines of the church, in the face of the fact that the Cartesian system seemed to deny some of them.

Influence of Cartesianism. Thus, Cartesianism proper should probably be viewed as having flourished only through the time of Régis, who published his *Système* in 1690. Benedict de Spinoza, however, an important secular Jewish Rationalist, is also, on occasion, classed as a Cartesian. Spinoza studied Descartes carefully, concluding that mind and matter cannot interact. His solution was to elevate God to the level of the only existing substance, from which mind and matter emanate as distinct attributes that are parallel in every respect but do not interact. Like Malebranche, Spinoza did not explain how mind and matter can interact but only why they appear to interact. In this broader Cartesian context, another Rationalist, Gottfried Wilhelm Leibniz, also a scientist and diplomat, likewise gave a parallelistic answer. Though the Leibnizian monads, or psychic units of reality, are self-complete and do not interact, each has a pre-established harmony with all the others so that the appearance of interaction is maintained. The Materialist Thomas Hobbes solved the problem by doing away with mind, saying that it is merely an epiphenomenal manifestation of interacting material objects. The phenomentalist George Berkeley, on the other hand, did away with matter, saying that material objects are simply constructions out of the mind's ideas. All of these single-substance systems—Spinoza's God, Leibniz' monads,

Monistic and parallelistic systems

Hobbes' matter, and Berkeley's mind—were developed as major solutions to the problems posed by the Cartesian dualism of mind and matter.

The influence of the distinction between primary and secondary qualities has also been significant. Thus, Galilean–Cartesian–Newtonian science, on the one hand, described primary properties almost exclusively, as does contemporary physics, whereas George Berkeley's phenomenalism, on the other hand, assimilated primary properties to secondary ones. Moreover, the Humean distinction between fact and value issued in part from the exaltation of what is mathematically objective over that which is merely emotional and subjective; and in contemporary philosophy, the primary- and secondary-property distinction is the ground of sense-datum philosophy. In contemporary metaphysics, this distinction returns once again with the *cogito* in the Phenomenology of the German philosopher Edmund Husserl and the Existentialism of the French philosopher and dramatist Jean-Paul Sartre.

Descartes also stands at the base of modern mathematics through his invention of analytic geometry, which laid essential ground for the discovery of the calculus by Leibniz and Newton. Cartesian method was brilliantly elaborated by the Jansenists (followers of the Dutch Catholic predestinarian theologian Cornelius Jansen) Antoine Arnauld and Pierre Nicole in works on logic and grammar that are fundamental to the science of linguistics. Even in ethics, Descartes's prudentialism prefigures the abstracted conservativism of the modern scientific community.

Contemporary significance of Cartesianism. Despite the early demise of the Cartesian system, Descartes's influence has been so broad and pervasive that philosophers in the West can all be said to be Cartesians, just as they are all Greeks, in the sense that, even when they are utterly opposed to Cartesianism, the stances they assume are responses to issues originally posed by Descartes. Descartes's skeptical method and his mathematics helped to underpin the New Science; his methods of analysis and conventional morality have formed Western man's modern consciousness; and his intense desire to master mind and matter is strongly reflected in contemporary thought.

Objections and rejoinders

Two major objections to Cartesianism survive in importance today. As Arnauld was the first to point out, Descartes's proof of the existence of God and thus of the external world is circular: the existence of God is first proved because the idea of God is seen to be clear and distinct; but an undeceiving God's existence is necessary to assure the philosopher of the indubitability of the criterion of clarity and distinctness. One answer to this charge, however, is that the truth that God exists is neither deduced nor dependent on any criterion but is, like the *cogito*, understood in a nondiscursive intuitive moment upon presentation of the idea.

Of more contemporary ferment is the question of the dualism of mind and matter, which most contemporary philosophers deny. Neutral monist positions, holding that the world and man can be described as material or mental depending upon one's interest, were developed by such philosophers as the distinguished logician Bertrand Russell and the U.S. Pragmatist William James; and the American John Dewey and Gilbert Ryle, an outstanding British Analytical philosopher, have made attacks on the dualism based on Pragmatic and behaviouristic principles that stress behavioural responses rather than introspective consciousness. All of these criticisms stem basically from the tradition of British Empiricism. From traditional Thomistic–Aristotelian and Rationalistic backgrounds, similar criticisms have been made by the two foremost medievalists, the French philosophers Étienne Gilson and Jacques Maritain.

The strongest defenders of the dualism of mind and matter continue to be physiologists. Those like the Australian Sir John C. Eccles and Wilfred E. Le Gros Clark, an English primatologist, who have looked deeply into the structure of the brain, sometimes view the mind as an entity existing on a plane other than the material. Their work is related to the widely discussed issue of whether machines can think.

A most important recent revival of Cartesian Rationalism has been made by the U.S. linguist Noam Chomsky. In discussing underlying principles that are basic to all languages, Chomsky argues that human beings can utilize principles that are not learned. Because both the principles and the capacity to use them can be said to be innate ideas, the mind might then be compared to a preprogrammed computer with creative capacities—a view that presents in contemporary form the old Cartesian questions: how can machines think? That is, how can computers be self-conscious? Does the existence of innate ideas prove the existence of God? That is, who—if anyone—programmed the computer?

BIBLIOGRAPHY

Works in English: For sources on René Descartes himself, see the bibliography for the article DESCARTES, RENE. For a guide to the critical literature, much of which is in other languages, see the indispensable work of GREGOR SEBBA, *Bibliographia Cartesiana: A Critical Guide to the Descartes Literature, 1800–1960* (1964). The best background studies for Cartesianism are found in EDWIN ARTHUR BURTT, *The Metaphysical Foundations of Modern Physical Science*, rev. ed. (1954); and RICHARD H. POPKIN, *The History of Scepticism from Erasmus to Descartes* (1960). See J.S. SPINK, *French Free-Thought from Gassendi to Voltaire* (1960), for a general view. Classic studies of Cartesians are found in A.G.A. BALZ, *Cartesian Studies* (1951). RICHARD A. WATSON, *The Downfall of Cartesianism, 1673–1712* (1966), shows the failures of Cartesianism as a complete metaphysical system. Perhaps the best general study of Cartesianism in the broadest sense is NORMAN KEMP SMITH, *Studies in the Cartesian Philosophy* (1902, reprinted 1962), which covers the failure of Rationalism from Descartes through Kant. LEONORA COHEN ROSENFIELD, *From Beast-Machine to Man-Machine*, new and enl. ed. (1968), poses most readably the question whether animals have souls and shows Descartes's important influence on modern physiology. NOAM CHOMSKY, *Cartesian Linguistics* (1966), combines historical exposition with the important claim that Cartesian Rationalism is the best general guide to the study of the language-originating mind of man. An overall study of reactions against Cartesian metaphysics is brilliantly presented by ARTHUR ONCKEN LOVEJOY, *The Revolt Against Dualism* (1930). Finally, GILBERT RYLE, *The Concept of Mind* (1949), uses a critique of Cartesian dualism as a springboard for the presentation of doctrines of contemporary linguistic philosophy and philosophy of mind.

Jahrhunderts* (1912); FRANCISQUE BOUILLIER, *Histoire de la philosophie cartésienne*, 3rd ed. (1868), a standard source, though somewhat unreliable; E.J. DIJKSTERHUIS *et al.*, *Descartes et le cartésianisme hollandais* (1950); ETIENNE GILSON, *Études sur le rôle de la pensée médiévale dans la formation du système cartésien* (1930); GEORGES MONCHAMP, *Histoire du cartésianisme en Belgique* (1886); PAUL MOUY, *Le Développement de la physique cartésienne, 1646–1712* (1934), for Cartesianism in physics; JOSEPH PROST, *Essai sur l'atomisme et l'occasionalisme dans la philosophie cartésienne* (1907); M.PH. DAMIRON, *Essai sur l'histoire de la philosophie en France, au XVII^e siècle* (1846); GASTON SORTAIS, *Le Cartésianisme chez les jésuites francais au XVII^e et au XVIII^e siècle* (1929) and *La Philosophie moderne depuis Bacon jusqu'à Leibniz* (1920).

(R.A.W.)

Cartier, Jacques

The French mariner Jacques Cartier was among the first to explore the coastline of North America west of the Grand Banks fishing grounds and within the Gulf of St. Lawrence. He appears also to have voyaged to Brazil.

Cartier was born at Saint-Malo in 1491. When King Francis I of France decided in 1534 to send an expedition to explore the northern lands in the hope of discovering gold, spices, and a passage to Asia, Cartier received the commission.

First two voyages

Cartier sailed from Saint-Malo on April 20, 1534, with two ships and 61 men; he explored the Gulf of St. Lawrence as far as Anticosti Island, then seized two Indians at Gaspé and sailed back to France. His report piqued the curiosity of Francis I sufficiently for him to send Cartier back the following year, with three ships and

110 men, to explore further. Guided by the two Indians he had brought back, he sailed up the St. Lawrence as far as Quebec and established a base near an Iroquois village. In September he proceeded with a small party as far as the island of Montreal, where navigation was barred by rapids. He was warmly welcomed by the resident Iroquois, but he spent only a few hours among them before returning to winter at his base. He had, however, learned from the Indians that two rivers led farther west to lands where gold, silver, copper, and spices abounded.

The severity of the winter came as a terrible shock, Quebec being farther south than Paris and no Europeans since the Vikings having wintered that far north on the American continent. Scurvy claimed 25 of Cartier's men. To make matters worse, the explorers earned the enmity of the Iroquois. Thus, in May, as soon as the river was free of ice, they treacherously seized some of the Iroquois chiefs and sailed for France. Cartier was able to report only that great riches lay farther in the interior and that a great river, said to be 800 leagues (about 2,000 miles [3,200 kilometres]) long, possibly led to Asia.

War in Europe prevented Francis I from sending another expedition until 1541. This time, to secure French title against the counterclaims of Spain, he commissioned a nobleman, Jean-François de La Rocque de Roberval, to establish a colony in the lands discovered by Cartier, who was appointed Roberval's subaltern. Cartier sailed first, arriving at Quebec on August 23; Roberval was delayed until the following year. Cartier again visited Montreal, but as before he remained only a few hours and failed to go even the few miles necessary to get beyond the rapids. The subsequent maps based on the knowledge he provided fail to indicate that he had reached a large island at the confluence of the Ottawa and St. Lawrence rivers.

Third voyage

The winter at his new base above Quebec proved as severe as the earlier one. Cartier appears to have been unable to maintain discipline among his men, and their actions again aroused the hostility of the local Indians. But what were thought to be gold and diamonds were found in abundance. In the spring, not waiting for Roberval to arrive with the main body of colonists, Cartier abandoned the base and sailed for France. En route he stopped at Newfoundland where he encountered Roberval, who ordered him back to Quebec. Cartier, however, stole away during the night and continued back to France. There, his gold and diamonds were found to be dross. Roberval enjoyed no better success. After one winter he abandoned the plan to found a colony and returned to France. The disappointment at these meagre results was very great. Not for more than half a century did France again show interest in these new lands.

Cartier received no new commissions from the crown. He apparently spent his remaining years attending to his business affairs at his estate near Saint-Malo, where he died on September 1, 1557. His claim to fame rests on his exploration of the St. Lawrence River to the height of navigation. Yet his failure to proceed any farther (when it would have been easy to do so), his treacherous dealings with the Iroquois, and his leaving Roberval in the lurch, detract somewhat from his stature.

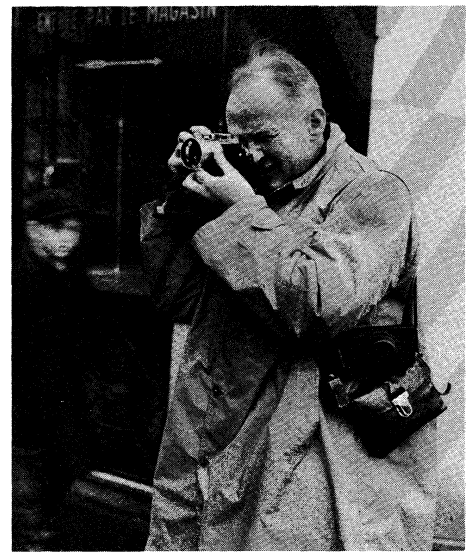
BIBLIOGRAPHY. The journals of Cartier's voyages, in original and translation, were edited by H.P. BIGGAR, *The Voyages of Jacques Cartier* (1924), as was *A Collection of Documents Relating to Jacques Cartier and the Sieur de Roberval* (1930). BERNARD G. HOFFMAN, *Cabot to Cartier* (1961), critically examines the source material. The best account of Cartier's voyages is in MARCEL TRUDEL, *Histoire de la Nouvelle-France: Les vaines tentatives 1524–1603* (1963). Briefer accounts, in English, are contained in J.B. BREBNER, *The Explorers of North America* (1933); and W.J. ECCLES, *The Canadian Frontier, 1534–1760* (1969).

(W.J.E.)

Cartier-Bresson, Henri

The works of the photographer Henri Cartier-Bresson are among the photographic images of the 20th century that linger most persistently: fat picnickers on the banks of the Marne; children of Spain playing in Civil War ruins; a grinning eunuch in Peking. Further, such images helped establish photojournalism as an art form. Cartier-Bresson took things as they came. He had an antipathy for arranged photographs and contrived settings and would not tamper with the image. But his photographs are more than random views of the world. No matter how spontaneous or automatic they were in the moment of making, they depended upon a richly nurtured intuition and a highly selective eye.

Jean Marquis—Magnum



Cartier-Bresson.

Henri Cartier-Bresson was born on August 22, 1908, at Chanteloup, not far from Paris, where he attended school. In 1927–28 he studied in Paris with André Lhote, an artist and critic associated with the Cubist movement. Lhote implanted in him a lifelong interest in painting, a crucial factor in the education of his vision. In 1929 Cartier-Bresson went to Cambridge, where he studied literature and painting.

As a boy, Cartier-Bresson had been initiated into the mysteries of the simple "Brownie" snapshot camera. But his first serious concern with the medium occurred in about 1930, after seeing the work of two major 20th-century photographers, Eugène Atget and Man Ray. Making use of a small allowance, he travelled in Africa in 1931, where he lived in the bush, recording his experiences with a miniature camera. There, he contracted blackwater fever, necessitating his return to France. The portability of a small camera and the ease with which one could record instantaneous impressions must have struck a sympathetic chord, and in 1933 he purchased his first 35-millimetre Leica. The use of this type of camera was particularly relevant to Cartier-Bresson. It lent itself not only to spontaneity but to anonymity as well. So much did Cartier-Bresson wish to remain a silent, and even unseen, witness, that he covered the bright chromium parts of his camera with black tape to render it less visible, and he sometimes hid the camera under a handkerchief. The man was similarly reticent about his life and work.

Preference for the 35-millimetre camera

In more than 40 years as a photographer, Cartier-Bresson wandered continually around the world. But there was nothing compulsive about his travels, and he explicitly expressed a desire to move slowly, to "live on proper terms" in each country, to take his time, so that he became totally immersed in the environment.

In 1937, the year of his marriage to Mlle. Ratna Mohini, Cartier-Bresson produced a documentary film, his first, on medical aid in the Spanish Civil War. The date also marked his first reportage photographs made for newspapers and magazines. His enthusiasm for film making was further gratified when, from 1936 to 1939, he worked as an assistant to the film director Jean Renoir in the production of *Une Partie de campagne* ("Picnic") and *La Règle du jeu* (*The Rules of the Game*). As a photographer

he felt indebted to the great films he saw as a youth. They taught him, he said, to choose precisely the expressive moment, the telling viewpoint. The importance he gave to sequential images in still photography may be attributed to his preoccupation with film.

In 1940, during World War II, Cartier-Bresson was taken prisoner by the Germans. He escaped in 1943 and the following year participated in a French underground photographic unit assigned to record the German occupation and retreat. In 1945 he made a film for the U.S. Office of War Information, *Le Retour*, which dealt with the return to France of released prisoners of war and deportees.

Though Cartier-Bresson's photographs had been exhibited in 1933 in the prestigious Julien Levy Gallery in New York City, a more important tribute was paid to him in 1947, when a one-man exhibition was held in that city's Museum of Modern Art.

The same year, Cartier-Bresson, in partnership with the U.S. photographer Robert Capa and others, founded the cooperative photo agency known as Magnum Photos. The organization offered periodicals global coverage by some of the most talented photojournalists of the time. Under the aegis of Magnum, Cartier-Bresson concentrated more than ever on reportage photography. The following three years found him in India, China, Indonesia, and Egypt. This material and more, taken in the 1950s in Europe, formed the subjects of several books published between 1952 and 1955. Such publications helped considerably to establish Cartier-Bresson's reputation as a master of his craft. One of them, and perhaps the best known, *Images à la sauvette* (*The Decisive Moment*), contains what is probably Cartier-Bresson's most comprehensive and important statement on the meaning, technique, and utility of photography. The title refers to a central idea in his work—the decisive moment—the elusive instant when, with brilliant clarity, the appearance of the subject reveals in its essence the significance of the event of which it is a part, the most telling organization of forms.

Books and exhibitions

He was singularly honoured by his own country in 1955, when a retrospective exhibition of 400 of his photographs was held in the Musée des Arts Décoratifs, Paris, and was then displayed in Europe, the United States, and Japan before the photographs were finally deposited in the Bibliothèque Nationale in Paris.

In the mid-1960s Cartier-Bresson continued to live in Paris and to make frequent trips abroad. In 1963 he was photographing in Cuba; in 1963–64 he was in Mexico, and in 1965, India. The French film maker Louis Malle recalled that, during the student revolt in Paris, in May 1968, Cartier-Bresson was there with his 35-millimetre camera, but despite the explosive activities, he took photographs at the rate of about four per hour.

In recent years Cartier-Bresson diverted most of his interest to making motion pictures. He believed that still photography and its use in pictorial magazines was, to a large extent, being superseded by television. On principle, he always avoided developing his own prints, convinced that the technical exigencies of photography were a harmful distraction. Similarly, he directed the shooting of films and did not wield the camera himself. With this medium, however, he was no longer able to work unobtrusively by himself.

His Leica—his notebook, as he called it—accompanied him wherever he went, and, consistent with his training as a painter, he always carried a small sketch pad. There was for Cartier-Bresson a kind of social implication in the camera. To his mind, photography provided a means, in an increasingly synthetic epoch, for preserving the real and humane world.

BIBLIOGRAPHY. Collections of Cartier-Bresson's work may be found in the Bibliothèque Nationale, Paris; the Museum of Modern Art, New York; and the George Eastman House, Rochester. A useful bibliography and several perceptive essays are included in LINCOLN KIRSTEIN and BEAUMONT NEWHALL, *The Photographs of Henri Cartier-Bresson* (1947). In more recent editions the bibliographies have been deleted. A selected bibliography appears in NATHAN LYONS (ed.), *Photographers on Photography* (1966), where also the complete text of Cartier-Bresson's essay in his *Decisive Moment* (1952) is reproduced. No complete biography of Cartier-Bresson exists. The present literature deals mainly with the character of his work. BEAUMONT NEWHALL, "The Instant Vision of Henri Cartier-Bresson," *Camera*, 34:485–489 (1955), is a valuable discussion of the photographer's equipment and manner of working. See also CARTIER-BRESSON'S work, *The World of Henri Cartier-Bresson* (1968).

(A.Sc.)

Carver, George Washington

A distinguished agricultural chemist and experimenter, George Washington Carver became a public benefactor of the entire American South and a black hero of popular history whose name has been appropriated by almost as many black schools, lodges, clubs, movie theatres, banks, and insurance companies as that of the famous educator Booker T. Washington. Adjusting himself to what he considered a transient racial situation in the South, Carver attempted to prepare rural Negroes for full citizenship rights by teaching them how to become skilled farmers and useful citizens. He dedicated his life to making Tuskegee Institute, Tuskegee, Alabama, an instrument of ministry to the needs of these people, and, in the process, he became an outstanding teacher, artist, humanitarian, and prophet.

Early life and education. Carver was born near Diamond Grove, Missouri, early in the 1860s, the son of a slave woman owned by Moses Carver. During the Civil War, slave owners found it difficult to hold slaves in the border state of Missouri, and Moses Carver, therefore, sent his slaves, including the young child and his mother, to Arkansas. After the Civil War, Moses Carver learned that all his former slaves had disappeared except for a child named George who had become ill with whooping cough. Frail and sick, the motherless child was returned to his former master's home and nursed back to health. The boy had a delicate sense of colour and form and learned to draw; later in life he was to devote considerable time to painting flowers, plants, and landscapes. He also became well-known among the blacks as a singer and organist. Though the Carvers told him he was no longer a slave, he remained on their plantation until he was about ten or 12 years old, when he left to acquire an education. He spent some time wandering about, working with his hands and developing his keen interest in plants and animals.

By both books and experience, George acquired a fragmentary education. Throughout his adolescence he was a stranger in a strange land, doing whatever work came to hand in order to subsist. The diversity of Carver's talents, later demonstrated in his scientific work, was forecast in these early years of wandering, when he supported himself by varied occupations that included general household worker, hotel cook, laundryman, farm labourer, and homesteader. In his late 20s, he managed to obtain a high school education in Minneapolis, Kansas, by working as a farmhand. After a university in Kansas refused to admit him because he was black, Carver matriculated at Simpson College, Indianola, Iowa, where he studied piano and art, subsequently transferring to Iowa State Agricultural College, where he received a degree in agricultural science in 1894 and a master of science degree in 1896.

Tuskegee Institute. Drawn to Tuskegee Institute because he believed its industrial type of education would help solve the race problem, Carver left Iowa for Alabama in the fall of 1896 to head the school's newly organized department of agriculture. He had learned of Booker T. Washington's efforts at Tuskegee to achieve the best interests of the black man through education rather than by political agitation and had been deeply moved by the educator's speeches, which tended to stress conciliation, compromise, and economic development for the black man. Despite many offers elsewhere, Carver remained at Tuskegee because he believed in its destiny as an institution for black people.

Influence of Booker T. Washington

After becoming the Institute's director of agricultural research in 1896, he devoted his life to research projects

aimed primarily at helping Southern agriculture. During his early years as an administrator, he spent most of his time demonstrating ways in which the Southern farmer could improve his economic situation. As an administrator Carver was unable to get along with his colleagues. He clashed not only with other members of the Tuskegee administration and faculty but even with Washington. He was, furthermore, unable to keep his department financially solvent. Nonetheless, his great ability and rare talents in other fields were unquestioned, and he was praised for his capacity as a teacher, lecturer, and experimenter, as well as for his unusual ability to demonstrate the use of various foods and their preservation. By 1910, however, Booker T. Washington had relieved him of his administrative duties, and Carver was able to devote most of his time to research.

Development of products from peanut and soybean

Products he derived from such soil-enriching crops as the peanut and the soybean helped to revolutionize the economy of the South by liberating it from excessive dependence on cotton, which depleted the soil. Peanuts and soybeans, since they belong to the legume family, could restore nitrogen to the soil and provide proteins essential for better health for farmers. When he arrived at Tuskegee in 1896, the peanut had not even been recognized as a crop. Within the next half century it became one of the six leading crops throughout the U.S., and in the South, the second cash crop (after cotton) by 1940. In 1942 the U.S. government allotted 5,000,000 acres of peanuts to farmers. Carver's research program ultimately developed 300 derivative products from peanuts—among them cheese, milk, coffee, flour, ink, dyes, plastics, wood stains, soap, linoleum, medicinal oils, and cosmetics—and 118 from sweet potatoes, including flour, vinegar, molasses, rubber, ink, a synthetic rubber, and postage stamp glue. He also succeeded in making synthetic marble from wood pulp. His exhibits were displayed throughout the South.

Among Carver's many honours were his election as a fellow of the London Royal Society for the Encouragement of Arts, Manufactures, and Commerce in 1916 and his receipt of the Spingarn Medal in 1923. Late in his career, Carver declined an invitation to work for Thomas A. Edison at a salary of over $100,000 a year. Presidents Calvin Coolidge and Franklin Roosevelt visited him, and his friends included Henry A. Wallace, a vice president under Franklin Roosevelt, Henry Ford, and Mahatma Gandhi. Foreign governments requested his counsel on agricultural matters: Joseph Stalin, for example, in 1931 invited him to Russia to superintend cotton plantations in southern Russia and to make a tour of the U.S.S.R., but Carver refused.

Reputation. Many scientists and some blacks were critical of Carver. Scientists thought of him more as a concoctionist than as a contributor to scientific knowledge and regarded with suspicion his reference to God as a collaborator in the laboratory. Though only a few blacks envied Carver's success, many were critical of his humility and regarded him as subservient—an Uncle Tom. Finally, this small, mild, soft-spoken, innately modest man, eccentric in dress and mannerism, who attempted to live up to Christian teachings, seemed unbelievable because he gave the impression that he disregarded the conventional pleasures and rewards of this life.

These qualities endeared Carver to many whites, who were almost invariably pleased by his humble demeanour and his quiet role in attending strictly to his work in self-imposed segregation at Tuskegee. As a result of his accommodation to the mores of the South, whites came to reward him with a sort of patronizing adulation. While he worked in the Deep South until his death at Tuskegee on January 5, 1943, people approached Carver as if he were part saint, part scientist, and part performing bear. The pattern of race relations at that time tended to distort the real significance of the contribution of black scientists and scholars, and Carver became increasingly a symbol of the intellectual achievements of Negroes. He fulfilled the white man's conception of the Negro, and he played a convenient role in "interracial politics." Accordingly, Carver's public image was built into that of an intellectual giant. His great desire in later life, nevertheless, was simply to serve humanity; and his work, which began for the sake of the poorest of the Negro sharecroppers, paved the way for a better life for the entire South. His efforts brought about a significant advance in agricultural training in an era when agriculture was the largest single occupation of Americans, and he extended Tuskegee's influence throughout the South by encouraging improved farm methods, diversification, and conservation.

Role as symbol to his race

BIBLIOGRAPHY. RACKHAM HOLT, *George Washington Carver: An American Biography*, rev. ed. (1963), although impressionistic, is still the most useful for adult readers. LAWRENCE ELLIOTT, *George Washington Carver: The Man Who Overcame* (1966), largely superficial and uncritical, emphasizes Carver's career during the 1920s and 1930s. ARNA WENDELL BONTEMPS, *The Story of George Washington Carver* (1954), is addressed to a juvenile audience, written with restraint and sensitivity. The George Washington Carver Papers and the Robert Russa Moton Papers are located at the Tuskegee Institute in Alabama. The Booker T. Washington Papers, located in the Library of Congress, are rich in Carver material from 1896 to 1915.

(J.L.Ki.)

Caryophyllales

The order Caryophyllales includes a wide variety of dicotyledonous plants (plants whose embryos have two leaves), ranging from attractive garden subjects and vegetables to bizarre succulent plants that resemble stones. The garden plants include carnations, pinks, four-o'clocks, amaranths, portulacas, and Madeira vines. Vegetables in the order include beet, spinach, rhubarb, and buckwheat. The carpetweed family (Aizoaceae) includes ice plants, sea figs, and living stones. Some authorities include the cacti (as the family Cactaceae) in this order as well; however, in view of evidence to the contrary and because the cacti are of such general interest, they are dealt with separately (see CACTALES).

General features. The name of the order is derived from that of the pink family, Caryophyllaceae, which was based upon a pre-Linnaean genus, *Caryophyllus*. The number of species in the order has been estimated between 6,500 and 8,500, depending upon the interpretation of the order; *i.e.*, which families are included in it and particularly whether the cactus family (Cactaceae) and the buckwheat family (Polygonaceae) are included. In this treatment of the order, the Cactaceae are excluded and the Polygonaceae are included.

The Caryophyllales include mostly herbs, but various families have shrubs, vines, and trees. On the whole, the order is not noted for the size attained by its members. Commonly, the species are most prevalent in moist temperate or tropical environments, but many members of the goosefoot family (Chenopodiaceae) are restricted to salty, alkaline soil. In some salt tolerant species, the leaves are succulent (fleshy). Leaf succulence is also common in the family Aizoaceae and remarkably so in its numerous South African members.

Ecological patterns

Natural history. The most striking single ecological feature in the order is the dominance of the Chenopodiaceae in alkaline situations and the prominence of succulent Aizoaceae in the deserts of southern Africa. The other members of the order occur in any of several types of vegetation, but in general none is conspicuous. Even the Aizoaceae in the southern African deserts are not conspicuous except when they are in flower.

Characteristic geographical distribution patterns occur in individual families, but none is typical of the order as a whole. The poke family (Phytolaccaceae) and the Madeira-vine family (Basellaceae) include plants primarily of the American tropics. The amaranth family (Amaranthaceae) is most highly developed in tropical America and tropical Africa. The four-o'clock family (Nyctaginaceae) is common throughout the tropics but occurs also in the warmer temperate regions. The carpetweed family (Aizoaceae) occurs over most of the Earth, but its chief centre of distribution is in desert and temperate latitudes of southern Africa. The Caryophyllaceae (pink family),

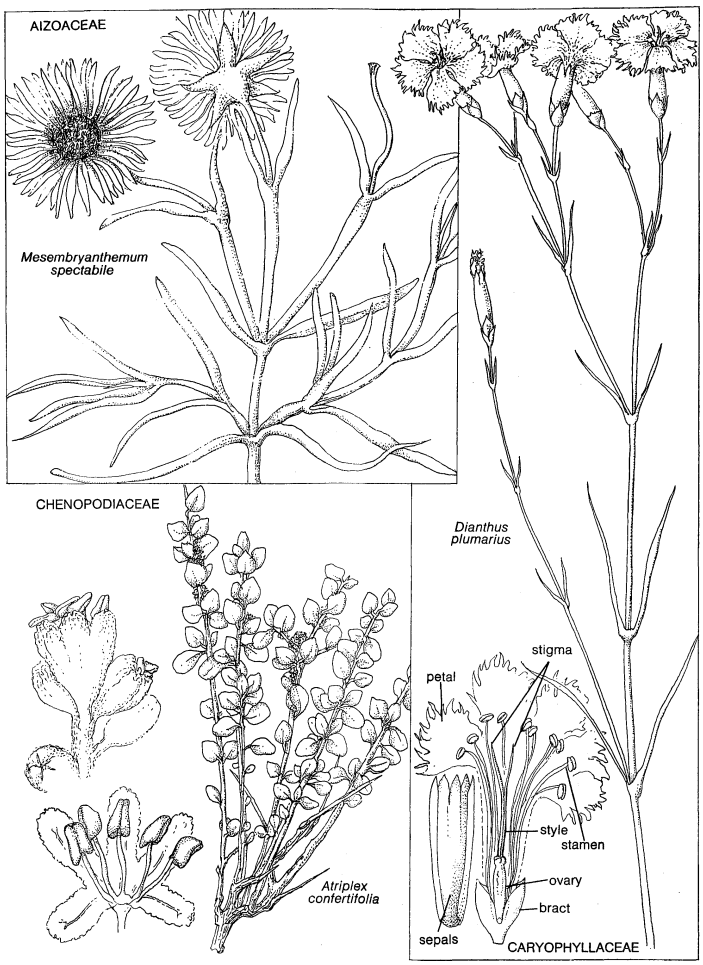


Figure 1: Representative plants from the three largest families of the pink order.
Drawing by M. Pahl

the Portulacaceae (portulaca family), and the Polygonaceae (buckwheat family) are characteristic of temperate regions. The goosefoot family (Chenopodiaceae) occurs throughout the world, but its greatest development is in salty or alkaline areas, particularly those of coastal salt marshes and deserts.

Form and function. *Vegetative characteristics.* The external vegetative characteristics of the plants in the Caryophyllales vary greatly; no specific feature can be singled out as indicative of the group. Certain tendencies are noteworthy but not distinguishing. Only rarely do the leaf bases bear stipules (leaflike tabs). Succulents occur in the Aizoaceae and in the Didiereaceae (a small Madagascan family), as well as in some of the Portulacaceae, Chenopodiaceae, Basellaceae, and Phytolaccaceae. Absence of stipules is almost a distinguishing characteristic of the order, but the presence of succulent tissues is not.

Two internal vegetative features characterize many members of the Caryophyllales. Eight of the families have some members in which conductive tissues (xylem and phloem) are produced from generative tissue called cambium at various depths inside the stem or the root, rather than only at the position of this tissue in most other plants. This produces additional cambial layers, as readily seen in a cross section of a beet root. Despite the commonness of this feature, it has not been proved to occur in all members of the order.

Pigments

The second internal feature is the chemical uniqueness of pigmentation in many of the Caryophyllales. In most flowering plants colours ranging from nearly red to nearly blue (*i.e.*, from violet to purple) are dependent upon the presence of chemical compounds called anthocyanins; colours ranging from yellow to reddish orange are dependent upon compounds called anthoxanthins. A distinct but parallel series of pigments occurs only in a large number of Caryophyllales and the cacti. These substances, known as betalains, include betacyanins, which produce colours from near red to near blue, and betaxanthins, which produce colours in the yellow to reddish-orange series. The presence of betacyanins especially, rather than anthocyanins, is presumed to be of taxonomic significance. Betacyanins have been found in many of the Caryophyllales but not in any members of the family Caryophyllaceae or the Molluginoideae (a group sometimes considered to be a separate family but included here as a subfamily in the Aizoaceae). Their presence also in the cacti is an indication of the relationship of these plants to the Caryophyllales and has led some authorities to include the cacti in this order.

Drawing by M. Pahl

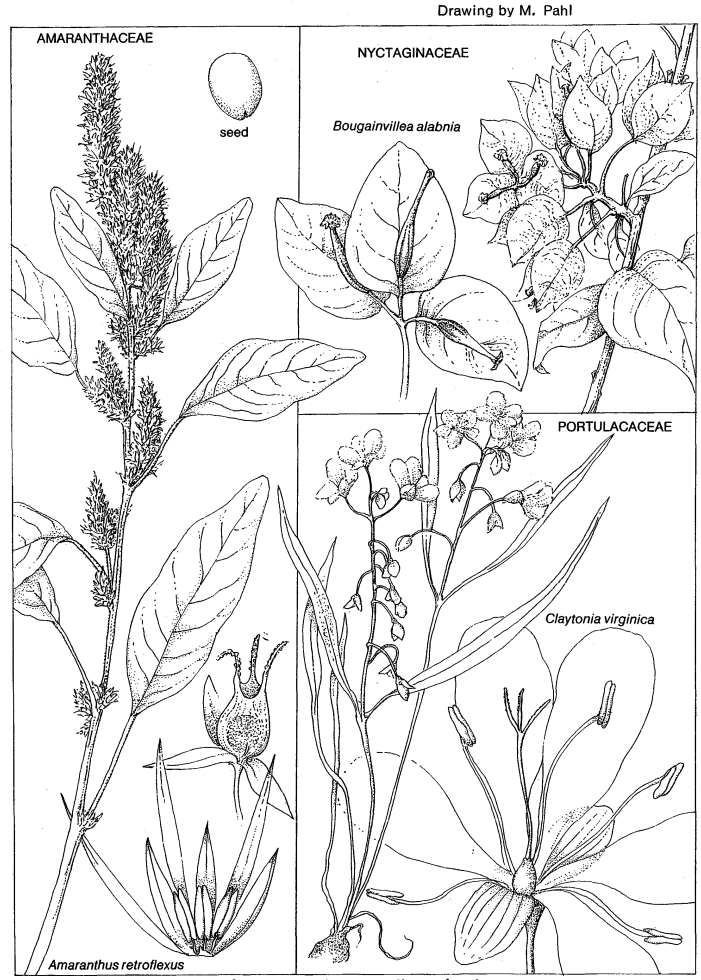

Figure 2: Representative plants from three medium-sized families of the pink order.

Reproductive characteristics. Throughout most of the order, the flowers have true sepals (modified petallike structures) but no true petals (*i.e.*, not embryologically derived from petal primordia). Some families that display what appear to be petals (Portulacaceae, Nyctaginaceae) are thought to have greatly modified sepals, in which case the sepallike appendages are then interpreted as bracts (specialized leaves subtending flowers). The Caryophyllaceae, however, apparently have true petals developed by the usual means; that is, through modification of individual stamens (the male parts of a flower) or portions of them. This is the only family in the order that, so far as has been determined, has ordinary petals.

In most members of the order, the stamens are in one or two series (concentric circles around the central axis of the flower) or sometimes in three series of three; in some cases, however, as in many of the Aizoaceae, there are numerous stamens.

The carpels (specialized leaves each forming all or part of a pistil, the female part of the flower) are united and

commonly enclose a single seed chamber, but there may be three to 12, one for each carpel. Usually, there are as many styles—extensions above a plant ovary bearing stigmas, structures that receive pollen grains at their tips—as carpels, and they are not united. The structure and positioning of the ovule in most members of the Caryophyllales differ from the common type in the flowering plants in being curved or coiled in a special way. The ovule is surrounded by two coverings (integuments), the inner being longer than the outer. The embryo lies toward the outside of the ovule, surrounding the food-storage tissue, which usually is not formed from a nutritive tissue (endosperm) during fertilization, as in most flowering plants. Commonly, most of the food is stored in the perisperm. The features of the ovules, embryos, and seeds are similar to those of the cacti, which further strengthens the case for a relationship of the two groups.

The placenta (the tissue that bears the ovules) in many Caryophyllales is either basal and low or forms a column arising from the base of the ovary. This type of placenta is rare in other orders of flowering plants. It does occur in the Primulales, probably indicating some relationship of these two orders.

Evolution and classification. *Evolution.* As is true of most other chiefly herbaceous orders of flowering plants, the Caryophyllales have left virtually no fossil record. Any evidence, therefore, of phylogeny must come primarily from a consideration of the living members of the order. The origin of the Caryophyllales, in consequence, is largely a matter of speculation. The order was presumably derived from the ancestral complex of the buttercup order (Ranales), but the present relationship of these orders is not close, and the lines of origin of the Caryophyllales are obscure.

Distinguishing taxonomic features. Consideration for inclusion in the order rests primarily upon such matters as absence of stipules (basal appendages of leafstalks), an unusual arrangement of cambial tissue, and the wide occurrence in the order of betalains, a unique class of pigment compounds. Disposition into families is based chiefly upon floral features such as numbers of parts and position of the ovary with regard to the floral envelope. Of taxonomic significance also are the number and position of ovules and the type of fruit.

Annotated classification.

ORDER CARYOPHYLLALES

Dicotyledonous plants; herbs, less frequently shrubs, rarely vines or trees. Flowers typically perfect (with male and female parts) but usually lacking true petals (except in the Caryophyllaceae and in some Aizoaceae). Betalain pigments occurring in most families. There are 10 to 16 families (depending on the authority); with more than 300 genera and between 6,500 and 8,500 species (an accurate figure is not possible because of the differences in interpretation of taxa by different authorities). Distribution is worldwide, with a concentration of species in the tropics and subtropics.

Family Phytolaccaceae (pokes)

Herbs, shrubs, trees, or rarely woody vines. Leaves simple, entire (with a continuous margin), alternate; stipules lacking or much reduced. Flowers commonly bisexual (but the plants sometimes monoecious), almost always radially symmetrical, hypogynous (borne under the ovary); epigynous (seemingly upon the ovary) in *Agdestis;* often arranged in racemes (stalked flower clusters with lowest flowers blooming first) or cymes (flower clusters with the terminal, or central, flower opening first); sepals (modified petallike structures) 4–5, persisting after flowering; no petals. Stamens (male parts of flowers) mostly 3–10, sometimes more, commonly in 1 or 2 series; carpels (specialized leaves each forming all or part of a pistil, the female part of the flower) 1–15 but usually 5–12. Ovary single, divided into chambers according to the number of carpels; placentation axile (ovules borne at or near the centre of the ovary) unless there is a single carpel; ovules solitary in the carpels. Fruit dry or fleshy, an achene (small, with tight, firm wall, or pericarp), utricle (bladderlike), berry, or drupe (stone fruit), the carpels separating at maturity. About 15 or 20 genera and 100 to 150 species; includes *Phytolacca* (the pokes). Centre of distribution is tropical America.

Family Aizoaceae (carpetweeds)

Herbs or small shrubs. Leaves simple, often succulent, opposite, but rarely appearing to be in whorls; stipules rarely present. Flowers bisexual, radially symmetrical; sepals 5–8, united; true petals absent, but with numerous staminodia (sterile stamens) resembling petals. Stamens 5 or numerous. Carpels 3–20, the ovary commonly with as many chambers, the styles (prolongations of plant ovaries bearing stigmas, which receive pollen grains at their tips) separate; placenta usually axile, ovules numerous. Fruit usually a dry capsule but sometimes leathery or berrylike. The number of genera and species described is great and dubious, having been subdivided beyond recognition, because members of the family (especially of the Ficoideae) are popular in horticulture. About 1,500 to 3,000 species is an estimate; includes *Mesembryanthemum* (ice plants) and *Lithops* (living stones). Chief distributional centre in southern Africa, where there is a special abundance of Ficoideae.

Family Nyctaginaceae

Herbs, shrubs, or trees. Leaves simple, entire, usually opposite; stipules lacking. Flowers usually bisexual, rarely otherwise, radially symmetrical, hypogynous or sometimes perigynous (or capable of being interpreted as perigynous); single flowers or flower clusters often surrounded by a calyxlike involucre of 2 to 5 leaflike or highly coloured bracts; sepals 5, often united and elongated, appearing as a corolla (or petals); stamens commonly 5 but sometimes 1 to 3. Carpel 1; ovule solitary. Fruit dry, an achene, commonly enclosed in the hardened persistent lower part of the calyx (the sepals as a group). From 25 to 30 genera with 200 or 300 species, includes *Mirabilis* (four-o'clocks) and *Bougainvillea.* Distributional centre is the tropics and warm regions of the world.

Family Polygonaceae

Herbs, shrubs; or trees, but rarely vines. Leaves simple, alternate; stipules usually present and sheathing the stem. Flowers nearly always bisexual, radially symmetrical, arranged in panicles, spikes, heads, or cymes; sepals 3–6, usually in 2 series of 3; petals usually 3. Stamens in 2 or 3 series of 3. Ovary 1-chambered; 1 ovule, basal. Fruit dry, usually a 3-angled achene. About 30 genera with perhaps 800 species; includes *Polygonum, Fagopyrum* (buckwheat) and *Rheum* (rhubarb). Chief distributional centre is the temperate region.

Family Chenopodiaceae

Herbs or shrubs, rarely small trees. Stems and leaves usually scurfy with drying external cells forming white scales. Leaves simple, sometimes succulent or scalelike, nearly always alternate; stipules absent. Flowers nearly always bisexual but sometimes staminate and pistillate and on the same plant, nearly always radially symmetrical; sepals ordinarily 5 but sometimes absent; petals absent. Stamens usually 5. Carpels commonly 2 but sometimes 3; styles commonly 2; ovary with a single chamber and a single ovule. Fruit dry at maturity, an achene or a utricle; embryo curved or coiled. About 100 genera and about 1,500 species; includes *Beta* (beets), *Spinacia* (spinach), and *Kochia.* Found particularly in alkaline habitats in North and South America, the Middle East, southern Africa, and Australia.

Family Amaranthaceae (amaranths)

Commonly herbs, rarely shrubs, trees, or vines. Leaves simple, commonly entire, either alternate or opposite; stipules absent. Flowers usually bisexual, radially symmetrical, commonly subtended by membranous bracts that persist in fruit; sepals usually 5, membranous, dry and persistent in fruit; petals absent. Stamens usually 5, the anthers (pollen-bearing structures) sometimes with only 2 (instead of the usual 4) pollen chambers. Carpels 2, rarely 3–5; ovary with a single chamber and a single basal ovule. Fruit a utricle, nutlet, or capsule, rarely a drupe or berry. From 50 to 60 genera and 500 to 800 species; include *Amaranthus* and *Celosia* (cockscomb). Centred in the American and African tropics.

Family Portulacaceae (portulacas)

Herbs, rarely small shrubs. Leaves simple, often more or less succulent, alternate or opposite, commonly forming basal rosettes; stipules commonly present and threadlike. Flowers bisexual, radially symmetrical, hypogynous or epigynous; apparent "sepals" (probably bracts) 2, petallike sepals 2–6; true petals absent. Stamens usually 5, opposite the sepals; carpels usually 2 but sometimes 3; ovary with a single chamber with several to numerous ovules; basal placentation. Fruit dry, usually splitting lengthwise, but sometimes opening by a terminal lid. Perhaps 15 genera and 250 species; includes *Portulaca* (rose moss) and *Lewisia* (bitterroot). Geographical centres are Pacific North America and southern South America.

Family Basellaceae

Herbaceous, perennial, somewhat woody vines, sometimes more or less succulent. Leaves simple, sometimes succulent, alternate; stipules absent. Flowers bisexual, radially symmetrical, hypogynous, arranged in cymes, racemes, or panicles;

sepallike bracts in a pair resembling a calyx; petallike sepals commonly 5, usually coloured and persistent at fruiting time; true petals absent. Stamens 5. Carpels 3; ovary with a single chamber and only 1 ovule. Fruit fleshy, a drupe; embryo forming a circle or a spiral. Five genera consisting of about 15 to 25 species; includes *Boussingaultia* (Madeira vine). Centred in the New World tropics.

Family Caryophyllaceae (pinks)

Herbs, but stems often woody at the bases. Leaves simple, usually opposite; stipules absent. Flowers bisexual, radially symmetrical, hypogynous, in complex (or simple) inflorescences; sepals 5 (rarely 4); petals 5 (rarely 4), separate. Stamens 3–10; ovary commonly 1-chambered but 2–5 chambered or partly so in the subfamily Sileneae; ovules usually numerous. Fruit dry, a capsule. About 75 genera and perhaps 2,000 species; includes *Dianthus* (pinks and carnations), *Lychnis* (campions), *Gypsophila* (baby's breath), and *Saponaria* (soapwort, or bouncing Bet). Of almost worldwide occurrence in temperate regions.

Family Didiereaceae (didiereas)

Trees with soft wood and with spines. Leaves simple, alternate; stipules absent. Flowers unisexual (plants dioecious), radially symmetrical, hypogynous; sepals petaloid; doubtful true petals 2. Stamens 8–10, basally somewhat united. Carpels 2; ovary with only 1 of the 3 chambers developing; ovules solitary, erect. Fruit 3-sided. Three genera native to Madagascar. This family is of uncertain relationships.

Critical appraisal. In some classifications six additional families are included as follows (their disposition in this article follows in parentheses): Gyrostemonaceae (Phytolaccaceae), Bataceae (Phytolaccaceae), Molluginaceae (Aizoaceae), Tetragoniaceae (Aizoaceae), Halophytaceae (Chenopodiaceae), and Hectorellaceae (Portulacaceae). The Polygonaceae are separated by some as the order Polygonales. The families Batidaceae and Thelygonaceae are sometimes grouped with the Caryophyllales but may be separated under orders of their own. The proposed alliance of the cacti with certain succulent members of the Aizoaceae (subfamily Ficoideae) is based on similarity of pollen grains, the presence of betacyanins, and distinctive common features of the ovules and embryos. The differences that serve to separate the cacti are dealt with in the article CACTALES.

BIBLIOGRAPHY. General reference works that list sources bearing on a specific member of the order include; L. BENSON, *Plant Classification* (1957); A. CRONQUIST, *The Evolution and Classification of Flowering Plants* (1968); G.H.M. LAWRENCE, *Taxonomy of Vascular Plants* (1951); and A. TAKHTAJAN, *Flowering Plants: Origin and Dispersal* (1969; Eng. trans. from the 2nd Russian ed., 1961).

Flora*, 21: 279–336 (1932); and B. MAGUIRE, "Studies in the Caryophyllaceae," *Bull. Torrey Bot. Club*, 73:326 (1946).

(L.Be.)

Casablanca

Casablanca (or White House; Arabic, ad-Dār al-Bayḍā'; colloquial Arabic, Dar el-Beida) has been so called since the 16th century because most of its houses are white. It is the largest and most important port and city in Morocco. By 1960 it had become the fourth largest city in the Arab world after Cairo, Alexandria and Baghdad. It is situated on the Atlantic coast of Morocco. In 1971 its population numbered about 1,500,000.

History. The origin of the town is not known. A Berber village called Anfa stood on the present-day site in the 12th century; it became a pirates' base for harrying Christian ships, and in consequence of this the village was captured and destroyed by the Portuguese in 1468. One of the most fashionable districts of Casablanca is now named Anfa.

The Portuguese returned to the area in 1515, this time with the intention of settling. They built a new town called Casa Branca (White House) in Portuguese, but it had to be abandoned in 1755 after a devastating earthquake. The ʿAlawī sultan Sīdī Muhammad ibn ʿAbd Allāh rebuilt the town in the late 18th century. The Moroccans were not interested in overseas trade, however, and left the use of its then insignificant harbour to Spanish merchants, who named it Casablanca and began to settle there. Other European traders arrived; the French after a time outnumbered other European settlers, and the name Maison Blanche became as common as Casablanca.

The French interregnum

Rioting broke out in the town in 1907, when the Moroccan Shawia tribes claimed that their cemetery had been desecrated by European construction workers in the port area. Eight Europeans were killed during the clashes, and this incident led to intervention by French troops and the killing of several thousand Moroccans. In the early years of the French protectorate over Morocco (1912–56), the French resident general, Marshal Louis-Hubert-Gonzalve Lyautey, embarked on a policy of expansion and development to make Casablanca the chief port of Morocco. Since then, the growth and development of the city have been continuous and rapid. During World War II the city was the seat of an Anglo-United States summit conference in 1943. In 1961 a conference at Casablanca, presided over by King Muḥammad V of Morocco, founded the Casablanca group of African states.

The contemporary city. Casablanca extends for 12 miles along the coast and for more than five miles inland. Its site is fairly flat, rising slowly inland at the rate of 50 to 100 feet every mile. In the extreme west is the Anfa Ridge, a ridge of dunes about 200 feet high that stretches obliquely along the coast toward Cap el-Hank, immediately northwest of the city. The underlying rocks of the area are mainly hard metamorphic types (formed by heat and pressure), such as schist (a coarse-grained rock) and quartzite. The surface is covered by recent sedimentary limestones and sandstones. To the west the lower parts of the surface are covered by reddish limestone, gray sand, or black silt. To the northeast the hard underlying rocks appear almost bare. Such surface differences probably influenced the planning of the town. The western section has been developed as a modern residential district, while an industrial area has been established in the northeast. The coast is mostly rocky and directly receives the shock of the ocean's strong surf. The hinterland consists of pastoral and poorly cultivated areas, in which the Shawia tribes still follow traditional methods of agriculture.

The man-made port of Casablanca has 16,000 feet of deepwater quays and is protected from the sea by a breakwater; it handles about three-quarters of Morocco's import and export trade. It is also a port of call for many cruise ships from western Europe; Boulevard Hansali, which leads to the port, is lined with shops for tourists.

The medina

Inland from the docks and the harbour is the old medina, the original Arab town. Still enclosed in parts by its original rampart walls, it is a maze of narrow streets and whitewashed brick or stone houses. In a semicircle outside the walls of the medina is the town built by the French. Avenues radiating from Muḥammad V Square are intersected by ring roads that reach to the coast on either side of the harbour. Muḥammad V Square, near the gateway of the old medina, and United Nations Square are the business and administrative centres of the town, where banks, hotels, and large modern shops are located. Farther south, overlooking the gardens of the Park of the Arab League, is the white Cathedral of the Sacré Coeur. West of the park and stretching toward the coast are the gardens and villas of residential districts, such as Anfa.

Beyond this French-built town, the new medina has been built—an immense area of 200,000 inhabitants.

Climate. The climate is pleasant most of the year, with monthly average temperatures varying between 54° F (12° C) in January and 73° F (23° C) in August. Daily and seasonal ranges of temperature are small. The average annual rainfall is about 16 inches. Rain may fall in any month, though it is scarce in summer.

Humidity is high the year around. The combination of humidity and high temperatures in summer can create rather oppressive weather. Gales and strong winds are frequent in winter. Fog often forms in the fall.

Ewing Galloway

Transport. As the town expanded, transport problems increased. People living in the suburbs and in the new medina were obliged to travel long distances to the central business district. Improvements were made, however, and communications within the city, as well as between Casablanca and other cities, are now generally easy and comfortable; buses are the principal means of public transport. Good roads join Casablanca with Rabat, Marrakech, Fès, Meknès, and other places; the best of these is the 55-mile highway to Rabat, the political capital of Morocco. There is also a railway line that runs northeastward to Rabat, Meknès, and Fès, after which it crosses the border into Algeria and Tunisia. There are two international airports, the Casablanca-Anfa to the southwest and the Casablanca-Nouaceur to the east of the city.

Population. At the 1971 census the population was 1,500,000. At the 1960 census the population of Casablanca was 965,000, comprising about 779,000 Moroccan Muslims, 72,000 Moroccan Jews, and 114,000 foreigners, mainly French and Spanish. The rate of population growth since the beginning of the 20th century has been about 6 percent annually. The total was 20,000 in 1907, 89,000 in 1920, 257,000 in 1936, and 680,000 in 1952. The million mark was passed in the 1960s. The exceptionally high rate of growth, which is in contrast to much lower rates in other Moroccan towns, has been caused by the immigration of Europeans and Moroccan Jews from other parts of the country, by the arrival of Europeans and other foreigners from abroad, and by an influx of Moroccan Muslims from rural areas.

The number of foreigners and Moroccan Jews in Casablanca in the 1960s and early 1970s remained approximately constant though many left the country, because others moved in from other parts of Morocco to take their place. Many used the town as a temporary place of residence before leaving the country. Moroccan immigrants are mainly poor Muslims who are attracted to the town by its prosperity and its industrialization. Their numbers have always been greater than the available employment vacancies, and many have, in consequence, remained unemployed for long periods. The influx of these immigrants has created a large poor community whose numbers have increased rapidly. They live in shantytowns known as *bidonvilles* ("tin-can towns"), which have spread rapidly on the outskirts of the city.

The *bidonvilles*

Housing. In the earlier years of the 20th century, Casablanca was divided into districts according to the wealth and nationality of the inhabitants. As a result of the continuous exodus of Europeans and Jews, however, the districts previously occupied by them—such as the fashionable Anfa and Le Polo quarters—are now for the most part inhabited by well-to-do Moroccan Muslims. In contrast, the *bidonvilles* clearly indicate the extreme poverty of a large section of the population. The more prosperous and industrialized the town becomes, the greater the influx of poor immigrants, and the greater the expansion of the *bidonvilles*. To check this tendency, a scheme for building large blocks of working-class flats in the new medina was started in 1944; although many such blocks have since been built, the *bidonvilles* nevertheless still constitute a serious social problem.

Architectural features. Most buildings in the modern districts of Casablanca follow the architectural style of Le Corbusier, the French-trained Swiss architect. They are supported by slender pillars and have large white walls and large windows protected from the sun by concrete screens; the radical modernization of the city has not, however, obliterated the traditional characteristics of the old medina with its ancient houses and narrow streets. There is a great mosque, built in the late 1700s. In the centre of the town, as already mentioned, is the large, busy Muḥammad V Square; from the square the palm-lined Boulevard Hansali leads down to the docks.

Economic life. The rapid commercial progress of Casablanca, especially the growth of its port, has established it as the economic capital of Morocco. It accounts for more than half of the bank transactions and industrial production of Morocco and possesses more than half of the country's industrial labour force. Casablanca's industries include textiles, electronics, leather works, food canning, and the production of beer, spirits, and soft drinks. Its industrial area has expanded very rapidly in the northeast in the direction of Fedala, which until 1960 was a separate suburb but has since become an integral part of the town. Fishing is important in coastal waters, where a fairly wide continental shelf provides a good fishing ground. The catch includes soles, red mullet, turbot, sea eels, crabs, and shrimps.

Government and services. Casablanca is administered as an urban prefecture; it is headed by a governor, appointed by the king and assisted by a secretary general. Police and fire services are each controlled from a central headquarters. In 1971 Casablanca had 24 medical clinics and about 225 doctors.

Education and cultural life. Casablanca has Arab and French schools at different educational levels. There are also various cultural and utilitarian institutes, such as the Goethe-Institut, the Municipal College of Fine Arts, the Municipal Library, a prehistory society, an institute of fishing, and an horticultural society.

Three daily French newspapers appear in Casablanca; there are also 16 periodicals. A television station was opened in 1962.

Recreation. Casablanca is Morocco's principal centre for entertainment and recreation. Along the seafront are a number of pleasant beaches, the most popular of which are Kon Tiki, Miami, Tahiti, and the Lido. There are several parks, including the Park of the Arab League, and attractive promenades along the seafront. Casablanca has cinemas, a modern municipal theatre, and a variety of hotels, restaurants, sporting clubs, and nightclubs.

Casimir III the Great, of Poland

The only one of the long line of Piast dynasts (who ruled Poland from its beginnings until 1370) to be dignified by the epithet "the Great," Casimir III (Polish Kazimierz Wielki) was king of Poland from 1333 to 1370. Although the epithet was given to him a century after his reign by the chronicler Jan Długosz to distinguish him from Casimir IV, it has survived among historians and in national legend because it expresses the sentiment that this peaceful ruler, "peasant king," and skilful diplomat, has more claim to greatness than Poland's many conquerors and warriors.

Casimir III, sarcophagus figure, after 1370. In Wawel Cathedral, Kraków.

Casimir was the second king of the reunited and resuscitated Poland that for nearly two centuries had been split up into numerous small principalities. His father, Władysław I, who had succeeded in reuniting Great Poland and Little Poland, renewed the long-forgotten kingship with his coronation in Cracow in 1320. Casimir continued the work of his father, adding two large and important regions (Red Russia and Masovia) to the country and making it a solid and respected partner among the other 14th-century powers in central Europe. In addition, he provided the country with a well-organized government, codified its unwritten law, and founded its first university (Cracow 1364). By all this he so strengthened feelings of popular unity that after his death (although he left no legal heir) there were no attempts at restoring the former duchies and principalities. Casimir was born on April 30, 1310. His mother was Jadwiga, daughter of Bolesław the Pious (Pobożny) of Great Poland. After the death of his elder brother in 1312, Casimir was regarded as heir and was prepared for the kingship by Jarosław, later archbishop of Gniezno and Casimir's counsellor. Of his three sisters, one, Elizabeth, who in 1320 married King Charles Robert of Hungary, figured prominently in his foreign and dynastic policy.

Dynastic alliances. In 1325 Casimir married Aldona Ona, the pagan daughter of Gediminas (Giedymin), duke of Lithuania. Baptized before the wedding, Aldona brought with her thousands of Polish prisoners of war (one chronicle tells of 24,000) as a sign of reconciliation between Poland and the then still heathen Lithuania. The marriage seems to have been unhappy, and the Queen died in 1339 leaving no sons. Two years later Casimir married a German princess, Adelhaid of Hesse, but this marriage proved barren, and Adelhaid was sent home in 1356. A third marriage in 1365 with the Silesian princess Hedwig of Glogau-Sagan still brought no legal heir. The question of a successor was, therefore, one of Casimir's main problems. He finally designated as his heir his nephew, Louis of Hungary. Since Louis had no sons either, Casimir named as his second choice Casimir of western Pomerania, a son of his eldest daughter. The act strengthened the position of the nobility whose consent had to be obtained by the granting of privileges.

Casimir's heirless marriages

The marriages of his daughters and grandchildren further strengthened Casimir's foreign support. His second daughter was married to Louis of Brandenburg (1345); the third was betrothed to Wenzel, son of the Holy Roman Emperor Charles IV (1369), and the emperor himself married first a grandniece and, later, a granddaughter of Casimir. The king thus had relatives in several important contemporary dynasties: the Wittelsbachs, the Anjous, the Luxemburgs, and the Lithuanians (later known as the Jagiellons). Casimir also had many mistresses, about whom little is known; the most famous of them, the beautiful Jewess, Esther, may have been invented by the chroniclers to explain the King's notable friendliness toward the Jews.

Foreign policy. Casimir's foreign policy reflected his own character: prudent, cool, obstinate, and self-controlled. He preferred diplomacy to war, though he did not entirely refrain from the latter, as evidenced by a series of forced occupations of foreign territory, notably Red Russia, in 1340 and 1349. At the beginning of Casimir's reign Poland was beset by several difficulties: the King of Bohemia claimed the Polish crown; the German knights of the Teutonic Order disputed East Pomerania; and the country lacked powerful allies. By a series of treaties concluded with Hungary, Bohemia, and the Teutonic Order between 1335 and 1348, Casimir obtained a strong ally in Hungary and dropped his claims to Silesia and East Pomerania (claims that would in any case have been difficult to realize). The Bohemian king, in exchange, dropped his claims to Poland; and the Order withdrew from the territories of Kujawy and Dobrzyn, which it had occupied. Having his western frontier secure, Casimir was now able to occupy the former duchies of Halič and Vladimir (Red Russia) and to unite them step-by-step (though never completely) to Poland. As a result of this carefully planned policy, the Masovian princes, long anxious to preserve their independence, declared themselves Casimir's vassals (1351–53); even in the West some German nobles preferred Casimir's to Brandenburg's lordship.

By 1370 Casimir, under different titles, had increased his territory to about 90,000 square miles (233,000 square kilometres) from about 50,000 at his accession. More important than these territorial gains, some of which were lost after Casimir's death, was the growth of the King's prestige throughout Europe. A congress held

The congress of Cracow

in Cracow in 1364 was attended by the kings of Hungary, Bohemia, Denmark, and Cyprus, as well as a great number of other princes. Casimir, who 30 years previously had been a humble petitioner at the Congress of Visegrád in Hungary, was now asked to arbitrate a quarrel between the Emperor and Louis of Hungary.

Domestic achievements. Domestically, Casimir encouraged economic activity and attempted to unite the country under one prince, one law, and one currency. He founded several new towns—two of them named Kazimierz after himself—and gave them, together with already existing towns, the so-called Magdeburg Law, the privilege of self-government. Casimir built more than 50 castles, fostered church building, and embellished the royal castle at Cracow. A special court was established in Cracow to arbitrate in all quarrels and to administer the law codified in the *Liber juris Teutonici* ("Book of Teutonic Law"). The former privileges of the Jews were confirmed and improved. Though Casimir was able to inaugurate his principle of one law in Little Poland and Great Poland, Masovia and Red Russia kept their own nonwritten law. Wishing to educate native lawyers and administrators, he founded the University of Cracow in 1364, which, however, flourished for only a few years before his death in a hunting accident in 1370.

Since little is known of Casimir's sympathies, personal interests, thoughts, and feelings, he must be judged on his deeds, which characterize him as an especially good, wise, and, to a degree, even modern ruler. He was a sober administrator but not a hero; a man who earned the respect of his contemporaries and posterity but was, perhaps, too cool, too aloof, and too faultless to obtain great sympathy.

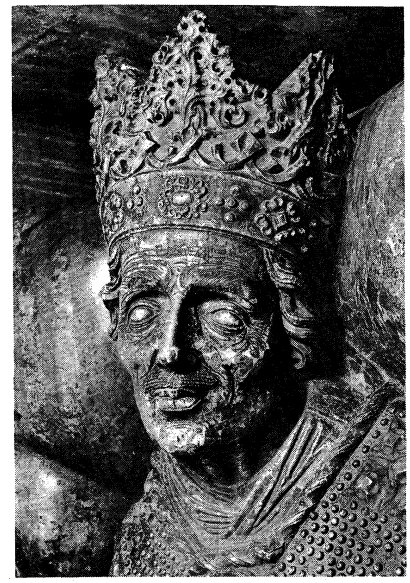
Casimir IV of Poland

Casimir IV, grand duke of Lithuania (1440–92) and king of Poland (1447–92), was neither a great warrior and builder nor a man of lively cultural interests. Nevertheless, he succeeded by his skillful and patient policy in securing for his lands a period of peaceful evolution and in making his dynasty one of the foremost in Europe, which, by the end of his life, occupied no fewer than four thrones. During his reign, the Grand Duchy of Lithuania was the most important power in eastern Europe; its frontiers in the northeast extended to within 100 miles of Moscow, and in the south it approached the shores of the Black Sea. At the same time, the kingdom of Poland defeated its old enemy, the Teutonic Order, in the Thirteen Years' War and obtained sovereignty over eastern Pomerania and, by that, the control of the mouth of the Vistula River.

Casimir was born on November 30, 1427, the second son of Władysław II Jagiełło and his fourth wife, Zofja Holszańska. His father was already over 75 at Casimir's birth, and his brother Władysław III, three years his senior, was expected to become king before his majority. Casimir was thus the second in succession to the throne, and, after Władysław had succeeded his father in 1434, he became the legal heir. Strangely, little was done for his education; he was never taught Latin, nor was he trained for the responsibilities of office, despite the fact he was the only brother of the sovereign. Yet the necessity of taking office was thrust upon him in 1440, when the grand duke of Lithuania, Sigismund, was murdered. The boy was sent to Wilna to act as governor for his brother, but he was proclaimed grand duke in a coup d'état by the leading boyars (nobles), who evidently hoped to use him as a convenient tool.

Grand duke of Lithuania

The coup practically severed the ties between Lithuania and Poland, but these were restored after Władysław III's death in the Battle of Varna against the Turks (November 10, 1444). The Poles, having to elect a new king, had no other candidate but Casimir. The young man, despite his lack of experience, knew how to wield his new power. He acted to preserve the hereditary rule of



Casimir IV, sarcophagus figure by Veit Stoss, 1492–93. In Wawel Cathedral, Kraków.

the dynasty in Lithuania with no connection with Poland other than the common monarchy; and when he was finally crowned king of Poland (June 25, 1447), he had succeeded in affirming his right to live in Lithuania and choose his counsellors freely. Considering his deeds and policy (no personal utterances of his are recorded), it may be inferred that he regarded himself more as the head of a dynasty than as the elected king of Poland. His policy, therefore, is partly family policy, and in cases of conflict between dynasty and state the former had priority. His marriage to Elizabeth of Habsburg in 1454 had clear political aims; as the daughter of Albert II of Habsburg, Elizabeth had claims to Bohemia and Hungary. In fact, this first connection between the Habsburgs and the Jagiellons was a happy one; because of her six sons and seven daughters (born between 1456 and 1483) Elizabeth was called the "mother of Jagiellons." Casimir did everything he could to provide his children with advantageous marriages. In this he was more than successful: the eldest son, Władysław, became king of Bohemia (1471) and of Hungary (1490); three others were his successors on the thrones of Lithuania and Poland; one became an archbishop and, later, a cardinal. Five of his daughters were married to German princes, as a result of which the Polish name Casimir became a familiar one among German dynasties. When he died June 7, 1492, he left a dynasty renowned among the courts of Europe.

Because of his neglected education, Casimir seems to have been personally narrow, preferring hunting in Lithuania to court life in Cracow; he often absented himself from the Polish capital for more than a year at a time. On the other hand, he evidently had a strong feeling of his dignity and was able to show it distinctly. His tombstone in Cracow Cathedral, carved by the Nürnburg sculptor Veit Stoss, who for many years lived in Cracow, vividly portrays Casimir's simplicity, energy, perseverance, and dignity mingled with pride.

Foreign policy

In foreign policy, Casimir had few far-reaching plans or great ambitions. He neither organized a crusade against the Turks as his brother had done, nor did he build up an efficient defense system against the aggressions of the Grand Duchy of Moscow. He failed also to support Moscow's enemies and contented himself with the favourable treaty of 1449, which, however, did little to prepare Lithuania for the attacks that were to begin in 1486. Thus, a number of Russian princes, vassals of Lithuania, went over to the Muscovite Grand Duke after 1486 because they had obtained no protection from Casimir. When, in 1484, two important harbours on the Black Sea, Kilia and Akkerman—previously under Lith-

uania's protection—were captured by the Turks, Casimir made little attempt to recover them. Although these territorial losses at the end of his reign did not seriously threaten Lithuania, they did weaken its former dominant position in eastern Europe.

Similarly, in Poland the King showed little initiative in foreign policy. When the Prussians, however, revolted in 1454 against their overlord, the Teutonic Order, and placed themselves under the protection of Casimir, he was aware that this was a unique opportunity to destroy the power of the Order and incorporated the whole of Prussia by the act of March 6, 1454. When, as a result, war broke out and Polish troops were severely defeated near Konitz (September 18, 1454), it was mainly the King's perseverance and stubbornness that led to the final success in the second Treaty of Toruń (Thorn; October 19, 1466). Though the Order retained a part of its former territory and "Royal Prussia" was not formally incorporated but only united with the kingdom while preserving its own diet and administration, this treaty was Casimir's most important foreign policy success. Thus, in spite of his own sympathies, his reign was more successful for Poland than for his beloved Lithuania.

Domestic policy

In domestic affairs Casimir was relatively passive but anxious to preserve the prerogatives of the crown, notably his right to nominate bishops. In the question of territories in dispute between his two states (Volhynia and Podolia) he was not impartial but favoured Lithuania. During the war against the Order he was forced to grant the Polish nobility substantial concessions by the Privilege (statute) of Nieszawa (November 1454); these, however, became important only after his death, and royal power was not greatly diminished during his lifetime. Casimir governed his realm mostly by counsellors of his own choice after the death of the almost all-powerful bishop of Cracow, Zbigniew Oleśnicki, in 1455.

Casimir was neither a splendid ruler nor a good and wise administrator, but a mistrusting, cautious, and sober head of a large family who regarded Lithuania as his personal estate; he enjoyed authority, and his reign was remembered as being both successful and peaceful.

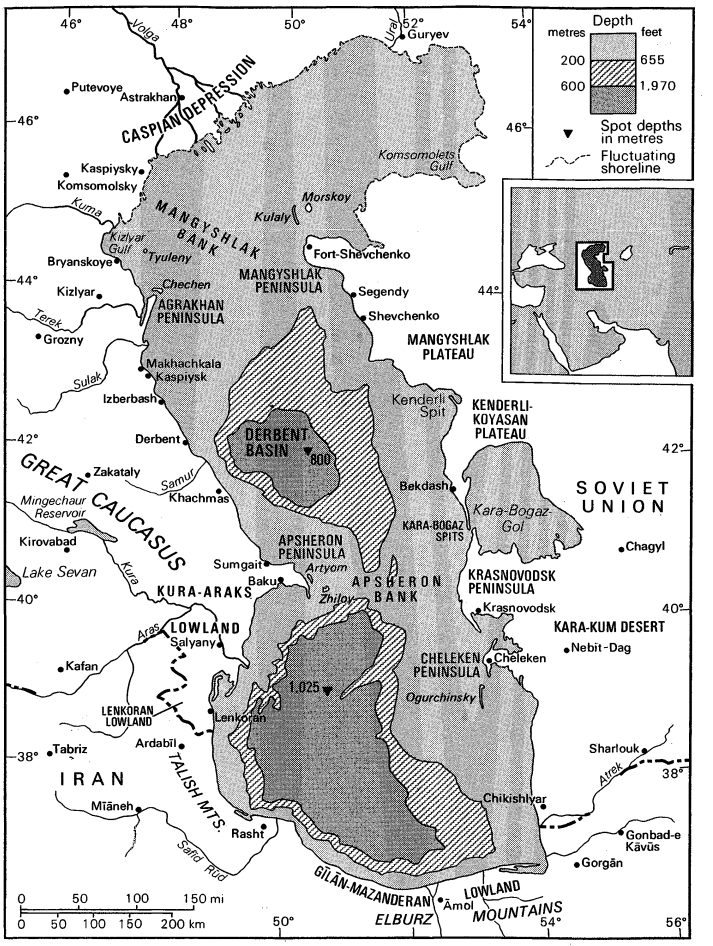
(G.K.S.R.)

Caspian Sea

The world's greatest inland sea, the Caspian Sea lies beyond the Caucasian mountain peaks at Europe's southeasternmost extremity and dominates the huge, flat expanses of western Central Asia. Its name derives from the ancient Kaspi peoples, who once lived in Transcaucasia to the west; among its other historical names, Khazarsk and Khvalynsk derive from former peoples of the region, while Girkansk stems from Girkanos, "the country of the wolves." Its elongated shape sprawls for nearly 750 miles (1,200 kilometres) from north to south, although its average width is only 200 miles (320 kilometres). It currently covers an area of 143,000 square miles (371,000 square kilometres)—larger than Japan—while its surface lies some 93.5 feet below ocean level. The maximum depth, toward the south, is 3,360 feet. Except for its southern shores, which lie at the foot of the giant Elburz Mountains of Iran six-sevenths of the Caspian coast runs through Soviet territory.

It is often stated that the Caspian is the greatest salt lake in the world, but this is not absolutely correct, as scientific studies have shown that, until geologically quite recent times, it was linked, via the Sea of Azov, the Black Sea, and the Mediterranean, to the world ocean. This factor has molded strongly all aspects of its physical geography. The Caspian is of exceptional scientific interest, because its history, particularly in respect to former fluctuations in both area and depth, offers clues to the complex geological and climatic evolution of the region. Man-made changes, notably those resulting from the construction of dams, reservoirs, and canals on the immense Volga River system (which drains into the Caspian from the north), have had their own effect on the contemporary hydrological balance. The Caspian is also of great importance in the transportation networks of the region and in the production of petroleum and gas. It is anticipated that the use of its splendid sandy beaches for health and recreation resorts will increase considerably in the future. (For related physical features, see CAUCASUS MOUNTAINS; VOLGA RIVER; and ELBURZ MOUNTAINS; for human geography, see the articles RUSSIAN SOVIET FEDERATED SOCIALIST REPUBLIC; KAZAKH SOVIET SOCIALIST REPUBLIC; TURKMEN SOVIET SOCIALIST REPUBLIC AZERBAIJAN SOVIET SOCIALIST REPUBLIC.)



The Caspian Sea.

Topography. The Caspian possesses as many as 50 islands, mostly small. Chechen, in the northwest, is the largest, followed by Artyom, Zhiloy, Tyuleny, Morskoy, Kulaly, and Ogurchinsky. The basin, as a whole, is usually divided into the North, Middle, and South Caspian, using relief and, in part, hydrological characteristics as the basis.

Shoreline features. The shores of the North Caspian are low and reflect the great accumulation of alluvial material washed down by the Ural, Terek, Sulak, and, above all, the Volga rivers, the deltas of which are extensively developed. The western shore of the Middle Caspian is hilly. The foothills of the Great Caucasus loom close but are separated from the coast by a narrow marine plain. The Apsheron Peninsula, on which the city of Baku is sited, thrusts out into the sea here, while, just to its south, the floodplain of the Kura and Araks rivers forms the Kura–Araks Lowland. The southwestern and South Caspian shores are formed of the sediments of the Lenkoran and Gīlān-Mazanderan lowlands, with the high peaks of the Talish and Elburz mountains rearing up close inland. The eastern shore of the South Caspian is also low and is formed by sediments resulting from wave action; it is broken sharply by the low, hilly Chele-

Importance of sea-level fluctuations

ken and Krasnovodsk peninsulas. For the most part, the eastern shore of the Middle Caspian is precipitous, with the sea destroying the margin of the limestone plateau of Mangyshlak and Kenderli–Koyasan. A most important feature of this area is the Kara-Bogaz-Gol, the Caspian's largest, split off from the main body of water by the Kara-Bogaz barrier spits; the Krasnovodsk and Kenderli spits are similar in type.

The major rivers—the Volga, Ural, and Terek—empty into the North Caspian, with their combined annual flow accounting for 88 percent of all river water entering the sea. The Sulak, Samur, Kura, and a number of smaller rivers flow in on the western littoral, contributing about 7 percent of the flow, and the remainder comes in from the rivers of the Iranian shore. The eastern littoral is notable for a complete lack of permanent streams.

Submarine features. The North Caspian, with an area of 30,000 square miles, is the shallowest portion of the sea, with an average depth of 13 to 20 feet, reaching a maximum of 66 along the boundary with the Middle Caspian. The bottom is formed of a monotonously rippling sedimentary plain, broken only by a line of southern bars and shoals—some of which provide foundations for Tyuleny, Kulaly, and Zhemchuzhny islands—reflecting underlying structural rises. Beyond this belt, known as the Mangyshlak Bank, the Middle Caspian, 53,000 square miles in area, forms an irregular depression with an abrupt western slope and a gentler eastern gradient. The shallowest portion—a shelf with depths up to 330–460 feet—extends along both shores, with the westernmost slope furrowed by submerged landslips and canyons. The remains of ancient river valleys have been discovered on the gentler northern slope; the bottom of the depression is formed of a plain that deepens to the west. The Apsheron Bank, a belt of shoals and islands rising from submerged elevations of older rocks, marks the transition to the South Caspian, a depression covering about one-third of the sea. This is fringed by a shelf that is narrow to the west and south but widening to the east. A series of submerged ridges breaks up the relief to the north, but otherwise the bottom of the depression is a flat plain, with the maximum depth of 3,360 feet.

The three main topographic divisions

Geological origins. The relief of the Caspian Sea reflects its complex geological structure. The northern portion forms a peripheral section of the North Caspian tectonic depression, a vast downwarp in the Earth's surface that is itself part of the great ancient structural block known as the Russian Platform. The Mangyshlak Bank links the mountainous peninsula of the same name to the east with underlying western shore structures; all the rocks concerned reflect an outlying structural uplift of the Hercynian mountain-building movement, which occurred some 290,000,000 years ago. The bottom of the Middle Caspian is very complex. To the west, the submarine shelf is part of the sagging edge of the Great Caucasus Geosyncline, while the submerged Turan Platform on the east swells up in the feature known as the Kara-Bogaz swell. The Apsheron Peninsula regions bear the impress of the Alpine mountain-building and folding period (dating from some 10,000,000–26,000,000 years ago), which created the Caucasian ranges, as do the folded structures of the western South Caspian depression. The entire South Caspian, in fact, has as its base a suboceanic-type basalt crustal structure, although this is overlain in the south by huge accumulations of sedimentary layers many miles thick. The great age thus indicated for the area has led geologists to postulate that this is the remnant of the geologically ancient Tethys Sea. Similarly, the North Caspian Sea bottom is also very old, dating back to Precambrian times, or at least 570,000,000 years ago. The bottom of the North and Middle Caspian has a continental-type crustal structure. It has been suggested that the Middle Caspian depression results from a sagging at the edge of these ancient structures that occurred in Late Paleozoic times, about 250,000,000 years ago; the border between the Middle and South Caspian is, in fact, still experiencing folding activity.

Until the upper Miocene, about 12,000,000 years ago, the sea basin of the Caspian was connected closely to the Black Sea, through the structural depression known as the Manych Trench. This link was broken after an upper-Miocene elevation, and the Caspian became an enclosed body of water, with oceanic submarine characteristics preserved today only in the Southern Caspian. The connection with the ocean was re-established in the upper Pliocene, about 2,500,000 years ago, and it is possible that there was also a link northward across the expansive Russian plain to the Barents Sea of the Arctic.

Pre-Miocene link with the Black Sea

In the ensuing Quaternary times, great glaciers advanced and retreated across the Russian plain, and the Caspian Sea itself—in successive phases known as Bakin, Khazar, and Khvalyn—alternately shrank and swelled out. This process left a legacy in the form of peripheral terraces, marking old shorelines, and can also be traced in the recent underlying sedimentary layers.

The Caspian Sea bottom is now coated with young sediments, finely grained in the shallow north but with shell deposits and oolitic sand—reflecting the high lime content of the Caspian waters—widespread in other coastal areas. Lime also affects the composition of the much deeper bottom layers.

Climate. The North Caspian lies in a moderately continental climatic zone, while all the Middle (and most of the South) Caspian lies in the moderately hot belt. The southwest is touched by subtropical influences, and this remarkable variety is completed by the desert climate prevailing on the eastern shores. Atmospheric circulation is dominated in winter by the cold, clear air of the Asiatic anticyclone, while in summer spurs of the Azores high-pressure and the South Asian low-pressure centres are influential. Complicating factors are the cyclonic disturbances rippling in from the west and the effect of the Great Caucasian ranges. As a result of these factors, northwesterlies (32 percent of occurrences) and southeasterlies (36 percent) dominate circulation patterns. Savage storms are associated with northerly and southeasterly winds.

Summer air temperatures are quite evenly distributed (average July–August figures: 75°–79° F [24°–26° C], with an absolute maximum of 111° F [44° C] on the sunbaked eastern shore), but winter temperatures range from 14° F (−10° C) in the north to 50° F (10° C) in the south. Average annual rainfall varies from 67 inches to eight inches over the sea. Most falls in winter and spring. Evaporation from the sea surface is very high, reaching 40 inches a year. Ice formation afflicts the North Caspian, which usually freezes completely by January, and in very cold years floating ice comes as far south as the Apsheron Peninsula region.

Fluctuations in water level. Short-term wind-induced fluctuations in the sea level can rise to up to seven feet, though such rises average about two feet. Seiches (rises induced by barometric pressure changes) can cause similar fluctuations. Tidal changes are but a few inches, and seasonal rises induced by high spring water in the rivers are not much more.

One of the more fascinating aspects of the study of the Caspian, however, is the reconstruction of long-term fluctuations over the centuries from archaeological, geographical, and historical evidence. It seems the Caspian reached a level of 72 feet below sea level about 4,000 to 6,000 years ago and again early in the 19th century AD. A still lower level held from the 7th to the 11th centuries, while the lowering that took place between 1929 and 1957 stemmed from the effects of climatic change resulting in lesser river influx and increased evaporation amplified by reservoir construction on the Volga, and from river water consumption for irrigation and industry. The flow of water into the Kara-Bogaz-Gol, now about 12 feet lower than the Caspian, has also had an effect. By the early 1970s, the water level was very close to the −93.5 feet level, reflecting a balance between input (rainfall, river inflow, subterranean upwelling) and consumption (evaporation, flow into the Kara-Bogaz-Gol, human usage) that gave the latter a slight edge and hence a projected annual lowering of the level by three inches. If, however, the north-flowing Vychegda and Pechora were diverted into the Volga, it would seem that the pres-

Recent attempts to preserve the sea level

ent level could at least be maintained (and increased, under favourable climatic conditions) until the year 2000. Soviet planners have given serious attention to such an ambitious project.

Hydrology and life forms. In summer, the average seawater temperature is 75°–79° F (24°–26° C), with the south a little warmer. There are, however, significant winter contrasts, from 37°–45° F (3°–7° C) in the north to 46°–52° F (8°–11° C) in the south. Upwellings of deep water at the eastern littoral—a result of prevailing-wind activity—can also bring a marked drop in summer temperature. Salinity in the Caspian is about 1.27 percent on average, but this conceals a variation from a mere 0.1 percent near the Volga outlet to a high of 32 percent in the Kara-Bogaz-Gol, where intense evaporation occurs. Caspian waters differ from those of the ocean in their high sulphate, calcium, and magnesium carbonate content and—as a result of river inflow—low chloride content.

Water mass circulation occurs, basically, in a north to south movement along the western shore, with a complex pattern developing further south, where there are several subsidiary movements. Currents can be speeded up where they coincide with strong winds, and the sea surface is often ruffled by wave action, with the maximum storm waves being observed near the Apsheron Peninsula.

There are about 850 animal and more than 500 plant species in the Caspian—a relatively low figure. Animal life has been affected greatly by changes in salinity. It includes, among the fish, sturgeons, herring, pike, perch, and sprat; several mollusks; and a variety of other organisms including sponges. Some 15 species of Arctic (*e.g.*, the Caspian seal) and Mediterranean types complement the basic fauna. Perch are important among freshwater fish varieties. Some organisms have migrated to the Caspian quite recently: barnacles, crabs, and clams, for example, have been transported by sea vessels; grey mullets have been deliberately introduced by man.

The human imprint. The Caspian was long famous for its sturgeon catch, but this has been reduced greatly in recent years, as a result of the decline in sea level, and the connected drying up of the most favourable places for spawning. The seal industry is, however, being developed in northern regions. Oil and gas have now become the region's most important resources, following extensive geological surveys in the 1940s and 1950s. Seabed oil is extracted from derricks and artificial islands, most of which are concentrated off the shores of the Azerbaijan S.S.R., supplying half that republic's total oil extraction volume. The extraction of such minerals as sodium sulphate from the Kara-Bogaz-Gol is also of considerable economic importance. Finally, the Caspian is of major importance for transportation in the region: petroleum, wood, grain, cotton, rice, and sulphate are the basic goods carried, while Astrakhan, Baku, Makhachkala, Krasnovodsk, and Shevchenko are the most important ports. They are also connected by regular passenger runs, while railway stock is transported direct, without unloading, on the Baku–Krasnovdsk run.

The future of the Caspian will depend on the success of measures to maintain the present sea level, on restoration and development of fishing resources, on further oil and gas exploitation, and on the creation of a large chemical complex at Kara-Bogaz-Gol. Further transportation developments will require, as a necessity, new port facilities and new ferries. The hitherto largely deserted eastern shores will benefit from development associated with oil extraction, and an extensive development of the fine shores of the sea as health and recreation resorts figures largely in Soviet long-term plans for the area.

Caste Systems

Caste systems are moral systems that differentiate and rank the whole population of a society in corporate units (castes) generally defined by descent, marriage, and occupation. Elaborately differentiated and ranked caste systems have developed especially in the regional societies of India and among adjacent Hindu and related populations in the territories of modern Pakistan, Bangladesh, Nepal, and Sri Lanka (Ceylon) over the past 2,000 years. Simpler caste systems have developed elsewhere. The nature, history, and variety of these systems, their significance for general understanding of human society and for particular understanding of South Asian society and religion are the subjects of this article.

CASTE SYSTEMS IN GENERAL

So intricate are the connections of caste systems in South Asia with regional systems of ideas regarding such matters as genetics, physiology, kinship, ethics, and cosmogony that they have been equated by some scholars with the whole culture of Hinduism and declared to be unique phenomena inseparable from it. Caste systems are found, however, in combination with other religions and cultures in South Asia and elsewhere. Their features as a general type may be compared with other systems of social class or stratification. (See SOCIAL DIFFERENTIATION AND STRATIFICATION.)

Caste systems compared to other systems of social stratification

Caste systems resemble racial stratification in their biological concern with differences of birth and marriage; they resemble stratified plural societies in their presumption of profound differences in group behaviour; they depart from both in conceiving of themselves simultaneously as unitary societies that are culturally integrated. Unlike racially or culturally plural societies, where prior intractable difference among groups is taken as a moral reason for the divided constitution of the society, established caste systems may differentiate into further, new units or they may reassemble their units into one.

Caste systems resemble the much more widespread systems of social and economic classes in containing ranks that tend to be culturally marked, occupationally linked, hereditary, and endogamous (marrying within a group). They differ from such systems in having as their ranked units not only individual persons and families but also larger corporate groups. Corporate caste units differ from social classes in being necessarily defined—rather than incidentally distinguished—by occupation, descent, and marriage. Castes have no other necessary cultural markings, although classes, being assemblages of persons on the basis of their attributes, necessarily do. The ranking of corporate units in caste systems creates an illusion of individual immobility (a feature sometimes taken as typical of caste systems); yet rates of individual rise and fall are not known to differ between class systems and caste systems, as the types are here defined.

Caste systems are comparatively rare among large-scale moral systems in making the differentiation and interrelations of corporate groups into major concerns; but in this they are at one with a large and diverse category of small-scale societies. The sharings and exchanges by which caste systems reckon the boundaries, alliances, and ranks of their corporate units have much in common with widespread forms of marriage and parent–child relationships, gift giving and tribute, ritual, sports competitions, communication networks, and dominance in animal as well as human societies. But caste systems are unique in their ways of combining these features—in having biological and behavioral schemes for differentiating and ranking occupational and ethnic units according to the determined way they relate to each other in sharings and exchanges. They have proven uniquely capable, in each of the regional societies of South Asia, of relating hundreds of units in dozens of higher and lower ranks and of generating new societal forms through combinations and transformations of existing schemes.

FOREIGN CONCEPTIONS OF SOUTH ASIAN CASTE SYSTEMS

For about two centuries, the explanation and analysis of South Asian caste systems have been matters of interest and controversy among foreign observers, who have brought with them assumptions and sensitivities peculiar to their own respective societies and times.

No visitor of ancient or medieval times seems to have felt that rank, corporateness, heredity, and endogamy among the occupational and ethnic groups of India were worthy of special mention. The Portuguese seafarers who

traded mainly on the west coast of India in the 16th and 17th centuries described groups they called *castas* (from which derive the English and French words *caste*), meaning "species" or "breeds" of animals or plants and "tribes," "races," "clans," or "lineages" among men. Only in the 18th century did the distinction that is now made between unranked tribes and ranked castes begin to be drawn clearly in the usage of the French and English.

Consideration of the thoroughgoing inequality and exclusiveness of the castes, as well as the peculiar occupational division of labour prescribed for them, generally produced a sense of shock in Western missionaries and officials of the turbulent 19th and 20th centuries. Attempts were made to explain the castes as an imagined rational legislation by some unknown past authority, as a self-serving invention by the system's top-ranking priestly castes, or (after Charles Darwin) as the unplanned evolution of successively higher castes through the growth of superior technological specialization.

Attempts by Western observers to explain castes

The insufficiency of these—or, indeed, of any—simple conjectures for explaining the origins of these apparently irrational systems strengthened a trend toward more complex historical speculation. Castes were seen as heirs of the Indo-European language family's common traditions of private kin-group ritual by Émile Senart, a late-19th-century Sanskrit scholar. In 1891 H.H. Risley, a British Indian census commissioner, reported that proportionally wider noses correlate with lower caste rank and also with a geographic gradation from northern to southern India; this suggested a hypothesis of repeated invasion from Central Asia and from the north to the south by longer nosed racial elements. Other official British Indian research stressed separate surveys of the physical traits and customs of each of the thousands of castes and tribes. Compendious reports of such surveys reinforced a conception of Indian society as a geographical accident and a political composite. Many authors speculated on historical factors favouring the development of the Indian caste systems—such factors as diffusions of primitive customs, ancient movements of peoples, and the mutually distancing adaptations of allegedly alien peoples to each other—and these speculations were compiled in a list of 15 factors by J.H. Hutton, census commissioner and ethnologist, at the end of the British regime in 1946.

What was missing from these atomistic historical analyses was any conception of a caste system as an integrated whole. Such conceptions were provided in nationalistic political contexts in the late 19th and early 20th centuries. Max Weber, a German sociologist, emphasized the connections of caste with Hindu religion as part of his larger effort to reveal why the West had progressed more rapidly than Asia. Skeptical toward Hindu religious explanations, the French sociologist Célestin Bouglé in 1908 postulated, from descriptions of the relations of the castes, an underlying set of social structural "ideas"—hereditary specialization, rank, and mutual repulsion concerned with purity and impurity—governing the whole system. Hutton held that social differentiation in caste systems requires an assumption of a once widespread preliterate philosophy concerning the powers of bodily and other substances and the dangers of magical contagion. The British social anthropologist A.M. Hocart, combining observations in Sri Lanka (Ceylon) and Polynesia with Vedic (early Indian-language) texts, saw caste systems as organizations for royal rituals of worship. In 1952 M.N. Srinivas, an Indian anthropologist working in southern India, attempted to derive both the unity and the ranks of Indian caste systems from the imitation by diverse groups of the customs of the highest Hindu castes, a process that he called "sanskritization."

Western social values reflected in explanations

Western comparative social theorists have generally placed caste systems not in a unique religious ideological or structural category by themselves but at the end of a theoretical series of types beyond medieval and ancient Europe and furthest from the equalitarian, competitive tendencies of the modern West in matters of social differentiation and social stratification. The enclosure of individuals in culturally diverse ranked ethnic groups (castes) was seen as poles away from a culturally homogenizing and individualizing modern society. The multiplicity of the castes and their apparent social distance and segregation from each other through endogamy and restrictions on contact seemed to exceed in stringency any but the most extreme differentiations (*e.g.*, Black and white in the U.S.) among ethnic groups of a single society in the West. Castes were also commonly regarded in Western comparative perspective simultaneously as social-status groups and as economic classes. They were considered rigidly closed classes, permitting recruitment of individuals into caste membership only by birth, not by achievement. Caste systems were further mistakenly thought to allow vertical mobility only through movement by the whole corporate unit, not through individual or familial movement. They were seen as guaranteeing the virtual immobility of groups, as well, owing either to the preponderant power of the conservative high-caste elite or to the strength of cultural consensus and traditional sacred sanctions or to both.

Although comparative sociology thus attempted to look at South Asian caste systems as extreme instances of presumed universal features of human society and implied a view of them as social systems rather than as accidental collections of ideas and peoples, its typifications of these systems remained sociocentric, reflecting modern Western society's assumptions about essential elements and processes, while reversing some cherished Western values. It did not attempt to base its understanding closely upon the cognitive assumptions actually prevalent in South Asia. For understanding of this sort, one must examine certain Indian social concepts that are known first from Vedic texts from 1000 BC. These are maintained to the present by the predominant Hindu population and are widely shared among persons of all religions residing in South Asia.

CASTE SYSTEMS IN SOUTH ASIA

Indian social concepts. *Substance and code in the relationships among castes.* The organization of South Asian society is premised on the ancient and continuing cultural assumption that all living beings are differentiated into genera, or classes, each of which is thought to possess a defining coded substance. One of the commonest words for genus in most Indian languages, *jāti*, is derived from an Indo-European verbal root meaning "genesis," "origin," or "birth." It is applied to any species of living things, including gods and humans. Among humans, *jāti* can designate a distinct sex, a race, a caste, or a tribe; a family, a lineage, or a clan; an ethnic group, a regional population, the followers of an occupation or a religion, or a nation.

Jāti

Every human genus (and therefore every caste) is thought to have as the shared or corporate property of its members a particular substance (*e.g.*, *śarīra*, "body," *rakta*, "blood") embodying its code for conduct (*dharma*). Each caste's inborn code enjoins it to maintain its substance and morality, its particular occupation, and its correct exchanges with other castes. Indian thought does not separate "nature" and "morality" or "law," so that castes are, in Western terms, at once "natural" and "moral" units of society. These units make up a single order, one that is profoundly particularized.

The persons of each caste are believed to transmit the particles of substance that are peculiar to their caste from one generation to the next through a series of natural and moral acts extending from birth to marriage. The male and female sexes, like castes, are thought to be composed of nonequivalent, complementarily coded bodily substances; the reproductive essence of each, variously conceptualized but often identified with semen and uterine blood, is required to make the child complete from birth in his caste's particular nature. Acts that wrongly mix bodily substances, such as improper procreation, are thought to alter the embodied morality of the caste and its offspring. Each caste must therefore be concerned with regulating marriage.

Castes are related to each other externally not by

hereditarily shared substance but by exchange of nonhereditary substances. Each caste is involved through its existence and its means of subsistence in transformations and exchanges of transformed natural substances. Of these substances, a caste's own bodily substances (*e.g.*, hair, blood, semen, and feces) and food (which is seen as becoming transformed into human bodily substance) are considered capable of creating, expressing, or altering relationships of rank and solidarity between it and other castes. The substances derived from each caste's pursuit of its occupation are also major media, along with services, of intercaste exchange. Each caste is thought to maintain or alter its moral standing (that is, its rank with respect to other castes), its hereditary substance, and its natural code according to the way that it receives or refuses to receive bodily substances, consumes or refuses to consume food, and gives or refuses to give services in exchanges with particular other castes.

Varṇa categories in the Vedic sacrifice. A conception of Indian society in terms of genus (*varṇa*, here synonymous with *jāti*) appeared first in the Ṛgveda, the oldest collection of Vedic priestly hymns, composed in Punjab about 1200–1000 BC. The Vedic people of that time saw themselves as members of a single "genus of respectable men" (*ārya-varṇa*), "the humans" (*manuṣa*). Their code enjoined them to offer sacrifice (*yajña*) to members of another genus of beings, the Vedic gods (*devas*); it also enjoined them to smite and enslave their enemies, "the nonhumans" (*dasyu-varṇa*), who were naturally and morally fit for service.

The conception of society as containing more than two *varṇa*s appeared only after 1000 BC, when descendants of these early Aryans began to settle in the upper Ganges region and built a more complex society containing towns and the beginnings of states. It appeared then in the increasingly elaborate body of Vedic sacred texts and ultimately reached its culmination in the classical moral code book (*Dharma-śāstra*) of the Manu school (*c.* 200 BC–AD 200).

Division of Puruṣa into specialized *varṇa*s

The whole later Vedic society continued to think of itself as sharing one original natural substance, conceived as the body of Puruṣa, the original code man. The division of Puruṣa by the gods into distinct specialized *varṇa*s mythically inaugurated the Vedic sacrifice. Henceforth, only those who had the substance of Puruṣa in their bodies were to follow the code of exchanges required by the sacrifice.

Sacrifice was seen as fundamental for upholding the natural and moral order of the cosmos. It required exchanges between the two specialized genera, gods and men. Gods, the beings who wield divine power (*brahman*), were seen as the ultimate source of bodily existence and well-being; men were the givers of the food that the gods needed to sustain themselves. Mutual exchange of food through the sacrifice thus created solidarity between gods and men.

Exchange in the sacrifice also created a ranked relationship between gods and men. Only pure food was fed to gods by men, while gods, after they had eaten, returned only their leavings for men to eat. These same asymmetrical events that created rank—that elevated the gods and lowered men—were conversely interpreted as expressions of rank previously established. Thus, men regarded their own food leavings as contaminated by saliva and therefore as impure and valueless to others but considered the leavings of the gods as transvalued—pure and incomparably valuable precisely because they were filled with the divine natural substance that brought human well-being.

Rank in this ancient South Asian moral order was thought of as being based less upon established possessions than upon generosity. Gods were of higher rank than men not so much because they possessed the attribute of divine power as because they were incomparably generous in bestowing that power on men. Men were of lower rank because they could not return this gift. They could give the gods the most valued foods, but they could not equal the value of the divine power contained in the gods' gift to men.

The same relationship existed among the specialized natural genera within the society of men—between the "once-born" and the genera of the "twice-born" (*dvi-jāti*), those who became divinized humans through a second, ritual birth. The once-born, called Śūdra (Servant), was not to hear the sacred Vedic words or to sacrifice directly or to receive the gods' leavings. He was instead to exchange with the twice-born in the same way that the twice-born, to whom the term *ārya* was exclusively applied, exchanged with the gods. Born of the lowest part of Puruṣa, the feet, the Śūdra followed a code enjoining him to serve the twice-born in exchange for maintenance. He could symbolize his ranked relationship, as was done in the sacrifice, by feeding pure food to his human superiors and eating their leavings in return. His service was a form of worship but an inferior one that properly brought only the divine gift of maintenance in return. Because the Śūdra was defined as being unable to return even this gift of maintenance, his moral rank was considered to be lower than the rank of the twice-born.

The twice-born was the divine human genus of Aryans, whose males came to share the divine sounds of the Veda through a second, divine birth and initiation into Vedic study and sacrifice. Their code also required married male householders to exchange gifts among themselves. The wife and children of a twice-born householder were forbidden, as was the Śūdra, from hearing Vedic sounds and from carrying on the sacrifice. But women and children were conceived as sharing the effects of those duties through having bodily substance in common with their household head.

The three types of twice-born persons

The code book enjoining sacrifice and exchange also defined three specialized genera of people within the twice-born genus. The substance of each of these had its distinctive ranked origin and inherent ranked powers, and the code for conduct of each was specialized. The Brāhmaṇa, born from the highest part of Puruṣa, his mouth, possessed godly power (*brahman*): he was to teach the Vedas, perform sacrifices for the Kṣatriya and Vaiśya, and accept gifts from them in exchange. The Kṣatriya, born from the arms of Puruṣa, possessed royal power (*kṣatra*): he was to fight enemies, give gifts and food to the Brāhmaṇa, and protect the Vaiśya; in exchange, he received a share in the leavings of the sacrifice from the Brāhmaṇa and wealth from the Vaiśya. The Vaiśya, born from the thighs of Puruṣa, possessed productive power (*viś*): he was to produce wealth for the Brāhmaṇa and the Kṣatriya through agriculture, commerce, and animal herding, and was to give a share of it as taxes to the Kṣatriya in exchange for protection.

Each superior genus is considered divine in relation to each inferior genus. The moral ranks of the genera were gauged in *varṇa* theory also by the values assigned to the different things they gave each other. Since the wealth given by the Vaiśya to the Kṣatriya was considered less valuable than the divine protection received in exchange, the Vaiśya ranked below the Kṣatriya. The Brāhmaṇa acting as representative of the whole society, fed the gods through the sacrifice and was first to eat their leavings, to take their power. In comparison to the Kṣatriya and the Vaiśya, he was therefore a "god on earth." Because the gifts and food given by the Kṣatriya and the Vaiśya to the Brāhmaṇa were considered to be less in value than the remainder of the sacrificial leavings that he gave to them, he was thought to have a higher rank than they. Beneath all three was the Śūdra, with his offering of mere labour, benefitting by the activities of all.

The four *varṇa*s of Vedic theory may have had a waning existence in parts of northern India when the theory was first being formulated, between 1000 and 300 BC. But the authors of the classical moral code books in the centuries following (*c.* 200 BC–AD 200) were concerned with reconciling this theory with the multitude of specialized *jāti*s of uncertain *varṇa* that they actually saw about them. They explained the existence of non-Vedic *jāti*s by a theory of miscegenation: the *jāti*s were offspring of improper mixing and remixing among descendants of

the four pure Vedic *varṇas*. The numerous *jāti* units, their varied codes for conduct, and many ranks were all seen in the Vedic scheme itself as responses to the requirements of particular places, times, and genera of persons. The four *varṇas* together with the sacrifice from which they were thought to spring were seen as the universal, eternal, and logically complete scheme for upholding nature and morality.

Hindu worship and the castes. The Vedic scheme concontinues to the present as a template, generating systematic conceptions of the local, everchanging castes (*jātis*) and their exchanges in the closely connected scheme of Hindu image worship, called *pūjā* (literally, "respect"). Evidences of the proliferous systems of castes connected with image worship appeared gradually after AD 500.

Complex systems of castes required by Hindu image worship

The Hindu gods to be worshipped are related among themselves, like men, by shared and exchanged natural substance. They have not merely abstract qualities and representations like the Vedic gods, but also particular lifelike images, biographies, bodily functions, and specialized relations to men. They are attached by particular codes of worship to particular occasions, communities, and genera of persons. The occasions for their worship are times of bodily events in their own or their worshippers' lives—births, weddings, deaths, and the routines of such things as the daily bath or meals—and in the natural cycles of the Sun, Moon, Earth, and other planets, whose heat and cold, dark and light, wet and dry, etc., are seen as bodily states affecting human beings.

The codes of Hindu worship require the existence of complex local communities of castes. Worship cannot proceed without a priest to bring the living substance of the god into the image, made by an image maker. The priest must utter formulas (*mantras*) that activate this divine life substance and other formulas that have the power to transform the ordinary materials of worship into sublime offerings. The priest must be a male of the highest, most godlike caste available—ideally a Brahmin skilled by heredity in the maintenance of ritual boundaries between substances, and empowered to transform them.

To sponsor the worship there must be a local worshipper of means, typically a ruler or man of wealth, who can by gifts entreat a priest to mediate with the god. There must be specialists of appropriate castes—*e.g.*, temple keeper, garland maker, cook, sweet maker, singer, musician, dancer—to feed, attend, and entertain the god. Before the worshipper can approach the god, he must prepare himself and his caste to be as godlike as possible and must remove as much as possible from his person and his caste any insulting, transmissible bodily substance. He does so through bathing and through engaging the services practiced by other castes, such as those who do the work of barber, washerman, midwife, funeral priest, leatherworker, scavenger, or sweeper. These castes are by their intimate receivings of bodily substance rendered subordinate to the worshipper, as a child's receiving of bodily substance renders him subordinate to his parents. Each caste contributes in its particular way to the worship, directly or indirectly, and each then receives in return and in order of rank a share, either in the transvalued leavings of the god's food (called *prasāda*, "favour") or in the leavings of those who do receive a share.

Hindu worship thus greatly ramifies the specialities assigned to the four *varṇas* and invites specialization by caste. One effect of such worship is a ranking of all participating castes by a pattern of exchanges in which natural substances and services go up and divinely transvalued substances containing divine benefits go down. Another effect is the establishment of a solidarity of substance among all the castes.

Varieties of caste systems. Caste groups range in size from hundreds up to millions, with their estimated median population lying between 5,000 and 15,000. Such populations are likely to be spread over dozens or hundreds of villages and cities and over hundreds of miles of territory. Thus, few castes ever meet as wholes in one place. Nevertheless, the universality of concern for a caste's substance and code and for its rank (which can be altered for all by the conduct of a single member) guarantees at least an informal, diffuse organization of authority within each caste. Recruitment of allies or a shift to a larger context of competition may lead a caste to fuse with groups otherwise treated as separate categories.

In the eyes of others, a caste is most often categorized in an occupational role. Each caste in fact owns a set of related occupations among which its members may choose according to their particular economic situation. Thus, for example, each of the "royal," traditionally warrior, castes (called Rājput) includes landlords, cultivating tenants, and landless labourers, as well as princes and soldiers. Least specialized are some of the tribal *jātis* in the hills and forests of central India, who traditionally do for themselves all work except metal-working and the literate professions. About one-third of all the South Asian population is in castes for whom some aspect of agriculture is the main traditional occupation. Another third, traditionally specialized by caste in nonagricultural work, in fact earns most of its living in agriculture.

Local communities and class

Settlements of fewer than 1,000 persons have contained most of the predominantly rural population of South Asia up to the 20th century. These settlements have commonly comprised members of from five to 20 castes —the number varying according to the density of the particular region and the wealth of the local population. Contact among persons of different castes is typically close and frequent in villages, being required by economic division of labour and by the forms of ceremony. Persons are readily identified by one another as members of known castes and the import of their actions accurately assessed. On the average, villagers agree with each other by majorities of 90 percent or more concerning the ranks of eight out of any 12 local castes.

Apart from their belonging to castes, the households of most villages are organized in economic and political systems that concentrate power in the hands of a landed or commercial minority. Membership in the local ruling class rarely corresponds closely with the membership of any local caste group: individuals, households, and families may rise or fall in their economic resources and influence, apart from the ranks of their castes. Local caste groups often differ greatly in their members' aggregate or average wealth and influence. Castes that have no other economic resources must serve and defer in ritual ways to those with power in order to subsist. Rank is traded in order to eat. Thus, the actual distribution of politico-economic power within a community can effect a rearrangement of the order of ranks among the castes.

The rankings of castes in villages are alterable but are not quickly altered, locally supported as they usually are by politico-economic interests, restrained by complex multilateral exchanges, and remembered by minds accustomed to a hereditary order. The mild but ubiquitous inclination of castes to improve their ranks can be estimated from the finding that the average villager believes the correct rank of his own caste to be about half a rank higher than what nonmembers of his caste are willing to concede. Efforts by rural caste groups to depart from the locally accepted line of precedence are numerous, even if moderate and slow to take effect. That castes' local ranks do change is known from case histories and from the differences in the same castes' ranks that occur from place to place.

The caste systems of rural people, as they are believed to have existed at the beginning of British rule in 1858 and as they continue to some degree into the present, can be divided into five major regions of South Asia.

Caste systems in southern India and Sri Lanka (Ceylon). Dravidian-speaking south India is characterized by a proliferation of castes, consistent with regional concern for the integrity of female bodily substance. Except in the matrilineal castes (in which membership is gained through the mother) of Kerala, both parents are thought

of as contributing caste code to their offspring. Marriages outside Kerala are uniformly made within the caste. Endogamous castes here tend to become very small and close, to divide into numerous smaller circles by the preferred repetition of reciprocal, protective marriages among cousins and other known kin. Distinctions between castes are more often marked by visible attributes. Only whole, uncooked foods, such as betel leaf and nut, are much exchanged beyond the caste and household.

The relatively small spread of each caste leaves it available to be ranked consistently by its members' exchanges with other castes in just a few nearby localities; there is little danger of conflict over precedence through comparisons with possibly inconsistent rankings of the same castes in any remote villages or kingdoms. At the same time, local communities are the largest and most complex in South Asia, averaging ten to 15 local caste groups in the southeast and 15 to 20 in the southwest.

The stability of rice agriculture and government in the lowlands of southern India have also favoured a formal administration of land tenure from the state down to the cultivator (*raiyatvāri* tenure), operating either through hereditary local officials whose castes (*e.g.*, the Nāyar) have been or become regarded as the high castes or through land-endowed temples administered by Brahmins. Dynasties have had long durations, and conquests by other than neighbouring kingdoms have been few. One result has been a frequently close identification of land-tenure positions with certain castes and a closer correlation than elsewhere between castes' ranks and their powers. Brāhmaṇa caste groups have in some areas taken the positions of rulers. Another result of these conditions has been the formal social organization of the whole village community on caste lines for the several purposes of legal administration, occupation, and ritual.

Rankings of local castes in 20 or more grades are encountered in Kerala. An extreme etiquette of formal speech, clothing, gesture, and distancing among the castes is required there. On the other hand, repetition of the sets of priestly and pollution-removing (*e.g.*, barber, washerman) castes for patrons at three or four ranks and marriage of women above their caste (intercaste hypergamy) integrate the many castes into single, ranked schemes. The central role of Hindu temples in focussing the services and ranks of castes continues from Kerala up the western coast of Mysore and also down to Sri Lanka (Ceylon), especially in its Kandyan highland region. In much of Sri Lanka (Ceylon), however, the small village settlements have few castes, favouring their Buddhist caste system.

The caste systems of villages in Tamilnadu and Andhra Pradesh are less centrally structured and somewhat less elaborately ranked than in Kerala. Local communities contain fewer castes, castes whose wealth and power are less closely correlated with their ranks and whose residences are divided into hamlets with separate caste-linked temples. In some districts castes are organized in competing sets—*e.g.*, castes of the "right hand" versus those of the "left hand"—reflecting rivalries between ruling castes, between indigenous and immigrant castes, or between agriculturalists on the one hand and traders and artisans on the other.

Caste systems in the northern plains of India. The region of the later Aryan settlement in eastern Punjab and in the upper Ganges Valley (in Uttar Pradesh) and of the plains in the north Indian area where Indo-Aryan languages continue to be spoken today (Bihār, West Bengal, and Gujarāt) are generally densely populated with moderately sized villages having caste systems somewhat less elaborate than those in southeastern India. Each settlement averages about 500 persons belonging to ten castes, nine of which are Hindu and one is Muslim.

Castes in the northern plains

Centralization and formal organization are slight. Villages in the northern parts generally have no temple at all; those of Gujarāt generally have many private temples but none that can bring all the castes of a locality together in a ranked order of worship; those of Bihār and West Bengal that have centralized worship, organized by a local landlord, are few. The intercaste organization in the villages of the northern plains, both for worship and for control of land and conflict, tends to be based upon a plurality of landed households, mostly of the higher castes. Each household conducts its separate worship, and each separately employs specialist members of five to 15 castes. Such specialists serve by heredity on fixed rates of annual payment either in land or crop shares.

The main occasions for proving the ranks of the castes, beyond the regularly rendered services and payments, are household-sponsored feasts. Intercaste feasts in this region use a class of perfected (*pakkā*) cooked foods that are based on clarified butter, need not be served hot, and are therefore thought to be not so open to combination with bodily substance. Such feasts are offered to representatives of every caste in the village, and the resulting acceptances and rejections of food make public show of each caste's relative standing.

Local rankings of the castes in most of the northern plains are less isolated and more subject to contravention by rankings occurring elsewhere, primarily as a result of the very wide range of marriage. Except in Bengal, clan terms of kinship are used locally among persons of all castes, and locally born women must marry outside their localities. Caste by caste, linear rankings of local castes become impossible. Nevertheless, high local agreement occurs on blocks of castes; about three-quarters of the possible ranks are distinguishable.

Some castes of the northernmost plains, with some higher castes of the central region and all castes of the western region, hold that their natural code is transmitted by the father alone. Many of these marry hypergamously, linking higher with lower clans and castes. Castes here tend to have larger spreads and the largest regional populations.

The small kingdoms and pockets of Hindu and Buddhist settlement on the Himalayan slopes of northern South Asia differ greatly from the plains and among themselves in their environments. Many villages here are composed of only one, two, or three castes or tribes and thus have a very simple division of labour. These villages may be quite isolated settlements, practicing close reciprocal marriages.

The more densely populated Himalayan areas, such as the valley of Nepal, were strongly Hinduized by Rājput and Brāhmaṇa immigrants, increasingly so after the Muslim conquests of the plains. Nepal contains dozens of Buddhist and Hindu castes that are elaborately graded and linked, both by position in the state and sometimes by intercaste hypergamous marriages. Both parents are believed to transmit caste-coded substance, and offspring of mixed marriages are assigned to third castes having ranks between those of their two parents' castes.

Caste systems in central India. The central Hindu region extending from Rājasthān in the north through Madhya Pradesh to Mahārāshtra on the south and Orissa on the east is characterized by relatively sparse rural population that tends to be concentrated in villages of moderately large size—500 to 700. The average number of castes present in these villages is less than in the northern plains, for in each state and locality two or three out of a few very large clusters of castes preponderate.

Caste systems in central India

Within the central zone, the regions of Rājasthān, Kutch, Kāthiāwār, and much of Madhya Pradesh contain large desert or hilly areas that can be exploited fully only by herders and semimigratory farmers. Where permanent villages exist, they organize hereditary intercaste services by household. But wide and flexible networks of organization are advantageous within the castes of these mobile farmers. They are essential for the controlling castes of Rājput and other warriors and among the numerous small Hindu and Jaina (a religion founded in India in the 6th century BC) trading castes of the region. Such networks are structured for these higher castes not by close caste councils such as those that prevail in southern India but rather by the rulers' deep and widespread corporate lineages and clans (recorded for them by genealogist castes), by belief in exclusively male

transmission of caste code, and by broad rules of marriage like those found in the northern plains. Within such rules, alliances may be sought and broken. Equipped with such effective structures for mutual aid in an otherwise famine-prone environment, cultivating (Rājput), herding (Gūjar, Ahīr), and merchant (Mārwāri) castes of the dry lands have spread into the neighbouring plains, often as predatory forces in politics and commerce. At the same time, the nondominant castes of Rājasthān, although widely dispersed, follow an opposite strategy of reciprocating, caste-endogamous marriage (inside the caste) that tends to consolidate rather than expand their scarce resources.

South of Rājasthān and north of Mahārāshtra is the fertile plateau of Mālwa, a crossroads of trade, migrations, and routes of conquest in all directions. Villages here, like villages in parts of southeastern India, are often divided between two sets of castes: on the one hand, those who eat meat, worship the Hindu goddesses, and follow the Rājput and local Brāhmaṇa codes and, on the other hand, those who are vegetarian, worship the Hindu god Viṣṇu, follow the Vaiśya code, and are often immigrant castes.

Farther south in the central zone is Mahārāshtra. The Mahārāshtrian village makes public feasting an important focus of intercaste relationships, although restricting feasting to the feeding of kinsmen and traditional servants; it also separates its lowest castes (*e.g.*, Mahār) from the others in a distinct residential hamlet, regards its specialist castes as serving the village as a whole, and organizes all its castes around one or more temples. What distinguishes and moderates intercaste relations in the Mahārāshtrian village is the strongly communitarian nature of village institutions: the village runs its affairs by decision of a village council that includes representatives of all castes and typically makes its main temple into a community centre. It shares some of these features with villages in adjacent sections of western Andhra Pradesh (Telingana or Telengana) and northwestern Mysore.

On the wide eastern and southern margins of the central zone and through its heart in the hills of the west and on both sides of the Narmada River Valley are forested areas inhabited largely by hundreds of tribal peoples—endogamous ethnic groups that have distinct moral systems, that trade their products in peasant markets, but that engage little if at all in the exchanges related to worship that would make them part of any neighbouring Hindu moral system of ranked groups. Non-Hindu tribes are also numerous in Assam and in the North East Frontier Agency (*e.g.*, Nāga). Many Hindu castes derive from such tribes.

Caste systems in Bangladesh and Pakistan

Caste systems in Bangladesh. The densely populated floodplain of the Ganges and Brahmaputra rivers differs radically from northern India in the ecology of its human settlement. A conception of the stable village of locally exchanging castes does not exist. Instead, the scattered households, loosely linked in shifting affiliation with the stronger leaders among them, seek to fill their needs for caste-specialized products through resort to cash exchanges at rotating markets. What specialized services and goods are not traded at markets are brought door-to-door by waterborne artisans and merchants. Even agricultural labourers are often itinerant and indistinguishable from mobile fishermen; only domestic service is generally rendered on long-term local contracts.

The rural population of this socially fluid region is also for the most part relatively undifferentiated by caste and even by kinship groupings of any considerable depth. Localities for miles may be inhabited by a single genus of Muslim cultivators: specialized Hindu castes concentrate themselves apart or cluster at the rare permanent markets and centres of land administration. Thus, neither the human materials nor the institutions of domestic or community worship are present to encourage any elaborate rankings of castes. Indeed, the region is not known to have been Hindu in any large degree or for any appreciable time. Its older past was Buddhist in regime; it came at last under the rule of a Hindu dynasty only a century before its conversion to Islām began in the 13th century. Both Buddhist and Islāmic treatments of caste are congenial to the peculiarities of the region.

Caste systems in Pakistan. Like Bangladesh, the provinces of Pakistan—the desert of Baluchistan, the hills of the Northwest Frontier Province and Kashmir, and the plains of Sind and West Punjab—passed from a Buddhist to an Islāmic regime without elaborate development of caste ranking in the Hindu style. Here, again, the ecology of much of the region does not permit the coresidence of many ethnic groups. Neither the mobile herdsmen of the desert and hills nor the cultivators in tiny hamlets on the Indus Plain can assemble many castes to construct complex local systems. Exchanges among the castes of these areas take place more often in towns and for cash at market rates.

Where villages are larger and richer, as in West Punjab, they have attracted members of numerous castelike lineages, or clans, and have become more than equal in ethnic complexity to villages of Hindu eastern Punjab. But here conditions of instability—like those noted for Rājasthān and Mālwa in the central region of India—play a part, for both West Punjab and the Northwest Frontier Province have been shattered socially by repeated tribal incursions. Parts of the same tribes and lineages have taken widely varying ranks, according to their political fortunes in different localities. Although marriage is spatially closer than in south India, tribal and lineal names are spread over great distances and tend to confound ranks based on local exchanges. Fewer than one-third of the possible ranks are therefore found to be distinguished among castes in villages and towns of this region.

Caste systems outside South Asia

South Asian caste systems overseas. Caste systems have been carried by South Asians to other continents but are found there only in drastically reduced versions.

Traders and settlers from India established elite cultures of Vedic, then Buddhist religion in many parts of Southeast Asia during the early centuries of the Christian Era, but only on the small Hindu island of Bali are traces of a caste society known to have survived beyond the advent of Islām. In Bali, the four Vedic *varṇa*s are employed as a ranked classification of patrilineal titles (those handed down through the father's line of descent) held by generally endogamous (sometimes hypergamously related) lineages. Higher titleholders are more likely to marry nonlocally. They often receive elaborate verbal deference from lowers. They may refuse cooked food from lowers to assert superiority without believing that food transfers alone can alter rank. Apart from some specialization in worship, Balinese caste titles in practice designate claims to rank, rather than major occupational groupings.

The millions of South Asians who went as labourers to Africa, Malaya, Fiji, Trinidad, Surinam, and Guyana in the 19th and 20th centuries proved unable to carry complex caste systems with them. The regional heterogeneity of those who migrated permanently made their caste identities and their codes of exchange mutually unintelligible. Original caste names have been changed, and identities of code and substance are everywhere merged by marriage into composite regional or linguistic and religious castes. Such a composite Hindu caste is commonly further divided by a single distinction into a priestly and nonpriestly caste. Only those overseas traders (in Burma, Malaya, or East Africa) who return periodically to their home regions are able to adhere to their original codes of marriage and caste identity. Nowhere abroad have modern South Asians set up local communities having a caste division of labour in work or worship, again excepting the Brāhmaṇa role among Hindus.

Caste systems in cities. Caste systems are also modified by the conditions of city life. Like overseas migrants, urban residents in South Asian cities of all regions and since ancient times have had to cope with the difficulty of identifying and ordering great numbers of regionally heterogeneous castes. They have attracted and supported specialized groups little known in rural areas. They have also had to cope with largeness of scale, with recognizing

the castes of thousands of mobile individuals. Their larger populations within each caste have furthermore tended to segregate themselves in self-sufficient enclaves, each with its own internal division of labour and its separate cult or sect. Finally, their intercaste exchanges have always tended to be mediated more by shifting power and prices in the marketplace than by corporate group codes.

Specialized mercantile, administrative, and military camp cities of the northern and western regions have seen these tendencies carried furthest, also suffering frequent depopulation and relocation with changes in their specific functions. Certain more permanent royal and religious cities, especially in the south, have seen these tendencies counteracted most fully by centralized exchanges at palace or temple among formal representatives of the various castes. Royal regulation of service, payment, residence, and consumption according to caste rank and unilateral arbitration of disputes over rank also reduced the urban potentialities of anonymity and disorder.

Caste and the religions related to Hinduism. Belonging to a caste is thought by South Asians of the indigenous religions to raise difficulties for the perfection of a person's "soul," his unique natural code (*ātman*). Yet a person cannot exist embodied in the natural order without belonging by birth to one of that order's natural genera and without being subject to its inborn generic code.

Religious attempts to find liberation from caste

Vedic liberation and caste. In the Vedic view, the soul is contained in two kinds of body: a gross body that is abandoned at death and a subtle body that clings to the soul. The gross body belongs to a natural genus, while the subtle body does not; yet, being still a unit in the natural order, the subtle body must go on to be reborn sooner or later within a gross body belonging to some natural genus. The moral actions (*karman*) of a person in following the code of his genus affect the quality of his natural substance; and this determines where in the ranked order of natural genera his soul will be reborn—among plants, animals, demons, gods, or in the same or some other caste of humans.

Further Vedic views stress not the unknowable ultimate rebirth of the soul but its long continuity in its original birth as a heaven-dwelling spiritual ancestor, fed by offerings from corporeal descendants, or as a dissatisfied terrestrial ghost, troubling living persons. These and still other Vedic views continue in the beliefs of some Hindu castes, along with popular theories of this-worldly punishment and reward for moral actions.

Liberation (*mokṣa*) from the endless flux (*saṃsāra*) of birth and rebirth—often called transmigration—is the highest goal of the Vedic religion. Liberation means absorption of the individual code or soul into Brahman, the divine, perfect substance that is the ultimate source of the natural and moral order. This goal is attainable only by a male of twice-born genus who has followed the sacrificial code through the three life stages of student, householder, and forest dweller. Only he is to enter the fourth, or ascetic (*sannyāsi*), stage by abandoning the sacrifice and performing his own funeral. As an ascetic, he is morally dead and thus need have no more concern for his caste nor it for him. He is to own nothing and give nothing to others but is to beg from others of any caste a minimum of food. Thus abasing himself, the ascetic reverses his former high rank. Through knowledge and meditation and aided by such austerities, he strives to obtain control over the relationship of his soul and body in order to effect their complete separation. At his second, natural death, if he has achieved control, his soul is thought to attain perfect liberation from the caste-bound natural order.

Hindu sects and caste. Later, in Hinduism, liberation is thought to be attained through the individual's participation in one of the numerous Śaiva, Vaiṣṇava, or Śākta "sects." Each sect is both a divine and a human moral order thought to have a code above and beyond the natural and moral codes that are inborn in the ranked human genera. Each sectarian order consists of three kinds of persons—gods, preceptors (gurus), and devotees. Persons of any caste or sex are thought eligible to participate. They are related within the sect not by their previous particular natures but by manipulations of divinely coded substance.

In some sects, liberation is attained by assembling these persons more closely. By means of direct personal devotion (*bhakti*) to a chosen supreme deity, devotees are believed to attain a permanent relationship of superior love (*parā-bhakti*) equivalent or superior to liberation. By accepting or eating substances, especially food leavings transvalued by preceptor and deity, the devotees bind themselves to the god and to each other as members of his divine family, overriding the ranks of their castes as they are ordinarily maintained through image worship.

In other sects, those called Tantric, liberation is attained by reversal. By means of secret words and prescribed collective ritual acts directly contrary to ordinary moral codes—*e.g.*, eating meat, drinking wine, having promiscuous sexual intercourse—a person is thought to destroy the bonds that normally link him to the lower human order. He is thereby thought to attain a superior liberated state (*parā-mukti*) while still in human form.

Liṅgāyats and Sikhs. The Liṅgāyat community of Mysore arose within Hinduism in opposition to Jaina and Brāhmaṇa domination during the 12th century; the Sikh community of the Punjab arose as a synthesis of Islām and Hinduism during the 16th century. Both religious communities make radical revisions by manipulating together the mutually immanent, nondual constituents of the Hindu systems that are seen either as encoded substances or embodied codes. Liṅgāyats and Sikhs both believe that they become a divine human genus when they are given initiation (*dīkṣā*) into the making of natural sacred sounds by their teachers (gurus). The Liṅgāyats believe that they become human incarnations of their supreme god, Śiva. Being divine, they reason that their bodily substances at birth, death, or menstruation no longer pollute, as do those of ordinary Hindus. The Sikhs believe that through initiation they incorporate their teachers, who are believed to be perfect and divine, even though human. Both Sikhs and Liṅgāyats believe that they attain liberation while still belonging to their many original castes. These castes are thought to continue as a simply human, therefore lower, order. Ranks of castes in these orders, as among Muslims, are expressed in upward transfer of daughters in marriage.

The higher divine order within both of these communities consists of the categories of teachers, priests, and disciples. These categories are also conceived to be both moral and natural. Any person of any caste or sex who comes to possess the sacred natural sounds of the Liṅgāyats or Sikhs may become a Liṅgāyat or Sikh disciple; and any Liṅgāyat or Sikh may in theory become a priest or teacher. In fact, it tends to happen that members of the higher castes are more likely to become teachers or priests, and members of the lowest castes are liable to be regarded as inferior disciples and therefore excluded in some ways. What distinguishes these communities from their Hindu neighbours, despite such discrimination, is their members' mutual sharing and exchange of transvalued substances. Thus, Liṅgāyat disciples and gurus mutually regard each other as gods, drinking the dirt of each other's feet, while Sikhs of all castes drink nectar from a common bowl and take food reciprocally.

Caste systems among non-Hindus in South Asia. Other major religious communities in South Asia share with Vedic and Hindu peoples some basic assumptions regarding the particularity of human genera, the unity of substance and code, and most of the meanings of exchanges. Unlike Hinduism, however, both indigenous Buddhism and the foreign religions are at pains to distinguish human from divine substance and the inferior order of castes from another order of superior morality.

Buddhism and caste. The Buddha and his followers advocated a universal moral code transcending all particular codes. By this code, each person should honour the Buddha and his followers with gifts and should be personally nonviolent, moderate, generous, and self-denying in emulation of the Buddha. Living by this code, any person eventually escapes both from the social order and

Buddhist conception of a universal moral code

from the world of nature. He attains a superior non-natural state called Nirvāṇa.

Buddhism relegates the natural Vedic *varṇas* to a lower moral order and distinguishes from it a higher moral order conceived as containing three new categories—householders, king, and monks. Householders of all castes, rather than only Vaiśyas and Śūdras, are seen as the providers of food, wealth, and service. The king and his officials are to be chosen from among the most qualified persons rather than from among Kṣatriyas only. The highest teachers of morality, the Buddhist monks, are to be chosen by personal qualifications, rather than being hereditary Brāhmaṇas.

Ranks among these social categories are conceived in Buddhist thought as emerging from exchanges like the Vedic exchanges. The Buddhist exchanges differ, however, in being conceived as contractual or voluntary in origin, rather than inherent in any genus. Householders owe taxes to the king as a reward for his godlike gifts of protection and charity. Both king and householders make gifts to the propertyless monks; monks should accept these regardless of the nature of the gift or the donor's sex or caste but should return no food substance, not even leavings, to their benefactors. Instead, monks are to return only the supreme gift—instruction in the words of the Buddha regarding knowledge of nature and regarding the code leading to liberation of the soul from the natural order.

The Buddhist conception of society prevailed among peoples on the trade-oriented peripheries of South Asia (the Himalayan borderland, the present Bengal-Bihār, Pakistan, and Sri Lanka [Ceylon]) and in scattered urban areas until the 8th to 13th centuries, when it was supplanted in most areas by Hinduism or Islam. Only in Sri Lanka did a Buddhist society survive along with castes until the British period. There, many gods and ranked systems of 20 or more natural castes are found, much as in Hindu South Asia. Above is the distinctive higher moral order of Buddhism, consisting of the Buddha and several orders of monks, the state, and householders, all concerned with the goal of personal spiritual liberation. In the modern Buddhist democracy of Sri Lanka, natural castes tend to lose their moral significance as units of exchange and rank, while the state's legislation is seen as "returning" the society more and more to the remade social order conceived by the Buddha.

Jainism and caste. Jainism arose at the same time and in the same region (Bihār) as Buddhism, and, like Buddhism, it conceives of certain householders and ascetics—not castes—as the social units of a transcendent moral order. It differs from Buddhism in that it does not present an alternative conception capable of embracing the whole of society. The Jaina code for conduct is more extreme than that of Buddhism, requiring adherence to a rule of thoroughgoing nonviolence. In theory, persons of any *varṇa* or *jāti* may become Jainas; but virtually all occupations, with exceptions such as banking and commerce, are considered to be violent. Hence, most adherents have been members of castes of merchants. Hundreds of small Jaina castes are now found in western India (Gujarāt, Mahārāshtra, Rājasthān).

Islām and caste. Islām was introduced into South Asia by merchants, conquering armies, and missionary Ṣūfīs (Muslim mystics). It became established by the 13th and 14th centuries and became the predominant religion in Pakistan and Bangladesh, where the Buddhist pattern of social organization had predominated. Like the Buddhists, Muslims of South Asia conceive of society as containing a lower and a higher moral order. The lower moral order consists of ranked genera—caste brotherhoods (*berādarīs*) thought to be related by the shared natural substance of blood.

Muslim conception of a lower and a higher moral order

The moral ranks of these rural blood brotherhoods in Pakistan are often based on a reputation for past violence and on the local, hypergamous exchange of women. A brotherhood should take care of its own women; hence, the brotherhood that gives women to another is thought to be morally deficient and to rank lower. In the northern plains of India, where Muslim castes live among Hindu majorities, their moral ranks are more likely to be based on food exchanges. In Muslim-majority communities, however, the public donation of cooked food shows a brotherhood's piety and raises its rank, although the receiving of such donations is not considered to lower its rank.

The moral order of blood brotherhoods, or castes, is felt by Muslims to be transcended by a number of purely social, contractual brotherhoods whose members are supposed to behave toward each other as if they were related by blood even though they are not. The largest purely social brotherhood in the higher moral order is a religious one and consists of those persons who worship Allāh and submit to the Islāmic code for conduct enshrined in the Qur'ān. The single Islāmic deity is said to be the source of the natural and moral order but to transcend it himself. Men depend on him for their bodily existence and salvation, but he does not depend on them, not even for food. Muslims offer up their total submission, but no material goods. However, exchanges of food are made among Muslims on ritual occasions to express the equality and solidarity of the members of a social brotherhood, and also to express the differences of rank in the higher social order. By reciting the sounds of the Qur'ān, eating substances animated by the words of saints, and venerating the remains of dead saints and of the Prophet (Muḥammad) himself, the worshipper becomes more like the saint or the Prophet. Servants of a landholder or followers of a village headman—also brotherhoods in the Muslim moral order—express their subordination by taking ordinary cooked food from him.

The relative ranks of these purely religious and social roles in the higher moral order usually coincide with the relative caste ranks of their occupants in the lower moral order. Persons who occupy the higher roles of saint, pious Muslim, and landholder are usually members of the higher castes, and persons who occupy the lower roles of casual Muslim and servant are usually members of the lower castes. Yet Muslims are quite clear that, when there is a discrepancy between the two, the role occupied by a person in the higher moral order takes precedence. As a result, there is a persistent strain in Muslim communities to bring the caste membership of a person into accord with the role he occupies in the higher Islāmic moral order.

Judaism and Christianity and caste. Other religions accommodate what are seen in South Asia as natural castes. Thus, in Bombay there are Jews of white, black, and recent immigrant descent; in Cochin, besides white and black, there are Jews of slave-mixed descent. Christian converts of many centuries marry and eat within their respective original castes or adopted sects, especially in south India. Adaptations in the higher moral spheres of these religions are much like those made within Buddhism and Islām.

Legal and political roles of caste. *During the pre-British period.* By Hindu conception, castes are categories essential to defining morality (*dharma*, sometimes translated "law"), but not to the calculations of political or economic advantage (*artha*) that all men make as individuals. Morality is conceived to be as highly particularized as nature. Its stratified principles are partly compiled in the moral code books, but its full contents include the varied and innumerable unwritten moral codes (*ācāra*) that are thought to inhere in particular corporate units of each specified kind—lineages (*kula*), castes, or localized communities (*deśa*). If individuals or groups of different castes compete for the same advantages or ends, their competition is not necessarily a matter of moral concern. However, one point of contact between self-interested behaviour and morality is elaborately considered by Hindu legalists: the office of the king. It is the moral duty of the ruler (properly a Kṣatriya) to use force (*daṇḍa*) so as to establish the moral order, especially in order to maintain the rank and separation of the castes, so that their internal self-government and their proper exchanges may continue.

Content of Hindu moral law

All rules, rewards, and punishments among the castes are systematically unequal. Lower castes are customarily

prohibited not only from participating in higher worship but also from such acts as touching the higher castes' water, wells, utensils, clothing, persons, or food and from trespassing on their furniture, buildings, roadways, light, sight, and air. Such acts of trespass, along with many more crimes, are scaled from more to less consequential, as the castes involved are ranged from high to low. Done at the command of a person of higher caste to a person of lower caste, such acts are thought to be privileged or acceptable, but, done on the lower's initiative, they cause insult or "pollution" to the higher and deserve graded retaliation or punishment.

During the British period. British administration took an interest in the Vedic moral code books as statements of abstract principle but followed their own views of law as essentially above nature and as unconnected with particular categories of men. As part of a policy of nonintervention in religious and social matters, they declined to play explicitly either the Hindu ruler's role of enforcing caste distinctions or the reformer's role of abolishing them. Local officials were generally as unsympathetic to reform as were local communities, so that, in effect, local caste codes of exchange tended to be supported. At the same time, other governmental measures and widened communications unintentionally encouraged an intensification of internal caste organization. Military units were recruited on a caste basis. The caste membership of individuals was registered in censuses and published in composite totals, and competitive claims by about one-fifth of the castes to affiliation with Vedic *varṇa*s were stimulated by court applications of Hindu personal law.

Limited reforms of the political relationships among castes were undertaken after 1919 in connection with the widening of political franchise. These reforms included reserved legislative seats and benefits in education and employment favouring the lowest ("Scheduled"; *i.e.*, officially listed) and very low ("Backward") castes and tribes. Such reforms underlined the separateness of caste groups and rewarded political allegiance to them and to the imperial government awarding the new advantages. Certain larger castes or merged clusters of similar castes also became politicized, forming associations to press for advantages in the widened arena of governmental competition. In all regions, effective organization for gaining power required less narrowly based political alliances, factions, and parties that could incorporate members of many castes.

Effects of the Indian independence movement

Such political changes during the later British era, along with the British exclusion of religion from governmental concern, stimulated leaders of the independence movement to try to reshape the Hindu social system, seen as a whole made up of particular natural genera, into a structure suited to the winning and the running of a nation of united citizens. B.G. Tilak in Mahārāshtra in the 1890s mobilized urban ceremonies of communal worship in which representatives of all Hindu castes and neighbourhoods offered prayers for political salvation to the Vedic and regional god Gaṇapati. Mahatma Gandhi, Tilak's pupil and the architect of India's freedom, in the 1930s urged a return from the multiplicity of *jāti*s and secular individualism to a neo-Vedic system of four *varṇa*s and stages of personal life (*varṇāśrama-dharma*). This was to be a system emphasizing the mutual responsibility of each to all, one in which men would affiliate themselves with *varṇa*s (interpreted as organically related socioeconomic classes) according to the way they reshaped their bodily natures by following codes of vegetarian and nonalcoholic diet, fasting, sexual abstinence, and public service. Gandhi's hope was to abolish the category of the lowest, sub-Śūdra castes—whose members he labelled Harijans (Offspring of God)—by reversing their former position in the code of exchanges. Harijans were made to serve cooked food to workers of the higher castes, while these in turn swept the garbage from the Harijans' streets. Harijans entered previously forbidden temples of southern India under Gandhi's leadership. Ultimately, as the reformers hoped, the many previous grades in worship tended to become reduced for all persons to the minimal two grades of priest and worshipper, if not to a single grade. The wide popular appeal of these and similar programs of revival and reform must be ascribed to their speaking initially in the caste idiom of substance and code. Their successes led to the strengthening and activation of still larger regional and religious castes, such as Hindus, Muslims, and Dravidian nationalists, which sometimes clashed with others in subsequent competition for power.

A still more innovative and prominent change in caste thinking, devised first in 19th-century Bengal, declares the land substance of India to be the nourishing mother of all her people, Hindu and Muslim, high caste and low. Mother India's code for conduct enjoins unity on all residents in her service and defense. This universalizing scheme spread officially through the nationalist movement to the new nations of India and Bangladesh.

Modernizing tendencies in caste thinking

Since 1947. The independent governments of South Asia have moved vigorously to modify caste conduct through legislative action. Most consistent with earlier Buddhist and Islāmic roles was Pakistan's declaration to be an Islāmic state having transcendent law and therefore having no need to recognize the natural castes.

A secular legislative Indian approach to conduct is seen in the Hindu code laws of the 1950s. These replace the particularistic Vedic moral code books by a uniform code taking no account of *varṇa*. They also abolish caste endogamy as a requisite for valid marriage. The legislative approach is seen fully in the Indian constitution of 1950, authored chiefly by B.R. Ambedkar, leader of a party of the lowest castes. The constitution rests on the notion that government must regulate individuals directly and not through autonomous corporate castes. It abolishes caste "untouchability" (now to be legally defined by courts), and forbids any other restriction on public facilities arising out of caste membership. Subsequent legislation against caste restrictions has proven generally influential at the urban temple or the crossroad coffeeshop but not at the village well. Ambedkar advised his followers to renounce Hinduism in favor of Islām or Buddhism, which he saw as providing casteless social systems.

Many modern South Asians consider caste-reform actions by government as necessary and desirable but regard the distribution of economic resources among castes as the most crucial problem. South Asian Marxists go further in their economic program, yet less far in their program for action, holding that castes are secondary and need not be a subject of policy; Marxists expect that castes will disappear by general intermarriage once the only real forces—the antagonisms of the economic classes—are resolved by revolution. The overall official Indian position on caste systems by the 1970s was a compromise: natural ethnic groups are relegated to a lower order that is devoid of legality, and provision of

comprehensive moral, economic, and political codes is a function reserved to the processes of the transcendent national state.

The ideas of South Asian citizens as to what caste systems are and should be vary widely among the positions sketched. Practice also differs. Thus, norms of caste endogamy appear generally to have stiffened, while marriages outside of certain small urban groups of high caste nevertheless may exceed 20 percent. Traditional caste occupations are followed by an overall minority that grows less each year, but these occupations are often replaced by similar substitutes. The forms of Hindu worship are subject to constant innovation, but worship itself—ranked exchange between the genera of men and gods—is not abandoned. Where prevailing opinion is conservative, as in most rural localities, caste codes of exchange may continue to be observed publicly although individuals violate them privately; where opinion follows the official position, as it often does in cities, ranked exchanges among the castes may be confused or transcended publicly but maintained by conservative families in the domestic sphere. Most individuals move among social compartments that differently organize the enduring linkage between substance and code.

CASTE SYSTEMS IN OTHER SOCIETIES

Caste systems need not be thought of as unique to South Asia or to its emigrants. Rudimentary caste systems have appeared elsewhere to the extent that similar situations, structures, and cultural concepts were present.

Situations of encroachment between alien ethnic groups have generally been productive of simple, short-lived caste systems like that of Aryans and Dasyus in northern India in early Vedic times. Many a society has opposed itself as a superior whole to a despised immigrant population of traders, artisans, or Gypsies but usually without developing systematic conceptions or mutual consensus regarding ranks. Many a society has incorporated but ranked separately, then in time assimilated a caste of foreign conquerors (*e.g.*, Peru), slaves (*e.g.*, Brazil), or noncitizens (*e.g.*, imperial Rome). Occasionally, a society such as Mexico, with its duality of European and Indian cultures, has preserved contrasting ethnic styles of life long after rank, descent, and marriage have ceased to insulate the onetime castes from each other socially.

A relatively small number of ethnically heterogeneous, expanding societies—certain medieval African tribal kingdoms and some recent European colonial states such as the United States, Rhodesia, and the Republic of South Africa—have used political means to perpetuate the ranks, occupations, and biological relationships of two to four ethnic categories. The legality of the black and white caste systems in the United States did not endure two centuries, and the moral future of other recently legislated colour-caste systems is in question, but there is no doubt that ritualized composite tribal kingdoms such as Mali and Rwanda in Africa did maintain simple caste systems with moral authority for some five centuries.

Castes have rarely developed out of a single society's classes. In East Asia, several homogeneous societies sharing Buddhist ideas regarding the bodily pollution of death (Tibet, Korea, Japan) have generated internally their own local fractions of morally abhorred specialists, originally leatherworkers. These occupationally outcaste persons constitute small, scattered populations, separated in marriage and descent from the local majorities, although not thought of as ethnic or corporate units. In the lower Mississippi Valley of North America, the Natchez and Chitimacha tribes developed internal caste systems tied to hereditary offices in village war and temple cults while absorbing alien ethnic groups as the lowest of four ranks. The relative success of the Natchez in developing an internal caste system may be attributed to their facing, like the later Aryans, sharply defined alien ethnic units with an internal moral system of sharing and exchange.

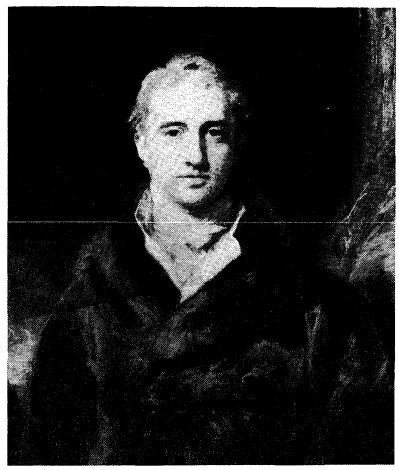
Castlereagh, Viscount

As British foreign secretary from 1812 to 1822, Robert Stewart, better known as Viscount Castlereagh, guided the Grand Alliance that defeated Napoleon and played a major part in the peace conference at Vienna that redrew the map of Europe after the Napoleonic Wars. In Britain, during his lifetime, he enjoyed a reputation for reaction and was distrusted as an associate of continental despots. Modern historians, however, are more likely to consider him one of the more forward-looking statesmen of his time. He certainly acted as a moderating force at Vienna and did much to develop diplomacy by conferences and the idea of the concert of Europe. Born Robert Stewart in Dublin on June 18, 1769, to a prominent Anglo-Irish family, from 1796 to 1821 he was known by the courtesy title of Viscount Castlereagh, and on his father's death became the 2nd marquess of Londonderry. Educated at Armagh and St. John's College, Cambridge, he was elected to the Irish parliament of 1790 as an independent member. In 1794 he married Emily Anne Hobart, a beautiful if slightly eccentric woman to whom he remained devotedly attached throughout their long and childless marriage. From March 1798 he served as acting chief secretary to his relative Earl Camden, then lord lieutenant of Ireland. In November 1798 he was formally appointed to that office by Camden's successor, Lord Cornwallis.

Chief secretary for Ireland

Castlereagh's tenure as chief secretary coincided with the two most important events of Irish history in the late 18th century: the 1798 rebellion and the union with Great Britain. While taking severe and successful measures to quell the revolt in 1798, Castlereagh shared the view of Cornwallis that a policy of clemency was essential to end the disturbances. The threat of French invasion and the 1798 rebellion convinced Castlereagh of the need for a parliamentary union with Britain. The passage of the Act of Union through the Dublin parliament in June 1800 provided the first great demonstration of Castlereagh's abilities as he singlehandedly forced the measure in the Irish Commons against bitter Protestant opposition. He believed that the union with Britain must be accompanied by the political emancipation of Roman Catholics. When, in February 1801, Pitt failed to obtain George III's consent to emancipation, Cornwallis and Castlereagh at once sent in their resignations.



Castlereagh, painting by Sir Thomas Lawrence (1769–1830). In the National Portrait Gallery, London.
By courtesy of the National Portrait Gallery, London

Though out of office after May 1801, Castlereagh continued to advise Henry Addington's ministry on Irish questions, and in July 1802 he was appointed president of the Board of Control responsible for Indian affairs. His energy and intellectual powers gained him an immediate influence in the Cabinet, and after Pitt's return as prime minister (May 1804), he also became in July 1805 secretary of state for war. His first important task, the dispatch of a British expeditionary force to Hanover, was rendered ineffectual by Napoleon's victory at Austerlitz (December 1805); but the move convinced Castlereagh of the strategic value of the British Army in continental warfare. On Pitt's death in January 1806 he left office and became the chief opposition spokesman on foreign and military affairs. He returned to the War Department in the Duke of Portland's ministry in 1807, and showed his determination to engage in major warfare against a continent now completely dominated by Napoleon. The adoption in 1808 of his plan for reorganizing the regular, reserve, and militia forces provided the country with adequate home defenses and a larger and more efficient army for overseas operations. When the Spanish revolt against Napoleon broke out the same year, it was decided at once to send a major expedition to the peninsula. Castlereagh was influential in securing the command for Sir Arthur Wellesley (later duke of Wellington) in 1809. In 1809 a British expedition sent by Castlereagh against Napoleon's naval base at Antwerp was allowed to waste away of disease on the island of Walcheren. The disaster was in no way Castlereagh's fault, but it brought to a head the long-standing divisions and intrigues in the Cabinet. Since March 1809, George Canning, the foreign secretary, had been pressing for a change of policy, and even before the Walcheren expedition he had secured secret agreement to the replacement of Castlereagh by the marquess Wellesley. When Castlereagh learned of the ignominious position in which Canning had placed him,

Duel with Canning

he challenged him to a duel that was fought September 21. Canning was slightly wounded and both men later resigned office. Castlereagh remained out of office for the next two and a half years.

In 1812 he rejoined the government as secretary for foreign affairs, and after Prime Minister Perceval's assassination in May he became leader of the House of Commons. British foreign policy then passed for a decade under unified control. Castlereagh's first task was to hold together the shaky and distrustful elements in the general European opposition to Napoleon; but as the end of the war drew near he worked increasingly to obtain preliminary agreement among the allies for the resettlement of Europe. In talks in Châtillon in 1814, he secured acceptance in principle of his plans for a peace settlement under the control of the great powers. By the Treaty of Chaumont (March 1814), he obtained provision for allied cooperation for 20 years after the war. On the fall of Napoleon the Treaty of Paris (May 1814) secured immediate British requirements (the restoration of the Bourbon monarchy and the separation of the Low Countries as an independent kingdom), and set Castlereagh free to play a commanding and mediatory role at the peace conference at Vienna. His main European objectives were to prevent the aggrandizement of Russia and to strengthen the weak central European areas of Germany and Italy. He and Metternich, the Austrian minister for foreign affairs, dominated the inner negotiations, though it was Castlereagh who took the lead in resisting the territorial demands of Russia and Prussia. The final settlement, with some compromises, was a practical embodiment of his principle of the "just equilibrium."

Castlereagh also attached fundamental importance to regular consultation by the great powers on matters of common concern; and the peace treaty contained specific provision for periodic meetings of the contracting parties. Though the practice of holding such meetings became known as the "congress system," Castlereagh's aim was to make possible diplomacy by conference rather than to establish any system to preserve the status quo in Europe or interfere in the internal developments of other nations. The distinction became increasingly apparent in the remaining seven years of his career. The Congress of Aix-la-Chapelle in 1818 readmitted France to the concert of powers. Castlereagh firmly resisted, however, a Russian attempt to institute a league of European powers to guarantee the existing order under sanction of military force. When the liberal movement in Germany after 1818 and the revolutions in Spain and in the Kingdom of the Two Sicilies in 1820 brought Austria and Russia closer together, he refused to treat their meeting at Troppau in October 1820 as a full European congress; and after the Congress of Laibach (1821) he openly repudiated the Troppau principle of intervention and coercion. His classic state paper of May 1820 emphasized the difference between the despotic states of eastern Europe and the constitutional structures of Britain and France, and made it clear that the British government could only act on the expediency of any given issue and within the limits of its parliamentary system. With the emergence in 1821 of the questions of Greek independence and the fate of the Spanish colonies, however, British political and commercial interests became directly affected and Castlereagh decided to attend in person the Congress of Verona in 1822. The instructions he drew up for himself showed plainly that he would not sanction forcible interference in either Greece or Spain, and that Britain would ultimately be prepared to recognize de facto governments resulting from successful revolutions. It is clear that Castlereagh was preparing for that detachment of Britain from the reactionary policy of the continental powers that was accomplished after his death.

This development was largely hidden from the British public by the personal nature of Castlereagh's diplomacy and his aloofness from public opinion. His apparent involvement with the eastern autocracies was disliked at home, and his role as spokesman for the government in the violent domestic politics of the postwar era kept him in a position of unpopular prominence. As leader of the House of Commons he was identified with the repressive policies of the years 1815–19, and with the cabinet's unsuccessful introduction in 1820 of a bill to dissolve George IV's marriage with Queen Caroline. He was savagely attacked by such liberal romantics as Lord Byron, Thomas Moore, and Shelley. After the abortive Thistlewood plot to assassinate the Cabinet in 1820, he always carried pistols in self-defense, and during the trial of Queen Caroline he was obliged to take up his residence in the Foreign Office for greater safety. The burden imposed on him by the royal divorce affair of 1820, in addition to his duties at the Foreign Office and in the House of Commons, probably hastened his final collapse. In 1821 he showed signs of abnormal suspiciousness, which by 1822 became outright paranoia. He was, or thought he was, being blackmailed on charges of homosexual acts, and on August 12, 1822, he committed suicide shortly before he was due to set out for Verona.

BIBLIOGRAPHY. H. MONTGOMERY HYDE, *The Rise of Castlereagh* (1933), is the best account of Castlereagh published in recent years. The *Memoirs and Correspondence of Viscount Castlereagh, Second Marquess of Londonderry*, ed. by CHARLES VANE, 12 vol. (1850–53), correspondence from Castlereagh to members of his family, provides source documents for historians.

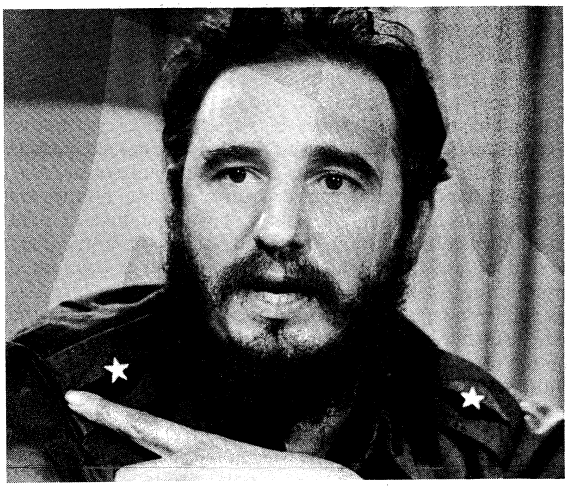
Castro, Fidel

Starting as a guerrilla leader with a few men at his side, Fidel Castro within three years ousted the dictator of Cuba and proceeded to transform the island of Cuba into his own version of a Socialist state. He has exercised a fascination over the minds of the young, the working classes, and the intelligentsia all over the world, exceeding even the veneration evoked by such similar figures as Lenin, Tito, and Nasser.

Elliott Erwitt—Magnum



Castro, 1964.

When Fidel Castro was born, Cuba was virtually a protectorate of the United States, producing sugar and tobacco for its giant neighbour. It served, also, as a resort for this neighbour's vacationers, with brothels and casinos controlled from Chicago, New York, and Los Angeles. The Cuban presidents, who held office between coups and countercoups, had been puppets tolerated by the United States government.

Early years

Fidel Castro Ruz was born on August 13, 1926, on a sugar plantation near Birán in Oriente Province. He was the son of a Spanish immigrant farm labourer, Angel Castro y Argiz, and his second wife, a Cuban Creole and his former house servant. They had seven children, including Raúl, Fidel's fellow revolutionary.

Hard-working and shrewd, Angel Castro eventually became a wealthy landowner with a sugar plantation of 23,000 acres (9,000 hectares). Attached to his land and its problems, neither he nor his wife saw any need to school their children; but Castro recounts that, as a child of six or seven, he threatened to burn down the house unless he was sent to school.

He attended two Jesuit schools before entering the law school at the Universidad de la Habana in 1945. His studies were interrupted, however, in 1947 by an escapade involving him in an abortive attempt to overthrow Pres. Rafael Trujillo of the Dominican Republic. Graduating in law in 1950, he devoted his time to defending the poor without fee.

While he was studying at the university, Fidel married a philosophy student, Mirtha Díaz Balart, despite the disapproval of her father, a government official. The marriage, to which one son was born, was short-lived.

After graduation, Castro contested a seat in Congress on an Ortodoxo Party ticket in order to give the constitutional method of fighting corruption a trial. Disillusioned, however, by Fulgencio Batista's removal of Pres. Carlos Prío Socarrás in a bloodless coup in March 1952, Castro abandoned all ideas of bringing about change by constitutional means.

Attack on Moncada Barracks

He first launched what was, essentially, a wildcat scheme; but it fired the imagination of the Cuban people. Castro sold all his possessions, raised a volunteer force of 150-odd men along with his brother Raúl, and collected about $16,000 for arms and uniforms. Early on July 26, 1953, the diminutive force attacked the Moncada Barracks in Santiago de Cuba, where 1,000 of Batista's troops were stationed. As a result of the fight, 75 of Castro's men were killed. The remainder were arrested.

Though it was a fiasco, the attempted coup fired the patriotic imagination of the Cubans. It brought back to the people memories of José Martí, the Cuban martyr who had died fighting the Spanish in 1895; and three years later the "26th of July Movement" provided the name for Castro's guerrilla campaign.

Castro was prosecuted for leading an armed uprising. Outstanding liberal lawyers advised him to plead not guilty, but the 26-year-old rebel simply refused to consider himself on trial. On the contrary, in an eloquent defense he put on trial the unpopular regime that had forced him into insurrection. His famed "History Will Absolve Me" peroration has since become part of Cuba's history. Castro and Raúl were given prison terms of 15 and 13 years, respectively. Many of their colleagues were tortured and executed.

By 1955 Batista was entrenched in power. Having crushed all opposition, he felt secure enough to announce a political amnesty for the rebels. But it was not long after Castro's release from prison, in May 1955, that he began preparing for the next phase of the assault on the Batista government. He slipped across to Mexico and gathered around him freedom fighters from other Latin American countries, including "Che" Guevara, the Argentine surgeon who became a revolutionary. Their greatest asset at this time, however, was Col. Alberto Bayo, one of the most successful Loyalist commanders and guerrilla fighters in the Spanish Civil War against Francisco Franco. He taught the Cubans to avoid their customary reckless open war with Batista's soldiers but to resort, instead, to guerrilla strategy.

The landing in Cuba

Eighty-two rebels set out in a ramshackle yacht, the "Granma," on November 25, 1956, for the planned attack on Cuba. They were scheduled to land on the southern shores of Oriente Province on November 30, coincident with an uprising directed by Frank País, one of the student leaders at the University of Santiago. For a brief period on that day, País almost held control of Santiago de Cuba; but Batista's forces soon suppressed the revolt. The "Granma," meanwhile, drifted in the rough seas, reaching the western coast of Oriente Province on December 2, 1956.

Here, alerted, Batista's forces lay in wait for the rebels. A frigate fired on the "Granma," which was soon abandoned. Castro and his men swam across the swampy beach, losing their ammunition, equipment, and food.

The 82 tired, hungry, and hunted men then began the march inland to Alegría de Pío. Betrayed by some peasants on the way, the group scattered. Some were caught in the gunfire of Batista's forces. Others were captured or surrendered.

Only 12, among them Castro, Raúl, and "Che," reached the inaccessible mountain shelter of the Sierra Maestra. The expedition had failed. The little band went without food and had neither arms nor money, but Castro refused to give up.

Guerrilla warfare in Sierra Maestra

For the next two years, Castro and his group continued to prepare for the final assault on the Batista regime. Young men flocked to Sierra Maestra. Guns and money poured in. Many of the farmers of Oriente Province supported the rebels. To these farmers—most of whom were poverty-stricken squatters—Castro promised that his revolution would transform Cuba's semicolonial social and economic structure into that of an independent, modern, Socialist state.

The fortunes of the rebel army fluctuated during this period, punctuated by daring exploits that shook Batista's fortress and by desperate runs for the safety of the Sier-

ra Maestra. The final drive began in August 1958, with the rebel columns fanning out into different parts of the island. The end came on January 1, 1959, when Batista and his associates fled to the Dominican Republic. Batista's forces were routed; Cuba was at Castro's feet.

Overthrow of Batista

Castro's trials had, however, just begun. He had won the revolution on promises; in implementing them, his major platform was land reform, an uncertain and cumbersome means of bringing about social change. His problems were increased by the plots of counterrevolutionaries in the United States, by that country's economic interests in Cuba, and, to a large extent, by the conviction of Presidents Dwight D. Eisenhower and John F. Kennedy that Castro's regime was, if not Communist in character, at least under Communist domination.

The United States boycott began with cuts in the sugar import quota from Cuba, the termination of the technical aid program, and the refusal by the United States oil refineries in Cuba to refine government-owned oil. These measures were accompanied by overt efforts to overthrow Castro, culminating in the disastrous Bay of Pigs invasion, on April 17, 1961, engineered by the United States Central Intelligence Agency and launched by Cuban exiles. It failed because President Kennedy, who learned the full facts too late, refused to back it with American bombers.

The missile crisis, in October 1962, in which a blockade by United States ships forced the Russians to dismantle and remove the missiles they had installed in Cuba, was essentially a conflict between the major powers; its outcome left Castro and Cuba disillusioned and frustrated but with their morale intact.

Castro has frequently and categorically denied being a Communist or having had secret relations with the Soviet Union. The economic pressure applied by the United States is presumably responsible for his decision to establish relations with the Soviet Union and the Communist bloc and, probably, also impelled him to make his controversial statement that he was a Marxist–Leninist from his student days.

Assessment

In launching his highly personal—and experimental—form of Socialism, Castro has introduced radical reforms that—although by no means always economically successful—have brought about a more equitable distribution of income. Although he has by no means fully succeeded in finding jobs or food or shelter for all, he has won great popular esteem by giving the people of Cuba for the first time an honest and dedicated, if somewhat romantic and inexperienced, government. He and his government have made a great many mistakes, but Castro—uniquely among leaders of underdeveloped countries—has been the first to admit them and publicly criticize himself. Above all else, he has liberated Cuba from the colonial status of a United States dependency and invested his country with a pride and dignity unique in that region.

BIBLIOGRAPHY. HERBERT L. MATTHEWS, *Castro: A Political Biography* (1969), the product of 12 years of intimate association with Castro, offers an exhaustive and close-range view of the man and his country, even though the author may be accused of being less than detached. THEODORE DRAPER, *Abuse of Power* (1968), gives cold analytical snatches of the American role and Castro's own failings. C. WRIGHT MILLS, *Listen Yankee: The Revolution in Cuba* (1960; British title, *Castro's Cuba*, 1961), is in general agreement with the argument of the Cuban revolutionaries. R.K. KARANJIA and RAMESH SANGHVI, *Castro-Storm over Latin America* (1961), is an account based on interviews with the Cuban leader.

(R.K.K.)

Casuariiformes

The order Casuariiformes includes two families of large flightless birds, Dromaiidae for the emu (*Dromaius novaehollandiae*), found only in Australia; and Casuariidae for three species of cassowaries (*Casuarius*), restricted to northern Australia, New Guinea, and nearby islands. Of the two groups, the emu is far better known, both biologically and popularly, being exhibited in zoos around the world. The emu was first discovered in 1788, more than a century after the first cassowaries were seen by Europeans; in 1697 a Dutch navigator, Willem de Vlamingh, had seen the emu's footprints in western Australia and had attributed them to a "Kasuarius." Cassowaries first became known to Europeans in the 17th century—there was a published reference to a "Casoaris" in 1658—when the Portuguese and Dutch colonized the East Indies (now Indonesia and Malaysia). Both names, emu and cassowary, were originally applied to cassowaries; the emu was known as the New Holland or New South Wales cassowary until the early 19th century, when the name emu was gradually transferred to it. By the late 19th century about 11 species of cassowaries were recognized, but greater understanding of variation within species has reduced the number to three: the double-wattled, or Australian, cassowary, *Casuarius casuarius;* the single-wattled, or one-wattled, cassowary, *C. unappendiculatus;* and the dwarf, or Bennett's, cassowary, *C. bennetti.*

Importance to man. The emu and cassowaries are important foods for the indigenous peoples of New Guinea and Australia; the flesh of the thigh muscles resembles beef. In New Guinea cassowaries are captured as chicks and held in enclosures until large enough to eat. The feathers are used as personal adornments. In Australia cassowary feathers formerly were used for the notorious Kudaitcha shoes, or "shoes of silence," worn by native executioners on nocturnal missions of tribal vengeance or punishment. During World War I members of Australian cavalry regiments wore tufts of emu plumes on their slouch hats. Since the time of European settlement in southeastern Australia, the emu has become much less abundant, and three island forms have been exterminated by hunting. In Western Australia, however, the bird has largely remained common and has become a pest in the wheat-farming areas, breaking fences and trampling and eating crops. In 1932 members of an army machine-gun unit were employed in a campaign against a concentration of emus, estimated to be about 20,000, in the vicinity of the wheat-belt centre of Campion. The outcome of this bizarre Emu War, as it was called, has been summarized by ornithologist D.L. Serventy as follows:

The Emu War in Australia

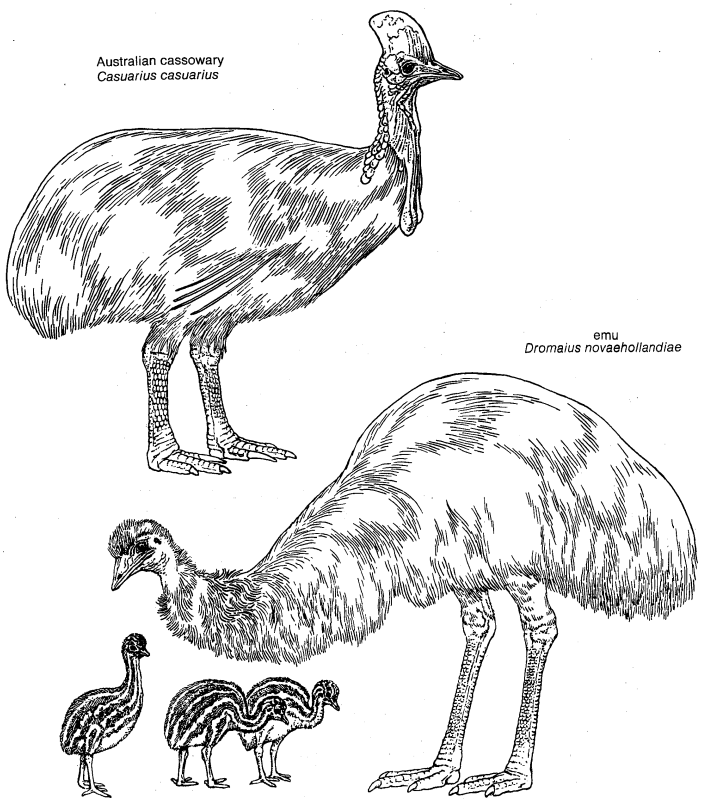
> . . . the machine-gunners' dreams of point blank fire into serried masses of Emus were soon dissipated. The Emu command had evidently ordered guerilla tactics, and its unwieldy army soon split up into innumerable small units that made use of the military equipment uneconomic. A crestfallen field force therefore withdrew from the combat area after about a month.

Yearly kills of emus in Western Australia for bounty payments vary from 5,000 to nearly 40,000 birds; but the birds remain plentiful, and in the early 1970s small parties could be seen within 15 or 20 kilometres (nine to 12 miles) of Perth, the capital of the state.

Natural history. *Reproduction.* Throughout its climatically varied range the emu is a winter breeder; egg laying begins at the end of April. The nest is a flattened bed of bark, grasses, and leaves near a tree or bush and is so situated that the sitting bird (always the male) has a good view of its surroundings. Despite their size, nests are extremely difficult to find. The large green eggs, with granulated shells, average about 130 millimetres (slightly over five inches) in length and 87 millimetres (3.4 inches) in width and weigh 450 to 800 grams (16 to 28 ounces). They are laid at intervals of about four days, and the male starts incubation when the hen has laid five to nine. The normal clutch size is eight, nine, or ten eggs, with large clutches up to 16. In exceptionally good seasons as many as 20 eggs may be laid, in poor seasons as few as four or five. Incubation varies from about 58 to 61 days, during which the male seldom leaves the nest, even to feed. The newly hatched chicks, which are concealingly streaked with black, are brooded by the male for two or three days before they move around in his company. Normally two years are required to reach maturity. In the nonbreeding season the groups coalesce into flocks, which may undergo local movements or more extensive migrations. Marking with numbered leg bands has proved that individual emus may travel hundreds of kilometres.

Reversal of parental roles of the sexes

Far less precise data are available on the annual cycle of the cassowaries. According to several observers, the



Emu and cassowary.
Drawing by R. Keane

eggs are laid in winter and are incubated by the male for 49–52 days. The eggs are paler green than those of the emu and there are fewer in the clutch, which varies from three to eight. Maturity may not be reached until the second or third year. Cassowaries are not gregarious in the nonbreeding season but live as pairs or family parties.

Ecology. Cassowaries are more pugnacious and aggressive than the emu. They are essentially creatures of the tropical rain forests, where they are very difficult to observe. Their diet is mainly fruit. Emus, on the other hand, live under a wide variety of environmental conditions, from dense temperate forest to open plains and arid scrub country. They often exhibit a curious inquisitiveness toward the activities of man and may be lured to close range by various devices, such as the waving of objects in the air, a habit that was utilized by the Australian Aborigines in hunting them. Though basically vegetarian, subsisting on fruits, seeds, and vegetation of all kinds, emus will also take insects, including caterpillars and grasshoppers, when they occur in great numbers.

The emu and cassowaries swim well and are fast runners. The emu is capable of a stride of nearly three metres (ten feet) and can keep up with an automobile travelling up to 40–50 kilometres (about 25–30 miles) per hour.

Vocalizations. Both sexes of the emu are reported to utter resonant drumming notes and guttural grunting calls, under varying conditions. Less is known about the calls of cassowaries, but scattered accounts indicate that they are similar to those of the emu.

Size and weight of emus

Form and function. Next to the ostrich (*Struthio camelus*), the emu is the largest and heaviest of living birds; large individuals stand between 1.5 and 1.8 metres (five and six feet) high and weigh up to 55 kilograms (120 pounds), although most are well below that weight. Females are slightly larger, averaging about 40 kilograms (90 pounds) while the males average about 36 kilograms (80 pounds). The sexes are alike in colour; the plumage is sombre, brown, or brownish black, and the naked skin on the head and neck is blue. All three species of cassowaries are black and, except for the dwarf cassowary, have fleshy pendulous wattles of red, orange, or yellow on the head and neck. The head is crowned with a horny casque or helmet, believed by some authorities to protect the bird from injury by branches during rapid movements in the forest. The plumage of casuariiforms is loose and hairlike due to the lack of barbules, the secondary branches that interlock to form the flat vane in the feathers of most birds. There are no feathers differentiated as tail feathers, but cassowaries have five quills of the wing modified into hollow, unbranched spines.

As with many running birds, casuariiforms have only three toes, the hindtoe having been lost. The inner toe of cassowaries is armed with an elongated, dagger-like claw, making the foot a formidable weapon in kicking.

The casuariiform skeleton is similar to that of the other large flightless birds (ratites) in the reduction of the wing elements and of the keel on the sternum (breastbone) and in the enlargement of the leg elements. Vestigial clavicles (collarbones) remain in the shoulder girdle, but the humerus (upper "arm" bone) is much reduced, being shorter than the combined forewing and manus ("hand"). The manus has a single digit, now believed to be the third, which bears a long claw.

The pattern of bones in the palate, an important diagnostic feature in the taxonomy of ratites, is of the palaeognathous or dromaeognathous type (common to all ratites), in which the vomer bones of the skull extend back to separate the palatines. The casuariiforms have the simplest form of this palate type, with large vomers and short palatines.

Evolution and classification. *Paleontology.* No fossil remains of casuariform birds have been found outside of the Australian region, and most of those recorded are from the Pleistocene, with one doubtfully from the Pliocene (about 4,000,000 years ago). The latter, although definitely a member of the emu assemblage, showed features linking it with the cassowaries. Despite the absence of fossil material, the order must have had a long evolution during the Tertiary Period (the last 65,000,000 years). The relationship of the Casuariiformes with the other orders of large flightless birds—the rheas (Rheiformes), ostriches (Struthioniformes), kiwis and moas (Dinornithiformes), and elephant birds (Aepyornithiformes), formerly grouped in a distinct subclass of birds, the Ratitae—is uncertain, but the Casuariiformes appears to be the most primitive of the living orders. The upper Pleistocene of Australia has produced several fossil species of emus assigned to the modern genus *Dromaius* and dating from as much as 100,000 years ago. Other Pleistocene finds from Australia have been placed in a separate family, Dromornithidae. These include *Dromornis*, known only from leg bones, and the gigantic *Genyornis newtoni*, almost the entire skeleton of which is known. The only known fossil cassowary is a species from Pleistocene cave deposits in the Wellington Valley, New South Wales, Australia, which resembles closely, and is probably identical with, the dwarf cassowary (*Casuarius bennetti*), now restricted to New Guinea and nearby islands. The distribution of the Casuariidae has evidently shrunk in recent millennia; the only species on the Australian mainland is the double-wattled cassowary (*C. casuarius*), restricted to New Guinea and the Cape York Peninsula of northern Queensland.

Relationship to other flightless birds

Classification. The following classification of the order is universally accepted.

ORDER CASUARIIFORMES

Large graviportal (ponderous) flightless birds with 3 toes. Other physical features described in *Form and Function*, above. Monogamous. Eggs green in colour.

Family Casuariidae (cassowaries)

Beak laterally compressed. Prominent horny casque on mesethmoid, nasal, and frontal bones of the skull. Coracoid bone of the shoulder much shorter than in emu. Bony union (symphysis) between various posterior elements of the pelvis may be present or absent. Femur not pneumatized by air sac system. Cervical vertebrae 18 or 19. Wing with 5 quills modified as long hollow spines. Pendulous coloured wattles on throat and neck (except in dwarf cassowary). Three species.

Family Dromaiidae (alternatively Dromiceiidae; emu)

Beak flattened dorsoventrally. Head not casqued. Pubic symphysis lacking. Femur pneumatic. Trachea with an aperture in front, leading to an inflatable neck sac. Pendulous

wattles absent. Fossil record limited to the Pleistocene of Australia and nearby islands. One Recent species.

Family Dromornithidae

Fossil only; Pleistocene of Australia; 2 genera, 2 species.

BIBLIOGRAPHY. D. FLEAY, "Nesting of the Emu," *Emu*, 35: 202–210 (1936), presents observations of this species in captivity. D.W. GAUKROGER, "The Emu at Home," *Emu*, 25:53–57 (1925), describes the nesting habits in the wild. A.L. RAND and E.T. GILLIARD, *Handbook of New Guinea Birds* (1967), is a summary of the biology and classification of cassowaries; and D.L. SERVENTY and H.M. WHITTELL, *Birds of Western Australia*, 4th ed. (1967), a summary of emu habits and statistics of kills. H.L. WHITE, "Notes on the Cassowary (*Casuarius australis* Wall)," *Emu* 12:172–178 (1913), presents field observations on habits and nesting in Queensland, with illustrations.

Cat

All cats are grouped in the family Felidae. From the largest, the tiger, to the smallest, the house cat, felids are characterized by supple, low-slung bodies, finely molded heads, long tails that aid in balance, and specialized teeth and claws that adapt them admirably to a life of active hunting. The family of cats belongs to the order Carnivora, the "flesh-eaters"; for an account of the family and its relationships, see CARNIVORA.

This article discusses domestic cats (*Felis catus*), which possess the features of their wild relatives in being basically carnivorous, remarkably agile and powerful, and finely coordinated in movement. It is noteworthy that the ancestors of man's other common household pet, the dog (and most of his other domestic animals as well), were social animals that lived together in packs in which there was subordination to a leader. The dog has readily transferred its allegiance from pack leader to human master. The cat, however, has not yielded as readily to subjugation. Consequently, the house cat is able to revert to complete self-reliance more quickly and more successfully than most other domestic animals.

ORIGIN AND HISTORY

The "cat pattern," established very early in the evolution of modern mammals, was a successful one: early cats were already typical in form at a time when the ancestors of most other modern mammalian types were scarcely recognizable. They first appeared in the early Pliocene Epoch, approximately 7,000,000 years ago, and they have continued with remarkably little change into modern times.

Domestication. Although its origin is hidden in antiquity, the domestic cat has a history that dates nearly 3,500 years to ancient Egypt. There are no authentic records of domestication earlier than 1500 BC, but it may have taken place sooner. Although the cat was proclaimed a sacred animal in the 5th and 6th dynasties (about 2500–2200 BC), it had not necessarily been domesticated at that time. It is probable that the Egyptians domesticated the cat because they realized its value in protecting granaries from rodents. Their affection and respect for this predator led to the development of religious cat cults and temple worship of cats.

Cats have long been known to other cultures. Wall tiles in Crete dating from 1600 BC depict hunting cats. Evidence from art and literature indicates that the domestic cat was present in Greece from the 5th century BC and in China from 500 BC. In India cats were mentioned in Sanskrit writings around 100 BC, while the Arabs and the Japanese were not introduced to the cat until about AD 600. The earliest record of cats in Great Britain dates back to about AD 936 when Howel Dda, prince of south central Wales, enacted laws for their protection. The first domestic cats in the United States date from around 1750.

Ancestry of breeds

Even though all cats are similar in appearance, it is difficult to trace the ancestry of individual breeds. Since tabby-like markings appear in the drawings and mummies of ancient Egyptian cats, present-day tabbies may be descendants of the sacred cats of Egypt. The Abyssinian also resembles pictures and statues of Egyptian cats. The Persian, whose colouring is often the same as that of mixed breeds (although the length of hair and the body conformation are distinctive), was probably crossed at various times with other breeds; the tailless, or Manx cat, may be derived from another species or may be a mutation. The ancestry of Persian and Siamese cats may well be distinct from other domestic breeds, representing a domestication of some Oriental wild cat (the ancestor of the Egyptian cat is believed to have come from Africa). In fact, nothing is known of the ancestry of the Siamese types, and there is no living species of Oriental cat that would serve as ancestor.

Associations with man. The cat has long played a role in religion and witchcraft. In the Bible "cat" is mentioned only in the apocryphal Letter of Jeremiah (Bar. 6:21). The cat figured prominently in the religion of Egypt, the Norse countries, and various parts of the Orient. The Egyptians had a cat-headed goddess named Bast, whose chief seat of worship was the city of Bubastis. Thousands of cat mummies have been discovered in Egypt, and there were even mouse mummies, presumably to provide food for the cats. More often, however, the cat has been associated with sorcery and witchcraft, and the superstitions regarding cats, common in all countries, are innumerable. Superstitions often took extremely vicious forms, and throughout the ages cats have been more cruelly mistreated than perhaps any other animal. Black

cats in particular have long been regarded as having occult powers and as being the familiars of witches. Cat lovers are called "ailurophiles"; persons in whom cats inspire fear are termed "ailurophobes."

The cat is a familiar figure in nursery rhymes and stories. The legend of Dick Whittington and his cat is a particular favourite. The writers Théophile Gautier and Charles Baudelaire have paid it homage and, in the 20th century, Rudyard Kipling, Colette, and T.S. Eliot wrote of cats. The influence of the cat also appears most clearly in everyday language where its many-sided character is crystallized in proverbs and sayings.

CATS AS PETS

The cat is of ever-increasing economic importance. There are businesses that manufacture and sell only cat foods or cat accessories, veterinarians who treat only cats, hospitals that cater to sick cats, cemeteries that bury cats, and special boarding places or kennels that keep cats.

Increasing popularity

The popularity of the cat continuously grows, especially that of pedigreed breeds. The cat's independent personality, combined with its grace, cleanliness, and subtle signs of affection, are traits that have wide appeal. Typically, cats are creatures of habit; they are inquisitive, but not adventurous, and are easily upset by sudden changes of routine. The ideal household cat has been raised in a clean home, kept away from unhealthy animals, separated from its mother between the ages of two and four months, and inoculated against common infectious cat diseases. The problems of discipline and training may be complicated in a household containing two cats of the same age. A year-old cat, however, may accept a new kitten, other than its own, and teach it, in turn, the disciplines that it has been taught.

A good disposition and overall good health are important criteria for any pet. Disposition varies only slightly between male and female cats. There are, however, distinct differences in intelligence and disposition between the alley cat (or mixed breed) and the pedigree. The mixed breed is a heterogeneous breed of unknown lineage; therefore, its temperament and disposition are difficult to assess. By chance the mixed breed may prove a happier, healthier, and more robust pet than a pedigree. On the other hand, the behaviour and vigour of the direct ancestors of pedigreed cats are indicative of the characteristics the offspring will possess as adults.

GENERAL FEATURES AND SPECIAL ADAPTATIONS

The average weight of the household cat varies from six to ten pounds, although among nonpedigreed cats weights up to 28 pounds are not uncommon. Average lengths are 28 inches for males and 20 inches for females. In keeping with a carnivorous habit, the cat has a simple gut; the small intestine is only about three times the length of the body.

The skin of the cat, composed of dermis and epidermis, regenerates and fights off infection very quickly. Tiny erector muscles, attached to all hair follicles, enable the cat to bristle all over. Thus, although the cat is a relatively small animal, it can frighten enemies by arching its back, bristling, and hissing.

Coordination and musculature. Cats are among the most highly specialized of the flesh-eating mammals. Their brains are large and well developed. Cats are digitigrade; *i.e.*, they walk on their toes. Interestingly, the cat, unlike the dog and horse, walks or runs by moving first the front and back legs on one side, then the front and back legs on the other side. Only the camel and the giraffe move in a similar way. The cat's body has great elasticity. The vertebrae of the spinal column are held together by muscles, rather than by ligaments as in man, so the cat can elongate or contract its back, curve it upwards, or oscillate it along the vertebral line. The construction of the shoulder joints permits the cat to turn its foreleg in almost any direction. Cats are powerfully built animals; these animals are so well coordinated that they almost invariably land on their feet if they should happen either to fall or be dropped.

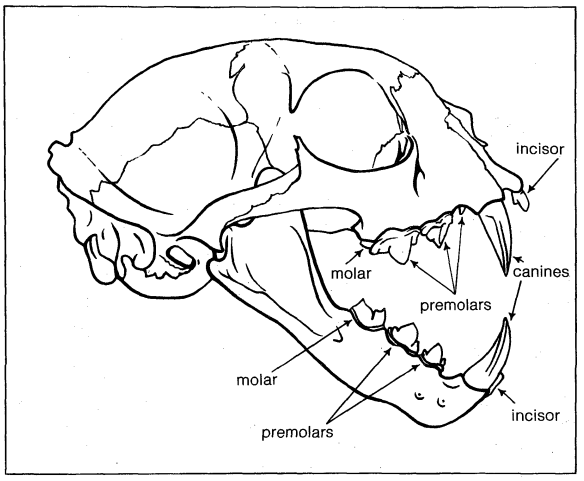

Figure 1: Skull of cat.

Teeth. One of the most characteristic and specialized features of the cat is its teeth (Figure 1). They are adapted to three functions: stabbing (canines), anchoring (canines), and cutting (molars). Cats have no flat-crowned crushing teeth and therefore cannot chew their food; instead, they cut it up. Other than the canines and molars, the teeth are more or less nonfunctional; most of the cheek teeth do not even meet when the mouth is closed. The dental formula in all cats, for either side of both upper and lower jaws, is: incisors 3/3, canines 1/1, premolars 3/2, molars 1/1. The total number of teeth is 16 in the upper jaw and 14 in the lower. Primary or milk teeth number 24; these are replaced by the permanent teeth at about five months in the domestic cat. Each half of the jaw is hinged to the skull by a transverse roller that fits tightly into a trough on the underside of the skull—making grinding movements impossible even if the cat had teeth suitable for grinding.

Retraction of claws

Claws. Another special adaptation is the cat's strong, sharp claws. There is a remarkable mechanism for retracting the claws when they are not in use (Figure 2). The claw is retracted or extended by pivoting the end bone of the toe (which bears the claw) over the tip of the next bone. The action that unsheathes the claws also spreads the toes widely, making the foot more than twice as broad as it normally is and converting it into a truly formidable weapon. This claw-sheathing mechanism is present in all species of the cat family except the cheetah. Although there are no nerve endings in the nail itself, blood capillaries are present in the inner part.

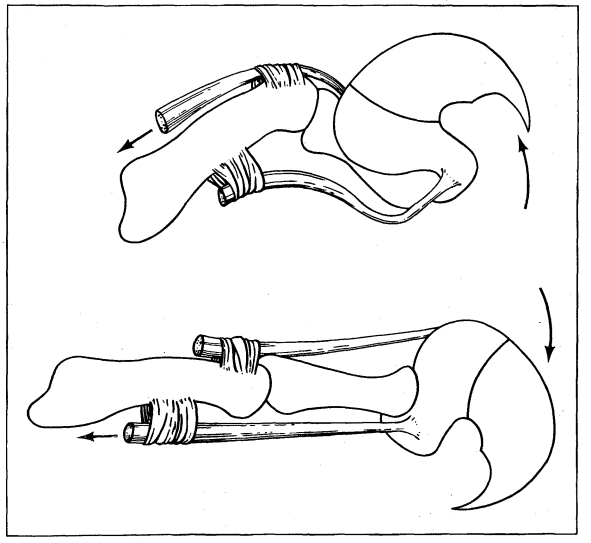

Figure 2: *Movement of retractile claw of a cat.*
(Top) When upper tendon is pulled, claw is retracted.
(Bottom) When lower tendon is pulled, claw is unsheathed.

Senses. *Sight.* Cats are generally nocturnal in habit. The retina of the cat's eye is made extra sensitive to light by a layer of guanine, which causes the eye to shine at night in a strong light. The eyes themselves, large with pupils that expand or contract to mere slits according to the density of light, do not distinguish colours clearly. Cats have a third eyelid, or nictitating membrane, commonly called the haw. Its appearance is used frequently as an indicator of the cat's general state of health.

Smell. The cat's sense of smell, well developed particularly in the adult, is crucial to its evaluation of food, so that a cat whose nasal passages become clogged as a result of illness may appear to lose its appetite completely. Cats can distinguish the odour of nitrogenous substances especially keenly (*e.g.*, fish).

Touch. The sense of touch is acute in cats. The eyebrows, whiskers, hairs of the cheek, and fine tufts of hair on the ears are all extremely sensitive to vibratory stimulation. The functions of the whiskers (or vibrissae) are only partially understood; however, it is known that if they are cut off, the cat is temporarily incapacitated. The toes and paws, as well as the tip of the nose, are also very sensitive to touch.

Hearing. Cats also have an acute sense of hearing. Their ears contain almost 30 muscles (compared with 6 in man); as a result they can turn them many times more quickly in the direction of a sound than can a dog. The ears of cats, although receptive to ultrasonic frequencies up to 25,000 vibrations per second, are slightly inferior to those of dogs, which register 35,000 vibrations per second.

Behaviour. *Grooming and tail-wagging.* The tongue of all cats, which has a patch of sharp, backward-directed spines near the tip, has the appearance and feel of a coarse file; the spines help the cat to lap up liquids and also to groom itself. The disposition to cleanliness is well established in cats; they groom themselves with their rasplike tongues and preen at length, especially after meals. Another peculiarity of behaviour is the nervous tail-wagging common to all cats, from the lion to the house cat; it is believed to be learned from the mother and is associated with early play, a prelude to adult habits of predation.

Purring. While lions and other big cats roar, the domestic cats and other *Felis* species purr. Purring has been described as a low, continuous, rattling hum and has been interpreted as an expression of pleasure or contentment. It has nothing to do with the true voice of the animal; the vibration frequency is far lower than that of the vocal chords. Purring in domestic cats appears to be introduced to the kittens by the mother, who uses it as a means of calling the young to nurse. At birth the kitten's eyes are closed, the ears undeveloped, and the sense of smell absent; purring is felt as a vibration by the kittens, who approach its source for food. When the kittens begin nursing, the mother stops purring. But since purring manifests itself in extremes of both pain and pleasure, no specific emotional connotations can be placed upon it; it seems merely to be a homing device. Little is known about the physical mechanism involved in purring.

NUTRITION

Cats do best on a diet similar to that of their wild relatives. Cats are adapted by nature to be flesh eaters, an assumption based on their alimentary tract and dentition. The cat uses its canines to catch and kill prey, the molars to cut it up. Lack of flat-surfaced teeth prevents it from chewing or gnawing. The cat has a short intestine, and its stomach secretes digestive juices that act primarily on meat. Cats, however, like all meat-eating animals, chew grass occasionally, and small quantities of vegetables may serve as both a laxative and hair-ball remover.

Raw meat (especially organ meat, lamb, and beef), cottage cheese, boiled fresh fish, processed cheese, and egg yolk with a pat of butter are among the foods required in an adequate and well-balanced cat diet. Pasteurized cow's milk is not the perfect food for cats and sometimes causes gastric disturbances difficult to remedy. In addition, many other foods important in human nutrition are unacceptable in the cat diet, including most cooked foods, egg whites, liver, pork kidney, horsemeat, vegetables, spicy cold cuts, cereals, ice cream, and sweets.

Polyunsaturates such as corn oil, peanut oil, or safflower oil are important dietary supplements, not only for their nutritive value but also because they act as lubricants to prevent constipation and eliminate hair balls. These oils have been known to arrest formation of kidney stones (*i.e.*, urinary calculi) in cats. On the other hand, mineral oil or preparations with a petroleum base can cause severe harm to cats if given routinely to eliminate hair balls.

REPRODUCTION

As a rule, domestic cats reach reproductive age between 7 and 12 months. A breeding female (called a queen) can be in heat or estrus as many as five times a year. During these periods, which last about five days, she "calls," or caterwauls intermittently. The gestation period for cats varies but averages 63–65 days, and the birth usually lasts about two hours. The birth is often known as kittening, and the kittens are known as a litter. The average litter numbers four; however, the Abyssinian usually has fewer, the Siamese more.

Each kitten is born in a separate amniotic sac that is generally broken open at the moment of birth. If it is not, the mother breaks it. She also severs the umbilical cord and eats the placenta (in many cases this stimulates lactation). The kittens are born blind, deaf, and helpless, as are many other carnivores; their senses only begin to function 10 or 12 days after birth. Soon after birth the mother licks her kittens; this action not only cleans them, but also helps stimulate their circulation. Kittens at birth lack distinction and beauty. Their markings are highly deceptive, and many do not acquire their characteristic markings and colour for weeks. For example, Siamese kittens are white at birth, while Blue Persians have tabby markings and Black Persians are brown.

Characteristics of newborn

A cat by nature is capable of bearing up to three litters every year. Obviously, regulation of the cat population cannot be left to nature alone, and relatively safe and simple operations, known as spaying, neutering, or altering, are desirable from a practical viewpoint. Cats that roam unsupervised may live eight or nine years; those supervised and cared for live an average of 14–15 years.

DISEASES AND PARASITES

Until relatively recently little research was concerned directly with cat diseases, their symptoms, or clinical cures. For many years cat treatments were simply extensions of those given dogs. Now, however, cat disorders of the skin, the eyes, the ears, the various systems (circulatory, respiratory, urinary, digestive, nervous, skeletal), and the blood, as well as contagious cat diseases, and external and internal parasites are studied, so that appropriate preventions and treatments can be developed.

Symptoms

Many cats suffer and die because their ailments become serious before their general conditions change sufficiently to reveal symptoms of illness. On the other hand, many symptoms used in diagnosing cat ailments are not definitive for given disorders. For example, signs of possible illness include general symptoms such as a dull coat, lack of appetite, and listlessness. Diarrhea may be a result of serious illness or simply a reflection of a change in diet. Tearing of the eyes may indicate conjunctivitis or a cold, especially when accompanied by sneezing. Since however, sneezing is the cat's only mechanism for blowing its nose, not all sneezing indicates a problem. Open sores, usually at the base of the ear, around the mouth, or on the toes, can point to a ringworm infection or to a fight with another animal.

Cats are attacked by several kinds of external and internal parasites. External parasites are most generally found in kittens, although they occur in adults. The most frequent parasites are fleas, but lice, ticks, and ear mites

also occur. Internal parasites include roundworms, tapeworms, and protozoan coccidia. Modern veterinary medicine has made all of these easy to control.

Panleucopenia, often called feline distemper, is the most well-known viral disease in cats. Highly contagious and infectious, with a high mortality rate, it is seen most often in young cats. Vaccines are effective protective measures. Feline pneumonitis, also caused by a virus, has become a common infectious disease of cats. The course of the disease is protracted, and there is no permanent immunization. Vaccines for pneumonitis have an effectiveness of from six to eight months. Rabies is less of a problem with cats than with dogs.

GENETICS

Cats have never been bred for economic purposes; their matings are extremely difficult to control unless the animals are completely confined. There has been relatively little scientific breeding of cats, and the facts of inheritance in these animals are not well known.

Cats are genetically far less plastic than dogs and therefore have not offered the same opportunities to breeders. The size differences between breeds in the domestic dog have no parallel in the domestic cat, nor has anything even remotely approaching the wide range of head shapes and body proportions in different breeds of dogs ever appeared among the cats. In cats the differences between one breed and another are largely differences in colour and texture of the coat. The basic classification is into long-haired and short-haired cats.

Colour. The commonest basic coat colours in nonpedigreed cats are black, yellow, white, and various combinations and dilutions of these colours, such as tabby or striped. Solid white is dominant to all other colours. The mode of inheritance of black is imperfectly understood; the possibility that it is sex-linked is widely accepted. Tortoiseshell, a piebald pattern of black, yellow, and white that results from crossing black and yellow, appears to be sex-linked in some way, for tortoiseshells are born only rarely and are sterile (there is, however, no monetary value for them).

Dominance of white

Siamese dilution, the typical coloration of Siamese cats, has been described as a case of imperfect albinism and has been compared to the Himalayan pattern in rabbits. Its heredity is not well understood. There are also dilutions of the other ordinary colours: blue is dilute black and cream is dilute yellow. White spotting also occurs and is dominant to uniform or self colour.

Other characters. The long-haired coat of the Persian (the usage Angora is archaic) appears to be a simple unit character. It is recessive to short hair. Eye colour is known to be inherited, but its mode of inheritance is not thoroughly understood. Blue eye colour seems to be associated with dilution in coat colour; blue-eyed white cats are usually deaf, a fact commented on by Charles Darwin. Asymmetry of eye colour is known to be inherited. Polydactylism, the presence of extra toes, is inherited and behaves as a dominant to the normal condition. It seems to be due to a single gene. The extra toes occur on the inner or thumb side of the foot.

BREEDS

Recognized show breeds and the characteristics valued most highly by show judges include those listed below.

Longhair division. These are the Persian cats. The perfect type should be cobby—low on the legs, deep in the chest, the head round and massive, eyes large and round, the coat long all over the body. The acceptable colour standards are:

White. Pure white, no coloured hairs; eyes deep blue or deep orange.

Black. Dense coal black from roots to tips of hair; eyes copper or deep orange.

Blue. One level shade of blue gray without shading from nose to tip of tail; eyes brilliant copper or deep orange.

Red. Deep, rich, clear, red orange without shading, marking, or ticking; eyes brilliant copper or deep orange.

Cream. One level shade of cream; eyes brilliant copper or deep orange.

Chinchilla (silver). The undercoat pure white, the coat on back, flanks, head, and tail tipped with black to give the characteristic "sparkling silver" appearance; eyes green; rims of eyes, lips, and nose outlined with black; centre of nose brick red.

Shaded Silver. Pure, unmarked silver; shades gradually down the sides, face, and tail, from dark on the ridge to white on chin, chest, belly, and under the tail; eyes green; rims of eyes, lips, and nose outlined with black, centre of nose brick red.

Smoke. Black, with white undercoat and black points and mask, light silver frill and ear tufts; eyes brilliant copper or deep orange.

Brown Tabby. Ground colour any shade of true brown affording good contrast with markings of dense black with clearly defined and broad pencillings; legs evenly barred, the "bracelets" coming up high to meet the body markings; tail barred; barring on neck and chest, like chains or "necklaces"; head barred with distinct "spectacles" on cheeks; eyes copper.

Silver Tabby. Pale clear silver with broad, dense black markings to conform in pattern to those described for brown tabby; eyes green or hazel.

Blue Tabby. Ground colour pale bluish ivory with fawn overtones; markings deep blue in pattern described for brown tabbies; eyes copper.

Red Tabby. Ground colour red orange, with markings as for brown tabby but in darker red; eyes copper or deep orange.

Tortoiseshell. Black, orange, and cream, the colours bright and well broken; half the nose black, half orange, known as the "blaze"; eyes copper or deep orange.

Calico. Three colours—black, red orange, and cream—well distributed, clearly patched and interspersed with white; white blaze desirable; eyes brilliant deep orange or copper.

Blue Cream. The two colours—blue and cream—bright and well defined, divided and broken into patches; eyes brilliant copper or deep orange.

Shell Cameo. The undercoat pale cream, the coat on the back, flanks, head, and tail tipped with red orange; eyes gold or copper.

Shaded Cameo. Pure, unmarked red orange, with gradual shading down the sides, face, and tail from dark on the ridge to whitish cream on the chin, chest, and stomach; eyes gold or copper.

Smoke Cameo. Deep reddish beige with white or cream undercoat; eyes gold or copper.

Tabby Cameo. Pale cream broken with well-defined reddish or beige tabby markings; eyes gold or copper.

Himalayan. Colour and points same as for Siamese (see below); eyes blue; correctly called a colour-point Persian or a Persian with Siamese marking, not long-haired Siamese.

Shorthair division. *Siamese.* A sleek, smooth coat; straight tail; and eyes that are not crossed; points (face mask, ears, feet, and tail) all the same colour; eyes vivid deep blue. The acceptable colours are:

Seal point: even, pale fawn to cream, shading gradually to a lighter colour on the chest and belly; deep seal-brown points.

Blue point: bluish white, shading gradually to oyster white on the chest and belly; points of definite blue, giving strong contrast.

Chocolate point: ivory all over; milk-chocolate-brown points.

Lilac point: even glacial white without shading; points frosty gray with pinkish tone.

Abyssinian. Larger than Siamese, with regal, alert posture; ruddy brown ticked with shades of darker brown or black; inside of forelegs and belly should harmonize with the main colour (preference is given to orange brown or burnt sienna); lip and chin lightest in colour, off-white or cream; eyes hazel, gold, or green.

Burmese. The ideal Burmese would be of medium size and rich sable-brown colour, with the head rounder than

in the Siamese; profile should show visible nose break; fine, glossy, satinlike coat; eyes yellow to gold.

Russian Blue. Bright blue gray even throughout and free from tabby markings and shadings; thick coat, different from that of any other breed of cat; eyes green.

Manx. Completely tailless with decided hollow at the end of the backbone, double coat, back legs to be longer than front giving characteristic hopping gait; all colours of Manx are recognized, including ticked and mackerel tabbies and parti-coloured.

Rex. One of the newly recognized breeds, it has a wavy coat, like Persian lamb to the touch; all coat colours and eye colours acceptable.

Domestic Shorthair. While the domestic shorthairs seen in shows may resemble ordinary mixed breeds, the breeding of the show type is as exacting as for other breeds; recognized in all Persian colours.

BREEDERS' ASSOCIATIONS AND CAT SHOWS

Innumerable societies and associations have been formed to foster interest in cats and to set standards for the recognized breeds. Unrelated organizations, promoting various breeds, have also set up breed standards. None of these organizations has absolute power and occasionally standards conflict.

Cat shows are held annually in many large cities. Shows usually are divided into at least three parts: all breed, shorthair specialty, and longhair specialty. Each short-haired or long-haired cat may compete in the all-breed and in the appropriate specialty show. Almost any healthy cat may be entered in a show, since often there are classes for kittens, altered cats, and household pets, as well as for pedigreed animals.

In general, an adult, pedigreed, show cat begins its career as a novice, at the age of eight months or older, when it may win its first blue ribbon for its particular breed and colour. It is not thereafter eligible for novice and must compete in the open class. Novice and open classes compete for the winners' ribbons, which designate championship points. Champions, having acquired sufficient ribbons, compete for grand championship status. "Finals" awards are made to best novice, open, etc., in show and "Best Cat in Show" is selected from these finalists.

Catalysis

The transformations that occur among atoms and molecules (or molecular fragments), bringing about new arrangements or alignments of the atoms within the larger structures, are known as chemical reactions. The rates of such reactions—that is, the velocities at which they occur—depend upon a number of factors, including the chemical nature of the reacting species and the external conditions to which they are exposed. A particular phenomenon associated with the rates of chemical reactions that is of great theoretical and practical interest is catalysis. This phenomenon is the acceleration of chemical reactions by substances not consumed in the reactions themselves—substances that have come to be called catalysts. The study of catalysis is of interest theoretically because of what it reveals about the fundamental nature of chemical reactions; in practice, the study of catalysis is important because many industrial processes depend upon catalysts for their success. Finally, the peculiar phenomenon of life would hardly be possible without the biological catalysts termed enzymes.

HISTORY

The term catalysis (from the Greek *kata-*, "down," and *lyein*, "loosen") was first employed by the great Swedish chemist Jöns Jacob Berzelius in 1835 to correlate a group of observations made by other chemists in the late 18th and early 19th centuries. These included: the enhanced conversion of starch to sugar by acids first observed by Gustav Kirchhoff; Sir Humphry Davy's observations that platinum hastens the combustion of a variety of gases; the discovery of the stability of hydrogen peroxide in acid solution but its decomposition in the presence of alkali and such metals as manganese, silver, platinum, and gold; and the observation that the oxidation of alcohol to acetic acid is accomplished in the presence of finely divided platinum. The agents promoting these various reactions were termed catalysts, and Berzelius postulated a special, unknown catalytic force operating in such processes.

In 1834 the English scientist Michael Faraday had examined the power of a platinum plate to accomplish the recombination of gaseous hydrogen and oxygen, the products of electrolysis of water, and the retardation of that recombination by the presence of other gases, such as ethylene and carbon monoxide. Faraday maintained that the essential for activity was a perfectly clean metallic surface (at which the retarding gases could compete with the reacting gases and so suppress activity), a concept that would later be shown to be generally important in catalysis.

Early applications of catalysis

Many of the primitive technical arts involved unconscious applications of catalysis. The fermentation of wine to acetic acid, the manufacture of soap from fats and alkalies, and the formation of ether from alcohol and sulfuric acid—all catalytic reactions—were well-known in man's early history. Sulfuric acid prepared by firing mixtures of sulfur and nitre (sodium nitrate) was an early forerunner of the lead chamber process of sulfuric acid manufacture, in which sulfur dioxide oxidation was accelerated by the addition of oxides of nitrogen. (A mechanism for the latter process was suggested by Sir Humphry Davy in 1812 on the basis of experiments carried out by others.)

In 1850 the concept of a velocity of reaction was developed during studies of hydrolysis, or inversion, of cane sugar. The term inversion refers to the change in rotation undergone by monochromatic light when it is passed through the reaction system, a parameter that is easily measured, facilitating study of the reaction. It was found that the rate of inversion was, at any moment, proportional to the amount of cane sugar undergoing transformation and that the rate was accelerated by the presence of acids. (Later it was shown that the rate of inversion was directly proportional to the strength of the acid.) This work was, in part, the precursor of later studies of reaction velocity and the accelerating influence of higher temperature on that velocity by J.H. van't Hoff, Svante Arrhenius, and Wilhelm Ostwald, all of whom played leading roles in the developing science of physical chemistry. Ostwald's work on reaction velocities led him in the 1890s to define catalysts as substances that change the velocity of a given chemical reaction without modification of the energy factors of the reaction.

This statement of Ostwald was a memorable advance since it implied that catalysts do not change the position of equilibrium in a reaction (equilibrium being that point at which the conversion of reactants to products is

equalled by the reconversion of products to reactants). In 1877 Georges Lemoine had shown that the decomposition of hydriodic acid to hydrogen and iodine reached the same equilibrium point at 350° C, 19 percent, whether the reaction was carried out rapidly in the presence of platinum sponge or slowly in the gas phase. This observation has an important consequence: a catalyst for the forward process in a reaction is also a catalyst for the reverse reaction. P-E-M. Berthelot, the distinguished French chemist, had confirmed this observation in 1879 with liquid systems when he found that the reaction of organic acids and alcohols, called esterification, is catalyzed by the presence of small amounts of a strong inorganic acid, just as is the reverse process—the hydrolysis of esters (the reaction between an ester and water).

Industrial applications

The application of catalysts to industrial processes was undertaken deliberately in the 19th century. P. Phillips, an English chemist, patented the use of platinum to oxidize sulfur dioxide to sulfur trioxide with air. His process was employed for a time but was abandoned due to loss of activity by the platinum catalyst. Subsequently poisons in the reactants were found to be responsible, and the process became a technical success at the turn of the 20th century. In 1871, an industrial process was developed for the oxidation of hydrochloric acid to chlorine in the presence of cupric salts impregnated in clay brick. The chlorine obtained was employed in the manufacture of bleaching powder (a dry substance that releases chlorine on treatment with acid) by reaction with lime. Again, in this reaction, it was observed that the same equilibrium was reached in both directions. Furthermore, it was found that the lower the temperature, the greater the equilibrium content of chlorine; a working temperature of 450° C produced the maximum amount of chlorine in a convenient time. Toward the close of the 19th century, the classical studies of the eminent French chemist Paul Sabatier on the interaction of hydrogen with a wide variety of organic compounds were carried out using various metal catalysts; this research led to the technical development of a German patent for the hydrogenation of liquid unsaturated fats to solid saturated fats with nickel catalysts. The development of three important German catalytic processes had great impact on the industrial scene at the end of the 19th century and in the early decades of the 20th. One was the so-called contact process for producing sulfuric acid catalytically from the sulfur dioxide produced by smelting operations. Another was the catalytic method for the synthetic production of the valuable dyestuff indigo. The third was the catalytic combination of nitrogen and hydrogen for the production of ammonia—that is, the Haber process for nitrogen fixation— developed by the German chemist, Fritz Haber.

HOMOGENEOUS CATALYSIS

When the catalyst and the reacting substances are present together in a single state of matter, usually as a gas or a liquid, it is customary to classify these as cases of homogeneous catalysis. Oxides of nitrogen serve as catalysts for the oxidation of sulfur dioxide in the lead-chamber process for producing sulfuric acid, an instance of homogeneous catalysis in which the catalyst and reactants are gases. Traces of water vapour catalyze some gas reactions; for example, the interaction of carbon monoxide and oxygen, which proceeds only slowly in dry conditions. Sulfuric acid used as a catalyst for the formation of diethyl ether from ethyl alcohol is an example of homogeneous catalysis in the liquid phase (when the products, water and ether, are continuously removed by distillation); by this method, considerable quantities of alcohol can be converted to ether with a single charge of sulfuric acid. The inversion of cane sugar and the hydrolysis of esters by acid solutions (see above) also are examples of homogeneous catalysis in the liquid phase.

The oxidation of sodium sulfite solutions by dissolved oxygen is greatly accelerated by minute traces of copper ions in the homogeneous liquid system. This system is of especial interest since it has been shown that the process is a chain reaction—that is, it is characterized by a succession of repeating reactions, proceeding to the same end point. In this case many thousands of molecules of sodium sulfite can be oxidized to sulfate if the initial activation process is produced by absorption of a limited number of quanta (discrete energy measures) of light. The best example of a light-initiated chain reaction is the photo-combination of hydrogen (H_2) and chlorine (Cl_2); as many as 1,000,000 molecules of hydrogen chloride can be formed by absorption of a single light quantum (designated $h\nu$). Here the sequence of reaction is

$$(1) \qquad Cl_2 + h\nu \rightarrow 2Cl\bullet$$
$$(2) \qquad Cl\bullet + H_2 \rightarrow HCl + H\bullet$$
$$(3) \qquad H\bullet + Cl_2 \rightarrow HCl + Cl\bullet$$

with reactions (2) and (3) repeated over and over again. It is of interest to note that such chain reactions can be retarded by the presence of negative catalysts, more commonly termed inhibitors. These are materials that slow down the overall reaction by shortening the reaction chains, generally by entering into a non-chain reaction with one of the chemical components that maintain the chain. A wide variety of substances, including alcohols, sugars, and phenols, has been found to act as inhibitors of the oxidation of sulfite solutions.

Basic mechanisms of homogeneous catalysis

A generalized treatment of homogeneous catalysis by acids and bases was given by the Danish physical chemist J.N. Brønsted in 1924 on the basis of his concept of acids and bases. According to the Brønsted theory an acid is a molecule that can furnish a proton, whereas a base is a molecule that takes up a proton. On this assumption, the range of acids includes such varied materials as bisulfate ion, HSO_4^-; acetic acid, CH_3COOH; water, H_2O; hydronium ion, H_3O^+; ammonium ion, NH_4^+; and the corresponding bases are sulfate ion, SO_4^{2-}; acetate ion, CH_3COO^-; hydroxide ion, OH^-; water H_2O; and ammonia, NH_3 (these substances accept protons to yield the listed acids). Brønsted studied a number of acid- and base-catalyzed reactions, including: (1) the acid-catalyzed hydrolysis of an ester, ethyl orthoacetate; (2) the basic catalysis of nitramide decomposition ($H_2N{-}NO_2 \rightarrow H_2O + N_2O$); and (3) the acid–base catalysis of the conversion (mutarotation) of glucose to a closely related form. In each case he observed a linear relationship (indicating a direct connection) between the catalytic velocities of the reaction and the logarithm of the acid or base strength of the solution.

Based in part on the ideas of Brønsted, a general scheme for a change of a substance A to another substance B catalyzed by a material C can be formulated thus:

$$(1) \qquad A + C \underset{k_2}{\overset{k_1}{\rightleftharpoons}} Z$$
$$(2) \qquad Z \xrightarrow{k_3} B + C$$

The designation Z refers to an intermediate stage, which is formed with a velocity indicated by k_1; Z can disappear either to reform $A + C$, with a velocity k_2, or it can decompose by path (2), with velocity k_3, to give the product B and regenerate the catalyst C. If k_3 is much greater than k_2 the intermediate Z is used up almost as quickly as it is formed. The product will then be formed at a rate governed by the expression $k_1[A][C]$, in which the square brackets indicate concentrations of reactant and catalyst. If k_2 is much larger than k_3, however, the velocity-determining process is the decomposition of Z, the rate of formation of the product being represented by the expression $k_3[Z]$, in which $[Z]$ is the concentration of the intermediate. Examples of both types of change have been studied.

In certain instances two or more catalysts present at the same time produce effects greater than either would produce alone. It is then customary to speak of promoter action. Thus, iron ions in solution fortify the action of copper ions in catalyzing a reaction between hydrogen peroxide and iodine. It is assumed that each catalyst activates only one of the reactants.

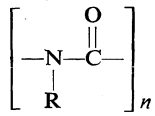
The most important modern examples of homogeneous catalyses are found in the petrochemical industry. The oxo reaction is one such process; in this process carbon

Homogeneous catalysis of industrial importance

monoxide and hydrogen are added to olefins (unsaturated hydrocarbons) at around 150° C and 200 atmospheres of pressure to form aldehydes and alcohols, oxygen-containing organic compounds. A cobalt carbonyl catalyst $Co_2(CO)_8$ is employed; this hydrocarbon-soluble catalyst is believed to activate hydrogen by formation of $HCo(CO)_4$, which then reacts with the olefin. This reaction has led to a number of studies of organometallic chemistry. Copper, silver, and mercury cations (positively charged ions) and permanganate anions (negative ions) also are known to act as homogeneous catalysts for hydrogen activation. Palladium chloride is employed industrially in the catalytic oxidation of ethylene to acetaldehyde in the presence of cupric chloride. The palladium is presumed to be repeatedly converted from the salt to the free metal, the function of the cupric chloride being to participate in the re-formation of the palladium salt from the metal.

Phosphoric, sulfuric, sulfonic, and hydrobromic acids are important agents in the industrial processes of isomerization, polymerization, hydration, and dehydration, as well as in the classical esterification reactions. Free radicals (molecular fragments bearing unpaired electrons) that are generated by the decomposition of peroxides or metal alkyls also initiate homogeneous catalytic processes.

The chemistry of organic isocyanates R–N=C=O (in which R equals an alkyl or aryl group) in the presence of water and alcohols has become in the second half of the 20th century a major concern of industry, especially in the manufacture of polyurethane foams. Bases, especially amines, together with organometallic salts of tin, are the important catalysts industrially employed in these reactions. Solid dimers and trimers (polymers with two and three monomers) are produced under certain conditions, but linear polymerization yields

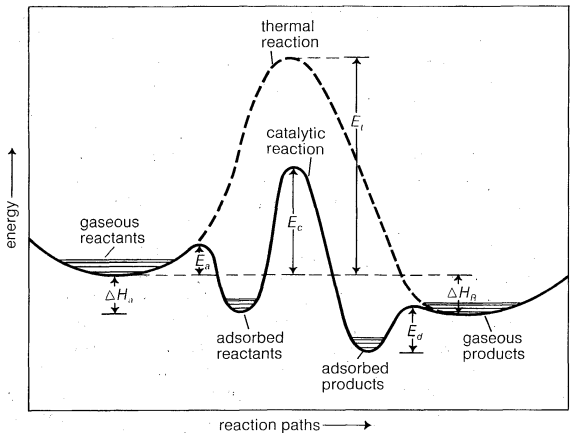


in which R is normally an aromatic group, usually phenyl (C_6H_5–) or tolyl ($CH_3C_6H_4$–). Reaction of these polymers with water or with polyhydroxy alcohols yields carbamic acids, which decompose with liberation of carbon dioxide gas to form the desired foams. When gas formation and polymer growth are suitably matched, foams with strength and other favourable qualities are achieved.

HETEROGENEOUS CATALYSIS

Many catalytic processes are known in which the catalyst and the reactants are not present in the same phase—that is, state of matter. These are known as heterogeneous catalytic reactions. They include reactions between gases or liquids or both at the surface of a solid catalyst. Since the surface is the place at which the reaction occurs, it generally is prepared in ways that produce large surface areas per unit of catalyst; finely divided metals, metal gauzes, metals incorporated into supporting matrices, and metallic films have all been used in modern heterogeneous catalysis. The metals themselves are used or they are converted to oxides, sulfides, or halides.

With solid catalysts, the reactants are chemisorbed (a portmanteau term for chemically adsorbed) by the catalyst. A catalyst is chosen that releases the products formed as readily as possible; otherwise the products remain on the catalyst surface and act as poisons to the process. Chemisorption can occur over a wide temperature range, the most effective temperature for adsorption depending on the nature of the catalyst. Thus, hydrogen is chemisorbed readily by many metals even at liquid air temperatures (below −180° C). With a series of hydrogenation–dehydrogenation catalysts—*e.g.*, zinc oxide–chromic oxide ($ZnO–Cr_2O_3$)—chemisorption of hydrogen often occurs above room temperature. Nitrogen is chemisorbed on synthetic ammonia-iron catalyst rapidly in the region above 400° C. It has been shown that iron films chemisorb nitrogen even at liquid air temperatures, with additional chemisorption found above room temperatures. It follows from such considerations that whereas physical adsorptions, which parallel the ease of liquefaction of the adsorbed substance, occur spontaneously, chemisorption, which involves the making and breaking of chemical bonds, often requires activation energies (energy needed to initiate reactions) as do uncatalyzed chemical processes. To be efficient catalytically, a process must involve energies of activation for all the steps involved that, at their maxima, are less than those required for the uncatalyzed reaction. This situation is illustrated graphically in the Figure, for a hypothetical reaction, which can occur by either an uncatalyzed or a catalyzed route. Two



Energy profiles for catalytic and thermal (noncatalytic) reactions in the gaseous phase: E_c is activation energy for catalytic reaction; E_t is activation energy for thermal reaction; E_a is activation energy of adsorption of gaseous reactants; E_d is activation energy of desorption of gaseous products; ΔH_a is heat of chemisorption of reactants; ΔH_R is heat of overall reaction.

Basic mechanisms of heterogeneous catalysis

competing proposals have been made concerning the mechanism of catalytic reactions at surfaces, and it has not been possible to choose between them. Originally, Irving Langmuir, the American physical chemist, proposed chemisorption of both reacting species at the surface, followed by interaction between adjacent species and evaporation of the products. An alternative proposal involves interaction between an impinging molecule and species already adsorbed on the surface. Subsequent developments have suggested various modes of attachment of the adsorbed and adsorbing species.

A major advance in the science of surface catalysis was the development of a method for determining the surface area of catalysts (and other materials) by measuring the multimolecular adsorption of nitrogen at liquid nitrogen temperatures or the adsorption of other gases close to their boiling points. It then became possible to calculate a quantity, designated V_m, which represents the volume of gas necessary to form a monolayer on the accessible surface; furthermore, the area of the surface can be determined from the known dimensions of the adsorbed molecules. It has also been found possible to titrate (measure quantitatively) the area of surfaces by chemisorption of gases.

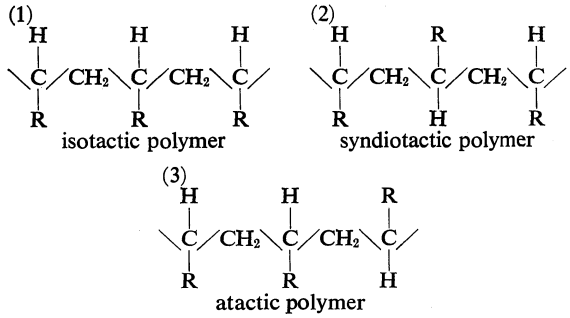
When measurements of surface areas became possible, it was seen at once that many constituents present in minor quantities in the main catalyst material—and known as promoters—could act by extending the effective surface area of the catalyst. It also was shown, however, that a promoter might produce an increase in the quality of the surface for the given reaction. Acting in a reverse direction are minor constituents of the reacting system or unwanted products of the reaction, which by preferential adsorption on the reaction sites and resistance to removal give rise to poisons for the process.

Much can be learned about mechanisms of surface processes by studying the behaviour of isotopic species of the reactants and products on the catalyst. An example

of such use concerns the technically important synthesis of ammonia from its elements, the well-known Haber process on promoted-iron catalysts. The synthesis of ammonia involves three types of bonds, hydrogen–hydrogen, nitrogen–hydrogen, and nitrogen–nitrogen, all of which can be studied using isotopes of hydrogen and nitrogen. The first of these can be examined on the reduced-iron catalyst by following the progress of the reaction $H_2 + D_2 \rightarrow 2HD$ (in which D equals the deuterium atom, an isotope of hydrogen) on the surface. The reaction is found to occur rapidly even at liquid air temperatures. Nitrogen–hydrogen bond activation can be studied by following the reaction $NH_3 + ND_3 \rightarrow NH_2D + NHD_2$. This proceeds steadily at room temperatures. The reaction involving only N–N bonds, however, studied by following the process $^{14}N_2 + {}^{15}N_2 \rightarrow 2{}^{14}N{-}{}^{15}N$ (in which ^{14}N and ^{15}N are stable isotopes of nitrogen), is shown to proceed only at the higher temperatures of ammonia synthesis, around 400° C. From these data one concludes that the activation of the nitrogen molecules is the slow step (the process that limits the overall reaction) in ammonia synthesis. This conclusion is confirmed by measurement of rate of adsorption of nitrogen on the iron catalysts. Other, similar isotopic studies have yielded valuable information on the reactions of hydrocarbons, using deuterium and carbon-14 as the isotopic tracers.

Catalysis in stereoregular polymerization

The importance of the concept of adsorption of reactants on the surface of catalysts has been greatly increased by the development of stereoregular polymerization processes—that is, methods that yield polymers whose molecules have definite three-dimensional patterns. Such processes were developed independently by the German chemist Karl Ziegler and the Italian Giulio Natta. An example is the polymerization of propylene with a titanium trichloride–alkyl aluminum catalyst. In the case of a generalized ethylenic compound, $CH_2{=}CHR$, stereoregular polymerization may yield three different arrangements of the polymer; an isotactic polymer, a syndiotactic polymer, and an atactic polymer. These have the following arrangements of their molecular chains:



In the isotactic polymer the monomer units have added head-to-tail, to give a series of C–R tertiary bonds with the same configuration in space; in the syndiotactic polymer, the tertiary carbon atoms in the chain have alternate (dextro and levo) spatial configurations; and in the atactic polymer there is no regularity in the distribution of steric configurations of the asymmetric carbon atoms. The various forms differ in their physical properties. Isotactic polypropylene has a density of 0.92 g/cm³ and a melting point of 165° C, whereas an atactic polymer has a smaller density, 0.85 g/cm³, and a melting point of −35° C. The more regular isotactic polymer is denser and has a higher melting point than the atactic product because of its greater tendency to crystallize (in spite of the fact that the substituent R may be quite large, hindering crystal formation). Stereoregular polymerization suggests a stereoregulated adsorption at the active centres of the catalyst. In the case of polypropylene, the catalytic centres have been identified by electron micrographs as α-$TiCl_3$ surfaces, which cover only a small fraction of the total surface area, whereas the β-$TiCl_3$ surfaces, which are more abundant, appear to be covered with polymer. The difference between the α- and β-surfaces lies in the random (α) and linear (β) arrangements of Ti^{3+} sites in the two surfaces.

Since the Ziegler–Natta studies, other stereoregulating catalysts have been investigated, notably oxides of chromium, vanadium, molybdenum, and tungsten on silica–alumina or other supports. Other cationic, anionic, and free-radical catalysts are known to produce stereoregulated polymerization. Stereoregular polymerization of dienes has undergone industrial development with the polymerization of isoprene to synthetic natural rubber.

Catalytically active centres

The nature of the active centres in catalytic material is further demonstrated by the enhancement of the catalytic activity of relatively inactive materials when they are subjected to intense radiation. Silica gel bombarded by gamma rays from cobalt-60 turns purplish in colour and becomes capable of inducing the reaction $H_2 + D_2 \rightarrow 2HD$ at liquid nitrogen temperatures. The colour centres, which are positive "holes" (deficiencies) trapped in the vicinity of an oxygen ion next to an aluminum impurity, are bleached *in vacuo* above 200° C and are destroyed by hydrogen even at room temperature.

The properties of dilute concentrations of platinum metals in oxide matrices, such as silica and alumina, as well as on carbon carriers have been studied by Soviet and American scientists. Such catalysts have technical significance in processes for the reforming of gasoline. In such catalysts—containing about 0.5 percent by weight of platinum or palladium—the degree of dispersion of the metal (that is, the ratio of the number of surface metal atoms to the total number present) is close to one. By contrast, on platinum foil the dispersion is only about 4×10^{-3}. The titration and adsorption procedures with hydrogen and oxygen (see above) are employed to evaluate these dispersions.

From these studies it becomes clear that there are two types of behaviour resulting from dispersion. For numerous catalytic processes, ranging from hydrogen–deuterium exchange to the hydrogenation of benzene and the hydrogenolysis of cyclopentane, the reactions are independent of dispersion in the critical region—with catalyst particle size of 50Å or less. Such structure-insensitive processes have been termed facile reactions. On the other hand, there are reactions, such as the isomerization of neopentane to isopentane and simultaneous cracking of the latter to isobutane and methane on platinum–alumina catalysts, where the selectivity for isomerization varies by a factor of 100 for the various catalysts studied (when the hydrogen–neopentane ratio is 10). Thus, the same 1 percent platinum-on-carbon catalyst showed a selectivity ratio of isomerization to hydrogenolysis of 2.5 when the catalyst was reduced in hydrogen at 500° C and a selectivity ratio of 13 when the catalyst was fired *in vacuo* at 900° C (the percentage dispersion remaining at 35 percent in both cases). Such structure-sensitive catalytic reactions have been called demanding reactions. The gain in selectivity appears to be due largely to a reduction in the rate of hydrogenolysis. Since other studies have shown that heating *in vacuo* to 900° tends to develop certain (111) facets of the metal, it is thought that the increase in selectivity is due to a more abundant triad-sorption of neopentane on the samples fired at high temperature. It has been shown that a crystallite of platinum about 20Å in size has unusual surfaces not present in a regular octahedral crystallite of similar size. A number of sites where an adsorbed molecule could be surrounded by five platinum nearest neighbours were found on the crystallite with the unusual surface.

Electronic factors in heterogeneous catalysis

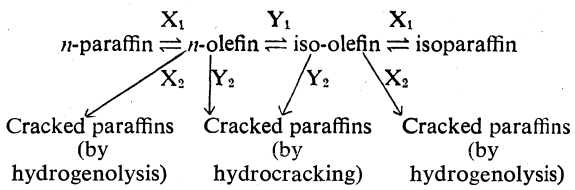
An alternative approach to the problem of surface catalysis involves the consideration of electronic factors in catalyst and reactants. Many catalytic materials are semiconductors. It is thought that these can form a variety of bonds with reactants depending on the free lattice electrons and the "holes" (deficiencies) in the catalyst lattice. Chemisorbed particles react in ways that are dependent on the form of attachment to the surface and that vary with the extent of coverage of the surface as well as with the available supply of electrons and holes. The surface behaves as would free radicals that are introduced di-

rectly into the reacting species, dependent on the electrochemical properties of the surface and the bulk of the semiconductor material. Such considerations have led to the determination of the character of the catalyst as a semiconductor and of the adsorbate as an electrochemical species, whether it is composed of positive or negative ions or free atoms or radicals. Catalytic activity also has been explored as a function of the *d*-band character —that is, the number of electrons in *d* orbitals, or pathways, in the atoms of the catalyst materials.

During the period from 1940 to 1970 various instrumental techniques were developed to explore the structure of catalytic materials and the character of the adsorbed species, even during the reaction itself. Among these techniques are electron microscopy, field emission microscopy, electron microprobe methods, magnetic measurements, infrared spectroscopy, Mössbauer spectroscopy, measurements of heats of immersion, flash desorption procedures, low energy electron diffraction studies, and nuclear magnetic resonance and electron spin resonance techniques.

Polyfunctional heterogeneous catalysis

The term polyfunctional heterogeneous catalysis is applied to a group of catalysts in which more than one component of the surface is active in the processes under study. One example of a bifunctional heterogeneous catalyst is the catalyst of metal (platinum or nickel) deposited on a silica–alumina "acidic" base. Such dual functional catalysts are involved in the interconversions of saturated hydrocarbons (paraffins) and unsaturated hydrocarbons (olefins), and normal (straight-chain) and iso (branched-chain) hydrocarbons, as well as in the splitting (cracking) of the hydrocarbon molecules. The interrelations involved are as follows:



in which X_1 and X_2 are metal-catalyzed processes and Y_1 and Y_2 are acid-catalyzed processes. Operating conditions can be altered to maximize the hydrocracking reactions relative to hydrogenolysis.

A variety of catalysts with "acidic" sites has been found to be active in the dehydration of alcohols and (as above) in the cracking and isomerization of hydrocarbons. Among these are: silica, obtained by calcination (heating) of silica gel; high purity alumina, prepared by the calcining of specially prepared aluminum hydroxide; and silica–alumina mixtures. The catalytic sites have been found to have varying degrees of acidity; their exact nature is still under discussion as well as their characterization in terms of the atomic architecture of the solid catalyst. In the case of silica–alumina, the sites are ascribed to the presence of trivalent aluminum ions Al^{3+}, in a matrix of quadrivalent silicon ions, Si^{4+}, which gives rise to charge differences in the neighbourhood of the aluminum ions. These acidic sites can be poisoned by ammonia and by amines, a finding that confirms their acidic nature. When these catalysts are treated with alkalies their catalytic character is greatly modified. On the other hand, treatment with halogens, especially fluorine or chlorine, enhances the acidic properties of these oxide materials.

Zeolites

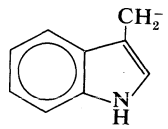
Zeolites are naturally occurring crystalline aluminosilicates having a porous structure and containing cations, generally of the alkali or alkaline earth metals. The cations can be exchanged reversibly with other metal ions without destroying the aluminosilicate structure. Because the zeolites rapidly adsorb certain molecules and exclude others, they have been given the name of molecular sieves. The adsorption characteristics of natural and synthetic zeolites have been studied since the 1930s. Manufactured zeolites, some of which have structures not found in nature, are employed as dehydrating agents but also may be used for the production of catalytic materials by exchange with cationic elements or by impregnation of metal salt solutions into the pores of the zeolite; a large number of zeolitic catalysts have been developed.

Electron donor–acceptor complexes

A class of compounds termed electron donor–acceptor complexes also has been studied for its catalytic activity. The class may be exemplified by a complex between metallic sodium (the donor) and anthracene, $C_{14}H_{10}$, a tricyclic hydrocarbon (the acceptor). The complex can be visualized as an anthracene anion and a sodium cation. Such complexes can exchange the hydrogen of the anion with molecular hydrogen that has been brought into contact with the complex. A complex represented by ZH (in which Z represents all of the molecule except for the exchangeable hydrogen) could undergo exchange with deuterium, as follows: $ZH + D_2 \rightarrow ZD + HD$. It could also take part in corresponding exchanges with hydrocarbons or bring about hydrogenation of hydrocarbons. Among other electron-acceptor catalysts are the metal phthalocyanines (compounds related to certain biological catalysts) and activated charcoal. Some donor–acceptor complexes synthesize ammonia from nitrogen–hydrogen mixtures. This reaction represents a close approach to the activity of biological and bacterial catalysts.

BIOLOGICAL CATALYSTS: THE ENZYMES

Enzymes are substances found in biological systems that are catalysts for specific biochemical processes. Although earlier discoveries of enzymes had been made, a significant confirmation of their importance in living systems was found in 1897 by the German chemist Eduard Buchner, who showed that the filtered cell-free liquor from crushed yeast cells could bring about the conversion of sugar to carbon dioxide. Since that time more than 1,000 enzymes have been recognized, each specific to a particular chemical reaction occurring in living systems. More than 100 of these have been isolated in relatively pure form, including a number of crystallized enzymes. The first enzymes to be crystallized were urease, isolated from the jack bean and crystallized in 1926 by James Batcheller Sumner, and pepsin, crystallized in 1930 by John Howard Northrop, both men being American biochemists. These purified materials were shown to be proteins, chain compounds of about 20 natural amino acids $RCH(NH_2)COOH$, ranging from the simplest, glycine, in which R is hydrogen, to tryptophan, in which R is



Not only have methods been worked out for determining the amino acids, found in an enzyme, but also the sequence of amino acids in an enzyme can be elucidated by a method developed by the English biochemist Frederick Sanger in determining the structure of the protein hormone, insulin. The first enzyme to have its complete amino acid sequence determined in this way was the enzyme bovine pancreatic ribonuclease, which has 124 amino acids in its chain and has a molecular weight of about 14000; the enzyme catalyzes the degradation of ribonucleic acid, a substance active in protein synthesis in living cells. In January 1969, the synthesis of this same enzyme was reported from two different laboratories. The activity of an enzyme depends upon a three-dimensional, or tertiary, structure, but this, in turn, appears to depend solely upon the linear sequence of amino acids. The success of a synthesis of an enzyme can be unequivocally checked by test of its enzymatic activity.

Enzyme reactivity

Enzymes are extremely reactive, as can be shown with a very simple reaction, the splitting of hydrogen peroxide to form water and oxygen, brought about by colloidal metals and by the enzyme catalase. It has been found that one molecule of the latter will cause several million molecules of peroxide to decompose per minute, a rate comparable to that obtained with the best colloidal prepara-

tions. This speed of catalase decomposition is probably a maximum for enzymes. Slower acting enzymes normally react at speeds of hundreds of reactions per minute. The rate of reaction is often expressed by an equation developed by L. Michaelis and M.L. Menten of the form:

$$\text{Rate} = \frac{V[S]}{K + [S]}$$

in which V and K are constants for the particular enzymatic process, K being termed the Michaelis constant, and $[S]$ is the concentration of the reactant undergoing change. At low concentrations of S the rate is $V[S]/K$ or proportional to the substrate concentration [S], whereas at high substrate concentrations the $[S]$ terms cancel out and the reaction is essentially independent of the substrate concentration.

A second characteristic of enzymes is their extreme specificity. It has been suggested that each biochemical process has its own specific enzyme. The biochemical processes induced by enzymes fall into broad classifications, such as hydrolysis, decomposition (or "splitting"), synthesis, hydrogenation–dehydrogenation; as with catalysts in general, enzymes are active for both forward and reverse reactions.

Like the laboratory catalysts, enzymes frequently have activators—coenzymes, which may be prosthetic groups (firmly bound to the enzyme itself) and inorganic ions. Adenosine triphosphate, ATP, is an important coenzyme participating in energy-producing processes and passage across cell membranes. Coenzymes often contain vitamins as parts of their structure. Calcium and magnesium ions are important enzyme activators. As with catalysts there are many substances that inhibit, or poison, enzymes. Cyanide ion is a potent inhibitor in many enzymic processes, as are such substances as nerve gases and insecticides.

Catherine II the Great, of Russia

As Empress of Russia Catherine II continued the work of her predecessor, Peter the Great: Peter gave Russia "a window on Europe," and Catherine opened wide the doors; Peter forced Europe to recognize the existence of a strong and independent Russia, and Catherine established Russia as a great European power; Peter destroyed ancient Russian culture in order to introduce Western culture, and Catherine laid the groundwork for a national culture influenced by Europe yet truly Russian. The woman who earned the name Catherine the Great correctly appraised her role in Russian history when she erected a statue of Peter the Great, bearing the inscription "Petro Primo Catharina Secunda" (Peter first, Catherine second).

The names of Peter and Catherine are forever linked in the minds of most Russians, even Soviet Russians. Peter inspires a deeper respect, yet Russians continue to admire Catherine, the German, the usurper and profligate, and regard her as a source of national pride. Non-Russian opinion of Catherine is less favourable. Because Russia under her rule grew strong enough to threaten the other great powers, and because she was in fact a harsh and unscrupulous ruler, she figured in the Western imagination as the incarnation of the immense, backward, yet

Catherine II the Great, portrait by A. Roslin (1718–1793). In the collection of Mrs. Merriweather Post, Hillwood, Washington, D.C.

forbidding country she ruled. One of Catherine's principal glories is to have been a woman who, just as Elizabeth I of England and Queen Victoria gave their names to periods of history, became synonymous with a decisive epoch in the development of her country.

Origins and early experience. Sophie Friederike Auguste von Anhalt-Zerbst was born in Stettin on May 2 (April 21, old style), 1729, the daughter of an obscure German prince, Christian August von Anhalt-Zerbst, but she was related through her mother to the dukes of Holstein. At the age of 14 she was chosen to be the wife of Karl Ulrich, duke of Holstein-Gottorp, grandson of Peter the Great and heir to the throne of Russia as the Grand Duke Peter. In 1744 Catherine arrived in Russia, assumed the title of Grand Duchess Catherine Alekseyevna, and married her young cousin the following year. The marriage was a complete failure; the following 18 years were filled with deception, humiliation, and disappointment for her.

Marriage in Russia

Russia at the time was ruled by Peter the Great's daughter, the empress Elizabeth, whose 20-year reign greatly stabilized the monarchy. Devoted to much pleasure and luxury and greatly desirous of giving her court the brilliancy of a European court, Elizabeth prepared the way for Catherine.

Catherine, however, would not have become empress if her husband had been at all normal. He was extremely neurotic, rebellious, obstinate, perhaps impotent, nearly alcoholic, and, most seriously, a fanatical worshiper of Frederick II of Prussia, the foe of the empress Elizabeth. Catherine, by contrast, was clearheaded and ambitious. Her intelligence, flexibility of character, and love of Russia gained her much support.

She was humiliated, bored, and regarded with suspicion while at court, but she found comfort in reading extensively and in preparing herself for her future role as sovereign. Although a woman of little beauty, Catherine possessed considerable charm, a lively intelligence, and extraordinary energy. During her husband's lifetime alone, she had at least three lovers; if her hints are to be believed, none of her three children, not even the heir apparent Paul, was fathered by her husband. Her true passion, however, was ambition; since Peter was incapable of ruling, she saw quite early the possibility of eliminating him and governing Russia herself.

The empress Elizabeth died on January 5, 1762 (December 25, 1761, old style), while Russia, allied with Austria and France, was engaged in the Seven Years' War against Prussia. Shortly after Elizabeth's death, Peter, now emperor, ended Russia's participation in the war and concluded an alliance with Frederick II of Prussia. He made no attempt to hide his hatred of Russia and his love of his native Germany; discrediting himself endlessly by his foolish actions, he also prepared to rid him-

self of his wife. Catherine had only to strike: she had the support of the army, especially the regiments at St. Petersburg, where her lover, Grigory Orlov, was stationed; the court; and public opinion in both capitals (Moscow and St. Petersburg). She was also supported by the "enlightened" elements of aristocratic society, since she was known for her liberal opinions and admired as one of the most cultivated persons in Russia. On July 9 (June 28, old style), 1762, she led the regiments that had rallied to her cause into St. Petersburg and had herself proclaimed empress and autocrat in the Kazan Cathedral. Peter III abdicated and was assassinated eight days later. Although Catherine probably did not order the murder of Peter, it was committed by her supporters, and public opinion held her responsible. In September 1762, she was crowned with great ceremony in Moscow, the ancient capital of the tsars, and began a reign that was to span 34 years as empress of Russia under the title of Catherine II.

Coronation as empress

Early years as empress. Despite Catherine's personal weaknesses, she was above all a ruler. Truly dedicated to her adopted country, she intended to make Russia a prosperous and powerful state. Since her early days in Russia she had dreamed of establishing a reign of order and justice, of spreading education, creating a court to rival Versailles, and developing a national culture that would be more than an imitation of French models. Her projects obviously were too numerous to carry out, even if she could have given her full attention to them.

Her most pressing practical problem, however, was to replenish the state treasury, which was empty when Elizabeth died; this she did in 1762 by secularizing the property of the clergy, who owned one-third of the land and serfs in Russia. The Russian clergy was reduced to a group of state-paid functionaries, losing what little power had been left to it by the reforms of Peter the Great. Since her coup d'etat and Peter's suspicious death demanded both discretion and stability in her dealings with other nations, she continued to preserve friendly relations with Prussia, Russia's old enemy, as well as with the country's traditional allies, France and Austria. In 1764 she resolved the problem of Poland, a kingdom lacking definite boundaries and coveted by three neighbouring powers, by installing one of her old lovers, Stanisław Poniatowski, a weak man entirely devoted to her, as king of Poland.

Her attempts at reform, however, were less than satisfying. A disciple of the English and French liberal philosophers, she saw very quickly that the reforms advocated by Montesquieu or Jean-Jacques Rousseau, which were difficult enough to put into practice in Europe, did not at all correspond to the realities of an anarchic and backward Russia. In 1767 she convened a commission composed of delegates from all the provinces and from all social classes (except the serfs) for the purpose of ascertaining the true wishes of her people and framing a constitution. The debates went on for months and came to nothing. Catherine's Instruction to the commission was a draft of a constitution and a code of laws. It was considered too liberal for publication in France and remained a dead letter in Russia.

Attempts at reform

Frustrated in her attempts at reform, Catherine seized the pretext of war with Turkey in 1768 to change her policy; henceforth, emphasis would be placed above all on national grandeur. Since the reign of Peter the Great, the Ottoman Empire had been the traditional enemy of Russia; inevitably, the war fired the patriotism and zeal of Catherine's subjects. Although the naval victory at Çeşme in 1770 brought military glory to the Empress, Turkey had not yet been defeated and continued fighting. At that point, Russia encountered unforeseen difficulties.

First, a terrible plague broke out in Moscow; along with the hardships imposed by the war, it created a climate of disaffection and popular agitation. In 1773 Yemelyan Pugachov, a former officer of the Don Cossacks, pretending to be the dead emperor Peter III, incited the greatest uprising of Russian history prior to the revolution of 1917. Starting in the Ural region, the movement spread rapidly through the vast southeastern provinces, and in June 1774 Pugachov's Cossack troops prepared to march on Moscow. At this point, the war with Turkey ended in a Russian victory, and Catherine sent her crack troops to crush the rebellion. Defeated and captured, Pugachov was beheaded in 1775, but the terror and chaos he inspired were not soon forgotten. Catherine now realized that for her the people were more to be feared than pitied, and that, rather than freeing them, she must tighten their bonds.

Revolt of 1773

Before her accession to power, Catherine had planned to emancipate the serfs, on whom the economy of Russia, which was 95 percent agricultural, was based. The serf was the property of the master, and the fortune of a noble was evaluated not in lands but in the "souls" he owned. When confronted with the realities of power, however, Catherine saw very quickly that emancipation of the serfs would never be tolerated by the owners, whom she depended upon for support, and who would throw the country into disorder once they lost their own means of support. Reconciling herself to an unavoidable evil without much difficulty, Catherine turned her attention to organizing and strengthening a system that she herself had condemned as inhuman. She imposed serfdom on the Ukrainians who had until then been free. By distributing the so-called crown lands to her favourites and ministers, she worsened the lot of the peasants, who had enjoyed a certain autonomy. At the end of her reign, there was scarcely a free peasant left in Russia, and, because of more systematized control, the condition of the serf was worse than it had been before Catherine's rule.

Thus, 95 percent of the Russian people did not in any way benefit directly from the achievements of Catherine's reign. Rather, their forced labour financed the immense expenditures required for her ever-growing economic, military, and cultural projects. In these undertakings, at least, she proved herself to be a good administrator and could claim that the blood and sweat of the people had not been wasted.

Influence of Potemkin. In 1774, the year of Russia's defeat of Turkey, Grigory Potemkin, who had distinguished himself in the war, became Catherine's lover, and a brilliant career began for this official of the minor nobility, whose intelligence and abilities were equalled only by his ambition. He was to be the only one of Catherine's favourites to play an extensive political role. Ordinarily, the Empress did not mix business and pleasure; her ministers were almost always selected for their abilities. In Potemkin she found an extraordinary man whom she could love and respect, and with whom she could share her power. As minister he had unlimited powers, even after the end of their liaison, which lasted only two years. Potemkin must be given part of the credit for the somewhat extravagant splendour of Catherine's reign. He had a conception of grandeur that escaped the rather pedestrian German princess, and he understood the effect it produced on the people. A great dreamer, he was avid for territories to conquer and provinces to populate; an experienced diplomat with a knowledge of Russia that Catherine had not yet acquired and as audacious as Catherine was methodical, Potemkin was treated as an equal by the Empress up to the time of his death in 1791. They complemented and understood each other, and the ambitious minister expressed his respect for his sovereign through complete devotion to her interests.

Potemkin's role in the expansion of Russia

The annexation of the Crimea from the Turks in 1783 was Potemkin's work. Through that annexation and the acquisition of the territories of the Crimean khanate, which extended from the Caucasus Mountains to the Bug River in southwestern Russia, Russia held the north shore of the Black Sea and was in a position to threaten the existence of the Ottoman Empire and to establish a foothold in the Mediterranean. Catherine also sought to renew the alliance with Austria, Turkey's neighbour and enemy, and renounced the alliance with Prussia and England, who were alarmed by Russian ambitions. Yet, during Catherine's reign, the country did not become involved in a European war, because the Empress scrupulously adhered to the territorial agreements she had concluded with several western European nations.

Catherine's glorification reached its climax in a voyage to the Crimea arranged by Potemkin in 1787. In a festive Arabian Nights atmosphere, the Empress crossed the country to take possession of her new provinces; the Emperor of Austria, the King of Poland, and innumerable diplomats came to honour her and to enjoy the splendours of what became known as "Cleopatra's fleet," because Catherine and her court travelled partly by water. She dedicated new towns bearing her name and announced that she ultimately intended to proceed to Constantinople.

Effect of the French Revolution. Catherine, like all the crowned heads of Europe, felt seriously threatened by the French Revolution. The divine right of royalty and the aristocracy was being questioned, and Catherine, although a "friend of the Enlightenment," had no intention of relinquishing her own privileges: "I am an aristocrat, it is my profession." In 1790 the writer, A.N. Radishchev, who attempted to publish a work openly critical of the abuses of serfdom, was tried, condemned to death, then pardoned and exiled. Ironically, the sentiments Radishchev expressed were very similar to Catherine's Instruction of 1767. Next, Poland, encouraged by the example of France, began agitating for a liberal constitution. In 1792, under the pretext of forestalling the threat of revolution, Catherine sent in troops and the next year annexed most of the western Ukraine, with Prussia helping itself to large territories of western Poland. After the national uprising led by Tadeusz Kościuszko in 1794, Catherine wiped Poland off the map of Europe by dividing it between Russia, Prussia, and Austria in 1795.

Division of Poland

Catherine's last years were darkened by the execution of Louis XVI, the advance of the revolutionary armies, and the spread of radical ideas. The Empress realized, moreover, that she had no suitable successor. She considered her son Paul an incompetent and unbalanced man; her grandson Alexander was too young yet to rule. On November 17 (November 6, old style), 1796, Catherine died of a stroke in St. Petersburg.

Assessment. At the end of Catherine's reign, Russia had expanded westward and southward over an area of more than 200,000 square miles, and the Russian rulers' ancient dream of access to the Bosporus Strait (connecting the Black Sea with the Aegean) had become an attainable goal. At the end of her reign Catherine claimed that she had reorganized 29 provinces under her administrative reform plan. An uninhibited spender, she invested funds in many projects. Over a hundred new towns were built; old ones were expanded and renovated. As commodities were plentiful, trade expanded and communications developed. These achievements, together with the glory of military victories and the fame of a brilliant court, to which the greatest minds of Europe were drawn, have won her a distinguished place in history.

Catherine's critics acknowledge her energy and administrative ability but point out that the achievements of her reign were as much due to her associates and to the unaided, historical development of Russian society as to the merits of the Empress. And when they judge Catherine the woman, they treat her severely.

Private life

Her private life was admittedly not exemplary. She had young lovers up to the time of her unexpected death at the age of 67. After the end of her liaison with Potemkin, who perhaps was her morganatic husband, the official favourite changed at least a dozen times; she chose handsome and insignificant young men, who were only, as one of them himself said, "kept girls." Although in reality devoted to power above all else, she dreamed endlessly of the joys of a shared love, but her position isolated her. She did not love her son Paul, the legitimate heir, whose throne she occupied. On the other hand, she adored her grandsons, particularly the eldest, Alexander, whom she wished to succeed her. In her friendships she was loyal and generous and usually showed mercy toward her enemies.

Yet it cannot be denied that she was also egotistical, pretentious, and extremely domineering, above all a woman of action, capable of being ruthless when her own interest or that of the state was at stake. As she grew older she also became extremely vain, for which there was some excuse; the most distinguished minds of Europe heaped flatteries on her that even she ultimately found exaggerated.

A friend of Voltaire and Diderot, she carried on an extensive correspondence with most of the important personages of her time. She was a patron of literature and a promoter of Russian culture; she herself wrote, established literary reviews, encouraged the sciences, and founded schools. Her interests and enthusiasms ranged from construction projects to lawmaking and the collection of art objects; she touched on everything, not always happily but always passionately. She was a woman of elemental energy and intellectual curiosity, desiring to create as well as to control.

BIBLIOGRAPHY

Contemporary sources: Mémoires de Catherine II, ed. by DOMINIQUE MAROGER (1953; Eng. trans., 1955), is of great importance for the history of Catherine's beginnings and for an analysis of her character. This edition is not complete but it constitutes a choice made among the various versions of the autobiography begun by Catherine; all versions stop very near to the date of her accession to power. Equally important are the *Correspondance* of Catherine II with Voltaire (published in various editions of the complete works of Voltaire, as well as in the Evdokimov edition of the complete works of Catherine II, 1893); the *Correspondance avec le Baron F.M. Grimm (1774–1796)*, Grot edition (1878), is interesting for its autobiographical character; Grimm was Catherine's confidant. See also *Lettres d'amour de Catherine II à Potemkine*, Georges Oudard edition (1934), unfortunately edited without chronological order.

Works about Catherine II and her reign: V.A. BILBASSOV, *Geschichte Katharina II*, 3 vol. (1891–93; also published in French as *Histoire de Catherine II*, 1900), is the most important work written about Catherine II, with quotations from many documents of the period; the last volume was banned in Russia under the tsarist regime. IAN GREY, *Catherine the Great: Autocrat and Empress of All Russia* (1961), a remarkable work, is a penetrating analysis of Catherine's character and notably of her relationships with Potemkin. OLGA WORMSER, *Catherine II* (1957), is particularly interesting for its analysis of the social and cultural situation in Russia (in French). Z. OLDENBOURG, *Catherine de Russie* (1964), is a work devoted primarily to the first half of Catherine's life (also in French).

(Z.O.)

Catherine de Médicis

As queen mother, Catherine de Médicis was the most prominent—though not the most powerful—figure in the history of France for 30 years from the death of her husband, Henry II, in July 1559 to her own in January 1589. Though still highly controversial, she nevertheless provides the principal element of continuity through seven of the eight so-called Wars of Religion that occurred within these years. Her contribution should be seen in terms of her incessant struggle for the security of France against the traditional enemy Spain, and against the breakdown of royal authority in the face of centrifugal forces that embraced and exploited the politico-religious conflicts released by the Reformation.

Catherine was born in Florence on April 13, 1519, to Lorenzo de'Medici, duke of Urbino, and Madeleine de la Tour d'Auvergne, a Bourbon princess related to many of the French nobility. Orphaned within days, Catherine was highly educated, trained, and disciplined by nuns in Florence and Rome and married in 1533 by her uncle, Pope Clement VII, to Henry, duc d'Orleans, who succeeded his father, Francis I, in April 1547. Artistic, energetic, and extroverted, as well as discreet, courageous, and gay, Catherine was greatly esteemed at the dazzling court of Francis I, from which she derived both her political attitudes and her passion for building. Of the chateaus she designed herself–including the Tuileries–Chenonceaux was her unfinished masterpiece.

In spite of Henry's abiding attachment to his mistress Diane de Poitiers, Catherine's marriage was not unsuccessful and, after 10 anxious years, she bore him 10 children, of whom four boys and three girls survived. She herself supervised their education. Thus occupied,

Catherine de Médicis, portrait by an unknown artist, 1561. In the Bibliothèque Nationale, Paris.
Giraudon

Regency

Catherine lived privately though she was appointed regent in 1552 during Henry's absence at the seige of Metz. Her ability and eloquence were acclaimed after the Spanish victory of Saint-Quentin in Picardy in 1557, possibly the origin of her perpetual fear of Spain, which remained, through changing circumstances, the touchstone of her judgments. It is essential to understand this in order to discern the coherence of her career.

Catherine's first great political crisis came in July 1559 upon the accidental death of Henry II, a traumatic bereavement from which it is doubtful if she ever recovered. Under her son, Francis II, power was retained by the Guise brothers. Thus began her lifelong struggle —explicit in her correspondence—with these extremists who, supported by Spain and the papacy, sought to dominate the crown and extinguish its independence in the commingled interests of European Catholicism and personal aggrandizement. It is also necessary to understand this political struggle of the Catholic crown with its own ultramontane extremists and to perceive its fluctuations in changing circumstances, in order to realize the fundamental consistency of Catherine's career. Her essentially moderate influence was first perceptible during the Conspiracy of Amboise (March 1560) an instance of tumultuous petitioning by the Protestant ("Huguenot") gentry, primarily against Guisard persecution in the name of the King. Her merciful Edict of Amboise (March 1560) was followed in May by that of Romorantin, which distinguished heresy from sedition, thereby detaching faith from allegiance.

Catherine's second great political crisis came with the premature death on December 5, 1560, of Francis II, whose royal authority the Guises had monopolized. Catherine succeeded in obtaining the regency for Charles IX, with Antoine de Bourbon, king of Navarre and first prince of the blood, as lieutenant general, to whom the Protestants vainly looked for leadership. The 10 years from 1560 to 1570 were, politically, the most important of Catherine's life. They witnessed the first three civil wars and her desperate struggle against the Catholic extremists for the independence of the crown, the maintenence of peace, and the enforcement of limited toleration. In 1561, with the support of the distinguished chancellor Michel de L'Hospital, she began by trying to propitiate the leaders of both religious factions, to effect reforms and economies by unassailably traditional methods, and to settle the religious conflict. Religious reconciliation was the conveners' purpose of the Colloquy of Poissys (September–November 1561). Catherine appointed a mixed commission of moderates that devised two formulas of consummate ambiguity, by which they hoped to resolve the basic, Eucharist controversy. Possibly Catherine's most concrete achievement was the Edict of January 1562, which followed the failure of reconciliation. This afforded the Calvinists licensed coexistence with specific safeguards. Unlike the proposals of Poissy, the edict was law, which the Protestants accepted and the Catholics rejected. This rejection was one basic element in the outbreak of civil war in 1562 in which—as she had predicted—Catherine fell, politically, into the clutches of the extremists, because the Catholic crown might protect its Protestants subjects in law, but could not defend them in arms. Thence-forth the problem of religion was one of power, public order, and administration.

Outbreak of civil war

Catherine ended the first civil war in March 1563 by the Edict of Amboise, an attenuated version of the Edict of January. In August 1563 she declared the King of age in the *Parlement* of Rouen and, from April 1564 to January 1566, conducted him on a marathon itinerary round France. Its principal purpose was to execute the edict and, through a meeting at Bayonne in June 1565, to seek to strengthen peaceful relations between the crown and Spain and to negotiate for Charles's marriage to Elizabeth of Austria. During 1564–68, Catherine was unable, for complex reasons, to withstand the cardinal de Lorraine, statesman of the Guises, who largely provoked the second and third civil wars. She quickly terminated the second (September 1567–March 1568) with the Peace of Longjumeau, a renewal of Amboise. But she was unable to avert its revocation (August 1568), which heralded the third civil war. She was not primarily responsible for the more far-reaching Treaty of Saint-Germain (August 1570), but she succeeded in disgracing the Guises.

For the next two years Catherine's policy was one of peace and general reconciliation. This she envisaged in terms of the marriage of her daughter Marguerite to the young Protestant leader, Henry of Navarre, (later Henry IV of France) and alliance with England through the marriage of her son Henri duc d'Anjou, or, failing him, his younger brother Francis duc d'Alençon, to Queen Elizabeth. The complexity of Catherine's position during these years cannot be briefly explained. To some extent she was eclipsed by Louis of Nassau and a group of Flemish exiles and youthful Protestants who surrounded the King and urged him to make war upon Spain in the Netherlands, which Catherine inevitably resisted. The issue of war or peace in the Netherlands was closely linked with the Massacre of St. Bartholomew's Day in Paris on August 23–24, 1572. Upon this occasion, following an abortive attempt against the life of the admiral Gaspard de Coligny, he and a number of his principal lieutenants, together with several thousand Huguenots, were killed. Catherine traditionally has been blamed for these events, which have therefore fashioned the interpretation not only of her subsequent, but frequently also of her previous, career, resulting in the familiar myth of the wicked Italian queen. There are two principal reasons for this. First, after some hesitation and inconsistency, the King assumed the responsibility by a declaration of August 26 in the *Parlement* of Paris, and "the crown" has been taken to mean Catherine. The second reason for the traditional inculpation of Catherine is the work of the pamphleteers and the polemical nature of the historiography of the event. It is impossible to establish the origin of the assault upon Coligny but, as a member of the court—the royal family and the council—Catherine was among those who appear to have authorized not the massacre itself, but the death of the admiral and his principal followers. This and the subsequent royal declaration of August 26 are both explained by the danger of the situation after the unsuccessful assault upon Coligny—in which the infuriated Huguenots allegedly threatened the court with extinction and the kingdom with war.

After the Massacre of St. Bartholomew's Day, Catherine was more concerned with the election of Anjou to the throne of Poland (May 1573) than the prosecution of the fourth civil war. Upon the death of Charles IX a year later, she assumed the regency with the support of the *Parlement* until the return from Poland of Henry in August. Catherine placed high hopes in her favourite, Henry, for the regeneration of France, for which she longed, but not without simultaneous misgivings, knowing his weakness of character and his previous subjection to the Catholics. For these reasons Catherine neither sought to dominate Henry nor to rule in his place but

rather suffered him to exploit her and strove with unremitting pains to supply his deficiencies. Until the death of Alençon in 1584, much of her attention was devoted to restraining his dangerous ambitions, which again threatened to involve France in hostilities with Spain. After the Treaty of Joinville (December 1584) between the Guises and Spain, at Henry's bidding, Catherine, though gravely ill, returned to this dual threat. But after three months of continuous effort, in order to avert a public breach between the crown and the Guises, she was obliged, by the Treaty of Nemours (July 1585) to commit the King to making war against the Huguenots. Having failed with the Guises, the crown turned to Navarre, the Protestant leader who, as heir presumptive, had an interest in the preservation of the throne. In July 1586 Catherine undertook the arduous journey to see him at Saint-Brice near Cognac. But there was nothing to which Navarre could safely commit himself. Thus, despite the heroic efforts of Catherine's old age, France was sinking into chaos when she died at Blois on January 5, 1589, eight months before the murder of Henry III. Nevertheless, her ultimate achievement was to have saved the kingdom just long enough to ensure the succession of the Bourbon Henry IV, by whom the royal authority was restored.

Catullus

Gaius Valerius Catullus, generally considered to have been the greatest lyric poet of ancient Rome, created from his intense capacity for love and hate a poetry that has few equals in its powers of direct emotional expression. His love lyrics have inspired poets of succeeding ages; but it is, above all, the self-revelatory quality in his work that speaks so strongly to his readers in the 20th century.

Life. *The facts.* No ancient biography of Catullus survives. A few facts can be pieced together from external sources, in the works of his contemporaries or of later writers, supplemented by inferences drawn from his poems, some of which are certain, some only possible. The unembroidered, certain facts are scanty. Catullus was alive 55–54 BC on the evidence of four of his poems and died young according to the poet Ovid—at the age of 30 as stated by St. Jerome (writing about the end of the 4th century), who nevertheless dated his life erroneously 87–57 BC. Catullus was thus a contemporary of the statesmen Cicero, Pompey, and Caesar, who are variously addressed by him in his poems. He preceded the poets of the immediately succeeding age of the emperor Augustus, among whom Horace, Sextus Propertius, Tibullus, and Ovid name him as a poet whose work is familiar to them. On his own evidence and that of Jerome, he was born at Verona in northern Italy and was therefore a native of Cisalpine Gaul (Gaul this Side of the Alps); he owned property at Sirmio, the modern Sirmione, on Lake Garda, though he preferred to live in Rome and owned a villa near the Roman suburb of Tibur, in an unfashionable neighbourhood. According to an anecdote in the Roman biographer Suetonius' *Life of Julius Caesar*, Catullus' father was Caesar's friend and host, but the son nevertheless lampooned not only the future dictator but also his son-in-law Pompey and his agent and military engineer Mamurra with a scurrility that Caesar admitted was personally damaging and would leave its mark on history; the receipt of an apology was followed by an invitation to dinner "the same day," and Caesar's relations with the father continued uninterrupted. (Suetonius cites the episode as an example of Caesar's clemency.)

Lampoon of Julius Caesar

Catullus' poetry reports one event, externally datable to *c.* 57–56 BC, a journey to Bithynia in Asia Minor in the retinue of Gaius Memmius, the Roman governor of the province, from which he returned to Sirmio. It also records two emotional crises, the death of a brother whose grave he visited in the Troad, also in Asia Minor, and an intense and unhappy love affair, portrayed variously in 25 poems, with a woman who was married and whom he names "Lesbia," a pseudonym (Ovid states) for Clodia, according to the 2nd-century writer Apuleius. His poems also record, directly or indirectly, a homosexual affair with a youth named Juventius.

Conjecture. Such are the stated facts. The conjectural possibilities to be gleaned mostly from the internal evidence of Catullus' poetry extend a little further. It is accepted that Catullus was born *c.* 84 BC and that he died *c.* 54 BC. His father's hospitality to Caesar may have been exercised in Cisalpine Gaul when Caesar was governor of the province, but equally well at Rome—Suetonius does not indicate time or place. Catullus' Roman villa may have been heavily mortgaged (depending on the choice of manuscript reading of one poem). A yacht retired from active service and celebrated in an iambic poem may have been his own, built in Bithynia, in northwestern Asia Minor, and therefore available to convey him on his way home to Sirmio after his tour of duty. His fellow poet Cinna may have accompanied him to Bithynia. For the governor Memmius, himself a litterateur (to whom the Roman philosophic poet Lucretius dedicated his poem on the nature of things, *De rerum natura*), such company might be congenial, and it is possible to speculate that Cinna was on board the yacht. The brother's grave could have been visited en route to or from Bithynia.

The poet's Clodia may have been a patrician, one of the three Clodia sisters of Cicero's foe Publius Clodius Pulcher, all three the subject of scandalous rumour, according to Plutarch. If so, she was most probably the one who married the aristocrat Metellus Celer (consul 60 BC, died 59 BC), who in 62 was governor of Cisalpine Gaul. It may have been at that time that the youthful poet first met her and possibly fell under her spell. She is accorded a vivid if unflattering portrait in Cicero's *Pro Caelio*, in which the orator had occasion to blacken her character in order to defend his client against Clodia's charge that as her lover after her husband's death he had tried to poison her. The client was Marcus Caelius Rufus, conceivably the Rufus reproached by Catullus in poem LXXVII as a trusted friend who had destroyed his happiness (but if so, the Caelius of poem C is a different person). This identification of Clodia, suggested by an Italian scholar of the 16th century, has found support in some uncertain inferences from the Lesbia poems: the poet's mistress besides being married perhaps moved in society, enjoyed fashionable amusements, was cultivated and witty, and was licentious enough to justify Cicero's attack. On the other hand, the poet twice appears to have included the protection of his own rank among the gifts he had laid at her feet.

The poetry. *Textual examination.* A consideration of the text of Catullus' poems and of its arrangement is of unusual interest. Its survival has been as precarious as his biography is brief. Not being part of the school syllabus, from roughly the end of the 2nd century to the end of the 12th century, it passed out of circulation. Knowledge of it depends on a single manuscript discovered *c.* 1300, copied twice, and then lost. Of the two copies, one in turn was copied twice, and then it was lost. From the three survivors—in the Bodleian Library at Oxford, the Bibliothèque Nationale in Paris, and the Vatican Library in Rome—scholars have been able to reconstruct the lost "archetype." Incorrect transcription in the preceding centuries (some 14 instances are beyond repair), however, has invited frequent and often uncertain emendation. Depending on whether one poem is divided or not, 113 or 114 poems survive. In the printed total of 116, numbers XVIII to XX were inserted by early editors without proof that they were written by Catullus. In 14 instances gaps are visible (eight of these of one or more lines), and in possibly six poems fragments of lost

Discovery of Catullus' poetry

poems have been left attached to existing ones. Ancient citations indicate the existence of at least five more poems. The surviving body of work is therefore mutilated and incomplete and (in contrast to the *Odes* of Horace) cannot in its present published form represent the intentions of either author or executors, despite the elegant dedication to the historian Cornelius Nepos that heads it. With these qualifications, it permits the reconstruction of a poetic personality and art unique in Latin letters.

The collection is headed by 57 "short poems," ranging in length between five and 25 lines (number X, an exception, has 34) in assorted metres, of which, however, 51 are either hendecasyllabic—that is, having a verse line of 11 syllables (40 such)—or iambic—basically of alternate short and long syllables (11). These rhythms, though tightly structured, can be characterized as occasional or conversational. There follow eight "longer poems," ranging from 48 lines to 408 (number LXV, of 24 lines, is prefatory to number LXVI) in four different metres. The collection is completed by 48 "epigrams" written in the elegiac distich, or pair of verse lines, and extending between two and 12 lines, a limit exceeded only by two poems, one of 26 lines and the other of 16.

Content, style, and influence. This mechanical arrangement, by indirectly recognizing the poet's metrical virtuosity and proposing three kinds of composition, justly calls attention to a versatility disproportionate to the slim size of the extant work. The occasional-verse metres and the elegiac distich had been introduced into Latin before his day. Traditionally both forms, as practiced by Greek writers after the 4th century BC and their Roman imitators, had served for inscriptions and dedications and as verse of light occasions, satirical comment, and elegant sentiment. Catullus and his contemporaries continued this tradition; but in some 37 instances the poet uniquely converts these verse forms to serve as vehicles of feelings and observations expressed with such beauty and wit, on the one hand, or such passion, on the other, as to rank him, in modern terms, among the masters of the European lyric—the peer of Sappho and Shelley, of Burns and Heine—but exhibiting a degree of complexity and contradiction that the centuries-later Romantic temperament would scarcely have understood. The conversational rhythms in particular, as he managed them for lyric purposes, achieved an immediacy that no other classic poet can rival.

Influence on the Augustans

In his longer poems Catullus produced studies that deeply influenced the writers and poets of the Augustan Age: two charming marriage hymns; one frenzied cult hymn of emasculation; one romantic narrative in hexameters (lines of six feet) on the marriage of Peleus with the sea goddess Thetis; and four elegiac pieces, consisting of an epistle introducing a translation of an elegant conceit by the Alexandrian poet Callimachus, followed by a pasquinade, or scurrilous conversation between the poet and a door (of poor quality, perhaps a youthful effort), and lastly a soliloquy (unless indeed this be two poems) addressed to a friend and cast in the form of an encomium, or poem of praise. The Augustan poet Virgil is content to imitate Catullus without naming him, even going so far, in the *Aeneid*, as thrice to borrow whole lines from him. Horace both imitated Catullus and criticized him. Tibullus, Propertius, Ovid, and later Martial both imitate and affectionately commemorate him.

In his lifetime, Catullus was a poet's poet, addressing himself to fellow craftsmen (*docti*, or scholarly poets), especially to his friend Licinius Calvus, who is often posthumously commemorated along with him. It is now fashionable to identify this coterie as the *poetae novi*, or "Neoterics" (the modern term for these new poets), who preferred the learned allusiveness and mannered and meticulous art of the Alexandrian poets to the grander but archaic fashion of Ennius, the father of Roman poetry. The school was criticized by Cicero and by Horace, who names Calvus and Catullus. To the degree that Catullus shared such conceptions of what might be called poetic scholarship, he is to be numbered in the company of Gerard Manley Hopkins, T.S. Eliot, and Ezra Pound rather than with the Romantics.

For the general reader, the 25 Lesbia poems are likely to remain the most memorable, recording as they do a love that could register ecstacy and despair and all the divided emotions that intervene. Two of them with unusual metre recall Sappho, the poetess of the Aegean island of Lesbos, as also does his use of the pseudonym Lesbia. As read today, these two seem to evoke the first moment of adoring love (number LI, a poem that actually paraphrases its Sapphic model) and the last bitterness of disillusionment (number XI). On the other hand, the poems of invective, which spare neither Julius Caesar nor otherwise unknown personalities, male and female, may not have received the critical attention some of them deserve. Their quality is uneven, ranging from the high-spirited to the tedious, from the lapidary to the laboured, but their satiric humour is often effective, and their obscenity reflects a serious literary convention that the poet himself defends. Between these two poles of private feeling lies a handful of transcendent and unforgettable compositions: the lament at his brother's grave; the salute to Sirmio his beloved retreat; the exchange of vows between Acme and Septimius; his elegy for the wife of Calvus; and even that vivid mime of a moment's conversation in a leisured day, in which the gay insouciance of a few young persons of fashion, the poet included, going about their affairs in the last days of the Roman Republic, is caught and preserved for posterity.

MAJOR WORKS

Catullus' 116 extant poems may be classified under the headings lyric, epithalamium, miniature epic, elegy, and epigram. They were mostly written between 61 and 54 BC, but cannot be dated exactly.

Apart from V, VII, VIII, XI, LVIII, and LXXVI, which, with many others, are all devoted to the theme of Lesbia, Catullus' mistress, whether in delight, sorrow, or anger, special mention may perhaps be made of XXX, to a false friend; of XXXI, on his home at Sirmio; and of CI, on his brother's death.

BIBLIOGRAPHY. The original Oxford text by ROBINSON ELLIS (1904) has been superseded by that of R.A.B. MYNORS (1958), whose *Praefatio* succinctly explains the procedures essential for reconstruction of the text and summarizes the history of the first printed Renaissance editions. This text may be supplemented by the German edition of MAURITIUS SCHUSTER (1949; rev. with additional bibliography by W. EISENHUT, 1958); and by the French Budé text of GEORGES LAFAYE (1922; 3rd ed. rev. by M. DUCHEMIN, 1949).

Commentaries: The second edition of ROBINSON ELLIS (1889) remains a classic despite its age. The American text and commentary of E.T. MERRILL (1893, reprinted 1951) was for a long time the only unabridged edition available in English; it is now joined by KENNETH QUINN, *Catullus: The Poems, Edited with Commentary* (1970). The otherwise exhaustive edition of C.J. FORDYCE (1961) omits certain poems of significant critical interest, either literary or biographical. The German commentary of WILHELM KROLL (1923, reprinted 1968) is a standard and complete work. That in Italian by M.L. DE GUBERNATIS, 2nd ed. (1933, reprinted 1953), stresses literary interpretation.

General: Estimates of Catullus' poetry and its place in Latin letters are offered by A.L. WHEELER, *Catullus and the Traditions of Ancient Poetry* (1934, reprinted 1964), who gives special attention to the longer poems; by E.A. HAVELOCK, *The Lyric Genius of Catullus* (1939, reprinted 1967), who sees the secret of the poet's significance in the short poems; and by KENNETH QUINN, *The Catullan Revolution*, 2nd rev. ed. (1969), who stresses the poet's place within the Roman tradition; as does DAVID O. ROSS, JR., *Style and Tradition in Catullus* (1969). The biographical approach to the poems, initiated over 100 years ago (SCHWABE, *Quaestiones Catullianae*, 1862), pervasive in Merrill's commentary and criticized by Havelock (pp. 73–86), has been revived by T.P. WISEMAN, *Catullan Questions* (1969).

Translations: These, unabridged, responding to a new tolerance of the obscene in literature, have recently proliferated. Aside from the Loeb Library edition (text and translation by F.W. CORNISH, 1912), versions in a more contemporary style include the following: F.O. COPLEY, *Complete Poetry of Catullus* (1957); R.A. SWANSON, *Odi et Amo: Complete Poetry* (1959); PETER WHIGHAM, *Poems of Catullus* (1966); and RENEY MYERS and ROBERT J. ORMSBY, *Catullus: The Complete Poems for American Readers* (1970).

(E.A.Ha.)

Caucasian Languages

The term Caucasian languages as used here includes groups of languages indigenous to the Caucasus region, between the Black and Caspian seas within the Soviet Union; it excludes the Indo-European (Armenian, Ossetic, Talysh, Kurdish, Tat) and Turkic languages (Azerbaijan, Kumyk, Noghay, Karachay, Balkar) and some other languages of the area, all of which were introduced to the Caucasus in historical times. The Caucasian languages are also referred to as Paleocaucasian and Ibero-Caucasian languages.

The Caucasian languages are found in the territory north and south of the main Caucasian mountain range; their number varies, according to different classifications, from 30 to 40. The concentration of so many languages in such a small territory is indeed remarkable. There are more than 5,000,000 speakers of Caucasian languages; their language communities range in size from only a few hundred people to large national groups of millions.

Three Caucasian language groups

The Caucasian languages fall into three typologically well-defined language families: the Northwest Caucasian, or Abkhazo-Adyghian, languages; the Northeast Caucasian, or Nakho-Dagestanian, languages; and the South Caucasian, or Kartvelian, languages (also called Iberian). From the typological point of view, the Northwest and Northeast Caucasian groups present opposite structural types, with South Caucasian holding an intermediary position.

The exact genetic relationships of the Caucasian languages are still unclear on many points, not only in regard to interrelationships of the three major groups but also to some internal groupings. Although the genetic relationships between Northwest and Northeast Caucasian seem probable, the interrelationships of North and South Caucasian are as yet uncertain because of the absence of any regular sound correspondences between them. At the present stage of comparative Caucasian linguistics, North Caucasian and South Caucasian must be viewed as separate language families.

The theories relating Caucasian with such languages as Basque and the non-Indo-European and non-Semitic languages of the ancient Near East also lack sufficient evidence and must be considered as inconclusive.

SOUTH CAUCASIAN (KARTVELIAN) LANGUAGES

Languages of the group. The Kartvelian (South Caucasian) language family comprises Georgian, Mingrelian (Megrelian), Laz (or Chan), and Svan. The speakers of these languages constitute the Georgian nation and number 3,245,000 (according to the 1970 census).

Georgian. Georgian (self-designation: *kartuli ena*), used as the language of literature and instruction, is the state language of the Georgian Soviet Socialist Republic. It is common to all speakers of the Kartvelian languages within the Georgian S.S.R. Beyond the Georgian republic, Georgian is spoken in the adjacent regions of the Azerbaijan S.S.R. and northeast Turkey. There are also 14 villages of Georgian speakers in the province of Isfahan, Iran.

The designation Georgian that is used in the European languages was coined during the Crusades; it is based on Persian *gorji* (Georgian), from which the Russian *gruzin* was also derived. The Greek term *ibēres* (Georgians) is connected with an Old Iranian name for Georgia.

The dialects of Georgian fall into two groups—East and West Georgian—divided by the Suram Mountains. These exhibit only slight differences.

Georgian literary tradition

Among the Caucasian languages, only Georgian has an ancient literary tradition, which dates back to the 5th century AD, when the oldest datable monuments were inscribed in an original script. This old Georgian script must have been derived from a local variety of Aramaic with influences—in regard to the order of the alphabet and the shape of some characters—from the Greek alphabet. The modern Georgian writing system is based on the round-form cursive, developed from the angular book script of the 9th century; the latter was a direct descendant of the old Georgian script. The Georgian writing system accurately reflects the distinctive sounds of the language.

During the Old Georgian period (from the 5th to the 11th century), original and translated literary monuments were produced, among them the Georgian translation of the Bible. The conventions of the New Georgian literary language, ultimately established in the middle of the 19th century on the basis of an East Georgian dialect, originated in the secular literature of the 12th century. New Georgian differs structurally in many respects from Old Georgian, but the old language is still comprehensible to the Georgians of today. Until the beginning of the 19th century, Old Georgian was still in use in religious services and theological writings.

Mingrelian. The Mingrelian language (self-designation: *margaluri nina*) is spoken in the territory north of the Rioni River and west of the Tskhenis-Tskali and along the Black Sea coast from the mouth of the Rioni up to the city of Ochamchire. The language is unwritten.

Laz. The Laz language (self-designation: *lazuri nena*) is spoken along the Black Sea coast from the Chorokh River (Georgian S.S.R.) to south of Pazar (Atina) in Turkish territory. The language is unwritten, Georgian being used as the literary language in the Georgian S.S.R. and Turkish in Turkey. In view of the structural closeness between Mingrelian and Laz, they are sometimes considered as dialects of a single language.

Svan. The Svan language (self-designation: *lušnu nin*), also unwritten, is located south of Mt. Elbrus, in the high valleys of the upper Tskhenis-Tskali and its tributary Kheledula and in the valleys of the upper Ingur. There are four fairly distinct dialects: Upper and Lower Bal in the Ingur region, and Lashkh and Lentekh in the Tskhenis-Tskali region.

Linguistic characteristics. Correspondences between sounds and meanings in words and word elements provide a basis for considering the Kartvelian languages as being closely related and descended from a common ancestral language (a protolanguage).

Phonology. The sound system of the Kartvelian languages is relatively uniform, with only the vowel systems exhibiting considerable differences. Apart from the five cardinal vowels *a, e, i, o, u*, which exist in all the Kartvelian languages, the Svan dialects show several additional vowels: the front (or palatalized) vowels, *ä, ö, ü*, and a high central vowel, *ə* (as the *a* in English "sofa"). All these vowels also have distinct lengthened counterparts, thus giving a total of 18 distinctive vowels in some dialects of Svan. Vowel length is not distinctive in the other Kartvelian languages.

Vowel differences in Kartvelian

Within the Kartvelian consonant system the stops and affricates have voiced, voiceless, and glottalized varieties. (Stops are produced by complete but momentary stoppage of the breath stream some place in the vocal tract; affricates are sounds begun as stops but released with local friction, such as the *ch* sounds in "church." Voiced sounds are made with vibrating vocal cords; in voiceless sounds, the vocal cords do not vibrate; glottalized consonants, indicated in phonetic transcription by dots below or above certain letters, are pronounced with an accompanying closure of the glottis (the space between the vocal cords). Fricative sounds (*e.g., s, z, v*), which are characterized by local friction, have only voiced and voiceless types.

Although most word roots begin with one or two consonants, instances of long consonant clusters in word-initial position occur quite frequently, especially in Georgian, in which such clusters may comprise up to six consonants; *e.g.*, Georgian *prckvna* "peeling," *msxverpli* "sacrifice," *brʒola* "fighting."

Grammatical characteristics. The Kartvelian languages exhibit a developed system of word inflection (*e.g.*, the use of endings, such as English "dish, dishes" or "walk, walks, walked") and derivation (word formation). Derivation is characterized by compounding, the combination of words to form new words, as well as by affixation, the addition of prefixes and suffixes; *e.g.*, Georgian *kartvel-i* "Georgian," *sa-kartvel-o* "Georgia"; Mingrelian *žir-i* "two," *ma-žir-a* "second."

The verb system distinguishes the categories of person,

number (singular and plural, with differentiation of inclusive and exclusive plural in Svan), tense, aspect, mood, voice, causative, and version (the latter defines the subject–object relations). These categories are expressed mainly by the use of prefixes and suffixes, as well as by internal inflection (changes within the verb stem), which is frequently a redundant grammatical feature.

Multipersonal verbs

The system of verb conjugation is multipersonal; that is, the verb forms can indicate the person of the subject (the agent) and of the direct or indirect object by the use of special prefixes. (The subject of the 3rd person is marked by endings in Georgian and Mingrelo-Laz and by a lack of ending in Svan.) An example is Georgian *m-çer-s* "he writes to me," *m-xaṭav-s* "he paints me," in which *m* denotes the 1st person as object and *s* marks the 3rd person as subject. The finite verb forms fall into three series of tenses: the present tense, the aorist (indicating occurrence, usually past, without reference to completion, duration, or repetition), and the perfect or resultative (denoting an action in the past not witnessed by the speaker).

There is a developed system of preverbs, elements preceding the verb stem and attached to it, with local meaning indicating location of the action in space, as well as its direction (especially in Mingrelian and Laz). Simple preverbs are combined into complex ones. The preverbs are also used to mark the aspect (nature of the action indicated by the verb, with reference to its beginning, duration, completion), which is used for the formation of future and aorist forms; *e.g.*, Georgian *çer-s* "he writes" versus *da-çer-s* "he will write" and *da-çer-a* "he wrote."

The nominal (noun, pronoun, adjective) system is distinguished by less structural complexity than the verb system and has cases varying in number from six to 11. The six cases common to all the Kartvelian languages are: nominative, marking subject of the intransitive verb; ergative (see below), modified in Mingrelian and Laz; genitive, marking possession; dative, marking indirect objects; ablative–instrumental, expressing relations of separation and source and means or agency; and adverbial, expressing goal of the action—*e.g.*, "to make it." There are also some secondary local cases (in New Georgian, Mingrelian) that indicate location and direction toward the object as well as from the object (rendered in English by such prepositions as "in," "on," "to," "from," and so on). The nominal system does not distinguish gender, which is absent even in pronouns, and there are no special articles (such as English "a," "the").

Ergative sentence constructions

A basic feature of Kartvelian syntax is the ergative construction of the sentence. The subject of a transitive verb (the agent) is marked by a special agentive, or ergative, case, while the case of the direct object is the same as that of the subject with intransitive verbs, traditionally called the nominative case; *e.g.*, Georgian *ḳac-i* (nominative) *midis* and Svan *māre* (nominative) *esʏri*, "the, or a, man goes" but Georgian *ḳac-ma* (ergative) *moḳla datv-i* (nominative) and Svan *mārēm* (ergative) *adgär däšdw* (nominative) "the, or a, man killed the, or a, bear." A specific feature of the Georgian and Svan ergative construction is its restriction to the aorist series. In the present-tense series the subject (agent) of transitive as well as intransitive verbs is put into the same nominative case, and the direct object is in the dative; *e.g.*, Georgian *ḳac-ma* (ergative) *moḳla datv-i* (nominative) "the man killed a bear" (aorist), but *ḳac-i* (nominative) *ḳlavs datv-s* (dative) "the, or a, man kills the, or a, bear" (present tense). In Mingrelian the ergative case in *k* extends in the aorist series to the constructions with intransitive verbs and results in a formation of two distinct subject cases. In Laz, conversely, the case in *k* extends to the constructions with transitive verbs in the present-tense series.

Vocabulary. The genetic closeness of the Kartvelian languages is evidenced by a large number of structural correspondences and of common lexical (vocabulary) and grammatical items. Though the Kartvelian languages abound in ancient loanwords from Iranian, Greek, Arabic, Turkish, and other languages, it is nevertheless possible to single out the basic vocabulary and grammatical elements of original Caucasian origin, which exhibit a system of regular sound correspondences. The common Kartvelian vocabulary comprises the kinship terms, names of animals, birds, trees, and plants, the parts of the body, as well as different human activities, qualities, and states. The words for the numerals from one to ten and the word for hundred are also original common Kartvelian terms.

Proto-Kartvelian. A comparative study of the Kartvelian languages enables specialists to outline the general structure of the parent language, called Proto-Kartvelian, which yielded the known Kartvelian, or South Caucasian, languages. One of the most characteristic features of the Proto-Kartvelian language is the functional vowel alternation, or ablaut; different forms of a word root or word element appear either with a vowel (**e*, **a*, **o*), called full grade, or without a vowel, called zero grade. (An asterisk [*] indicates that the following form is not attested but has been reconstructed as a hypothetical ancestral form.) In a sequence of word elements (called morphemes) only one element may occur in full grade, the others being in either zero or reduced grade forms (*i.e.*, in a form with **i*). To a word root with a full-grade vowel, for example, a suffix in zero may be added, and vice versa: **der-ḳ-* (intransitive) "stoop, recline" and **dr-eḳ-* (transitive) "bend." When a full-grade ending is added to these stems, the preceding full-grade element is shifted to zero or a reduced grade; *e.g.*, **der-ḳ-* plus the ending **-a* becomes **dr-k-a*. In such patterns the lengthened grade, a long vowel, may also appear.

Ablaut in Proto-Kartvelian

These ablaut patterns, strikingly parallel to those of the Indo-European languages, and other linguistic features may have arisen in Proto-Kartvelian as a result of contacts with Indo-European at a comparatively early date. Such contacts between Kartvelian and Indo-European are further evidenced by a number of Indo-European loanwords in Proto-Kartvelian, such as Proto-Kartvelian **ṭep* "warm" (compare Indo-European **tep* "warm"), Proto-Kartvelian **mḳerd* "breast" (compare Indo-European **ḱerd* "heart"), and others.

In Mingrelo-Laz the ancient ablaut patterns were eliminated and new forms were set up with a stable, non-interchanging vowel in each word element. The ancient ablauting models were better preserved in Georgian and especially in Svan, in which new ablauting patterns, in addition to the old structures, were established.

The pronominal system of Proto-Kartvelian is characterized by the category of inclusive–exclusive (*i.e.*, there are two forms of the pronoun "we," one including the hearer, and the other excluding him), which survived in Svan but has been lost in other languages of the family. Along with it, Svan has preserved a certain number of archaic structural features of the Proto-Kartvelian epoch, setting it apart from Georgian and Mingrelo-Laz, which share a number of common lexical and grammatical innovations. Svan must have been separated fairly early from the rest of Proto-Kartvelian, which later yielded the Mingrelo-Laz and Georgian languages. (Th.V.G.)

NORTH CAUCASIAN LANGUAGES

The North Caucasian languages are divided into two groups: Abkhazo-Adyghian, or the Northwest Caucasian, languages, and Nakho-Dagestanian, or the Northeast Caucasian languages.

Abkhazo-Adyghian languages. The Abkhazo-Adyghian group consists of the Abkhaz, Abaza, Adyghian, Kabardian (Circassian), and Ubykh languages. Abkhaz, with about 80,000 speakers, is spoken in the Abkhazian A.S.S.R. (in the South Caucasus, Georgian S.S.R.). The other languages are spread over the western part of the northern Caucasus. Abazians (25,000) live in the Karachay-Cirassian Autonomous Oblast; Adyghians (100,000), in the Adyghe Autonomous Oblast; Kabardians or Kabardino-Circassians (about 320,000) dwell mainly in the Kabardino-Balkar A.S.S.R. Both Adyghians and Kabardians call themselves *adəge*. The Ubykh language was formerly found to the north of the area where Abkhaz is spoken, in the vicinity of Tuapse. In 1864 Ubykhians as well as a substantial part of the Abkhaz- and Adyghe-speaking population migrated to Turkey,

where before long they lost their native tongue. In the early 1970s Ubykh was spoken by about 20 people living near the Sea of Marmara. The total number of people speaking Abkhazo-Adyghian languages is 530,000 (in the U.S.S.R.). Many Circassians speaking Abkhazo-Adyghian languages live in the countries of the Near East—Turkey, Jordan, and Iraq.

All Abkhazo-Adyghian languages, with the exception of Ubykh, are written. From the dialectological point of view, the Abkhazo-Adyghian languages are not widely differentiated, the differences being mainly of phonetic character. In Abkhaz two dialects are distinguished; Adyghian and Kabardian differentiate four dialects each. Abkhaz and Abaza are very close to each other and are considered by some scholars to be dialects of the same language. The same kind of affinity exists between Adyghian and Kabardian. Ubykh occupies an intermediate position between the Abkhaz-Abaza and Adyghe-Kabardian languages.

Phonology. A characteristic feature of the sound system of the Abkhazo-Adyghian languages is a rather limited number of distinctive vowels—*a* and *ə* (pronounced as the *a* in English "sofa"). Some scholars consider it possible to posit only one vowel, which, depending on the position, can be realized in different ways: *a, ə, i, o, e.* On the other hand, the languages are notable for a great diversity in their consonant systems. The number of consonants distinguished reaches about 70 (in the Abkhaz and Adyghian languages) or even 80 (Ubykh). Along with the consonants that occur in all the Caucasian languages, the Abkhazo-Adyghian languages are characterized by different sets of labialized consonants (formed by rounding the lips), strong (hard or tense) consonants, half-hushing consonants, and velarized consonants (formed with the back of the tongue approaching the soft palate).

Few vowels, very numerous consonants

Grammatical characteristics. The grammatical characteristics of the Abkhazo-Adyghian languages include an extremely simple noun system and a relatively complicated system of verb conjugation. There are no grammatical cases in Abkhaz and Abaza, and in the other languages only two principal cases occur: a direct case (nominative) and an oblique case, combining the functions of ergative, genitive, dative, and instrumental. In nouns, possession is expressed by means of pronominal prefixes; *e.g.,* Abkhaz *sarra s-č:ə* "my horse" (literally: "I my-horse"), *wara u-č:ə* "your horse" (pertaining to a man), *bara b-č:ə* "your horse" (pertaining to a woman), and so forth. (The symbol *:* indicates that the preceding consonant is a strong consonant.)

The Abkhaz and Abaza languages distinguish the grammatical classes of person and thing (the latter class includes all nouns denoting nonhuman objects). The class of person also differentiates between the subclasses of man and woman.

The verb in the Abkhazo-Adyghian languages has a pronounced polysynthetic character; that is, various words combine to form a composite word that expresses a complete statement or sentence. The most important verbal categories are expressed by prefixes, although suffixes also form tenses and moods. The principal verb categories are: dynamic versus static, transitivity, person, number, class, tense, mood, negation, causative, version, and potentiality. "Dynamic versus static" is a verb form expressing action versus state of being; "version" is a verb category denoting for whom the action is intended (compare Georgian *v-çer* "I write," but *v-u-çer* "I write for him"); "potentiality" is a category expressing the possibility of an action (*e.g.,* Abkhaz *s-zə-ɷuam* "I cannot write"). The verb is multipersonal and can denote up to four persons.

Adverbial relationships (such as "where," "when," "how") are expressed by prefixes following the personal markers. On the whole, the verb forms appear as a long string of word elements expressing the above mentioned categories; *e.g.,* Abkhaz *i-u-z-d-aa-sə-r-g-an* "that (thing)-you (a man)-for-them-hither-I shall make-bring" (*i.e.,* "I shall make them bring that for you"). In a sequence of prefixes, up to nine morphemes are possible.

The simple sentence has three constructions: indefinite, nominative, and ergative (in Abkhaz and Abaza only indefinite). An indefinite construction has the subject in the indefinite case (*i.e.,* not marked with a special suffix); a nominative construction has the subject in the nominative case. The same personal markers, depending on their arrangement, can denote both the subject and various objects: *e.g.,* Abkhaz, *wara sara u-s-šweiṭ* "I kill you (a man)," *sara wara s-u-šweiṭ* "you (a man) kill me."

Three sentence types

Nakho-Dagestanian languages. The Nakho-Dagestanian group consists of the Nakh and Dagestanian languages. Some investigators subdivide the Nakho-Dagestanian languages into two independent groups: Central Caucasian languages (Nakh) and East Caucasian languages (Dagestan), although the great proximity of these groups, and their equal remoteness from the Abkhazo-Adyghian languages, may justify regarding them as a common group of languages.

The Nakh languages consist of Chechen (613,000 speakers), Ingush (158,000), and Bats (or Tsova-Tushian, about 3,000 speakers). The Chechens and Ingushes live in the Chechen-Ingush A.S.S.R.; the Bats dwell in the village Zemo-Alvani in the Akhmeta district of the Georgian S.S.R. Both Chechen and Ingush, which are fairly close to one another, are written. The Bats language is unwritten; Georgian is used as the literary language for Bats speakers, and they consider Georgian as their mother tongue.

The Dagestan languages are numerous. The following groups can be distinguished:

Groups of Dagestan languages

1. The Avaro-Ando-Dido languages: These occupy the central and western part of Dagestan and part of the Zakataly region of the Azerbaijan S.S.R. The member languages are the Avar language; the Andi subgroup of languages, including Andian, Botlikh, Godoberi, Chamalal, Bagulal, Tindi, Karata, and Akhvakh; and the Dido subgroup, including Dido, or Tsez, Khvarshi, Hinukh, Bezhta, and Hunzib, or Kapucha.

The Avaro–Ando–Dido language with the most speakers (about 400,000) is Avar, a written language. All Andi–Dido languages are unwritten, and most of them are spoken by about 3,000 to 5,000 people each. From ancient times the Andi–Dido nationalities used the Avar languages for intertribal communication. Avar is still widely known and spoken among them. The Andi languages are phonetically and grammatically very close to each other. The same affinity is observed among the Dido languages, to the effect that Hinukh is considered by some specialists as a dialect of Dido, while Bezhta and Hunzib are viewed as two dialects of the same language. In respect to dialectology, the majority of Avaro–Ando–Dido languages are widely differentiated.

2. The Lakk-Dargwa languages: Lakk (or Lakh, with 86,000 speakers) and Dargwa (or Khjurkili, with 231,000) are spoken in the central part of Dagestan. Both are written languages. The Lakk language is quite homogeneous with regard to its dialects; Dargwa, however, possesses several diversified dialects—sometimes considered as separate languages (*e.g.,* Kubachi). Some view Lakk and Dargwa as independent language groups.

3. The Lezgian languages: This group includes Lezgi (Lezghi), or Kuri (with 200,000 speakers in the Dagestan A.S.S.R. and about 100,000 in the Azerbaijan S.S.R.); Tabasaran (55,000); Agul (about 9,000); Rutul (about 12,000); Tsakhur (about 11,000); Archi (1,000); Kryz (or Dzkek, about 6,000); Budukh (1,000); Khinalug (about 1,000); and Udi (about 4,000). The majority of Lezgi languages are found in Dagestan occupying its southern part, but some of them (Kryz, Budukh, Khinalug, Udi, partly Tsakhur) are spoken in Azerbaijan; and one village of Udi speakers is located in Georgia. It must be noted that in Azerbaijan, as well as earlier in Russia, all Dagestanians—including Avars—called themselves Lezginians. Among the Lezgian languages, Lezgi and Tabasaran are written. The inclusion of Archi in this group gives rise to some doubt, and it has also been noted that the Khinalug language stands out from the Lezgian group in many respects. The Udi language is supposed to be one of the languages of ancient Caucasian Albania.

Phonology. The sound systems of the Nakho-Dagestanian languages are diverse. There are up to five vowels (*a, e, i, o, u*); in some languages *o* is only now becoming an independent distinctive unit. Along with these cardinal vowels, in a number of languages there are also long and nasalized vowels (the Andi languages), pharyngealized vowels (in Udi), and labialized vowels (in Dido). In the Nakh languages (Chechen) the vowel system is fairly intricate, the number of distinctive vowels amounting to 30 (including diphthongs and triphthongs).

Nakh and Dagestanian consonants

The consonant systems of the Nakh languages are relatively simple, coinciding, on the whole, with those of the South Caucasian languages (apart from a number of pharyngeal consonants characteristic of all the Nakh languages and a lateral sound peculiar to Bats). The opposition of strong and weak voiceless consonants is typical of the majority of the Dagestanian languages. This contrast has been lost in a number of languages and dialects; *e.g.*, in the Dido languages, in some dialects of Avar. The labialized clusters *kw, qw, sw,* and so on are widespread. In the Avaro-Ando-Dido languages and in Archi there are fricative and affricate lateral sounds (*i.e.*, different types of *l*), with the maximum possible number being six (in Akhvakh).

All the Caucasian languages have a series of stops of three types—voiced, voiceless aspirated, and glottalized (*i.e.*, pronounced, respectively, with vibrating vocal cords; with vocal cords not vibrating but with an accompanying audible puff of breath; and with accompanying closure of the glottis [space between the vocal cords]). In some languages strong and weak consonants also contrast. Usually, in the languages with a strongly developed vowel system, the system of consonants is comparatively simple (*e.g.*, Chechen, Ingush, Dido), and vice versa (*e.g.*, Avar, Lakk, and Dargwa have complicated consonantisms and relatively simple vowel systems).

Grammatical characteristics. There are several common structural features in morphology (word structure), the most characteristic being the existence of the grammatical category of classes (eight classes in Bats; six in Chechen and Andi; five in Chamalal; four in Lakk; three in Avar; two in Tabasaran).

In a number of languages (Lezgi, Udi), noun differentiation by classes has disappeared. The class of "thing" is distinguished from the "person" class, which can be differentiated into the subclasses of man and woman. Compare, for example, Avar *emen w-aċana hani-w-e* "father has come here" (in which *w* is equivalent to the marker of the class of man), *ebel j-aċana hani-j-e* "mother has come here" (in which *j* is equivalent to the marker of the class of woman), and *ču* (*kavat*) *b-aċana hani-b-e* "a horse (a letter) has come here" (in which *b* is equivalent to the marker of the class of thing). In the plural there are usually fewer grammatical classes denoted.

Nouns have many cases, both in singular and in plural; there are cardinal cases (nominative, ergative, genitive, dative) and local cases that denote the location of a thing ("on," "in," "near," "under"), with a specification of movement ("where," "which way," "from where," "over what"). The ergative case, the case of the real subject of transitive verbs, is present in all the Nakho-Dagestanian languages. Nouns have different stem forms in the nominative and the oblique (non-nominative) cases; *e.g.*, Avar *gamač* "a stone" (nominative), *ganč̣-i-c:a* (ergative), and *ganč̣-i-da* "on the stone." In pronouns the category of inclusive–exclusive is distinguished; *e.g.*, Avar *nil'* "we with you," *niž* "we without you."

The class of the noun in the nominative case (*i.e.*, in the case of the subject of intransitive verbs and of the direct object of transitive verbs) is reflected in the verb; *e.g.*, Avar: *was* (nominative, class I) *w-aċana* "the boy has come," *jas* (nominative, class II) *j-aċana* "the girl has come."

In the Lezgi language, a characteristic structural feature is agglutination, the combination of various elements of distinct meaning into a single word. A typical feature of Nakho-Dagestanian syntax is the presence of the ergative construction of the sentence (the subject of transitive verbs is put in the ergative case and the real object in the nominative case). Complex sentences are usually formed with participial and adverbial–participial construction; *e.g.*, Avar *haniwe waċaraw či dir wac: wugo* "the man who arrived here is my brother" (literally, "the here arrived man my brother is").

Vocabulary, writing, and alphabets. The original vocabulary of the North Caucasian languages has been fairly well preserved in the modern languages, although there is a substantial number of words borrowed from Arabic (through Islām), the Turkic languages, and Persian. There are also loanwords from the neighbouring languages (Georgian, Ossetic). Russian has played a major part since the late 19th century and is currently the main source for new words, especially technical terminology.

Sources of loanwords

The written languages of the area are the state languages. Newspapers, magazines, and books, as well as radio and television programs, use the local languages, and children in primary schools are taught in their mother tongue.

The alphabets of the North Caucasian written languages (Abkhaz, Abaza, Adyghe, Kabardian, Chechen, Ingush, Avar, Lakk, Dargwa, Lezgi, Tabasaran) are based on the Cyrillic alphabet, which was introduced for these languages in 1936–38 (in Abkhaz, from 1954). Previously, from 1928, the modified Latin alphabet was used; it superseded the Arabic script, which was adapted to the local languages in the Soviet period, at a time when a number of North Caucasian languages became literary languages.

Some written attempts had been made earlier. In the 18th century an insignificant number of monuments were created (with the use of Arabic writing) in Lakk and Avar. Stone crosses with Old Georgian–Avar bilingual inscriptions, dating from not later than the 14th century AD, have been preserved in central Dagestan. (T.E.G.)

KUIPERS, "Caucasian," in THOMAS A. SEBEOK (ed.), *Current Trends in Linguistics*, vol. 1, *Soviet and East European Linguistics*, pp. 315–344 (1963), a useful brief survey of Caucasian linguistics, with a selected bibliography; A. DIRR, *Einführung in das Studium der kaukasischen Sprachen* (1928), contains a survey of the structure of individual Caucasian languages and their interrelationships; "Yazyki Narodov SSSR," IV. *Iberijsko-Kavkazskie jazyki* (1967), a brief exposition of the structures of all the Caucasian languages, with a selected bibliography.

South Caucasian languages: The following is a selection of the more important special works on the South Caucasian languages: G. DEETERS, *Das kharthwelische Verbum: Vergleichende Darstellung des Verbalbaus der südkaukasischen Sprachen* (1930), a comprehensive comparative study of the verb structure of the Kartvelian languages; A.S. CHIKOBAVA, *Drevnejšaja struktura imennyx osnov v kartvel'skix jazykax* (1942; in Georgian, with a Russian and French summary), a comparative analysis of the ancient structure of nominal stems in the Kartvelian languages, with an interpretation of certain prefixes as the ancient classmarkers; K.H. SCHMIDT, *Studien zur Rekonstruktion des Lautstandes der südkaukasischen Grundsprache* (1962), a detailed analysis of sound correspondences with a reconstruction of the Proto-Kartvelian phonemic system; T.V. GAMKRELIDZE and G.I. MACHAVARIANI, *Sistema sonantov i ablaut v kartvel'skikh iazykakh* (1965; in Georgian with a Russian summary), a detailed comparative analysis of the Kartvelian phonological and morphophonological system, with a reconstruction of resonants and ablaut alternations in Proto-Kartvelian and their typological evaluation. For the grammars of the individual languages see A.G. SHANIDZE, *Osnovy gruzinskoj grammatiki*, vol. 1 (1953), a most comprehensive exposition (in Georgian) of the structure of modern Georgian; and H. VOGT, *Grammaire de la langue géorgienne*, rev. ed. (1971). An account of the Georgian sound system is given in G. AXVLEDIANI, *Osnovy obščej fonetiki* (1949, in Georgian). For a detailed descriptive analysis of the Svan verb system according to dialects, see

V.T. TOPURIA, *Svanskij jazyk*, vol. 1, *Glagol* (1931; 2nd ed., 1967), in Georgian, with a Russian summary. Much useful information about Georgian and the history of Georgian (Kartvelian) studies is contained in S.V. DZIDZIGURI, *The Georgian Language* (Eng. trans. 1968). A useful practical guide to Georgian is K. TSCHENKELI, *Einführung in die georgische Sprache*, vol. 1, *Theoretischer Teil*, vol. 2, *Praktischer Teil* (1958).

North Caucasian languages: P.K. USLAR, *Etnografija Kavkaza. Jazykoznanie*, 6 vol. (1887–96), contains descriptive grammars of the individual North Caucasian languages; A. TSCHIKOBAVA, "Die ibero-kaukasischen Gebirgssprachen und der heutige Stand ihrer Erforschung in Georgien," *Acta Orientalia Academiae Scientiarum Hungaricae*, 9:109–161 (1959), a brief survey of the North Caucasian languages, containing an extensive bibliography; N. TRUBETZKOY, "Nordkaukasische Wortgleichungen," *Wiener Zeitschrift für die Kunde des Morgenlandes*, vol. 37, no. 1–2 (1930), establishes sets of sound correspondences between the West and East Caucasian languages and deals with the history of their consonantism; G. DUMEZIL, *Études comparatives sur les langues caucasiennes du nord-ouest (morphologie)* (1932), a comparative analysis of the grammatical structure of the Abkhazo-Adyghian languages; A.H. KUIPERS, *Phoneme and morpheme in Kabardian (Eastern Adyghe)* (1960), a detailed analysis of the phonemic structure of morphemes in Kabardian with a typological comparison with other linguistic systems; W.S. ALLEN, "Structure and System in the Abaza Verbal Complex," *Transactions of the Philological Society of London*, pp. 127–176 (1956), a comprehensive analysis of the verb structure in Abaza; A. SOMMERFELT, "Études comparatives sur le caucasique du nord-ouest, *Norsk Tidsskrift for Sprogvidenskap*, vol. 7 and 9 (1934–38), a comparative study of the sound system of the Nakh languages; E.A. BOKAREV, *Vvedenie v sravnitel'no-istoričeskoe izučenie dagestanskix jazykov* (1961), a comparative study of the vocalism and consonantism of the languages of Dagestan; T.E. GUDAVA, *Konsonantizm andijskix jazykov* (1964), a reconstruction of the original consonant system of the Avaro-Ando-Dido languages.

(Th.V.G./T.E.G.)

Caucasus Mountains

The great historic barrier of the Caucasus Mountains rears up across the wide isthmus separating the Black and Caspian seas, at that extreme southern portion of the European section of the Soviet Union where Europe and Asia converge. If the ranges are placed in Europe, then Mt. Elbrus, at 18,510 feet (5,642 metres) their highest peak, is also the highest point in Europe; but the environment of the whole region is so subject to Asian influences that there is a good case for assigning the Caucasus to western Asia. Traditionally, the watershed of the Great Caucasus Range (Bolshoy Kavkaz), the backbone of the system, is regarded as part of the line dividing the continents.

The ethnic and linguistic heritage

The name Caucasus is a Latinized form of "Kaukasos," which the ancient Greek geographers and historians used, and the Russian "Kavkaz" is of the same origin. The ultimate derivation is thought to be from "Kaz-kaz," the Hittite name for a people living on the southern shore of the Black Sea. This ancient nomenclature reflects the historical importance of the region: the Greeks made the mysterious range the scene of the mythical sufferings of Prometheus, and the Argonauts sought the Golden Fleece in the land of Colchis, nestling against the range on the Black Sea coast. The ranges also filtered cultures of the ascendant civilizations of the Near Eastern "fertile crescent" through to the north, besides nurturing their own distinctive societies. The peoples of the region have exhibited an extraordinary variety since early times: the Colchians, for example, as described by the 5th-century-BC Greek historian Herodotus, were black skinned, and the subsequent centuries witnessed successive waves of peoples migrating across Eurasia, adding to, and being molded by, the Caucasian cultural heritage. Not surprisingly, a larger quantity of different languages is spoken in Caucasia than in any other area of similar size in the world.

Caucasia is defined as the region including not only the soaring mountain ranges of the Caucasus proper but also the country immediately north and south of them. The northern country is called Ciscaucasia (Predkavkaz; *i.e.*, Hither Caucasia); the southern is Transcaucasia (Zakavkaz, or Farther Caucasia). The whole region, which has an area of 170,000 square miles (440,000 square kilometres), is nevertheless predominantly mountainous. It extends from the lowlands of the Kuma and Manych basins southward to the political frontiers separating the Soviet Union from Turkey and from Iran and so comprises the southernmost divisions of the Russian S.F.S.R. (including Dagestan), the Georgian S.S.R., the Armenian S.S.R., and Soviet Azerbaijan, besides several minor administrative units constituted on an ethnic basis. For related information on the human geography of the area, see the articles AZERBAIJAN SOVIET SOCIALIST REPUBLIC; ARMENIAN SOVIET SOCIALIST REPUBLIC; and GEORGIAN SOVIET SOCIALIST REPUBLIC; also the article RUSSIAN SOVIET FEDERATED SOCIALIST REPUBLIC; for linguistic information, see CAUCASIAN LANGUAGES; see also URARTU AND ARMENIA, HISTORY OF.

THE NATURAL ENVIRONMENT

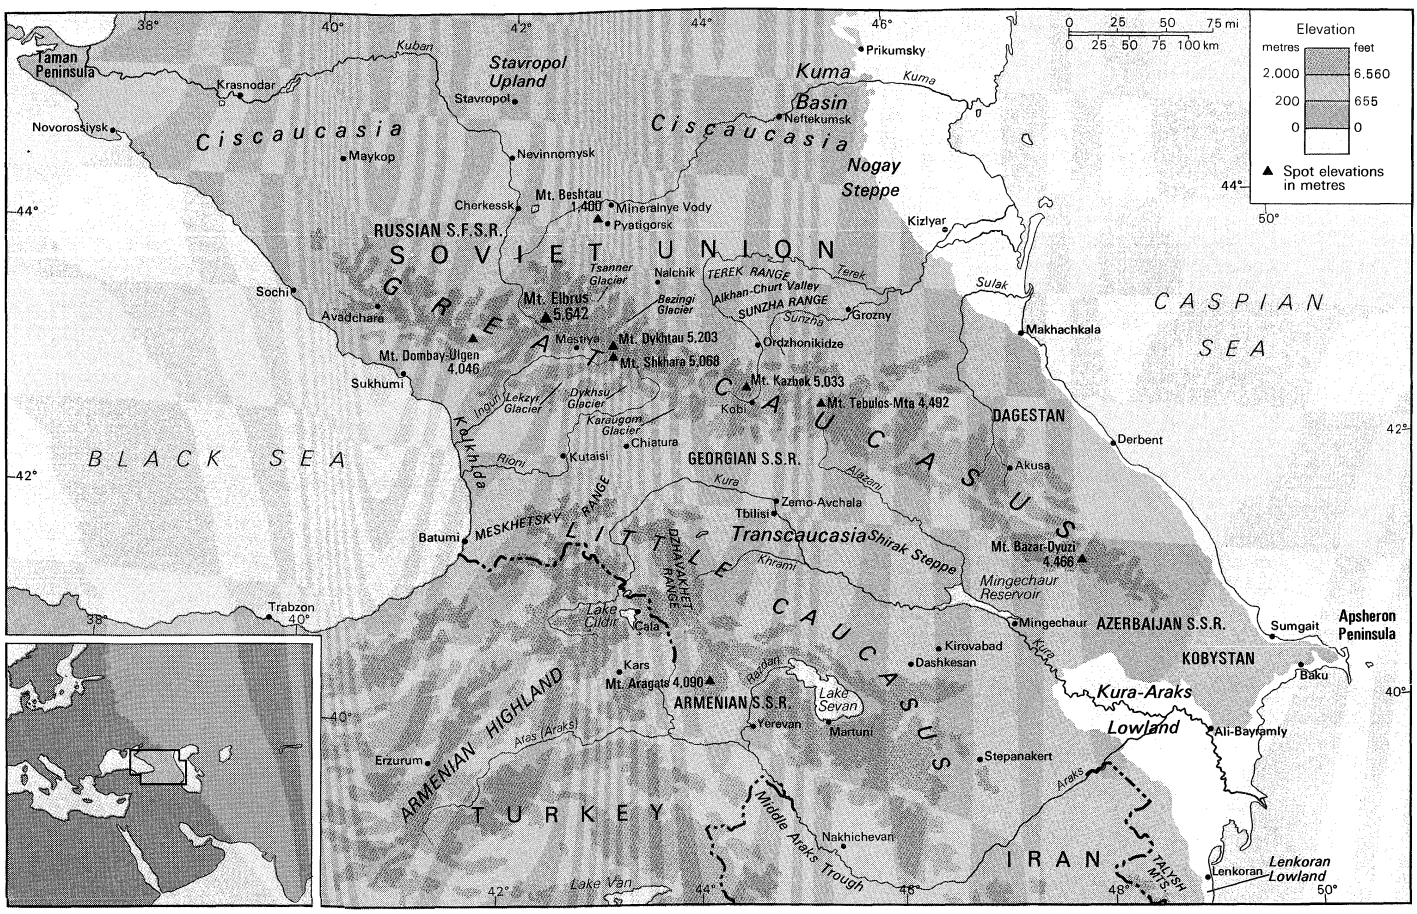
Relief and geological structure. The Great Caucasus extends for approximately 750 miles southeastward across the Caucasus from the Taman Peninsula (Tamansky Poluostrov) thrusting between the Black Sea and its northern extension, the Sea of Azov, to the Apsheron Peninsula (Apsheronsky Poluostrov), which juts into the Caspian past the oil-rich port of Baku. The vast plains and uplifted areas of Ciscaucasia stretch from its northern foothills to the Kuma-Manych depression lying southwest of the huge Caspian delta of the Volga. Western Ciscaucasia consists largely of plains: from the lowland north of the Kuban River, the delta of which adjoins the broad, low ridges of the Taman Peninsula, a plain slopes gradually southward up to the foothills of the mountains. Central Ciscaucasia comprises not only the Stavropol Highland (Stavropolskaya Vozvyshennost), mainly characterized by tablelands of limestone or sandstone and by deep valleys, but also the Mineralnye Vody-Pyatigorsk zone to the southeast (where Mt. Beshtau rises to 4,593 feet [1,400 metres] from a surrounding plateau) and, still farther southeastward, beyond the middle Terek River, the highlands backing the Terek and the Sunzha, with the Alkhan Churt Valley between them. Eastern Ciscaucasia is lowland traversed by the lower Terek and, to the north beyond the sands of the vast Nogay Steppe, by the Kuma. Both rivers flow into the Caspian.

The northern slopes of the Great Caucasus are not as steep as the southern. The middle of the system is comparatively narrow, but its western and eastern ends have widths of 100 miles or more. The watershed and a lateral range to the north of it, which together constitute the axis of the system, contain, in addition to Mt. Elbrus itself, such magnificent lofty peaks as Mt. Dombay-Ulgen, 13,274 feet (4,046 metres), in the western sector; Mts. Shkhara, Dykhtau, and Kazbek, all well over 16,000 feet, in the central sector; and Mts. Tebulos-Mta and Bazar-Dyuzi, both over 14,000 feet, in the east. Spurs tonguing north and south from the main axis in places reach heights approaching 10,000 feet.

The Great and Little Caucasus

South of the Great Caucasus, on the Black Sea coast, lies the alluvial plain of Kolkhida (ancient Colchis). On the Caspian side, in the basin of the Kura River, plains and such uplands as the long Shirak Steppe (Shirakskaya Step) succeed one another till the level falls sharply into an extensive depression, in the centre of which the Kura receives its major right-bank tributary, the Araks. To the northeast, the hills of southeastern Kobystan separate the Kura-Araks Lowland (Kura-Araksinskaya Nizmennost) from the Apsheron Peninsula. From the extreme southeast of the Kura-Araks Lowland, the narrow Lenkoran Lowland (Lenkoranskaya Nizmennost) extends southward between the Caspian Sea and the Talysh Mountains, which reach heights exceeding 8,000 feet.

West of the Kura-Araks Lowland rises the Little Caucasus, which is continued southward by the Dzhavakhet mountain range and the Armenian Highland, the latter straddling the Soviet–Turkish frontier. East of Lake Sevan, the highest peaks rise to 12,000 feet or more, while Mt. Aragats (Alagez), west of the lake, rises an-



The Caucasus Mountains.

other 1,000 feet. From their western sources in the Armenian Highland, the Kura and the Araks both flow round the Little Caucasus, the one north of it, the other south, before their confluence in the east.

The greater part of Caucasia originated in the vast structural downwarp in the earth's crust known as the Alpine Geosyncline, dating from about 25,000,000 years ago, and thus reflects the mountain-building movement that produced the younger mountains of Europe. Northern and central Ciscaucasia has a platform-like construction, with a foundation of folded structures dating from Hercynian times, about 345,000,000 years ago. Southwestern and southeastern Ciscaucasia lie on the margins of the vast downfold in the earth's surface that rose later in the Alpine mountain-building movement, with the collapse deepest on the lower courses of the Kuban and Terek rivers. The surface of Ciscaucasia is composed essentially of Tertiary and Quaternary rocks less than 65,000,000 years old; on the Stavropol Highland there are layers of various ages in folded, platform-like structures.

Structurally the Great Caucasus represents a great upfold, or anticline, thrown up at the margin of the Alpine Geosyncline about 25,000,000 years ago and subsequently altered by fresh cycles of erosion and uplift. Hard, crystalline, heat-altered rocks such as schists, gneisses, and granites, of pre-Jurassic origin (more than 190,000,000 years old), have been exposed at the core of the western sector, while somewhat softer, clayey schists and sandstones of Lower and Middle Jurassic origin have emerged in the east. The spurs of the Great Caucasus are composed of younger limestones, sandstones, and marls.

Kolkhida and the Kura-Araks Lowland are both structural depressions linked to the Alpine Geosyncline; the former is related to the formation of the Black Sea, the latter to that of the Caspian. In Kolkhida, the overall surface of Quaternary deposits laid down less than 25,000,000 years ago is broken, at the foot of the mountains, by the emergence of slightly earlier sedimentary rocks. Late Tertiary and Quaternary rock also underlies the Kura-Araks Lowland.

The structures of the Little Caucasus, of the Talish Mountains, and of the Dzhavakhet–Armenian ranges likewise reflect folds uplifted from the Alpine Geosyncline. While the western sector of the Little Caucasus and the Talish are formed chiefly of deposits of Tertiary Age (about 50,000,000 years ago) laid down in the great former downwarp of the geosyncline, the intervening eastern sector of the Little Caucasus consists, north of Lake Sevan, of layers of Jurassic and Cretaceous sedimentary and intruded volcanic rock, which are at least twice as old. Volcanism and the intrusion of heat-altered rock have everywhere played a great role: the folded base of the Dzhavakhet Range and of the Armenian Highland is masked by debris from eruptions of Tertiary–Quaternary date. Much older rocks emerge largely between the middle course of the Araks and the latitude of Lake Sevan.

Mineral resources. The geologically recent rock layers around the Great Caucasus, notably in the Kura-Araks Lowland and beneath the Caspian Sea, contain oil-bearing deposits. These also occur, together with fuel gases, among the earlier rocks of Ciscaucasia, while, in Dagestan, oil, fuel gas, and coal deposits are found. Metallic ores are associated with magmatic rocks thrust up from deep in the crust: magnetite iron occurs near Dashkesan, in Azerbaijan; copper and molybdenum are found in several parts of the Transcaucasian upland; several metallic ores lie in the Great Caucasus; and manganese is found near Chiatura, in Georgia. Building materials include the cement marls of Novorossiysk south of the Taman Peninsula and the rose-coloured tufas of Aragats. The mineral-water springs of the Caucasus are known throughout the Soviet Union.

Climate. Standing on the border between the temperate and subtropical climatic zones, the Great Caucasus accentuates the difference between them by impeding the movement of cold air masses from the north into Trans-

caucasia and, conversely, that of warm air masses into Ciscaucasia from the south. Thus average January temperatures, which range from between 23° and 28° F (−5° and −2° C) in Ciscaucasia, are between 40° and 43° F (4.5° and 6° C) in Kolkhida and between 34° and 38° F (1° and 3.3° C) in eastern Transcaucasia. In summer, when differences of temperature between north and south are small, there is a more noticeable contrast between the west (average temperatures 73°–79° F [23°–26° C]), with its maritime climate, and the continental east (77°–84° F [25°–29° C]).

Temperature ranges

Ciscaucasia has a moderately continental steppe climate in the west and a more continental, drier, semidesert one in the east. In Transcaucasia, Kolkhida has a humid, subtropical climate with mild winters and an annual rainfall of 47 to 71 inches (1,200 to 1,800 millimetres); as does the Lenkoran Lowland but with a dry season at the start of the summer; the Kura-Araks Lowland has a dry subtropical climate, an annual rainfall of eight to 16 inches (200 to 400 millimetres), but lower in the east, and mild winters and hot summers, which favour the cultivation of cotton; and the Middle Araks Trough in the Armenian Highland has a climate like that of the lowland downstream, but not so warm.

In the Great Caucasus, temperatures naturally fall, and agricultural seasons become shorter, as altitude rises; more rain falls on the mountain slopes than on the neighbouring plains. From the altitude of approximately 6,500 feet, a westerly air current prevails, strengthening maritime influences: average air temperatures reach 18° F (−8° C) in January and 55° F (13° C) in August. As the Great Caucasus stands at an angle to the westerly air currents, the heaviest precipitation, reaching a maximum of no less than 160 inches (4,000 millimetres), accumulates on the south-southwest-facing slopes. Higher up, a cold climate with severe humidity prevails, and perennial snow shrouds the highest crests. In the northern Black Sea coast region, the climate is Mediterranean, with humid winters and dry summers.

The slopes of the Little Caucasus facing toward those of the Great Caucasus have a climate similar to that of the latter at corresponding altitudes, with rainfall concentrated in the west. On the slopes of the Talysh Mountains, the climate is humid, with yearly precipitation up to 68 inches (1,700 millimetres). The Armenian Highland has a climate more continental than that of the Great Caucasus at corresponding altitudes (at 6,500 feet the average temperature 10° F [−12° C] in January, 64° F [18° C] in July). Snow cover lasts for four or five months. Annual precipitation averages 20 inches (500 millimetres), with a spring maximum. The climate of the upland steppe plateaus is moderately cold and continental, whereas that of the heights is more humid and Alpine, with cool summers and cold, prolonged winters.

Rivers and lakes. The Kura (with its tributary the Araks), the Sulak, the Terek, and the Kuma rivers flow into the Caspian Sea; the Rioni and the Inguri, into the Black Sea; and the Kuban, into the Sea of Azov. In the warm season, when snow and ice begin to melt, rivers of the Great Caucasus and some of those of the Little may be in flood for six months; and other Transcaucasian rivers are characterized by spring flooding. The rivers of the southern slope of the Great Caucasus generally have summer floods also. The rivers of Ciscaucasia, except those flowing from the Great Caucasus, flood in spring and freeze in winter but become very shallow and sometimes even dry up in summer, while the Stavropol area is artificially irrigated from the Kuban River. In the eastern and central Caucasus, brief storm flooding occurs. The soluble limestone spurs of the Great Caucasus have karst-type rivers that intermittently plunge beneath the earth.

Flood perils

The lower reaches of the Kura, of the Kuban, and of the Rioni are navigable. Water from many of the rivers serves to irrigate the arid zone of Ciscaucasia, the Kura-Araks Lowland, and the lands around the Middle Araks. Hydroelectric stations have been built on the Kura at Mingechaur and at Zemo-Avchala, near Tbilisi; on the Khrami (a right-bank tributary of the Kura); on the Rioni; and on several rivers of the Great Caucasus.

Ozero Sevan in the Transcaucasian Range is the largest lake of Caucasia. Its overflow, draining into the Razdan tributary of the Araks, is exploited for hydroelectricity by a chain of stations and also for the irrigation of the south of the Armenian S.S.R. The high parts of the Little Caucasus contain numerous small lakes, while saltwater lakes occur in the arid regions of northeastern Caucasia.

Glaciers. The Great Caucasus has 2,200 glaciers, occupying 1.36 percent of its total area. About 70 percent of them occur on the northern face, with a concentration in the centre. The largest, notably Dykhsu, Bezingi, and Karaugom, on the northern face, and Lekzyr and Tsanner, in Svanetian Georgia, are often eight miles or so long. The desolate flanks of Mt. Elbrus are streaked by many glaciers.

Plant and animal life. In western and central Ciscaucasia, steppe vegetation used to prevail on the rich black soils but has now largely been plowed up. Forest-steppe vegetation, with oaks and beeches, is found on the higher ground of the Stavropol Highland, around Pyatigorsk, in the west sector of the Sunzha Range (Sunzhensky Khrebet), and at the foot of the Great Caucasus. Eastern Ciscaucasia is semidesert, with grasses and sagebrush (*Artemisia*) on chestnut soils and saltworts where the soil is salty. *Artemisia*, saltworts, and ephemeral species on gray soils characterize the arid Kura-Araks Lowland; and similar vegetation occurs in the Middle Araks Trough. In Kolkhida and in the Lenkoran Lowland, subtropical broad-leaved forest has given way before the advances of agriculture.

In the mountains themselves, at altitudes between 2,000 and 3,000 feet, arboreal brushwood predominates. On the Black Sea slopes of the Great Caucasus and in the mountainous hinterland of Kolkhida, there are mixed forests—beech, oak, hornbeam, chestnut, and alder—with evergreen undergrowth and lianas on red and on yellow soils. In the Talysh Mountains, forests of chestnut-leaf oak and *Parrotia persica* flourish on yellow soils likewise. On the heights backing the Kura-Araks Lowland, there are xerophytic (adapted to a limited water supply) leaf-bearing forests and brushwood on brown soils. On the northern face of the Great Caucasus, oak forests and secondary brushwood occur.

In the next zone, at altitudes up to 6,500 feet, both the Great and the Little Caucasus sustain forests of oak and hornbeam and of beech on brown soils; but these trees are superseded at the higher levels by Caucasian elm and Nordmann fir in the west and in the southwest and sometimes by pine farther east. Feather grass and needlegrass cover the black soil of the steppes on the lava plateaus and plains of the Armenian sector. Steppes and meadow steppes are widespread also among the mountains of Dagestan.

Above 6,500 feet in the Great Caucasus and in the Transcaucasian Range, mountain-meadow vegetation covers three belts, sub-Alpine, Alpine, and subnivean, up to the lonely zone of glaciers and perpetual snow—which begins at about 10,000 feet.

The animal life of the Great and of the Little Caucasus includes certain indigenous species—the West Caucasian and the Dagestanian bison, or tur, the Caucasian black grouse, and the Caucasian pheasant, or ular—and even indigenous genera, such as the long-clawed mole-vole (*Prometheomys schaposchnikowi*). It also includes chamois, red deer, bear, lynx, and fox. Ciscaucasia's fauna is connected both with eastern Europe's and with Central Asia's; and the latter connection is also evident in the Kura-Araks Lowland, which has the Persian gazelle (*Gazella subgutturosa*), the long-eared hedgehog, the jerboa, and the reed cat (*Felis chaus*). The fauna of the Talish Mountains, which includes leopard and porcupine, is related to that of more southerly territories, while that of the Armenian Highland is related to that of Anatolia, with the ground squirrel, or suslik (*Citellus*), and the mountain jerboa (*Allactaga williamsi*). (N.A.G.)

Indigenous animals

THE HUMAN IMPRINT

The people. According to the Soviet census of 1970, the total population of Caucasia amounts to 22,800,000.

Of this total, 12,300,000 live in Transcaucasia and 10,500,000 in the north. About half of the people live in towns, notably 1,261,000 in Baku, 889,000 in Tbilisi, 767,000 in Yerevan, 465,000 in Krasnodar, 341,000 in Grozny, and 236,000 in Ordzhonikidze. The rural population is unevenly distributed. The most densely populated area is on the Black Sea coast; the Rioni Valley and several smaller valleys in Transcaucasia are intensively cultivated; and the foothills of the mountains also have a considerable density of population. The Alpine regions of the Caucasus and the arid steppes and lowlands of the Caspian littoral are sparsely populated.

Caucasia has long played a major role as a link between Europe and Asia, and through it the culture of ancient Mesopotamia spread northward. Indigenous cultures also arose; in particular, Caucasia was one of the most ancient centres of bronze working from the first half of the 2nd millennium BC. Autochthonous peoples of the Caucasus are mentioned by Herodotus and by later writers such as Strabo. In the centuries between pre-Classical antiquity and the 14th century AD, Caucasia underwent successive invasions by various peoples, including Scythians, Alans, Huns, Khazars, Arabs, Seljuk Turks, and Mongols; and contacts were also maintained with the Mediterranean world. All this history has left its imprint on the culture of the Caucasian peoples: Near Eastern and Middle Eastern influences, in particular, disseminated Iranian languages on the one hand and Islāmic and Christian religion on the other. The later history, beginning with a long period of rivalry between Ottoman Turkey and Iran, is marked by the advance of Russian culture, which penetrated farther and farther into Caucasia from the 16th century onward. Throughout this process, individual ethnic groups, under pressure from stronger neighbours, took refuge in the ravines of the mountain ranges to preserve themselves in isolation.

Ethnic succession

More than 50 different peoples inhabit Caucasia. Russians and Ukrainians, who constitute more than 80 percent of the total population of Ciscaucasia, speak Slavic languages of the Indo-European family. The Armenians also speak an Indo-European language, but one that stands by itself. The Ossetes, the Kurds, the Tats, and the Talysh speak Indo-European languages of the Iranian branch. The majority of the peoples, however, speak tongues that are sometimes tentatively classed together as belonging to a Caucasian language "family," although not all the languages in this "family" are genetically related to one another. The most important Caucasian language is Georgian, spoken by a nation into which numerous tribes have long been amalgamated. Georgian and its many dialects belong to the Kartvelian group of Caucasian, the other groups being the Adyghian and Abkhazian, the Nakhian, and the Dagestani. Adyghian and Abkhazian comprise the languages of Kabarda, of the Adygei, and of the Cherkes, or Circassians (all three of them closely related), as well as those of the Abaza and of the Abkhaz (who have both been strongly influenced by the neighbouring Georgians); Nakhian comprises Shishan (Chechen) and Ingush; and the Dagestani group of the "family" is chiefly represented by the languages of the Lezgian, of the Tabasaran, of the Dargante, and of the Laki peoples, together with those of the 15 minor nationalities collectively described as Avarian. The Dagestani group of "Caucasian" languages is of course quite distinct from the Turkic languages spoken in Dagestan, namely those of the Kumyk and of the Nogay. Other Turkic languages of Caucasia include Karachay and Balkar—besides the extensive Azerbaijani. If Caucasia is the world's best stocked linguistic museum, Dagestan is Caucasia's.

High up in the Caucasus, the people can only raise cattle, grow some mountain crops, and pursue a few domestic crafts. On the plains and on the foothills, viticulture is traditional. The Soviet governments promote heavy or light industry wherever practicable. (S.I.B.)

Mapping and climbing. Modern cartographic studies of the region were begun by Russian scientists in Ciscaucasia about 1815, and some medium-scale maps were drawn up in 1862. Large-scale maps began to appear in 1866; and a survey of the heights of the Great Caucasus, from 1881, provided the basis for the study of its glaciation. The first ascent of Mt. Elbrus was achieved in 1829 by a Kabard mountaineer, Killar Khashirov, who reached the eastern peak; the higher western peak was first climbed in 1874 by four Englishmen. Another Englishman, Douglas Freshfield, made a useful exploration later in the 19th century; but contemporary geographers rely chiefly on Russian research and on the works of indigenous experts.

Prospects. The exploitation of Caucasia's natural resources can be further integrated. Mining and, in particular, hydroelectric development could produce greater yields. The same is true of agriculture, not only in irrigable areas but also higher up. Similarly, forestry and stock raising could be improved, without exhausting the woods and pastures. The tourist trade could be increased if the sanatoriums, spas, and sports centres (for skiers and mountaineers) had better facilities and were made more accessible.

BIBLIOGRAPHY. Н.А. ГВОЗДЕЦКИЙ, *Кавказ* (1963), discusses the wealth and diversity of the nature of the Caucasus; special attention is given to the economic value of the natural resources. D.W. FRESHFIELD, *Exploration of the Caucasus*, 2 vol. (1896–1902), is the classic work of the famous English alpinist about his investigations of the alpine Caucasus.

(N.A.G.)

Cavendish, Henry

One of the leading physicists and chemists of the 18th and early 19th centuries, Henry Cavendish achieved a breadth of interest, originality, and lasting significance in his work that makes him the peer of the major men of science. His contributions fall into five partially overlapping categories: chemical researches, the discovery of the composition of water, electrical researches, researches on heat, and studies in meteorology and dynamics. Cavendish was born in Nice on October 10, 1731, a descendant of two great families, with the duke of Devonshire and the duke of Kent as his grandfathers. His mother died two years later, after giving birth to his brother Frederick. In 1742 he entered the Hackney seminary near London and during 1749–53, he was at Peterhouse College at the University of Cambridge, but he did not take a degree, possibly because he balked at the required declaration of adherence to the Church of England. After a tour of the Continent, he lived in London with his father until the latter's death in 1783. It was during this period that he carried out all of his electrical, and most of his chemical, researches, starting as an assistant to his father, whose own experimental skill was remarkable enough to draw the praise of Benjamin Franklin. Father and son lived in relatively modest circumstances at first, but when Henry Cavendish was 40 he became a millionaire through the inheritance of a fortune that made him, according to Jean-Baptiste Biot, a contemporary French scientist, "the richest of all learned men, and very likely also the most learned of all the rich."

Riches and intellect

His wealth made little difference to his style of living. As before, most of his expenditures went for scientific apparatus and books; in time he accumulated a large library, which he then made available to other scientists. To the outside world he appeared to be a shabby, eccentric man who spoke little and then only hesitantly in a shrill, thin voice. One aspect of his shyness is revealed in an incident later adapted by Aldous Huxley and ascribed to a character in the novel *Point Counter Point* (1928). It occurred when his banker called on Cavendish to suggest the investment of a portion of his funds and was ungraciously told by Cavendish never to plague him again about the growing balance: "If it is any trouble to you, I will take it out of your hands!" Except at meetings of fellow scientists, he almost never appeared in public and was so pronounced a misogynist that he communicated with his housekeeper by daily notes and ordered all female domestics to keep out of his sight. Not only did he not marry, he apparently never formed a sympathetic attachment with any person outside of his family. The costume he usually wore consisted of a

Cavendish, drawing by William Alexander (1767–1816). In the British Museum.

faded, crumpled violet suit of an earlier time, with a high collar and frilled cuffs, and a three-cornered hat. Even among fellow scientists he was so taciturn as to lead Lord Brougham, who knew him, to remark that he

> probably uttered fewer words in the course of his life than any man who ever lived to fourscore years, not at all excepting the monks of La Trappe.

Cavendish's scientific intellect was of a calibre that appears rarely. For all that, he lacked popular acclaim. In part this lack was the result of his own disdain for public reputation, although he did accept such honours as being made Fellow of the Royal Society (1760) and being elected one of the eight foreign associates of the Institut de France (1803). Though he did write for publication, beginning with a three-part paper on the preparation of various gases in 1766, he also completed many researches without publishing the details and sometimes baffled contemporaries by using the results of his own unpublished work in papers describing subsequent work.

Experiments with gases

Experiments on gases form the bulk of his chemical researches. In addition to being among the first to recognize hydrogen, which he called inflammable air, as a separate substance, and performing ingenious experiments with carbon dioxide, then called fixed air, he noted that a small residue remained when air was decomposed into oxygen and nitrogen; this finding was crucial in the discovery of argon and other inert gases more than a century later. He also made other contributions to chemical theory and anticipated later scientists in unpublished experiments with arsenic acid.

Cavendish's experiments on air, described in 1784–85, led to the discovery that water is not an element but a compound and to the discovery of nitric acid. Joseph Priestley, an English scientist, had noted that when a mixture of hydrogen and air is exploded by means of an electric spark—a method that had been proposed a few years before—the walls of the vessel are covered with moisture, a fact that Priestley disregarded. By a careful repetition of Priestley's experiment, Cavendish concluded that this moisture was mainly water. An analogous conclusion was reached at about the same time by James Watt, the Scottish engineer, and communicated to Priestley and to the Royal Society. The great controversy that ensued over priority of discovery was complicated by the fact that authors of papers, and editors, too, had the right to interpolate additions between the reading of the paper and its publication, and that during this particular interval the Royal Society elected a new secretary who had previously assisted Cavendish in some of his experiments. Much of the earliest biography of Cavendish by George Wilson (1851) is taken up with this controversy over who had discovered the fact that when hydrogen burned in air, water was formed. The principals themselves resolved their differences amicably after Watt was made Fellow of the Royal Society in 1785.

The electrical researches of Cavendish were equally remarkable and, had they been published, would alone have brought him fame. Cavendish discovered for himself that the force between a pair of electrical charges is inverse to the square of the distance between them, a basic law of electrostatics subsequently established by a French physicist, C.A. Coulomb, and known by his name as Coulomb's law. Cavendish anticipated Michael Faraday in demonstrating that the capacity of a condenser depends on the substance inserted between its plates. He freely used the concept of potential (then called degree of electrification, from the practice of measuring it by noting the angle formed between the two gold leaves of an electrometer when they become charged and repel one another), well known in mathematics but not previously used in connection with electrical experiments, in developing the idea that all points on the surface of a good conductor are at the same potential with respect to a common reference, the earth. This concept, first made explicit by Cavendish, was of paramount importance for the further development of electrical theory. Finally, in a series of experiments on various conductors, he discovered that the potential across them was directly proportional to the current through them, thus anticipating the law enunciated by George Simon Ohm, a German physicist, in 1827. The last finding was the more remarkable since Cavendish had no means of measuring current and managed only by turning his own body into a meter, estimating the strength of the current by grasping the ends of the electrodes with his hands and noting whether he could feel the shock in his fingers, up to his wrists, or all the way up to the elbows. All these researches were subsequently repeated, after the discovery of his notebooks and manuscripts over a century later, by the great Scottish mathematical physicist, James Clerk Maxwell, who devoted the last five years of his life to the task and published an annotated version of the electrical papers of Cavendish in 1879.

Cavendish's researches on heat likewise remained largely unpublished during his lifetime. They anticipated later work by a Scottish chemist, Joseph Black, and there is some evidence that Cavendish deliberately delayed publication of this work so as not to appear to be competing with Black.

Not all of his work was in pure science. He also interested himself in meteorology and other applied sciences. On one occasion, he served as member of a committee charged with the practical task of devising the best method of protecting a powder magazine at Purfleet from lightning; on another, he helped to investigate the physical properties of gold alloys, in response to the government's concern over the loss of gold in coins, owing to wear.

The Cavendish experiment

His last research, performed when he was nearly 70, was the very difficult and exacting job, known as the Cavendish experiment, of deducing the density of the earth from measurements made by means of an intricate apparatus involving a highly sensitive torsional balance—a horizontal rod suspended from its center by a thin wire or fibre that resists a twist. A British physicist, John Henry Poynting, who later developed an analogous method employing a common balance, said in his book *The Earth* (1913) that Cavendish made his experiment "in a manner so admirable that it marks the beginning of a new era in the measurement of small forces."

An English physicist and physiologist, Thomas Young, in the *Supplement to the Encyclopædia Britannica* (1815–24), said that Cavendish, after his election to the Royal Society in 1760,

continued for almost fifty years to contribute to the *Philosophical Transactions* some of the most interesting and important papers that have ever appeared in that collection, expressed in language which affords a model of concise simplicity and unaffected modesty, and exhibiting a precision of experimental demonstration commensurate to the judicious selection of the methods of research and to the accuracy of the argumentative induction; and which have been considered by some of the most enlightened historians, as having been no less instrumental in promoting the further progress of chemical discovery, by banishing the vague manner of observing and reasoning that had too long prevailed, than by immediately extending the bounds of human knowledge with respect to the very important facts which are first made public in these communications . . . . Such were the diversified labours of a philosopher, who possessed a clearness of comprehension and an acuteness of reasoning which had been the lot of very few of his predecessors since the days of Newton.

Cavendish died in his 78th year after what was very likely his first illness and was buried in what is now Derby Cathedral, England. He left his considerable fortune to his relatives, most of it to Lord George Cavendish, the son of his first cousin. He left nothing to science, an omission that the Cavendish family repaired in 1871 by endowing the Cavendish Laboratory in Cambridge University where, under a succession of brilliant directors, much of the development of modern physics took place.

BIBLIOGRAPHY. A *Life* by GEORGE WILSON was published in 1851. The previously unpublished *Electrical Researches*, edited and partially repeated by J.C. MAXWELL, came out in 1879. In 1921, a two-volume edition of previously published papers, together with some of the unpublished experiments, appeared as *The Scientific Papers of the Honourable Henry Cavendish, F.R.S.;* vol. 1 (rev. by SIR JOSEPH LARMOR), contains the electrical researches, and vol. 2 (ed. by SIR THOMAS EDWARD THORPE, with additions by CHARLES CHREE and others), the chemical and dynamical work. More recent biographies include: W.R. AYKROYD, *Three Philosophers* (1935); and A.J. BERRY, *Henry Cavendish: His Life and Scientific Work* (1960).

Among articles dealing with specific aspects of the work of Cavendish are: C. SUSSKIND, "Henry Cavendish, Electrician," *J. Franklin Inst.*, 249:181–188 (1950), which emphasizes his contributions to electrical theory; and R. MCCORMMACH, "Henry Cavendish: A Study of Rational Empiricism in Eighteenth-Century Natural Philosophy," *Isis*, 60:243–306 (1969), which traces his descent from Newton. This theme is elaborated in the same author's entry on Cavendish in *Dictionary of Scientific Biography*, vol. 3 (1971), which also contains an extensive bibliography of original and secondary works.

(Ch.S.)

Caves and Cave Systems

Definitions

Caves are natural cavities in the ground, including all subterranean voids except mines and tunnels fashioned by man. According to this definition, small cavities in rocks buried deep in the earth, natural conduits filled with water, and shallow rock overhangs commonly described as grottos or rockshelters also are caves. Although the term cave is sometimes restricted to air-filled, subterranean galleries and chambers penetrating to total darkness and passable to man, it is used in the broad sense in this article. The related word cavern is commonly used in the plural interchangeably with cave, as in Carlsbad Caverns, New Mexico. A cavern is a chamber-like, underground cavity; hence a cave composed of a number of chambers is properly described as a series of caverns.

Likewise, a cave system can be an assemblage of caverns interconnected by smaller passageways. Although sometimes applied to a cluster of neighbouring caves, whether connected or not, some form of channel-like communication is required during their evolution to permit at least water or air to interchange; this justifies their union as a system. One cannot pass underground among all of the caves comprising the nearly 250 kilometres of explored passageway underlying Mammoth Cave National Park, Kentucky, yet at some time they have been hydraulically interconnected and share a common origin as the Mammoth Cave system.

The study of caves and cave systems is called speleology. Like oceanography, it is the science of an environment, involving a variety of disciplines applied specifically to the explanation of subterranean phenomena. Branches of speleology include cave geology, cave hydrology, cave anthropology, and cave biology, or biospeleology. In addition, the study of karst, landscape resulting from solution processes underground, is an important facet of speleological research.

Though some solution caves have been accidentally opened through mining, most known caves possess natural entrances (Figure 1). These range in size from narrow squeeze-ways to broad gaping holes like the entrance to Carlsbad Caverns. Entranceways may extend horizontally or gently descend (even ascend) toward the interior; others are vertical chasms attaining depths of several hundred metres, demanding mountaineering equipment for descent. Cave interiors can be as varied

as their portals. In some, long horizontal galleries on different levels are interconnected by vertical pits, and huge chambers are separated by long, tight crawlways, admitting only the most persevering explorers. Lower regions of caves commonly contain streams, waterfalls, and lakes, enabling cave proprietors to provide boat trips for their visitors. Scuba divers have discovered unforeseen galleries of cave systems by diving beneath underwater barriers in cave lakes. Mirrored in the cave waters and decorating most of the largest limestone caves is a variety of cave deposits that transform otherwise bare rock walls and mud banks into enchanting stone forests of stalactites, stalagmites, and crystals.

Distribution of caves

Caves of one kind or another can be found in most countries of the world (Figure 2). Solution caves, penetrating deep underground and richly decorated with carbonate deposits, are the best known and can be found in most areas underlain by rocks soluble in natural waters. These rocks include limestone, marble, dolomite, gypsum, and salt. Limestones in the Ozark and Appalachian mountains of the United States are literally riddled with caves, many of which have been developed into showplaces for visitors. In desert areas of the southwestern United States one finds caves dissolved during former wet climates, whereas beneath the glaciers and snowfields of the Canadian Rockies, caves are just beginning to form from the meltwater.

Europe is famed for its highly ornate solution caves that range from Belgium, France, and Spain eastward through the Alps to the Karst of Yugoslavia, where cave formation has occurred on a grand scale. Many European caves have yielded priceless remains of early man and anthropoids, as have cave sites in southern Africa. Caves in rock salt occur in Bulgaria and the U.S.S.R., whose steppes and mountains contain gypsum and limestone caves as well. Solution caves are plentiful in southern China, Southeast Asia, and the larger islands of the southwest Pacific including Australia and New Zealand. Even Antarctica is represented by crevasses and ice caverns deep beneath its glaciers.

Volcanic caves accompany lava fields around the world. Their distribution correlates with areas of present and former volcanism, notably the circum-Pacific volcanic belt linking the Andes, western North America, and Alaska with the volcanoes of Japan and the South Seas.

Theories of cave origin

Speleology is one of the youngest sciences. The exploration of caves gained little headway until the 18th century because of superstitions which were defied only occasionally by ambitious miners in quest of ore.

Early writers on cave origin attributed the unexplored abysses to earthquake and volcanism. During the Age of Enlightenment, about the mid-18th century, scholarly curiosity stimulated the excavations of European caverns for their fossil remains; with it came an appreciation for the role of underground water in forming voids in limestone and depositing carbonates. At first, underground streams were believed to carve their tunnels by mechanical erosion. Even within the present century, some authors attributed vaulted chambers and cylindrical tunnels to mechanical corrasion by powerful eddies of torrential water. The important role of solution, however, became accepted gradually. Controversy then reigned over the manner in which it acted. Scholars studying alpine caves containing high gradient streams tended to view all caves as the product of descending underground rivers. Those working in the lowlands and in integrated cave systems, however, witnessed solution acting within a continuous underground reservoir, whose upper boundary they called the karst water table. Some confined solution to a zone just below this level; others, basing their argument on the discovery of cavities at depth in mines and drill holes, felt that circulating ground water generated caverns at considerable depth. There is, no doubt, some truth in all the theories, depending on the geologic setting and stage of development of a particular cave. A truly comprehensive theory of cave origin in soluble rocks must at least explain the several lines of evidence. This will be later discussed under the heading *Origin of caves and cave systems.*

Caves have made a major contribution to the welfare of man in the form of shelter. The greater part of our present knowledge of man's origins has come from artifacts and skeletal material found within caves. Discoveries of remains in the Sterkfontein and other African caves suggest that man originated on that continent. More highly developed species appear in caves in China. Neanderthal man, an early type, was first discovered in a German cave and since has turned up in many other European sites. Cro-Magnon man, succeeding *Homo neandertalensis*, left as his memorial some remarkable paintings depicting man and contemporary animals. These occur in sites such as the caves of Altamira, Spain, and Lascaux, France. Since Paleolithic time, man has continued to utilize caves as temples, fortresses, and sanctuaries as well as shelter. No remains of such antiquity have been found in American caves, but evidence of the presence of early man is accumulating. Sandia Cave, New Mexico, Danger Cave, Utah, and caves in Oregon and Nevada contain remains

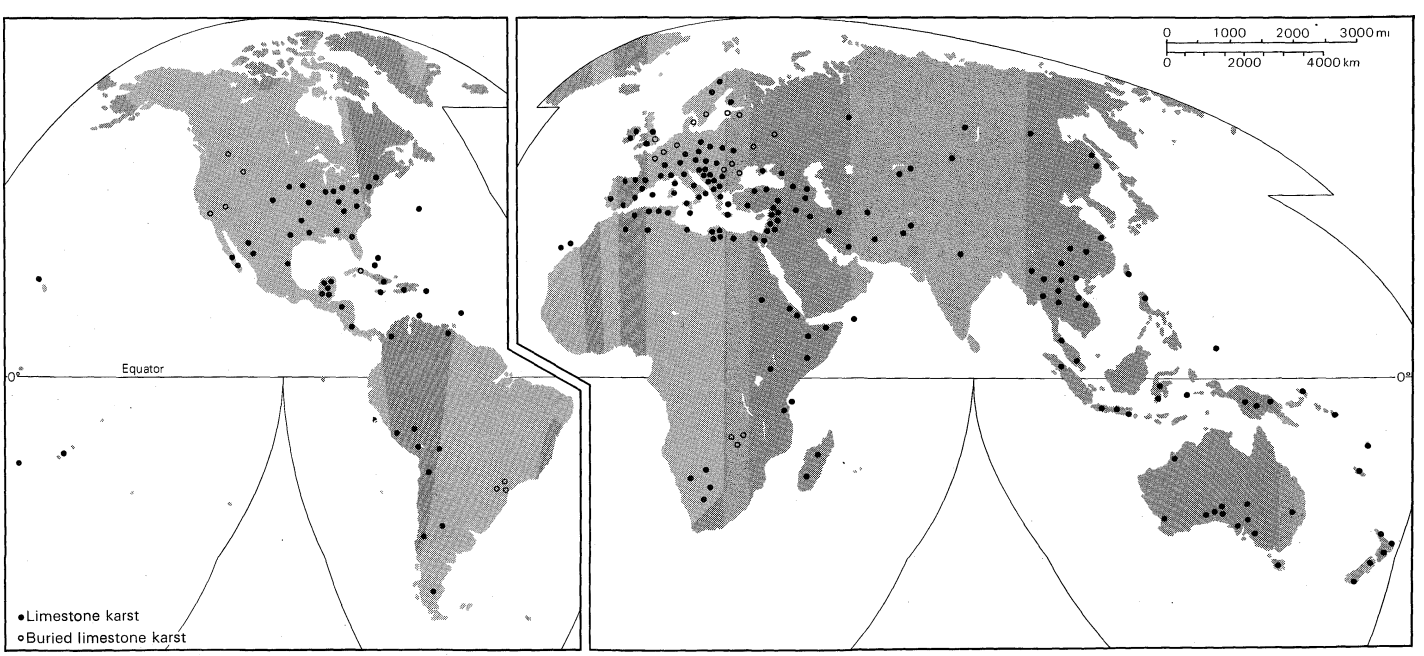

Figure 2: World distribution of exposed and buried limestone karsts.

and artifacts that extend the presence of man beyond 10,000 years in North America.

Caves play an important role in man's present-day environment but in ways other than the providing of shelter. Much of the world's surface is underlain by caves and solution conduits that divert runoff into underground streams. In most of these areas, underground water is scarce except where wells intercept these channels or where springs discharge. The questions of where to drill for water in karst terrain and how to prevent contamination of underground streams undergoing little or no filtration demand an understanding of the origin of caves and karst drainage. Subsidence and collapse of structures and roads, as well as leakage and failure of reservoirs built on soluble terrain, compound the problem.

Life in caves

Caves have been more influential on the development of animals than they have on man. The deep interiors of caves provide an environment of total darkness and relatively constant climate, to which many forms of animal life, as well as plants and micro-organisms, have adapted. Species have evolved that lack eyes and pigment in adulthood, properties not needed for survival underground. The European cave salamander, *Proteus anguinus,* and the cave fish *Amblyopsis spelaea,* from Mammoth Cave, Kentucky, are the best known troglobites or cave dwellers. Many other cave-adapted creatures are represented among the spiders, insects, and lower orders.

Although no mammal species spend their entire lives underground, many do nest, hibernate, or roost in the protective, constant cave environment. Some mice, wood rats, and particularly bats spend much of their lives underground. The many puzzling questions that arise concerning the evolution of cave life, its ecology, and habits comprise the subject matter of the biospeleologist. Several caves have been equipped to serve him as natural laboratories for the observation and investigation of cave life, among them the Laboratoire Souterraine de Moulis, at Moulis, France, and the Ozark Underground Laboratory, near Branson, Missouri.

ORIGIN OF CAVES AND CAVE SYSTEMS

Caves originate in a variety of ways, which fall conveniently into two major groups, depending on their relationship in time with the host rock. Primary caves form during the time when the host rock is being laid down or solidifying. The cavities in lava that result from the cooling of magma around pockets of gases are an example. Secondary caves develop after consolidation of the host rock—in some cases, after the passage of several geologic periods. Limestone solution caves and sandstone rock shelters are the commonest examples.

In much the same way that soft ground beneath a carelessly engineered road can result in cracks and chuckholes, so the primary cavities and caves carried over into later geologic times become the setting for fracturing and secondary cave making. At least some caves can therefore be formed by the compounding of primary and secondary cave mechanisms.

Lava caves

Primary caves. Several kinds of caves are known to form during the cooling of lava discharged from volcanic vents. Most spectacular are lava tubes. These are more or less cylindrical tunnels that extend along the path of flow of a lava field. They usually are entered by means of a hole in the ceiling resulting from collapse or erosion. Their roofs are, as a rule, only a few metres in thickness. Inside the larger tubes one might walk several hundred metres in either direction along a rather uniform floor of ropy lava containing flow patterns frozen in place at the time of cooling of the lava. In places, the stream of molten rock enveloped fallen ceiling blocks that remain protruding from the floor like boulders in a flood. The nearly uniform, almost monotonous cross section of the tunnel may be interrupted by cones of talus made up of rock fallen from the ceiling after solidification. Where collapse has broken through to the surface, one may have to climb outside and re-enter beyond the blockage in order to proceed. Tubes not blocked by collapse terminate in a pinch-out, where ceiling and floor meet.

Although most lava tubes consist of a single, unbranching tunnel, some, like Catacombs Cave in Lava Beds National Monument, California, divide at intervals to form interlacing side passages that either end in rockfall or rejoin the main channel. Nearby Crystal Cave contains several levels, representing cave making in successive lava flows, one atop the other, and at different times. Breakthrough of their roofs permits one to pass vertically among them.

Lava tubes are conventionally explained as the result of cooling and solidification of the surface of a lava flow, accompanied by the draining of the still molten interior to leave the characteristic cylindrical void. The solidified lava streams that form the floors of most lava tubes demonstrate that such draining did indeed occur as the magma cooled. Hot gasses, however, also played an important role in providing the pressure necessary to sustain the ceiling as it solidified. Evidence of these fluid pressures is seen in the high domed ceilings of some caves; where their pressure exceeded the competence of the roof, the gases broke forth to the outside, forming crater-like vents (see also IGNEOUS ROCKS, EXTRUSIVE; VOLCANOES).

Lava tubes are embellished by a variety of dripping and flowing lava structures, notably stalactite-like lava pendants resulting from drippage of the cooling ceiling or remelting by hot gasses. In lava tubes in temperate and cold regions, ice accumulates from the settling of cold air and evaporation, producing "skating rink" floors, overhung with a translucent decor of icicles, and ice crystals and draperies. Coloration of the rock by mineral stains contribute to the beauty and interest of many lava tubes.

Lava tube systems occur throughout the lava fields of northwestern United States and in almost all lava flows around the world that have not suffered excessive erosion. The longest known is Cueva de los Verdes (6.1 kilometres) on the Canary Islands. Iceland, Japan, Mexico, Kenya, and Hawaii all contain noteworthy examples of lava tubes.

Coral and tufa caves

With the progressive expanding and uniting of colonies of coral in shallow, warm waters, submarine voids remain between the lacy or bulbous walls of the living reef. Where shorelines have risen or sea level fallen, these coral caves have been exposed to wave action and surface weathering, both of which tend to enlarge or obliterate the voids and their features. Where reefs have been deeply buried by later sediments, the cavernous reef rock has formed reservoirs of ground-water and petroleum that are prime targets for exploration drilling.

Where surface streams heavily charged with calcium bicarbonate are exposed to a warm, arid, or tropical environment, calcium carbonate can be deposited rapidly, along with suspended matter, in a form called tufa or travertine. The process is aided by aeration in spray, facilitating evaporation and the release of carbon dioxide. Plant life, especially mosses, aid evaporation and supply a ready matrix for deposition. As tufa-laden streams plunge over cliffs and canyon walls, umbrellalike canopies build outward from the spray. These enclose small caves in terraces of alcoves, as in Mooney Falls of Havasu Creek, Arizona. Tufa canopies built out from springs in canyon walls can completely bridge the river below, forming natural tunnels. Among the largest of these are Tonto Natural Bridge, near Payson, Arizona, and that of the Gokteik Gorge, Burma.

Smaller constructional caves are sometimes found around hot spring deposits and the shorelines of lakes in arid regions where tufa is deposited from wave spray.

Secondary caves of mechanical origin. The majority of caves form after deposition or consolidation of their rock medium. They are the result of mechanical and chemical processes, usually a combination of both. One or the other may predominate, however, thus permitting caves to be classified in this manner.

Fissures in rock are produced by tectonic disturbances, such as earthquakes, intrusions, and rock folding at depth, and also by surface disturbances, namely local subsidence, rock creep, and shearing by moving ice of

glaciers. Some fissures remain empty and dry to considerable depths, others fill with ice and snow, and still others carry streams that eventually may erode them into gorges.

Where the walls of open fissures converge or overhang, they form, in effect, caves. Great vertical cracks in limestone and sandstone beds of the Colorado Plateau at Wupatki National Monument, Arizona, have been explored to a depth of 200 metres, deep beyond the reach of daylight. Similar fissure caves occurring in deep gorges form parts of Ausable Chasm, New York, and the Canyon of Olhadibie in the French Pyrenees.

Landslides sometimes roof vertical fissures with boulders, as in Pinnacles National Monument, California. In colder regions such roofs are frequently composed of snow and ice; and in glaciers, treacherous crevasses walled entirely by ice result from shear within the moving ice mass. Finally, caves occur between the blocks of talus or boulders dumped by glaciers or landslides commonly along the base of high cliffs. The Indian Caves of Yosemite National Park, California, are an example.

Shoreline and water-worn caves

The mechanical action of water along the shores of streams, lakes, and oceans plays a major role in the generation of strandline caves. Sea caves or marine grottoes form where a sea cliff, either containing incompetent rock at tide level or weakened by fracturing, is exposed to wave action. Quarrying takes place through grinding by contained particles that range from sand to boulders (corrasion) and by hydrodynamic pressure changes within the waves that pry cliff blocks loose (see also WATER WAVES; COASTAL FEATURES).

Chemical processes and the boring of organisms also aid in excavating sea caves. Some found high above sea level contain marine shells, which indicates that the land has risen relative to sea level. On the other hand, some marine grottoes contain underwater stalactites; these features that form in air-filled caves provide evidence that the shoreline has been submerged.

Sea caves are found along most of the world's more rugged coastlines. Most famous are the Blue Grotto on Capri, Italy, and Fingal's Cave on the Island of Staffa, the Hebrides, both in basalt; and La Jolla sea caves near San Diego, California, in marine shale and sandstone.

Caves also form by wave action along the shoreline cliffs of inland seas and lakes. These lacustrine caves have been utilized by man throughout his development as fishing camps and shelter. Their floor deposits contain valuable clues to man's history and origins, including the famed Dead Sea Scrolls, discovered in a cave along an elevated shoreline in Jordan.

Streams and rivers also are effective in quarrying caves in their banks, using as tools the contained silt, sand, and gravel, particularly during flood stages. Gigantic meander cuts, such as Redwall Cavern in Marble Gorge of the Colorado River and the massive sandstone alcoves in which Pueblo Indians erected their famed cliff dwellings, were formed mainly in this way. Rainbow Bridge, in southeastern Utah, resulted when such a meander cut completely through a spur in the canyon wall. Small caves also are generated in riverbeds and banks in the form of circular potholes. Caves also form beneath the ice of glaciers in ways similar to those of streams.

Weathering cavities and ice caves

Innumerable honeycomb-like cavities, small caves, and rock-shelters result from exposure of rock faces to the elements. Weak zones in the rock are attacked and excavated by rain, wind-driven sand, and alternating freezing and thawing, hydration and drying. Spring sapping by water seeping through cracks aids in the quarrying process as do plants growing from the rock or tree roots wedging apart its blocks. Although weathering cavities form in all kinds of rock, they are particularly prevalent in sandstone terrain, where expansive, picturesque alcoves decorate cliffs and prominences, providing dwelling sites, fortresses, and settings for temples.

Where weathering (*q.v.*) attacks two sides of a narrow ridge, a breakthrough joins the two cavities, leaving a rock window or natural arch. Arches National Park, Utah, is famed for its variety of sandstone arches.

Although ice is regarded as a rock by geologists, caves formed therein result more from melting than from mechanical processes. Glacier crevasses that result from fracture are an exception. Meltwater flowing beneath glaciers sculptures intricate labyrinths within and along the base of the ice. Similarly, in snowfields streams and wind currents create translucent blue-tinted tunnels whose scalloped semicircular walls become glazed with ice.

Secondary caves formed by solution. The most extensive and best known caves and cave systems of the world principally result from chemical dissolution of a soluble, weakened host rock (Figure 3). These include the vast underground showplaces like Carlsbad Caverns and Mammoth Cave, which are renowned for their ornamentation and magnitude. The solution process that creates these great voids is highly complex in detail but elementary in principle. Just as a block of rock salt will dissolve away along its faces when subjected to rainfall, all rocks dissolve in certain natural acids. They dissolve not only on their exposed outer surfaces but also on their interiors, where fractures and partings permit solvent to circulate. Rocks other than salt that are particularly soluble in natural solvents are limestone, dolomite, gypsum, and anhydrite. Caves formed in these media, although preconditioned by fracturing and abetted by weathering and mechanical erosion, enlarge predominantly by chemical solution.

The formation of caves can be illustrated by the solution of limestone host rock, composed mainly of calcium carbonate ($CaCO_3$). In naturally occurring carbonic acid (H_2CO_3), made up of carbon dioxide and water, the following equilibrium condition will prevail:

$$H_2CO_3 \rightleftharpoons H_2O + CO_2.$$

The water and carbonic acid dissociate to form acids, and the bicarbonate ion also dissociates according to:

$$H_2O \rightleftharpoons H^+ + OH^-,\ H_2CO_3 \rightleftharpoons H^+ + HCO_3^-,$$
$$HCO_3^- \rightleftharpoons H^+ + CO_3^{=}.$$

The released acid reacts with the limestone, which dissociates as follows:

$$CaCO_3 \rightleftharpoons Ca^{++} + CO_3.$$

These ions in equilibrium with the other ions yield calcium bicarbonate in solution, effectively giving the result:

$$CaCO_3 + CO_2 + H_2O \rightleftharpoons Ca(HCO_3)_2.$$

The forward reaction summarizes the dissolution of limestone; the reverse, the precipitation of calcium carbonate, usually in the mineral form calcite, from which many varieties of speleothems or cave deposits are constructed.

Natural waters not in dynamic equilibrium according to the above ionic equations can dissolve limestone and create a cave. The rates of reaction and solubility are dependent on temperature, pressure, concentration of added salts, pH, and total carbon dioxide in solution. In general, the less saturated the water and the more frequently it exchanges, the more rapidly solution proceeds. Thus, a swiftly moving fluid, particularly if accompanied by turbulence, permits rapid washing of limestone walls with fresh solvent.

Calcium carbonate is only slightly soluble in pure water, but where the water contains carbon dioxide, the resulting calcium bicarbonate can attain concentrations up to 1,600 parts per million (ppm), depending on the partial pressure of the carbon dioxide (CO_2). Along the ground surface, water in equilibrium with carbon dioxide dissolves only small amounts of calcium carbonate (63 ppm measured), but within air trapped in soil, amounts up to 400 ppm have been recorded. Thus, water trickling through soil tends to dissolve an underlying limestone mass quite readily. If descending waters penetrate the cracks of limestone to emerge into an air-filled chamber, a new environment of temperature and partial pressure affects the constitution of the fluid. If the partial pressure of CO_2 within the chamber is less than that in the cracks and soil, then CO_2 is released from the water. If saturation results from this release, calcium carbonate precipitates, giving rise to stalactites, draperies, or other speleo-

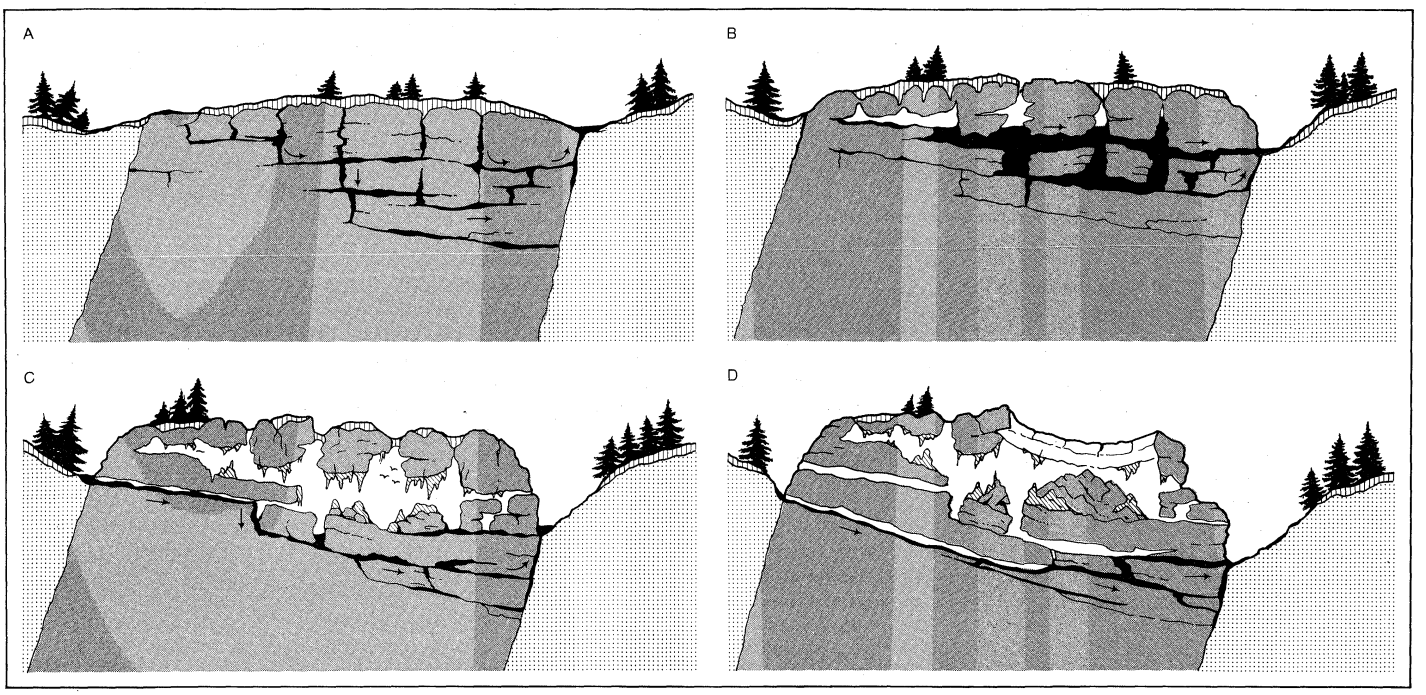

Figure 3: *Evolution of a limestone cave system.*
(A) Fracture pattern conducts surface drainage toward discharge in a subriver spring along contact with nonsoluble terrain. (B) Low resistance paths enlarge by solution into trunk channels causing water levels to fall and sinkholes to form on the surface. (C) Deepening stream on the right drains upper portions of cave, inducing local collapse, while carbonate deposits form from trickling water; surface stream on the left has been pirated to the underground system. (D) Surface erosion and stoping from below result in extensive collapse of the cave roof, while solution continues along deeper fracture paths.

thems. Furthermore, under ambient, above-freezing conditions, an increase in temperature lowers the CO_2 concentration of water; therefore, trickling winter drainage entering a warm underground chamber may release CO_2, tending to deposit calcite. Reversal of these conditions may redissolve calcite deposited during the previous winter or during an earlier climatic episode. This will leave a characteristic lacework of corroded speleothems; eventually these may be obliterated completely.

As solvent waters penetrate underground, partially or totally filling cave conduits, they become increasingly concentrated unless diluted by tributary sources along the way. In many cave systems, underground streams discharge as springs long before saturation is attained; in others they become fully saturated, to the point of depositing calcite along the channel walls, just as scale forms in metal pipes. With dilution by an incoming, less saturated stream, increased solution can take place downstream from the juncture. Paradoxically, the mingling of two or more saturated streams can result in an undersaturated mixture capable of further solution under certain conditions. This recently discovered phenomenon is called mixture-solution and is believed to be a possible explanation of cavern generation beyond the penetration distance or limit of undersaturation of a single cave stream.

Other naturally occurring acids, such as sulfuric and organic acids, also attack limestone; and corresponding equilibrium equations can be written for their reactions. Dolomite, $CaMg(CO_3)_2$, behaves similarly to limestone. Gypsum ($CaSO_4 \cdot 2H_2O$) often derives from the hydration of anhydrite ($CaSO_4$), a mineral deposited in shallow saturated seas and lakes. Anhydrite expands in contact with water so that its alteration to more soluble gypsum is accompanied by fracturing that facilitates attack by ground water. Gypsum is much more soluble in natural waters than is limestone, hence gypsum caves form rather rapidly. Other evaporites, especially rock salt (NaCl) are still more soluble, so that caves evolve rapidly in salt beds, but these have a relatively short life span because surficial erosion proceeds at a commensurate rate.

The role of fracturing

In granular rocks such as sandstone, surface runoff from precipitation trickles downward through the rock pores until it meets the zone of saturation, namely, a more or less continuous reservoir of groundwater whose upper boundary is commonly called the water table. Within this reservoir, groundwater (*q.v.*) migrates through the pores as a unified body. In dense limestones, on the other hand, the bulk of the underground water movement takes place through rock partings and openings; only a relatively small amount of water moves through the pores. With localization of flow along fractures, these partings then enlarge by solution to accommodate additional fluid. The fracture patterns of the host rock, therefore, become the scaffold along which a developing cave system grows.

Two kinds of fractures are important in cave making: joints, along which no slippage has occurred; and faults, whose walls have moved parallel to one another. Faults accompanied by considerable open fracturing and brecciation (crushing of rock) form highly permeable zones for the passage of dissolving waters. Hence, they are responsible for some of the largest cave systems.

Surface drainage and groundwater

Most limestone cave systems are dissolved by meteoric waters draining downward and laterally away from a collecting area of the ground surface toward springs and discharge zones in valleys or beneath the sea. Surface water penetrates underground through fractures in outcrops or soil-covered limestone, conducting it vertically downward, dissolving and enlarging the feeder cracks along the way. Surface runoff thus has little chance to flow along the ground and collect as streams that normally would carve surface drainage paths along the topographic gradient, as on sandstone and other nonsoluble terrains. In limestone, the "valleys" instead are vertical and represent the initial stage in the development of a typical solution landscape called karst.

Drainage cannot continue, however, to proceed downward unless it encounters a through path to a discharge point. If permeability permits, the waters will find a route to a discharge zone at lower elevation in a valley or perhaps on the sea floor. Because the solution rate increases with gap width, tight fractures are not more likely to pass

water and enlarge than is the rock itself. Thus, solution channels must originate along at least partially open fractures or along openings already present in the rock, such as primary caves formed in earlier geologic time. If the network is short and relatively open, dissolving may continue throughout; otherwise, initial solution may be confined to the upper supply zone of undersaturated water or to the discharge zone of higher velocity flow. In time these zones may enlarge and unite. Meanwhile, the geometry of the primitive solution network is determined by the fracture path and geologic structure.

With the widening of interstices, accompanied by accelerated solution, the pattern of underground water movement alters, channelling flow along the lower resistance paths of shorter conduits with larger diameters. These develop into underground drainage trunks at the expense of the longer, tighter routes. So long as recharge and discharge keep pace, the connecting system remains water filled. If blockage of the discharge route occurs, the entire system up to the surface can be impounded, spilling over across the collecting surface and clogging its lower paths with sediments. If, on the other hand, discharge gains over recharge, upper portions of the system fill with air, permitting the formation of a chain of underground lakes that become standpipes of the system, with perhaps interconnecting free-flowing streams and waterfalls. With progressive enlargement of feeder channels, collapse, or surface erosion, portals may develop that make the partially drained cave accessible to man.

In general, continuous faults give rise to long, linear solution passages, as typified by New River Cave, Virginia. The extent of passage ramification, in these cases, depends on the degree of subsidiary fracturing accompanying the fault. In contrast, joint sets that parallel the axis of an anticline or arched fold enlarge along with associated bedding plane faults to construct a reticulated maze of cavern passages of which the elaborate labyrinth of Anvil Cave, Georgia, is a classic example. Most caves, however, form along less regular patterns of faults and joints, expressing the diversity of geologic events that preceded cave making.

In regions of high relief, the steep hydraulic gradient between uplands and canyon discharge points favours solution along steeply inclined fractures, producing cave systems made up of vertical fissures, pits, and underground canyons. In gentler terrain, horizontal lineaments provide the shortest paths to discharge points and, hence, favour formation of more or less horizontal cave passages related to valley levels.

A stream originating in upland, nonsoluble terrain is subject to diversion into underground channels where it crosses karst rock. Subterranean piracy (diversion) may conduct the stream only a short distance underground, to re-emerge at the downstream terminus of the limestone. In other cases it is known to abduct the stream away from its regular watershed, beneath surface divides, even passing beneath other valleys, to emerge as springs in neighbouring or distant drainage basins. The resurgences of such "lost rivers" are identified and correlated by means of radioactive and dye tracers committed to the water where it disappears from the surface. Many of the large springs of Missouri, Arkansas, and Arizona are believed to derive their water from karst sinks many kilometres distant.

THE EVOLUTION AND DEMISE OF CAVES AND CAVE SYSTEMS

The development of an open, air-filled cave from a system of fractures and primitive solution tubes has been described above as a more or less continuous process which involves progressive solution, enlargement, partial draining, and gradual lowering of water stands within the system. Mountain building, canyon cutting, and changes in climate, however, can dramatically alter the course of events underground. If, for example, a limestone block containing a solution network is uplifted, canyons on the surface become incised, valleys are deepened, and underlying fractures are exposed and become new routes for draining of the cave waters. The previously submerged cave thus will be left hanging high and dry in the canyon walls. Rapid dissection by the Colorado River and its tributaries in Grand Canyon, induced by uplift of the surrounding plateau, has drained numerous caverns and cave springs that discharge as waterfalls down the limestone cliffs. An episodic course of events brought on by uplift in that manner is called the two-cycle theory of cave development, as advanced by William M. Davis to illustrate the cave-making process. The theory has been augmented by J. Harlen Bretz, who describes the earlier, submerged phase of enlargement as phreatic and the subsequent air-filled phase as vadose.

Regional uplift

The two-cycle process may be likened to that of a valley reservoir or lake that is filling with sediment carried down by streams from the hills. Should uplift of the land cause headward erosion to the retaining dam, the lake could drain and its emptied basin undergo a new phase of stream dissection. Some cave systems undoubtedly experience just such a course of events; others, however, must be interpreted as the product of continuous subterranean processes through time. Solution, draining, and gravity stream flow, resulting in a chain of underground lakes that are connected by streams and filled tubes, with local water levels determined by intervening resistance paths, seem probable in many instances. Upper regions of such caves may be completely drained and dry, while the nether regions remain completely submerged.

The action of cave draining and opening can be reversed through either increased precipitation, subsidence of the host rock, or damming of valleys. Landslides, glacial moraines, and artificial dams can result in the flooding and silting of cave systems. Numerous caverns in the Tennessee Valley are no longer accessible since partly or totally submerged by man-made reservoirs.

Subaerial processes

Portions of a newly drained cave are subjected to a variety of subaerial processes that tend either to enlarge or to reduce the volume of the void. Flowing water, whether in the form of gentle rivulets collecting from ceiling drippage or large surface streams and storm water, corrades and dissolves the limestone walls and excavates or deposits sediments. Boulders and gravels dumped underground by subsiding torrents attest to the great volume of material carried through alpine caves during spring runoff and in times of glacial retreat. The Nakimu Caves of Glacier National Park, British Columbia, contain giant potholes scoured in the marble floors by rubble borne on glacial meltwater.

The deposition of calcite and related minerals in the form of subaerial speleothems commences with the draining of the cave, provided that water trickling downward is saturated when it encounters the cave air. Stalactites, stalagmites, draperies, flowstone, and many other familiar cave structures coat the rock walls and cave fill, in effect decreasing the volume of the void. Under conditions particularly favourable to deposition, passages can become completely blocked by barriers of calcite. The main tourist route of Cueva de Cacahuamilpa, Mexico, terminates in this way.

Rockfall and subsidence effect profound modification of cave form. Unstable ceiling blocks eventually give way, either through solution of their binding joints, earthquake, or through loss of buoyancy upon draining of the cave. Progressive stoping (material removal) in this manner can transform an originally flat ceiling into an arched vault whose ultimately stable shape coincides with the tension dome prescribed by stress patterns within the rock. The rubble accumulating beneath the vault forms huge mounds of talus that frequently block passages, divert subterranean streams, or bring about impounding. The 41-metre high Monument Mountain in Wyandotte Cave, Indiana, formed in this manner beneath an expanding vaulted ceiling. Most of the largest underground chambers, such as the Big Room in Carlsbad Caverns, New Mexico, exhibit vaulted ceilings and talus mounds brought about by ancient rockfall. Solution and flushing by streams aid in reducing the volume of debris that collects as a result of the breakdown process.

In caverns near the surface, underground material removal often breaks through the roof, which, in turn, produces a collapse sink or collapse doline that serves as a portal to the cave. Most large, near-surface caverns contain collapse openings of this sort. The underlying talus cones usually contain the remains of animals that have had the misfortune of accidentally plunging into the cave from the surface.

The walls of caverns can open in a different manner, with excavation proceeding from without. This occurs when streams cut laterally into their banks and intercept a cavern or sever cave passages as they deepen and extend their valleys. With further downcutting by the stream, cave portals are left perched in the walls, where they have served as the retreat and dwelling places of primitive man throughout his development.

The opening of caves to the atmosphere in these and other ways initiates the destruction of their passages through progressive collapse, weathering, and erosion. With denudation of the terrain and encroachment of valleys, additional portions of the cave galleries become revealed. Natural arches and tunnels stand for a while between collapse zones; in time, these too give way, leaving only a trench and perhaps fragments of speleothems to mark the site of the former cavern passage. These cave vestiges may become buried beneath later sediments to become "fossilized" in the geologic record

CAVE FEATURES

The dissolving of caves under submerged and subaerial conditions sculptures the rock walls with forms characteristic of solution and flow processes. Continuous and discrete structures forming in this way can be interpreted to determine the manner of origin of cave passages. Such excavated structures or forms are called speleogens and include ceiling and wall pockets, floor slots, and vertical shafts.

Features formed by solution. Uniform solution, wherein removal of rock proceeds equally at all points along its walls, is approximated in submerged portions of many caves where flow patterns are rather random. The future shapes of an initial structure, such as a block of limestone subjected to uniform solution (Figure 4), can be predicted through mathematical analysis and results in the following rule: successive cross sections of the rock are described by the paths of a hypothetical circle rolled inside the rock but kept in contact with the outline of the structure. The interior envelope described by the rolling circle (in three dimensions, a sphere) represents the rock boundary at some future time determined by the radius of the circle. Thus a planar wall retreats parallel to itself. Two walls making a projecting angular corner retreat parallel to themselves, preserving the sharp corner. The inside corner, on the other hand, rounds, because the imagined circle pivots at the apex, describing an arc. Filamentary tubes expand radially in concentric cross sections. The future sculpture of any irregular cave walls can be determined in this manner, as demonstrated by the hand specimen of marble shown in Figure 5, that was dissolved in a nearly uniform acid bath in the laboratory. In nature, the effects are borne out by the characteristic solution relief of irregular ceiling and wall pockets separated by cuspate ridges found in most formerly submerged caverns.

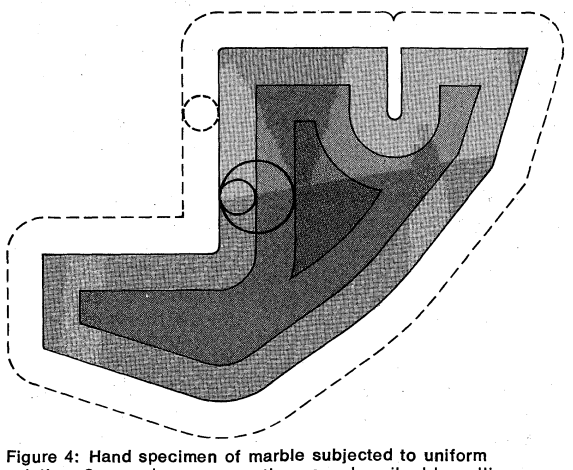

Figure 4: Hand specimen of marble subjected to uniform solution. Successive cross sections are described by rolling a circle along the outline from within. The outer dashed outline would result from uniform deposition around the specimen, as described by rolling the dashed circle around the outside.

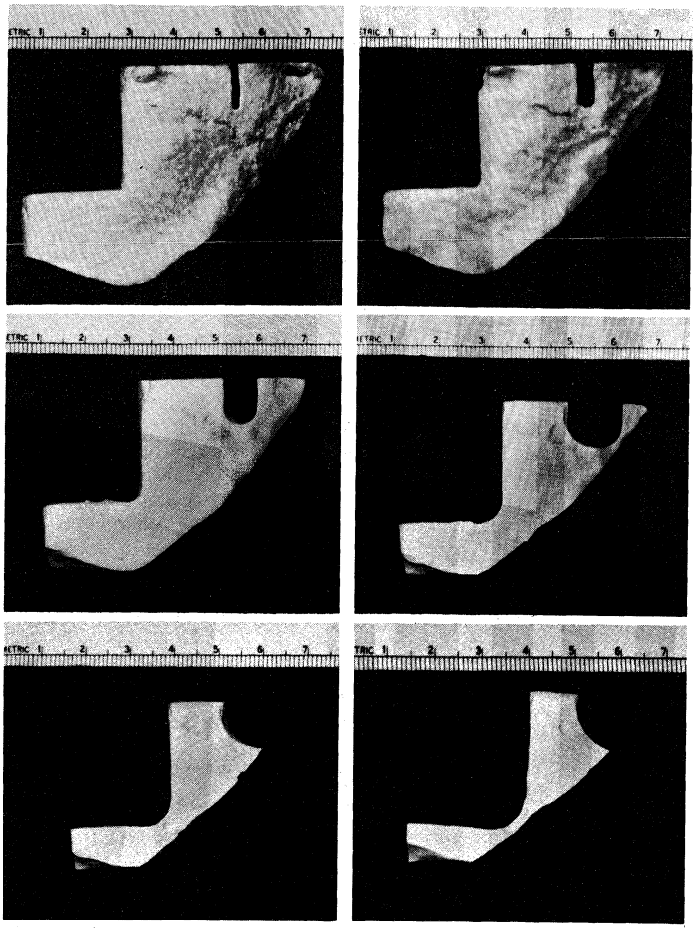

Figure 5: Successive stages of solution of a hand specimen of Yule marble dissolved in a weak nitric acid bath. Experiment demonstrates the preservation of projecting corners and the rounding of inside corners.
From G. Mowat, *Cave Notes*, vol. 4, no. 6 (1962)

Particular speleogens that indicate former episodes of submerged, uniform solution include dissolved fallen ceiling blocks whose projecting corners have been preserved, the rounded inside corners remaining in the ceiling, angular pillars resulting from the recession of vertical joint sets, and circular-cylindrical solution tubes formed radially from the line of intersection of two joints.

Other speleogens originate from conditions of nonuniform solution. A stepwise solution gradient consisting of uniform solution beneath a constant water level, above which dissolving has ceased, produces truncated ceilings called water-level planes, which usually can be related to a spillover point elsewhere in the cave. These features are extremely valuable in establishing former underground water levels. Unequal directional dissolving takes place where silting accompanies solution, because the veneer of sediments accumulating on positive slopes less than their critical angle of repose discourages further retreat of the underlying rock. The resulting planes of repose exhibit a constant slope and can be found at various heights. When they form in conjunction with water-level planes, continuous overhanging grooves ring cave chambers, indicating solution in a turbid cave lake.

Boxwork, scallops, and speleothems

Boxwork, as illustrated from Wind Cave, South Dakota, is composed of projecting fragile veins of minerals less soluble than the wall rock, proving that quiet solution with virtually no accompanying corrasion has taken place. Scallops, by way of contrast, are parabolic ripples dissolved in limestone walls from eddies in definite currents. Where they appear on ceilings, they show that the passage was once completely filled with water flowing in the direction indicated by their concave arcs. Free-surface streams incising both downward and laterally excavate slots in passage floors and meander niches in wall rock. Trickling and dripping water produces still other forms. The most spectacular of these are the vertical shafts corroded by water from overlying granular caprock, falling down vertical cracks into a lower drainage channel. Vertical shafts more than 100 metres in height are encountered in caves in eastern United States and Mexico, proving a great challenge to explorers. Excellent examples can be seen in the region called the Ruins of Karnak in Mammoth Cave, Kentucky.

The deposition of calcite and other cave minerals from aqueous solution builds forms that are characteristic of the underlying rock structures, flow patterns, chemistry, and deposition rate. The resulting structures are termed speleothems and comprise the feature attractions of many well-known caves. Speleothems can form under water as well as in air.

Features formed by deposition. Uniform deposition, analogous to uniform solution, takes place within pools of saturated water. Clusters of delicate dogtooth spar crystals and amorphous crusts of calcite and other minerals coat the walls in bulbous masses. The cross section of these crusts is described in a way similar to that of uniform solution; that is, by rolling a circle along the original wall, but in this case within the fluid, rather than the rock. The crust assumes the shape of the envelope of the moving circle, with the result that projecting sharp corners become rounded, whereas inside corners remain as sharp hollow cusps. Mammillary crusts formed in this way cover walls of some caves to a thickness of several metres.

Along the surfaces of pools, where carbon dioxide is released directly to the cave air, undersaturated water can locally saturate and deposit a crusted strand of calcite, ringing projections in patterns resembling lily pads. Where pools spill over, aeration aids deposition, and natural dams elevate themselves through the accretion of calcite. These are genetically akin to the rimstone dams of tufa that form in surface streams. In very quiet pools, fragile rafts of calcite, which resemble ice, and calcite "bubbles" float upon the surface.

Irregular knobby growths of calcite, appropriately named cave coral, form within cave pools, as well as in the air, where films of moisture deposit. Flowing films of water moving down positive-sloping walls, build up layers of flowstone, usually white or translucent but locally stained by minerals carried by the water. Films descending over-hanging walls and ceilings collect along the steepest gradients, irregular ridges, and prominences, from which they deposit outward and downward wavy curtains of calcite, often stained by colourful bands of mineral matter. These beautiful speleothems, called draperies, adorn numerous caves.

Stalactites and stalagmites

Water entering a cave chamber through ceiling cracks can deposit at its point of emergence when conditions favour deposition. A stalactite commences growing in this manner from a delicate film of calcite covering the hanging water drop. As it falls, the film is broken except along a ring of attachment. Subsequent drops build successive rings in the form of a cylinder resembling a soda straw, typically six millimetres in diameter, through which the descending water must pass. All true stalactites begin in this manner and contain a central canal. The falling drops splatter as they hit the floor, where a bulbous upward building mass, a stalagmite, forms from the spray and spilled water. Given sufficient time, the stalactite and stalagmite may meet to form a column. Changing conditions, however, can bring about blockage of the stalactite, or it may redissolve or shatter in an earthquake.

Stalactites can thicken radially either from water exuding outward through the walls of the tube or from the flowing of ceiling moisture down the outside. A conical or tapered stalactite, much more rigid than the original soda straw, results. The massive stalactites and columns typical of the Big Room in Carlsbad Caverns formed in the manner described, though over long periods of time and varieties of conditions.

Helictites resemble soda-straw stalactites because they are cylindrical and pass water through a central canal. They differ in that they grow from walls and floors, as well as ceilings, in winding, contorted patterns that seem to defy gravity. They are fed through small openings in the rock, but at so slow a rate that the drops evaporate at the tips of the structure rather than fall to the floor. The forces of surface tension and the crystal habit of calcite exceed that of gravity and determine a direction of growth substantially independent of the latter. Helictites of both aragonite and calcite decorate several well-known caves, notably Skyline Caverns, Virginia, and Caverns of Sonora, Texas.

Cave flowers grow from the base rather than the tip, exuding from the cave walls and curling back like squeezed toothpaste. Gypsum flowers up to 25 centimetres long can be seen in portions of Mammoth Cave.

Shields, sometimes called palettes, are believed to form from water seepage from cracks. Ridges of calcite are deposited on both walls of a crack, and these ridges grow

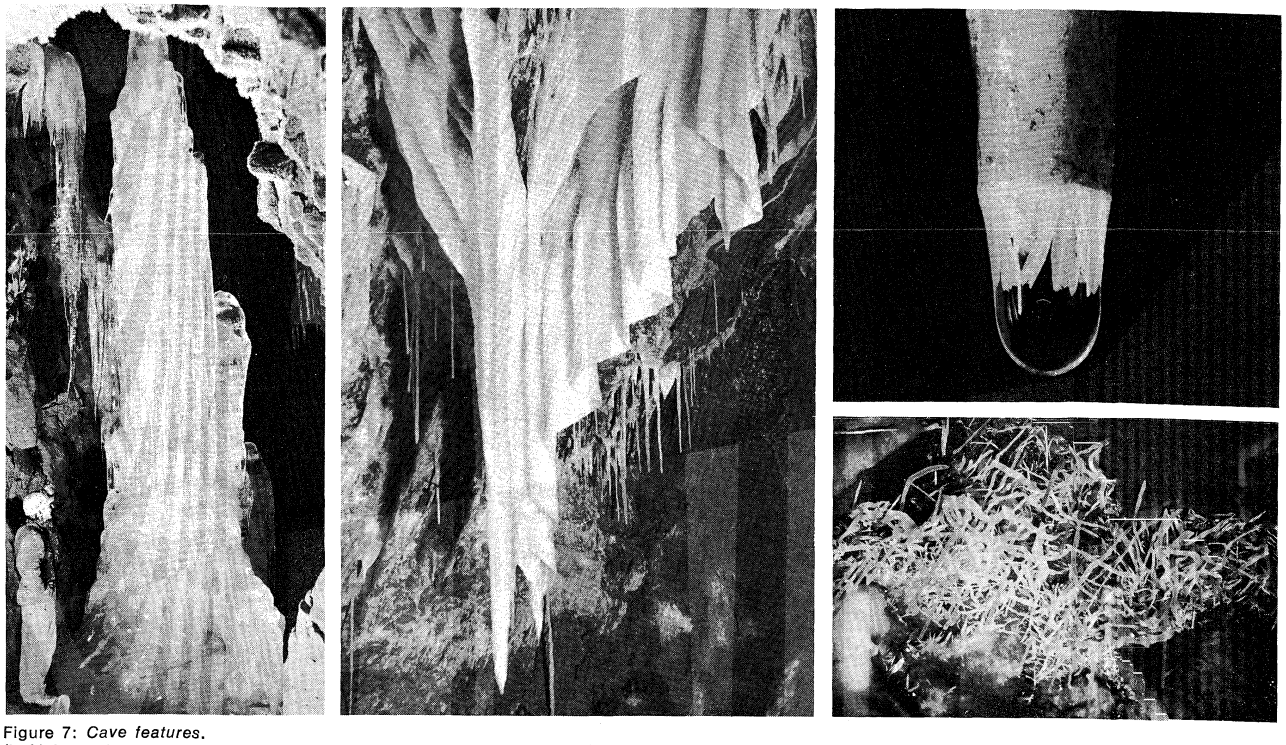

Figure 7: *Cave features.*

radially outward as parallel plates, or disks, separated by a thin parting, the extension of the original crack, through which seepage continues. The shield expands in its plane toward an ever more circular form. When water supply exceeds evaporation, overflow descends from the rim, building draperies. Shields of several metres in diameter are feature attractions at Lehman Caves National Monument, Nevada, and Grand Caverns, Virginia.

A speleothem seldom seen except in newly discovered caves forms in floor depressions where saturated water drips with such vigour that a coherent stalagmite cannot form. Gravel and sometimes fragments of bone contained in the pocket become coated at the same time that agitation polishes and rounds them. These concretions, approaching in form spheres, are known as cave pearls and owe their scarcity to their unattached condition and the collecting instinct of cave visitors.

Numerous attempts have been made to date stalactites and other speleothems based on a measured rate of growth, such as the rate of lengthening of a stalactite over a period of several years. Most of these age estimates, though not necessarily unreasonable, assume constant rates of accretion over the centuries. Many documented cases of alternating depositing and resolution of calcite, as well as extreme variations in flow rate within stalactites, invalidate this method of age dating. Greater success is being experienced by the recent application of radiocarbon and other isotope methods to the dating of chemical constitutents of speleothems.

Cave ice and sedimentation. Wherever frigid winter air settles into downward leading caverns, or where moisture freezes by evaporation in currents of cold air, a variety of underground ice formations can arise.

Alpine ice cave systems

Although splendid examples of caves containing permanent ice can be found in the lava tubes of northwestern United States, none begin to match in magnitude or grandeur the limestone ice cave systems of the Alps. Most renowned is the Eisriesenwelt (Ice Giant World) in Austria, a labyrinthine wind tunnel whose frozen landscape of underground cascades and draperies extends through more than 40 kilometres of passage.

Some cave sediments originate underground from solution of the rock walls, but others are carried in from the outside. During the early phases of cave excavation, when solution is expanding a network of small cracks into conduits, particles of clay contained within the limestone fall out as residues. Those that do not discharge with the fluid collect in low points of the system, tending to discourage further solution downward. Larger rock fragments, bones, and shells also are released from the rock by solution and these accumulate amid the fill. Oxidized residues derived from surface weathering of limestone wash into the cave through feeder cracks and constitute dense deposits of clay in some caves.

The air-filled phase of cave evolution is characterized by a greater variety of sediments than the submerged phase. Perennial streams diverted into underground channels bring in silt, sand, and cobbles of upland rocks. Floods can wash in debris as large as boulders, sometimes even trees, blocking passages and filling entire caves. Rockfall from ceiling failure forms rubble heaps mingling with fluvial deposits and residues. Breccia working downward through surface fissures contributes its own characteristic rubble. Open portals permit windblown material to circulate within the cave, from which layers of aeolian sand, glacial dust, and volcanic ash settle on cave floors and in underground pools. Incorporated pollen and the ash from known volcanic eruptions aid in dating these strata. Most animal remains, such as bones, guano, and debris, accumulate during the subaerial phase.

KARST TOPOGRAPHY

The presence of solution channels and caves in a rock permit surface runoff to drain directly underground instead of forming dendritic valleys. As a result, characteristic solution features evolve to comprise what is called karst terrain, or simply karst. Its prototype is the Karst of the Dinaric Alps, Yugoslavia, where caves and solution landscape have formed on a grand scale.

Temperate karst. Drainage trickling through soil and into the small vertical cracks that feed underlying caves

enlarges cracks with the aid of weathering. Jagged pinnacles called orgeln and karren form as residual rock masses between the cracks, beneath soil, and on exposed rock, respectively. Amid them occur solution depressions (dolines) and openings (ponors) that connect with caves below.

"Lost rivers" and waterfalls

Streams entering karst may disappear through open sinks, or swallow holes, and may reappear elsewhere in a spring called a karst rise or resurgence, usually at the lower boundary of the soluble rock. In the Indiana limestones, karst windows resulting from collapse provide glimpses of the "lost rivers" in their course between sink and rise. Downstream from the rises in warm, dry climates, precipitating carbonates build up rimstone dams, waterfalls, and tufa caves from the saturated karst waters.

The karst landscape just described is typical of the Mediterranean and other temperate lands. It can come about wherever fractured soluble rocks reach the surface and rainfall is plentiful. The landscape can assume the countenance of rugged rock badlands of gaping holes and crags (barren karst) or rolling meadows and forests (covered karst), depending on geographic factors such as precipitation, relief, and forestation. Barren karst is typical of Alpine limestones of Europe as well as the mountains of western North America. Covered karst is found in lowlands of Europe and central United States (notably Mammoth Cave National Park) but is also well developed in the high plateaus of northern Arizona and Utah.

Tropical karst. In the tropics, karst formation proceeds at a high rate, aided by heavy rainfall and abundant amounts of organic acids in the soil. In the uplands, the jungle-covered, pocketed terrain of giant sinkholes is given the name cockpit country. As this very irregular surface lowers toward sea level, surface planation encroaches upon the residual rock that protrudes in high mounds and pinnacles called mogotes, forming a tower karst. Tropical karst landscapes have been frequently described from Jamaica, Puerto Rico, Cuba, Southeast Asia, and Java.

Floridian karst. Flat-lying limestones near sea level in warm climates develop a peculiar kind of karst composed of large solution conduits of low gradient, through which ground water slowly makes its way from distant hills to discharge as offshore submarine springs of fresh water. In the Yucatan Peninsula of Mexico, bottle-like collapse sinkholes called cenotes lead down to the subterranean streams, where drowned archaeological remains of Mayan civilization have attracted anthropologist-divers. The Ocala limestone plain of Florida contains similar features, some of which discharge on land as large springs.

BIBLIOGRAPHY. The literature on caves and cave systems is vast. Because much research originated in the Balkans, valuable information is contained in books and journals of lesser known Slavic languages. The following references represent only a sampling of the world literature on this subject but will lead the reader to additional books and articles on particular aspects.

General discussions on cave origin and speleology include: C.H.D. CULLINGFORD (ed.), *British Caving: An Introduction to Speleology* (1953); E. MARTEL, *Les Abîmes* (1894); G.W. MOORE and G. NICHOLAS, *Speleology: The Study of Caves* (1964); H. TRIMMEL, *Höhlenkunde*, (1968); and F. TROMBE, *Traite de Spéléologie* (1952).

More specific treatments of cave origin and fauna can be found in: V. BAILEY, *Cave Life of Kentucky, Mainly in the Mammoth Cave Region* (1933); T.C. BARR, "Caves of Tennessee," *Bull. Tenn. Div. Geol. 64* (1961); M. BOULE and H. VALLOIS, *Fossil Men* (1957); J.H.BRETZ, "Vadose and Phreatic Features of Limestone Caverns," *J. Geol.*, 50:675–811 (1942); W.E. DAVIES, "Caverns of West Virginia," *W. Va. Geol. Surv. Rep. 19* (1949); W.M. DAVIS, "Origin of Limestone Caverns," *Bull. Geol. Soc. Am.*, 41:475–628 (1930); and A. LANGE, "Introductory Notes on the Changing Geometry of Cave Structures," *Cave Stud.*, 11:69–90 (1959).

Among the many important works on karst are: J. CVIJIC, "Das Karstphänomen," *Geogr. Abh.*, 5:217–330 (1893); S.N. DICKEN, "Kentucky Karst Landscapes," *J. Geol.*, 43:708–728 (1935); N.A. GVOZDETSKY, *Karst*, in Russian (1954); and O. LEHMANN, *Die Hydrographie des Karstes* (1932).

Popular accounts on cave exploration include: N. CASTERET, *Darkness Under the Earth* (1955); G. DE LAVOUR, *Caves and Cave Diving* (1958); H. KUHN, *On the Track of Prehistoric Man* (1955); C.E. MOHR and H.N. SLOANE (eds.), *Celebrated American Caves* (1955).

The largest source of information on this subject is found in periodicals. Some of the most prominent in the English language, devoted exclusively to speleology, are: *Caves and Karst*, formerly *Cave Notes* (1959–); *National Speleological Society Bulletin* (1941–); and *Studies in Speleology* (1964–).

(A.L.L.)

Cavour, Count

Camillo Benso, conte di Cavour, Piedmontese statesman largely responsible for uniting Italy under the House of Savoy and first prime minister of the Kingdom of Italy, was born at Turin on August 10, 1810, the second son of Michele Benso, marchese di Cavour, and Adele di Sellon. The Cavours were an ancient family that had served the House of Savoy as soldiers and government officials since the 16th century. Genevan by birth and Calvinist by religion, his mother brought into the Cavour family the influence of Geneva, a city open to all the political, religious, and social movements of the period.

Years of growth. The French Revolution imperilled the fortunes of the Cavours because of their close ties with the *ancien régime;* but the energy of the marchese Michele re-established the family in an eminent position in Napoleonic society. Camillo even had as godparents Prince Camillo Borghese—after whom he was named—and Pauline Bonaparte, the Prince's wife and the favourite sister of Napoleon.

The restoration of the House of Savoy in Piedmont-Sardinia caused yet another crisis for the Cavour family, which had compromised itself by its prominent association with the Napoleonic regime: but the marchese Michele succeeded in establishing a lasting friendship with the future king of Piedmont-Sardinia, the hereditary prince Charles Albert of Carignano, when the prince was suspected and deserted by both legitimists and liberals as a result of his equivocal participation in the constitutionalist military coup of 1821. Thus, his father was able to enroll the lively and domineering Camillo at the age of ten at the Military Academy of Turin. As the younger son who could not hope for the economic and social position that would fall to his elder brother, Camillo saw a brilliant career open up before him under the protection of the court. Yet Camillo had to endure the academy's harsh discipline, inspired by 18th-century regulations, from 1820 to 1826, when he obtained a commission as lieutenant in the corps of engineers.

Education

During those six years that, forever after, he remembered as the worst period of his life, his liveliness and youthful intolerance, always disconcerting to those close to him, increased. His acts of open insubordination made life difficult for him and for his superiors, who—from the commanding officer of the academy down—were bound by ties of friendship to his family. The rigours of military discipline strengthened rather than weakened his pride and the consciousness of his own superiority, as well as the ambition to assert this superiority. He soon distinguished himself in mathematics and history, while making little progress in Latin and literary subjects in general. In those years, political ideas began to fascinate him; echoes of the constitutionalist Piedmontese revolution of 1821 reached the academy, provoking in some of its members a flash of liberal and national spirit that was, however, immediately extinguished. Among his family, Camillo heard the great issues of the day being discussed: the internal politics of France under the restored Bourbons; the revolt against Turkish repression in Greece; the liberal Decembrist rising in Russia in 1825. He showed his sympathy, in his usual enthusiastic manner, with the liberals and with personalities such as Benjamin Franklin and Santorre di Santarosa, the famous ill-fated leader of the 1821 revolution in Piedmont, who was also a distant relative. One close friendship at the academy seems to have had a particular influence on his political views. The cadet Baron Severino Cassio, three years older than Camillo, was the first purely Italian person to whom he attached himself with real affection. Until that time all his affections had centred on his parents and relatives, who constituted a privileged cosmopolitan group that by then was completely committed to the ideas of the restoration.

Friendship with Severino Cassio

Severino Cassio, suspected of republicanism, imbued Camillo with patriotic ideas. Later, on leaving the academy, Cassio was also suspected of Socialism. The Cavour family, greatly disturbed by their son's association with a cadet holding such compromising political views, ordered Camillo to terminate it—not without provoking his indignation and bitterness. This interference of the family was dictated by expediency, for in July 1824 the marchese Michele had obtained for Camillo the appointment as personal page to Charles Albert. The fees for the academy would henceforth be paid by the court, but, above all, the appointment held the promise of a splendid future for the new page of the king-to-be. The person who showed least enthusiasm was Camillo himself, who publicly displayed his resentment at having to wear the red page-boy's uniform—he called it a "livery"—fit for court lackeys. This demonstration caused a scandal and confirmed the growing suspicions about the rebellious disposition of the young count Cavour. An even greater scandal, however, took place when Camillo, after obtaining his commission, appeared publicly for the last time as a page and expressed his satisfaction at "finally doffing that lobster's livery." The phrase referred to Charles Albert, who banished Camillo from court and—vainly—tried to persuade King Charles Felix to strip Camillo of his commission. The episode created an irreparable break between Camillo and the hereditary prince and for about 20 years made it impossible for Cavour to take any part in official political life.

Military career and foreign travel. His military career began in the engineers. He was first stationed in Turin, then in various frontier posts, where fortifications were being constructed; yet, wherever he was, Cavour remained dissatisfied. He tried to find compensation in gambling and in philandering; in fact, he never gave up these distractions until his death. In 1830 he was sent to Genoa, where he met Anna Giustiniani Schiaffino. Three years older than he, a beautiful and passionate woman, she espoused ultrademocratic and republican ideas, and her salon was frequented by many members of the Carbonari, the secret revolutionary society whose guiding force then was Giuseppe Mazzini, who was to become the key figure in the risorgimento, the movement for the unification of Italy. Cavour and Mazzini may well have met at that time. Cavour's fervent radicalism was inspired by his love for Anna Schiaffino and by his renewed friendship with Severino Cassio, now a fellow officer in the engineers at Genoa.

Early radicalism

The French revolution of July 1830, which overthrew the last Bourbon, Charles X, and installed Louis-Philippe, "the citizen king," also played a great part in strengthening Cavour's revolutionary ardour. Under the direction of Severino Cassio, he studied English in order to follow more easily the newspapers reporting political events in Europe. On hearing of the fall of Charles X, he was unable to restrain his enthusiasm—going so far as to cry "Long live the Republic!" in the officers' quarters. Cavour's state of exaltation did not, however, endure for long. His affection for Anna Giustiniani waned quickly, causing the suicide of the sensitive woman, and his republican ideas were for a time relegated to a place among his cherished memories of a youthful enthusiasm. Yet he had already made his choice in those years—the choice of liberty and progress as opposed to obscurantism, the choice of reason and civilization as opposed to ignorance. Influenced by the liberal ideas of the French writers Benjamin Constant and François Guizot, Cavour's adversaries remained those of his childhood: paternalistic absolutism; legitimist reactionaries representing the landed interests, the aristocracy, and the clergy; and the union of throne and altar. Of necessity this attitude pitted him consciously against the caste to which he belonged.

The influence of the events in France on the temperamental Cavour once again aroused official suspicions, and this time he was subjected to police surveillance. As usual, his father's intervention helped to avert more serious consequences; in this case he was simply transferred to a remote mountain fort. It had become obvious, however, that he could no longer remain in the army. When the threat of war caused by the revolutionary upheavals of 1830–31 in Italy and elsewhere had passed, he handed in his resignation, in November 1831. He went to live in his father's palace at Turin, though still opposing, often violently, the political views of his family, with whom he was forced to live. His father found him a sort of occupation: he was appointed mayor of a village south of Turin and also became the administrator of extensive holdings in the vicinity belonging to his uncles.

Although these modest occupations served to fill his time and to insulate him from his family, they aggravated his despondency by demonstrating the contrast between what he considered his true worth and the conditions to which he had been reduced. Only a few years before, he had believed that one day he could be prime minister of the kingdom of Italy. His condition embittered him, often plunged him into despair, and, impulsive and excitable as he was, brought him to the brink of suicide. Only his amorous intrigues succeeded to some extent in providing a distraction, although nothing equalled his overwhelming political passion. Frequent visits to the French Embassy at Turin—where two young diplomats soon became good friends of his—allowed him to satisfy his thirst for news and discussions about the liberal regime in the France of Louis-Philippe, for it was now his desperate hope that Piedmont might be blessed with a similar government. Social interests began to absorb him: the problems of poverty and of prisoner education became the subjects of his researches. In 1834 he wrote a memoir on poverty in Piedmont, which was published the following year in London in the *Report from His Majesty's Commissioners for inquiring into the Administration and practical Operation of the Poor Laws.* A second pamphlet on the history of the Poor Laws in England was edited and published by Cavour in 1835 at Turin.

Writings

During those years he was at last able to make his first long-awaited visit to Paris and London, thus widening his knowledge of Europe. In addition to his frequent visits to his relatives in Geneva and his correspondence with them as well as with others of his cosmopolitan acquaintances, he now came to know the two greatest and most advanced Western capitals—both ruled by constitutional and liberal regimes (however much they differed in character) and both attempting to effect the boldest economic and social changes. His journey was an

exhausting combination of study and worldly pleasure, though even on social occasions he managed to study political and social problems. In the salons he met the most important personalities of the epoch and talked with them about these problems. He personally knew, or listened to the speeches of such French statesmen as Guizot, the duc de Broglie; and Adolphe Thiers; the English statesmen Sir Robert Peel and Lord John Russell; the English chemist Michael Faraday; and the French historian Alexis de Tocqueville. He took a feverishly active interest in the parliamentary life of England and France; he attended university lectures and visited factories, railways, ports, hospitals, schools, and prisons. The experience he acquired in the two Western capitals and in Geneva set him firmly on the path he had already instinctively chosen: always to follow the "golden mean." He was repelled equally by the revolutionaries who wished to destroy society through terror in order to construct a better one without realizing that their methods would defile human dignity, and by the reactionaries, who, in blindly opposing all progress, eventually provoked revolutionary uprisings. Rejecting all extremes, he wanted above all to be a good European. Yet Cavour always remained a patriot. When his worth and his great ambition were acknowledged in France and one of his friends invited him to abandon the small, petty, and wretched Piedmont of Charles Albert for a brilliant career in France, Cavour rejected the invitation.

Revolution and reform, 1848–49. In 1835, after his return from his travels, he began to engage in a fruitful series of enterprises that helped him to become a leading agriculturalist, an expert financier, and a dynamic industrialist. He chose activities that would not attract the attention of the police but would at the same time satisfy his longing for action and profit. Starting as a lowly cadet with few resources, he was to accumulate, before beginning his career as minister and then prime minister, a considerable fortune; but this fortune was in fact to decrease rather than increase during the ten years in which he occupied the most important posts in his country. He also achieved a certain reputation with his writing. Even without directly facing the question of Italy's future political structure, all his writings proclaimed social or economic principles that could in no way be reconciled with the prevailing conditions in Italy. Above all, the economic measures and the construction of railroads proposed by Cavour would have transformed the Italy of that period beyond recognition.

Financier and industrialist

Gradually, as the year 1848 drew near and the first gusts of the great revolutionary storm of that year could be felt, Cavour's interest in politics began once more to dominate all others. This is shown by the chronological sequence of his writings. His transition to politics was completed when King Charles Albert decided to embark on measures of reform and to concede a certain amount of freedom to the press. Cavour took advantage of this to found the newspaper *Il Risorgimento*, which soon became the champion of increasingly drastic reforms and eventually also of the constitution that Cavour insisted must be the pillar supporting every type of reform.

Cavour now entered the final and culminating phase of his life. From 1848 to 1861, the year of his death, he made himself a part of political events in Piedmont, Italy, and Europe—often aiming to divert these events imperceptibly from their natural course toward ends he felt were better, sometimes being violently dragged into their vortex and almost overwhelmed by them, but finally dominating them by means of his accomplished political and diplomatic talents.

His life was now inextricably involved with one of the most glorious chapters in the history of Europe, a period that witnessed, through a series of continual crises and wars, both the birth of Italy as a new nation, free and independent, and the emergence of prospects for the liberation and creation of other nations. After taking a leading part in persuading Charles Albert to grant a liberal constitution, Cavour used *Il Risorgimento* to propagate the idea of an immediate war with Austria (which still ruled Lombardy and Venetia) as a historical necessity. Once elected a member of Parliament in June 1848, however, he assumed an intermediate position between the conservatives and the revolutionaries, thus calling forth the enmity of both left and right.

Internal and foreign policy, 1850–58. The war against Austria was undertaken, but developments went against the Piedmontese. This prompted Cavour to offer his services as a volunteer until, on being elected a deputy in the third Legislature (July 1848), he began to fight for the approval of a peace treaty with Austria, although the extremists of the left wanted to continue a war that was, in effect, already lost. The intelligence and expertise he displayed in the debates on financial and military questions gained him a prominent place among the deputies of the majority that supported the right-wing government of Massimo d'Azeglio. In October 1850, he was offered the post of minister of agriculture and soon became the most active and influential member of the Cabinet. His advancement was helped by the fact that d'Azeglio, a man of artistic and literary rather than political bent, was glad to leave everything to Cavour, who was not only an expert in political and administrative problems but tackled them with enthusiasm despite their apparent tediousness. Through a series of treaties with France, Belgium, and England, Cavour attempted to bring about the greatest possible amount of free trade. He also sought to form a network of economic interests with the great powers to pave the way for a political alliance against Austria. His appointment as minister of finance in 1850 was evidence of his growing ambitions. His politics seemed too daring and liberal to the extreme conservatives of his own party, who began to oppose him, and he was compelled to assume leadership of the moderates. The latter favoured cautious reforms and found support among the opposition deputies of the centre left.

Minister of finance

Cavour now sought to create an alliance between the centre right and the centre left that would form a new majority with greater ability to move toward a policy of secularization and modernization in Piedmont. The alliance, called the *connubio* ("marriage"), brought about the resignation of d'Azeglio, whose parliamentary standing had been completely destroyed. After vain attempts to restore an effective d'Azeglio ministry, Victor Emanuel II, who had succeeded his father Charles Albert in 1849, resigned himself to entrusting the formation of a government to Cavour, who from that time (November 4, 1852) until his death was his country's acknowledged political leader. Piedmont's swift political, financial, economic, and military progress made it a model for the Italian states and provided a foretaste of what all of Italy could become if it were liberated from Austrian domination and from inept local governments.

The European drama into which Cavour was drawn against his will began in 1854 with the Crimean War (1853–56), which saw France and England allied against Russia in order to defend the integrity of the Turkish territory threatened by Russia's determination to open the Dardanelles for passage from the Black Sea to the Mediterranean. Since the English and French had no common frontiers with Russia, they had to fight an expensive war with little possibility of rapid success in the far-distant Crimea unless they could induce Austria to join them. Urged by the allies to enter the war on their side, the Austrian emperor refused because the Piedmontese threat forced him to keep his troops in the Po Valley. London and Paris thereupon put pressure on Turin to join them against Russia in order to invalidate Vienna's pretext for preserving its neutrality. Victor Emanuel immediately pledged his help to the French and English representatives. Cavour, whose ministers voted against the Crimean venture, was on the point of being dismissed by the King if he rejected the alliance or of being forced to resign by his colleagues if he accepted it. Accepting the alliance with customary boldness and self-confidence, he averted dismissal by the King and embarked upon war. The turning point of the war came with the Anglo-French-Sardinian victory that persuaded Austria to cast aside its neutrality and, by means of an ultimatum, force Russia to make peace.

Congress of Paris

With some difficulty, Cavour secured the participation of the small power of Piedmont in the peace negotiations at the Congress of Paris (1856), at which the greatest European powers were represented. Fully aware that these negotiations were not likely to yield any gains for Piedmont that would justify the Crimean adventure in Italian eyes, he tried to send Massimo d'Azeglio to Paris as his country's representative. When d'Azeglio refused, Cavour was forced to assume the responsibility for what was regarded as an inevitable diplomatic failure. But his special abilities focussed European attention on his performance at the congress. By supporting Napoleon III's undeclared yet obvious intention to intervene militarily in Italy in the near future and by taking advantage of the general animosity toward Austria, which had joined the allies in the Crimean War only when victory over Russia was assured, Cavour succeeded in proposing the discussion of the Italian problem on the grounds that it was one that threatened European peace. In his view, peace was threatened by Austrian enchroachment, papal misgovernment in Central Italy, and the autocratic rule of the Spanish Bourbons in southern Italy. Thus, for the first time, the Italian question was presented for diplomatic consideration in a manner favouring the liberation of the peninsula. The difficulty was to persuade the two great powers, France and England, to persevere in their support of an anti-Austrian policy on the part of Piedmont. England, however, was not prepared to weaken Austria, which was needed to maintain a political balance against both France and Russia. In France, too, a strong faction consisting of many influential personages of the Second Empire—including the Empress herself—desired a policy of peace with Austria and with the pope, in order to strengthen the new dynasty.
