Earth, Figure of

The definition of the figure of the Earth—that is, its size and shape—usually does not involve the description of mountains and valleys but, rather, the size and shape of the mean sea-level surface and its continuation under the land. This hypothetical surface, called a geoid, is a reference surface from which topographic heights and ocean depths are measured. Because of the irregular mass distributions inside the Earth, the geoid is not a simple mathematical surface and consequently is not a suitable reference surface for a geometric figure of the Earth.

The geoid

As reference figures of the Earth, but not for its topography, simple geometric forms are used that approximate the geoid. For many purposes an adequate geometrical representation of the Earth is a sphere, for which only the radius of the sphere must be stated. When a more accurate reference figure is required, an ellipsoid of revolution is used as a representation of the shape and the size of the Earth. It is a surface generated by rotating an ellipse 360° about its minor axis. An ellipsoid that is used in geodetic calculations to represent the Earth is called a reference ellipsoid. This ellipsoid of revolution is the shape most frequently used to represent a simple geometric reference surface, although a triaxial ellipsoid has been suggested. The latter is an ellipsoid that has three mutually perpendicular unequal axes and thus requires three parameters (quantities) for definition. Geodetic calculations using a triaxial ellipsoid are unnecessarily complicated, and its use as a reference surface has been limited. Theoretically, more complicated mathematical models could be used as a geometric representation of the Earth, but in practice they have been found to be impractical for ordinary geodetic computations. It is more convenient to represent the deviations from an ellipsoid of revolution and take them into account in computations than it is to use more complicated representation; on the other hand, the presentation of the surface of the Earth in a three-dimensional Cartesian coordinate system is used in some modern geodetic work. When there are three-dimensional coordinates for a large number of points evenly distributed around the world, the information reflects the shape and the size of the Earth.

An ellipsoid of revolution is specified by two parameters, a semi-major axis (equatorial radius for the Earth) and a semi-minor axis (polar radius), or the flattening. Flattening (f) is defined as the difference in magnitude between the semi-major axis (a) and the semi-minor axis (b) divided by the semi-major axis, or $f = (a - b)/a$. For the Earth, the semi-major axis and semi-minor axis differ about 21 kilometres (13 miles) and the flattening is about one part in 300. The departures of the geoid from the best fitting ellipsoid of revolution are about ± 100 metres; the difference between the two semi-axes of the equatorial ellipse in the case of a three-axial ellipsoid fitting the Earth is only about 80 metres. This shows why the simple ellipsoid of revolution is the most used geometric representation of the size and shape of the Earth.

One of the main reasons for knowing the shape and size of the Earth is to establish a relative position of two or more points in the same reference system. This is achieved by establishing a geodetic datum, or reference point, that fixes the origin of the computational system and the surface over which the computations are to be made. A large number of points given in a geodetic datum form what is called a control network. For practical work, such as mapping relatively large areas of the globe, this type of control network is essential. In the construction of interstate highway systems, the location of ships at sea, or the establishment of real property lines, for example, uniform geodetic control plays an important role. In addition, a soundly based geodetic system is important in the general field of navigation and inertial guidance, including space travel and tracking satellites. Once the locations of points in a uniform geodetic system are known, analyses can be made of positional variations of points as a function of time, recording such phenomena as continental drift and sea-floor spreading (*qq.v.*).

The control network

This article provides a historical review of the determination of the Earth's figure and treats world geodetic systems based on gravimetric, satellite, and other kinds of measurements. International agreements on geodetic values are treated in the final section. For further information on the Earth's internal properties that are of concern in physical geodesy, see EARTH, GRAVITATIONAL FIELD OF and EARTH, STRUCTURE AND COMPOSITION OF. Major relief features that cause departure of the Earth's figure from the reference geoid or reference ellipsoid are covered in the article EARTH, PHYSIOGRAPHY OF. See also SURVEYING; MAPS AND MAPPING; and HYDROGRAPHIC CHARTING for treatment of the application of geodetic reference systems in practice.

HISTORICAL REVIEW

Spherical era. *The ancients.* It is astonishing that ancient civilized people such as the Babylonians, who were active in astronomy only a few thousand years ago, believed that the Earth is flat. Some of them surely must have noticed that the Earth's shadow creeping across the Moon at an eclipse is circular. They should have noticed also that by travelling farther south they could see stars that were below the horizon at home. Almost anyone should have noticed that a low island seen from the shoreline disappeared when they went swimming. Homer, however, about 900–800 BC, did describe the Earth as a convex disk surrounded by the Oceanus stream, but, according to others of that time, the Earth is a circular plate supported by four elephants standing on a big sea turtle. Although there is now some suggestion that the Egyptian builders of the Great Pyramid at Giza (*c.* 2550 BC) incorporated information on the spherical size and shape of the Earth into dimensions of the pyramid, credit for the idea that the Earth is spherical is usually given to Pythagoras (born 532 BC) and his school, who reasoned that because the Moon and the Sun are spherical, therefore, the Earth is, too. Notable among other Greek philosophers, Hipparchus and Aristotle (4th century BC) came to the same conclusion. Aristotle devoted a part of his book *De caelo* to the defense of the doctrine. He also estimated that the circumference of the Earth is about 400,000 stadia (one Greek stadium is 185.2 metres, or 607 feet), almost twice the true value. This seems to be the first scientific attempt to estimate the size of the Earth. Eratosthenes (3rd century BC), however, is considered to be one of the founders of geodesy because he was the first to describe and apply a scientific measuring technique for determining the size of the Earth. He used a simple principle of estimating the size of a great circle passing through the North and South Poles (Figure 1). Knowing the length of an arc (l) and size of the corresponding central angle (α) that it subtends, the radius of the sphere can be obtained from the simple proportion that length of arc to size of the great circle (or circumference, $2\pi R$, in which R is the Earth's radius) equals

Eratosthenes' measurement

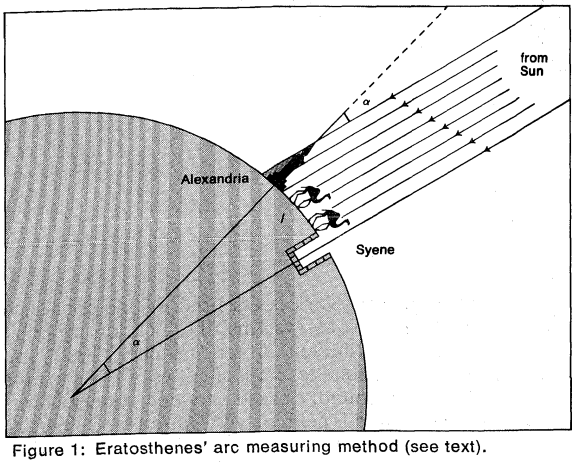

Figure 1: Eratosthenes' arc measuring method (see text).

central angle to the angle subtended by the whole circumference (360°).

$$l : 2\pi R = \alpha^\circ : 360^\circ$$

In order to determine the central angle α, Eratosthenes selected the city of Syene (the modern Aswān on the Nile) because there the Sun in midsummer shone at noon vertically into a well (see Figure 1). He assumed that all sunrays reaching the Earth were parallel to one another, and he observed that the sunrays at Alexandria at the same time (midsummer at noontime) were not vertical but lay at an angle 1/50 of a complete revolution of the Earth away from the zenith. Possibly using the travel time of a camel caravan between Alexandria and Syene, he estimated the distance (l) between these two cities to be 5,000 stadia. From the above equation he obtained for the length of a great circle, $50 \times 5{,}000 = 250{,}000$ stadia, which is 46,300,000 metres (152,000,000 feet). The result is about 15 percent too large in comparison to modern measurements, but his result was extremely good considering the assumptions and the equipment with which the observations were made.

The second known determination of the size of the Earth was made by Poseidonius (1st century BC). He used the distance between Alexandria and Rhodes Island, where the star Canopus was at the horizon at the same time, when it was 1/48 of a complete revolution of the Earth above the horizon in Alexandria. The distance was estimated using the time it took a sailboat to travel between these two points. He encountered many problems, such as those caused by refraction, but his result was only 11 percent too large.

The introduction of triangulation. A new era in determining the size of the Earth began through the introduction of triangulation. The idea of triangulation was apparently conceived by the Danish astronomer Tycho Brahe before the end of the 16th century, but it was developed as a science by a contemporary Dutch mathematician, Willebrord van Roijen Snell. Snell used a chain of 33 triangles to determine the length of an arc essentially in the customary way used today. The resulting size of the Earth, however, was 3.4 percent too small. The idea of triangulation is to establish a network of stations that form connecting triangles. One side of the first triangle in the chain, called the baseline, and all angles of the triangles are accurately measured. Using the law of sines from spherical trigonometry, the lengths of all sides thus can be computed starting from a known baseline. When the lengths and angles are known, coordinates can be computed for each point provided that the coordinates of one point and one azimuth are known. Triangulation points are usually placed on the tops of the hills because the neighbouring points must be clearly visible. Commonly, more complicated figures such as quadrilaterals with diagonals are used in triangulation.

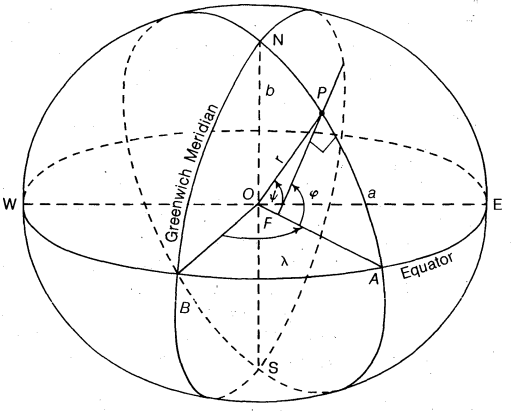
In 1669, Jean Picard, a French astronomer, first used a telescope in the determination of latitude and in measurement of angles in triangulation that consisted of 13 triangles and extended from Paris 1.2° northward. His observations and results were extremely important because his length of arc on a great circle corresponding to 1° was used by Newton in his theoretical calculations to prove that the attraction of the Earth is the principal force governing the motion of the Moon in its orbit.

Ellipsoidal era. The period from Eratosthenes to Picard can be called the spherical era of geodesy. A new ellipsoidal era was begun by Sir Isaac Newton and Christiaan Huygens. In the Ptolemaic astronomy it had seemed natural to assume that the Earth was an exact sphere with a centre that, in turn, all too easily became regarded as the centre of the entire universe. But, with growing conviction that the Copernican system is true—the Earth moves around the Sun and rotates about its own axis—and with the advance in mechanical knowledge due chiefly to Newton and Huygens, it seemed natural to conceive the Earth as an oblate spheroid—that is, a sphere flattened at the poles. In one of the many brilliant analyses in his *Principia*, published in 1687, Newton deduced the Earth's shape theoretically and found that the equatorial semi-axis would be 1/230 longer than the polar semi-axis (true value about 1/300).

First estimate of flattening

Experimental evidence supporting this idea came in 1672 as the result of a French expedition to Guiana. The explorers found that a pendulum clock that kept good time in Paris lost 2½ minutes a day at Cayenne near the Equator. At that time no one knew how to interpret the observation; but Newton's theory that gravity must be larger at the poles (because of closer proximity to Earth's centre) than at the Equator was a logical explanation.

It is possible to determine whether or not the Earth is an oblate spheroid by measuring the length of an arc corresponding to a geodetic latitude difference at two places along the meridian (the ellipse passing through the poles) at different latitudes, which means at different distances from the Equator. This can be seen from Figure 2,



$\overline{OE} = a$ = semi-major axis
$\overline{ON} = b$ = semi-minor axis
$\angle PFA = \varphi$ = geodetic latitude
$\angle POA = \psi$ = geocentric latitude
$\angle BOA = \lambda$ = geodetic longitude
$OP = r$ = radius vector
N and S = poles
FP normal to ellipsoid at P

Figure 2: Elements of a reference ellipsoid (see text).

in which the geodetic latitude at any point (P) is represented by the angle made between a line perpendicular to the ellipsoidal surface at the point P and the equatorial plane. This angle differs from the geocentric latitude that is determined by a line directed from the point P toward the Earth's centre. Such measurements of arc were made by Jean-Dominique Cassini and his son Jacques Dominique in France by continuing the arc of Picard north to Dunkirk and south to the boundary of Spain. Surprisingly, the result of that experiment in 1720 showed the length of a meridian degree north of Paris to be 111,017 metres or 265 metres shorter than one south of Paris (111,282 metres). This suggested that the Earth is a prolate spheroid, not flattened at the poles, but elongated, with the equatorial axis shorter than the polar axis. This was completely at odds with Newton's conclusions.

In order to settle the controversy caused by Newton's theoretical derivations and the measurements of Cassini, the French Academy of Sciences sent two expeditions, one to Peru led by Pierre Bouguer and Charles-Marie de La Condamine to measure the length of a meridian degree in 1735 and another to Lapland in 1736 under Pierre-Louis Moreau de Maupertuis to make similar measurements. Both parties determined the length of the arcs using the method of triangulation. Only one baseline, 14.3 kilometres (8.9 miles) long, was measured in Lapland, and two baselines, 12.2 and 10.3 kilometres (7.6 and 6.4 miles) long, were used in Peru. Astronomic observations for latitude determinations from which the size of the angles was computed were made using the zenith sectors having radii up to four metres (13 feet). The expedition to Lapland returned in 1737, and Maupertuis reported that the length of one degree of the meridian in Lapland was 57,437.9 toise. This result, when compared to the corresponding value of 57,060 toise near Paris, proved that the Earth was flattened at the poles. Later, large errors were found in the measurements, but they were in the "right direction."

After the expedition returned from Peru in 1743, Bouguer and La Condamine could not agree on one common interpretation of the observations, mainly because of the use of two baselines and lack of suitable computing techniques. The mean values of the two lengths calculated by them gave the length of the degree as 56,753 toise, which confirmed the earlier finding of the flattening of the Earth. As a combined result of both expeditions, these values have been reported in the literature: semi-major axis, $a = 6{,}397{,}300$ metres; flattening, $f = 1/216.8$.

Numerous arc measurements were subsequently made, one of which was the historic French measurement used for definition of a unit of length. In 1791 the French National Assembly adopted the new length unit, called the metre and defined as 1:10,000,000 part of the meridian quadrant from the Equator to the pole along the meridian that runs through Paris. For this purpose a new and more accurate arc measurement was carried out between Dunkirk and Barcelona in 1792–98. These measurements combined with those from the Peruvian expedition yielded a value of 6,376,428 metres (20,914,684 feet) for the semi-major axis and for the flattening, 1/311.5 (more modern values are 6,378,160 metres [20,920,365 feet] and 1/298.25), which made the metre 0.02 percent "too short" from the intended definition.

Adoption of the metre unit

The length of the semi-major axis, a, and flattening, f, continued to be determined by the arc method but with some modification for the next 200 years. Gradually, instruments and methods improved and the results became more accurate. Interpretation of the results was made easier through introduction of the statistical method of least squares.

Geoidal era. The above-mentioned method of determination of the size and shape of the Earth would have worked properly if the mass of the Earth were uniformly distributed. The plumb line used as reference in astronomic observation would then be normal (perpendicular) to the mathematical reference surface, the ellipsoid of revolution, because for an ellipsoid with a homogeneous distribution of mass, a plumb bob would hang truly perpendicular to the surface. Mass irregularities exist, however, and therefore the plumb line and the normal to the ellipsoid cannot be considered as the same direction. The angle between the direction that a plumb line actually takes and the direction of a corresponding normal to the reference ellipsoid at the point is called a deflection of the vertical. It is usually divided into two components: ξ, meridian component, north–south direction, and η, a prime vertical component, east–west direction. The plumb line is perpendicular to the geopotential surface going through the point; this means that at sea level a plumb line is perpendicular to mean sea level. The mean sea level and its imagined continuation under the land is a good approximation of the geoid. The deflection of the vertical is caused by mass anomalies—visible, such as mountains or oceans, or invisible mass surpluses or deficiencies. These mass irregularities have an effect on gravity.

When an ellipsoid is considered as an equipotential surface for gravity, defined as the combination of gravitational and centrifugal accelerations, there are two additional parameters to be defined. It has been customary to use the symbols γ_0 and m as these parameters, in which γ_0 is the value of gravity at the Equator and m is the ratio of the centrifugal acceleration at the Equator to γ_0. These parameters are related so that the parameter m is equal to the square of the rate (ω) of rotation of the Earth with respect to inertial space times the semi-major radius (a) divided by the gravity at the Equator; *i.e.*, $\omega^2 a/\gamma_0$. The parameters γ_0 and m are connected to the mass of the Earth (M), together with the constant of gravitation (G) and the flattening (f), by:

$$GM = a^2\gamma_0 \left[1 - f + \frac{3}{2}m - \frac{15}{14}mf + 0(f^3)\right].$$

The product GM is called the geocentric gravitational constant. The term $0(f^3)$ symbolizes a remainder of neglected terms. The formula for the theoretical gravity (γ) at geodetic latitude ϕ is expressed as a sum of sine functions:

$$\gamma = \gamma_0 \left[1 + \beta_2 \sin^2\phi + \beta_4 \sin^2 2\phi + 0(f^3)\right],$$

in which the factors β_2 and β_4 have the values

$$\beta_2 = \frac{5}{2}m - f - \frac{17}{14}mf, \text{ and } \beta_4 = \frac{1}{8}f^2 - \frac{5}{8}mf.$$

Gravity anomalies

By measuring gravity at a point and taking differences between the measured gravity (g) and the value (γ) computed for the same point using a theoretical gravity formula for the reference ellipsoid, and a proper reduction, a gravity anomaly (Δg) is obtained: $\Delta g = g - \gamma$. The basic mathematical formula for computations of undulations of the geoid surface about the ellipsoid surface, N, using gravity anomalies was derived by an English physicist, George Stokes, in 1849. There is no direct relationship between the gravity anomaly Δg at a point and the geoid undulation N at the same point, and an integration over the entire surface of the Earth must be performed. Corresponding formulas for computations of the deflections of the vertical from gravity anomalies were derived by a Dutch geophysicist, Felix Andries Vening Meinesz, in 1928. These derivations are important because they are the basic computational formulas for gravimetric geodesy. Unfortunately, these formulas require that gravity anomalies be known over the entire surface of the Earth; therefore they had hardly any practical value at the time of their derivations.

Because of deflections of the plumb line, latitude differences computed from astronomic observations and from geodetic computations are not equal. The difference between astronomic latitude and geodetic latitude (see above *Ellipsoidal era*) at a point is called the astrogeodetic deflection component in meridian, and the corresponding difference in longitudes, properly scaled, is called the astrogeodetic deflection component in prime vertical. Deflections of the plumb line have caused tremendous difficulties in computations of the size and shape of the Earth using measured arcs and astronomic observations, because the central angle computed from astronomic observations is not the corresponding central angle of the arc on an ellipsoid.

During the triangulation in India close to the Himalayas, the difference in astrogeodetic deflections of the vertical in the meridian at the Kaliana and Kalianpur stations was observed to be 5.24 seconds of arc. The effect of the visible topographic masses was computed to cause a difference of 15.88 seconds of arc. From this, J.H. Pratt in 1854 surmised that the mean density of the crust under the mountains was less than under the lowlands, to compensate the attraction of the mass of the mountains to the plumb-line direction. Pratt explained that mountains rose from the subcrust area like a fermenting dough, the density of which would be smaller as it rose higher. This is one of the principles of isostatic equilibrium that was developed from the measurements in a scientific sense. An English astronomer, George Biddell Airy, came to a similar conclusion in 1855, although

he explained isostatic equilibrium in a different way. He reasoned that the high mountains of Asia had sunk in a more dense substratum and were floating, just as timber or icebergs would float in water. According to Airy's theory, mountains have "roots" and oceans have "anti-roots" to compensate for mass surpluses and mass deficiencies. Airy's theory is more acceptable today than Pratt's explanation. The depth of the compensation according to current evidence is between 30 and 40 kilometres (20 and 25 miles).

In order to improve the accuracy in determinations of the size and shape of the Earth, it was recognized that the deflections of the vertical have to be taken into account in the computations. Because there were not enough gravity observations around the world, isostatic-topographic deflections of the vertical were computed using topographic information and various assumptions of isostasy. Simultaneously, the arc method was expanded to the area method; for example, in 1910 U.S. geodesist J.F. Hayford computed the dimensions of the ellipsoid based on arc measurements covering the entire United States. His results were considered sufficiently accurate to be adopted as the International Ellipsoid by the International Association of Geodesy in 1924, chiefly because of the inclusion of the deflection of the vertical information into computations. Later, it was found that this determination was not the most accurate of the time.

As stated above, there were several determinations of the dimensions of the reference ellipsoid between 1800 and 1960. Some of these results are given in Table 1. The ellipsoids of Bessel, Clarke, Hayford, and Krassowski have been generally used as reference surfaces in geodesy.

WORLD GEODETIC SYSTEM

Astrogravimetric method. *Gravimetric geodesy.* As stated above, the irregular deflections of the plumb line have caused problems for geodesists in determination of geodetic positions and, consequently, in all computations related to the size and the shape of the Earth. Even if a reasonable dimension of a reference ellipsoid had been established, deflections would have caused problems in establishing a geodetic datum from a geocentric datum.

Geodetic datum

A geodetic datum, normally referred to simply as datum, is defined by the location of the central point (initial point or datum origin) with respect to the centre of the reference ellipsoid selected. This has been customarily achieved by astronomic latitude, longitude, and azimuth determinations at the initial point; by defining the size and shape of the reference ellipsoid; and, preferably, by fulfilling the condition through the Laplace equation that the rotation axis of the ellipsoid be parallel to the mean rotation axis of the Earth. If the deflection components and undulation of the geoid are absolute (*i.e.*, not relative), then the datum is geocentric. Because the determination of these absolute values at the initial point of a datum is difficult, each country commonly has had its own relative geodetic datum. If a country is not too large in area, any reasonable reference ellipsoid and datum are satisfactory for practical mapping and control system of the country. Because there was no way of determining differences between the geodetic systems located on different continents or islands, it was difficult to utilize all geodetic measurements simultaneously for determination of the shape and size of the Earth. It was necessary, therefore, to find a method that could bring geodetic datums into one worldwide system.

The utilization of isostatic-topographic deflections of the vertical would have brought all geodetic datums into one system provided that the Earth had been in isostatic equilibrium according to the assumption used; however, with observed gravity data it has been shown that this is not the case. The alternative method to be considered was to make gravity observations around the entire surface of the Earth and compute the absolute deflections of the vertical and relative undulations of the geoid for orientation of all geodetic datums. If the gravimetric deflection components ξ_g and η_g are known, the astronomic latitude ϕ', longitude λ', and azimuth A' can be converted to the geodetic quantities ϕ, λ, and A through the formulas:

$$\phi = \phi' - \xi_g,$$
$$\lambda = \lambda' - \eta_g \sec \phi,$$
$$A = A' - \eta_g \tan \phi.$$

This is the principle of the astrogravimetric method for determination of coordinates of control points in a uniform world geodetic system. When these quantities and N, undulations of the geoid, are known at several points in each geodetic datum, the existing geodetic systems can be converted into a single world geodetic system. It was recognized that a common scale for all geodetic measurements was a prerequisite to a world system. This was provided by the light interference method, invented by the Finnish astronomer Yrjö Väisälä, and put into practice in 1923 by the Finnish Geodetic Institute. The standard baselines have been observed at the following locations: Nummela, Finland; Buenos Aires; Loenermark, The Netherlands; Ebersberg, West Germany; Potsdam, East Germany; Matadas Virtudes, Portugal; and Mansfield, Ohio. The reported accuracy of the measurements is up to 1:17 million for 864 metres (2,834 feet) distance.

The astrogravimetric method seemed to be the only feasible way of getting a world geodetic system during the pre-satellite era. This seemed to become possible also because of extensive developments of instrumentation in measuring absolute and relative gravity values. In absolute measurements, it is necessary to measure actual gravity at the observation point. In relative measurements it is necessary to measure only the difference, or the ratio, between g_0 at the base station and the gravity g_i at the field station. In the Stokes and Vening Meinesz formulas only relative gravity values are needed. Until about 1935 all gravity measurements were made with pendulum apparatuses. The principle is a simple one: if the length and the period of a pendulum are measured, the gravity (g) can be obtained from the formula that gravity (g) is equal to a constant ($4\pi^2$) times the pendulum length (l) divided by the period (T) squared; *i.e.*, $g = 4\pi^2 l/T^2$. The period is relatively easy to determine, but the measurement of the length of the pendulum is much more difficult. For relative measurement or for the ratio, pendulum length is eliminated from the formula, and the formula takes the following simplified form: the ratio of the gravity at the field station (g_i) to the gravity at the base station (g_0) is inversely equal to the ratio of their periods (T_i and T_0) squared; *i.e.*, $g_i : g_0 = T_0^2 : T_i^2$. Thus the accuracy of the relative gravity measurements depends only upon the accuracy of the period-of-time measurements.

Pendulum measurements

The invention of an apparatus for gravity observations at sea (the Vening Meinesz pendulum) gave a boost to the gravimetric method, but with the invention of portable gravimeters a new era began in the gravity surveys. With pendulums it took several hours, sometimes even days, to make an observation; with new gravimeters, however, the measuring time was reduced to 10–15 min-

utes. Because of this speed, complete systematic gravity surveys were made in several countries.

Using the vast amount of data available, there were several attempts to compute the shape of the geoid. One of them was the result of the effort started by W.A. Heiskanen at Ohio State University (Columbus) in 1951. In this program all gravity observations around the world were collected and transferred into one uniform system related to the gravity value at Potsdam, East Germany, which was internationally accepted as the principal reference station. The first result from this program was the "Columbus geoid" published in 1957. Some of the results of the program indicated that the flattening of the Earth is less in the Northern Hemisphere than in the Southern Hemisphere, a phenomenon later confirmed by other methods. The attempts to create a world geodetic system, however, were hindered by lack of uniform distribution of gravity observations around the world. There have been tremendous developments in the theoretical side in physical geodesy since World War II, but lack of uniform distribution of gravity observations around the world has made it impossible to compute accurately the shape of the Earth. It has been necessary to develop other techniques in which all available information is combined in the system—information such as astrogeodetic deflections of vertical, astrogeodetic undulations, information from astronomic and geodetic measurements, and all information from gravity measurements. One of the most extensive combinations of this kind was made by the American geodesist William Kaula in 1959.

Other techniques. Parallel to the work in gravimetric geodesy, other developments occurred that have contributed to the determination of the size and shape of the Earth. Techniques in geodetic measurements were improved by the introduction of a new kind of instrumentation. In past years it was easier to get more accurate measurements of directions or angles than distances, but the development of the Geodimeter in the 1920s reversed the situation. It was possible to measure distances with the Geodimeter with an accuracy of one part per million. The instrument measures the time it takes light to travel back and forth between two points. The largest uncertainty in the measuring system comes from propagation anomalies caused by changing atmospheric conditions. This instrument, as well as others based on measuring the velocity of electromagnetic waves, has made a significant contribution to accuracy of geodetic networks.

Geodimeter measurements

Other techniques, such as utilizing the speed of the shadow of the Moon on the Earth (solar eclipse methods) or observing the moment when the stars disappear behind the Moon (occultation or Moon camera methods), were tried to establish a common world geodetic system with somewhat less success. Also, measurements of certain small irregularities in the motion of the Moon and observations of the Earth's axis in relation to the stars were utilized for determination of the Earth's flattening. Table 2 shows some of the results of other methods for the determination of the shape of the Earth.

Satellite measurements. *Dynamic method.* A new era began in October 1957, when the first satellite, Sputnik 1 of the Soviet Union, was launched. Artificial satellites close to the Earth offered a new and far more accurate instrument for measuring the Earth's flattening and size. The first results were better values of the flattening. The key to the technique that gave this kind of information was the observation of perturbations in the orbits of the satellites. If the Earth were a perfect equal-density-layer sphere and had no atmosphere, a satellite would pursue the identical orbit month after month when the small attractions of the Sun and Moon are ignored. Because the Earth is not a sphere, its gravitational pull varies as a function of latitude, and the orbit of the satellite is therefore distorted.

Undulations of the geoid

The geoid, the actual equipotential surface of the Earth, is generally expressed by its undulations (N) above or below the ellipsoid of revolution at the point for which the geodetic latitude and longitude (the geodetic longitude is the angle between the meridian on which the point is located and the Greenwich meridian) and φ and λ. Be-

*Gravimetrically. †Astronomically.

cause the flattening is only about 1/300 and N/r is, at maximum, 1.8×10^{-5}, simple spherical harmonics can be used to express undulations N:

$$N = \sum_{n=2}^{\infty} \sum_{m=0}^{n} P_{nm}(\sin \varphi)(L_{nm} \cos m\lambda + M_{nm} \sin m\lambda),$$

in which $P_{nm}(\sin \varphi)$ is the Legendre associated function, the solution of a differential equation proposed by the French mathematician Adrien-Marie Legendre, and L_{nm}, M_{nm} are the independent coefficients. Spherical harmonics are written as one equation, representing different solutions of Laplace's differential equation according to the coefficient used. Undulation N is related to the difference between actual gravitational potential (W) at a point and potential (U) of the ellipsoidal reference figure by:

$$N = \frac{W - U}{g} = \frac{T}{g},$$

in which g is the actual gravity on the geoid and T is the disturbing potential. The difference between g and γ is the gravity anomaly, $\Delta g = g - \gamma$. Because the geoid undulations N and the disturbance of the potential T are related, there is a set of potential spherical harmonic coefficients C_{nm}, S_{nm} equivalent to the undulation coefficients L_{nm}, M_{nm}. These coefficients are most convenient when the potential of gravitation is required:

$$V = \frac{GM}{r}\left[1 + \sum_{n=2}^{\infty} \sum_{m=0}^{n} \left(\frac{a}{r}\right)^n P_{nm}(\sin \psi)\right.$$
$$\left.(C_{nm} \cos m\lambda + S_{nm} \sin m\lambda)\right],$$

in which ψ is a geocentric latitude.

An often used alternative notation for C_{n0} is $-J_n$, for which n takes values 1, 2, 3, 4, etc. The most important of these coefficients is J_2, which is customarily related to the flattening f, under the assumption of an ellipsoidal equipotential by

$$J_2 = \frac{2}{3}f[1 - \frac{1}{2}f] - \frac{1}{3}m[1 - \frac{3}{2}m - \frac{2}{7}f] + 0(f^3).$$

The gravitational potential (V) can be used in the equations of motion of a close Earth satellite. Satellites behave according to Newtonian laws of mechanics. The six orbital elements necessary to refer the orbit to Earth are: the orbital inclination—the angle between the orbital plane and the Earth's equator; the orbital period—the elapsed time of one orbit of the Earth; the eccentricity—departure of the orbital ellipse from a circle; the argument of perigee—the angle of the northward crossing of the Earth's equator to perigee measured along the orbital ellipse; the longitude of the ascending node—the angle from the vernal equinox to the point of north passage across the Equator; and the time of perigee passage. When the parameters GM, a, the coefficients $C_{nm}S_{nm}$, ini-

tial position r_0, and velocity dr_0/dt are given, the orbit can be calculated for any specified duration of time, as has been seen, for example, with Gemini rocket flights.

When sufficient numbers of observations of positions and velocity are given, values for GM, a, C_{nm}, S_{nm}, r_0, and dr_0/dt can be inferred from the orbit. Practical limitations of the scheme are that in addition to the gravitational potential, satellite orbit perturbations are also caused by such things as atmospheric drag and attraction of the Sun and Moon, which should be filtered out. Also, inadequate distribution of tracking stations offers only irregular coverage of observations. Furthermore, errors in tracking-station positions affect the observations.

The orbit of Sputnik 1 was not as accurately determined as the orbit of Sputnik 2, which came a month later. Sputnik 2 was a bright object, and an extensive series of accurate observations were made with kinetheodolites and other optical instruments. From these observations, the orbit of the satellite was fairly accurately determined. The first satellites of the U.S., Explorer 1 and Vanguard 1, were launched early in 1958 and were tracked with minitrack radio systems. The satellites were moving eastward, and the flattening of the Earth made their orbits precess westward. The British and American results of observations of this drifting suggested that the flattening of the Earth is closer to 1/298 than to 1/297. This finding is in accordance with present analyses.

Encouraged with the early results, extensive observation programs were set up in the U.S. under the National Aeronautics and Space Administration. Observations for geodetic purposes were carried out mainly by the Smithsonian Astrophysical Observatory, and the satellites' orbits were analyzed for geodetic purposes.

Geometric method. The above application of satellite observations is called a dynamic method. Parallel to this method, the geometric method has been employed. The importance of geometric satellite geodesy has to be assessed by the fact that a geometrical solution of satellite triangulation provides geodesy, for the first time, with the means to create a three-dimensional, world-wide reference system without reference to either the direction or magnitude of the force of gravity. The main objective of geometric satellite geodesy is the establishment of three-dimensional positions of a selected number of points on the physical surface of the Earth. The feasibility of spatial triangulation of a selected number of non-intervisible points on the physical surface of the Earth, using auxiliary target points sufficiently elevated above the surface in connection with the star background, has been demonstrated in the last two decades by numerous scientists. It suffices to describe the basic geometric principles of Yrjö Väisälä's astronomical method of triangulation. The principle of the method is as follows: two conjugate rays emerging from the end points of line AB (see Figure 3) define a plane in space, the spatial orientation of which can be computed from the measured directions of the two rays. Point S_1 is a satellite position. If two such planes containing the line AB are observed, the direction of the line AB can be computed by intersecting the two planes under consideration. Five planes are sufficient for establishing a unique solution for a spatially oriented station triangle. Any one of these planes contains two stations and a specific satellite position. It is obvious that the principle can be applied to any number of triangles forming a three-dimensional triangulation scheme. This particular method calls for observations of satellites simultaneously at several stations but does not require precise knowledge of the satellite orbit.

Satellite triangulation

Using the principle of this method, a worldwide triangulation net has been worked out. The U.S. Echo satellites have been the main targets in this work. All observational work for this net has been finished and the analysis of the data became available in 1971–72. This work has been coordinated by Hellmut Schmid, of the National Ocean Survey (former U.S. Coast and Geodetic Survey). Expected accuracies for the three-dimensional coordinates are approximately plus or minus six metres.

There is also the orbital method, which is used to locate a point on the Earth's surface with reference to the Earth's centre of gravity. It requires continuous tracking and subsequent determinations of a satellite orbit. Tracking from several stations enables the linkup of the stations geocentrically as compared to the geodetic basis of the simultaneous observations. A variation of the orbital method, called a short-arc method, is used to connect geodetically unknown stations to known stations that are too far away for the satellite to be observed from all stations simultaneously. These methods have been employed for extension of the geodetic network by the U.S. Department of Defense and others. Similar programs are under way in eastern and western Europe. Short-arc methods also require continuous prediction of the orbit.

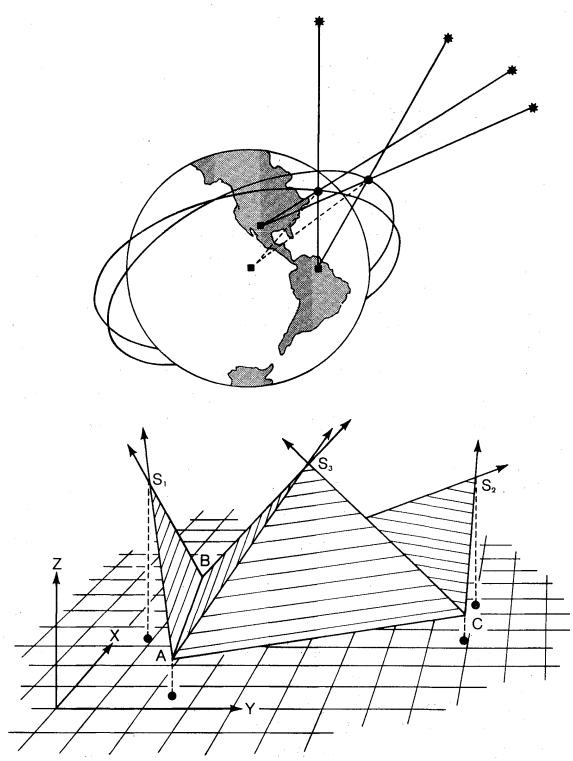

Figure 3: (Top) Simultaneous observation of satellite against star background photographed from two or more known stations and one unknown site. (Below) Principle of satellite triangulation (see text).

Combination of different types of data and methods. The ultimate aim in geodesy, of course, is to get the best uniform world geodetic system. It is logical that the system should be consistent from whatever point of view it is examined. To get this type of system, it may be best to include all available information related to the problem in a mathematical model and to formulate a consistent system. For example, by combining the results of a strictly geometrically executed worldwide satellite triangulation with the results of interpretations of satellite orbits, it is evident that a unified approach to the basic problem of geodesy can then be envisaged. Similarly, all other related data (such as surface gravity data) should be combined with the potential coefficients derived from satellite data. One of the latest results of this kind of combination is the geoid giving the undulations in metres and referring to the best fitting ellipsoid as having a flattening of 1/298.258. This geoid is a result of analyses and computations at the Smithsonian Astrophysical Observatory.

The results obtained from the observations of satellites and from combinations of data have confirmed that the flattening of the Northern Hemisphere is different from that of the Southern Hemisphere, giving a so-called pear-shaped Earth; also, it has been confirmed that the geoid undulations are approximately plus or minus 100 metres, therefore there does not seem to be any other simple mathematical figure that can approximate the geoid significantly better than the ellipsoid of revolution, except a high-order spherical harmonic representation.

INTERNATIONAL REFERENCE SYSTEMS

Current definitions and values. The International Association of Geodesy adopted an International Ellipsoid at the General Assembly in Madrid in 1924. This ellipsoid was defined through adopting numerical values for the semi-major axis of an ellipsoid of revolution: $a = 6{,}378{,}388$ metres, and for the flattening of this ellipsoid: $f = 1{:}297$, which were the numerical values obtained by J.F. Hayford (1909). The formula for theoretical gravity (γ) in terms of the geodetic latitude (φ) on this ellipsoid was adopted by the Association at the General Assembly in Stockholm (1930) as:

$$\gamma = 978.0490\,(1 + 0.0052884\sin^2\varphi - 0.0000059\sin^2 2\varphi)\ \text{gal}.$$

Gal is a unit of acceleration, one centimetre per second per second. The equatorial value of gravity for the formula was computed by a Finnish geodesist, W.A. Heiskanen (1928), from isostatically reduced gravity data, and coefficients were computed by an Italian geodesist, G. Cassinis (1930), from the values corresponding to the ellipsoid.

As time passed, however, the above defined system proved to be less and less adequate for scientific purposes in the light of new observational data and their evaluation by various scientists as described above. The results of the new observations refined the parameters. During each of the General Assemblies of the International Union of Geodesy and Geophysics, new parameters were discussed, but it was found to be advisable to postpone the adoption of new values. Because of large discrepancies between the earlier adopted values and the then available information, however, the International Astronomical Union found it necessary to adopt a new reference figure in 1964. After having obtained the advice of the International Union of Geodesy and Geophysics regarding the choice of the parameters of the figure of the Earth and its gravity field, the International Astronomical Union adopted at its XIIth General Assembly in Hamburg its new system of constants. This system contains the following three basic parameters: equatorial radius of the reference ellipsoid, a; geocentric gravitational constant of the Earth including the atmosphere (gravitational constant times Earth's mass), GM; and the dynamic form factor of the Earth, defined as the coefficient of the second-degree zonal harmonic of the potential, J_2. The adopted numerical values are:

Three basic parameters adopted by the International Astronomical Union

$a = 6{,}378{,}160$ metres (20,920,365 feet)
$GM = 393{,}603 \times 10^9$ metres/second^2
$J_2 = 0.0010827$.

Besides the participation of geodesists in the elaboration of the above system of constants, there soon arose a general feeling that a revision of the international reference system of 1924–30 was necessary. It is true that a reference system serves primarily as a set of approximate parameters to which the observed data may be related, so that the adopted values are arbitrary within certain limits. On the other hand, it is preferable to adopt values that are close to reality, and one of the responsibilities of the International Association of Geodesy is to define the best parameters characterizing the figure of the Earth and its gravity field. Even though the values adopted by the International Union were not the best values available, it was finally necessary, to maintain uniformity and to avoid the proliferation of closely similar geometric and dynamic systems, for the International Association of Geodesy to submit for approval by the International Union of Geodesy and Geophysics the Geodetic Reference System 1967, which had values for a, GM, and J_2 identical to those defined by the International Astronomical Union. This was done during the General Assembly at Lucerne in 1967. Table 3 shows a set of constants derived for the Geodetic Reference System 1967. The gravity formula corresponding to the Geodetic Reference System 1967 is called the Gravity Formula 1967. Normal gravity γ corresponding to the Gravity Formula 1967 may be computed by means of the closed formula:

$$\gamma = \gamma_e \frac{1 + k\sin^2\varphi}{\sqrt{1 - e^2\sin^2\varphi}};$$

or if the extraction of square roots is to be avoided, the Chebyshev approximation:

$$\gamma = 978.03185\,(1 + 0.005\,278\,895\sin^2\varphi + 0.000\,023\,462\sin^4\varphi)\ \text{gal}$$

may be used, for which the maximum error is 0.004 milligal. The conventional formula

$$\gamma = 978.0318\,(1 + 0.005\,3024\sin^2\varphi - 0.000\,0059\sin^2 2\varphi)\ \text{gal}$$

is less suited for direct use because its accuracy is limited (0.1 milligal).

Table 3: Constants Derived for the Geodetic Reference System 1967

Geometric constants	
Semi-major axis	$a = 6{,}378{,}160$ metres (exact)
Semi-minor axis	$b = 6{,}356{,}774.5161$ metres
Polar radius of curvature	$c = 6{,}399{,}617.4290$ metres
e = first eccentricity, $e^2 = \frac{a^2 - b^2}{a^2}$	$e^2 = 0.00669460532856$
Flattening	$f = 1/298.247167427$
Length of meridian quadrant	$Q = 10{,}002{,}001.2313$ metres
Area of surface	$A = 510{,}069{,}262$ sq km
Volume	$V = 1{,}083{,}218{,}915 \times 10^3$ cu km
Mean radius $R_1 = (2a + b)/3$	$R_1 = 6{,}371{,}031.5054$ metres
Radius of a sphere of same surface area as the ellipsoid	$R_2 = 6{,}371{,}029.9148$ metres
Radius of a sphere of same volume as the ellipsoid	$R_3 = 6{,}371{,}023.5234$ metres
Physical constants	
Geocentric gravitational constant	$GM = 398{,}603 \times 10^9$ m^3 sec^{-2} (exact)
Angular velocity	$\omega = 7.2921151467 \times 10^{-5}$ radians per second (exact)
Normal potential at ellipsoid	$U_0 = 6{,}263{,}703.0523$ kilogal-m
Spherical harmonic coefficients	$J_2 = 0.0010827$ (exact)
	$J_4 = -0.00000237126440$
	$J_6 = 0.00000000608516$
	$J_8 = -0.00000000001428$
Normal gravity at Equator	$\gamma_e = 978.03184558$ gal
Normal gravity at pole	$\gamma_p = 983.21772792$ gal
$k = (b\gamma_p - a\gamma_e)/a\gamma_e$	$k = 0.00193166338321$

Recent developments. The results from 1970 measurements, which came mainly from observations of satellites and from combinations of all information, indicate that the values for the best fitting ellipsoid of revolution are:

$a = 6{,}378{,}140$ metres (20,920,299 feet), with standard error of 3 metres (10 feet)
$f = 1/298.258$.

The geodetic measurements have become so accurate that changes can be recorded as a function of time. In precise levelling, for example, results in certain geographical locations have been reduced to a certain epoch (*i.e.*, to a fixed time) in order to have consistent results because of continuous changes in elevation during the time period, such as noticeable uplift of the crust in Scandinavia and in the eastern parts of Canada. Time has become a fourth dimension in most geodetic measurements. Horizontal motions have been monitored, for example, in California, and there are theories about continental drifts. A new generation of instruments and measuring techniques such as very long base line interferometry (VLBI) and geoceivers, now being used, will be capable of detecting continental drift (*q.v.*) in a relatively short period of time. There have been speculations about changes in the universal gravitational constant G. A suggestion has been made that the Earth's polar moment of inertia is increasing and that the gravitational constant is decreasing at the rate of the order of one part in 10^8 per century. These estimates agree in order of magnitude with the rate of upward transport of material at the mid-ocean ridges (see SEA-FLOOR SPREADING), but these should be considered only as conjectures. To discover whether or not gravity is actually changing as a function of time, it has been suggested that the values of gravity be monitored at several locations around the world with the new type of drift-free gravimeters now under development.

Detailed shape of the local geoid can be obtained from local gravity data observed using usual existing gravimeters, airborne gravity instrumentation, or gradient measuring techniques. These undulations also may be detected through use of altimeter data from satellites or data obtained from satellite to satellite tracking. Only the future will show how stable the Earth's size and shape really are. The problems have become more complex and extensive. International cooperation as well as cooperation of scientists in different disciplines is needed.

BIBLIOGRAPHY. The historical background of the determination of the figure of the earth is covered in C.R. BEAZLEY, *The Dawn of Modern Geography*, 3 vol. (1897–1906); A.D. BUTTERFIELD, *A History of the Determination of the Figure of the Earth from Arc Measurements* (1906); J.B.L. DELAMBRE, *Grandeur et figure de la terre* (posthumous work ed. by G. BIGOURDAN, 1912), and *Histoire de l'astronomie ancienne*, 2 vol. (1817). General coverage of geodesy, including modern mathematical methods, as well as the use of satellites, is provided by W.A. HEISKANEN and F.A. VENING MEINESZ, *The Earth and Its Gravity Field* (1958); GUY BOMFORD, *Geodesy*, 2nd ed. (1962); G. VEIS (ed.), *The Use of Artificial Satellites for Geodesy*, 2 vol. (1963–67), proceedings of the first and second international symposia on the use of artificial satellites for geodesy; IVAN I. MUELLER, *Introduction to Satellite Geodesy* (1964); WILLIAM M. KAULA, *Theory of Satellite Geodesy* (1966); W.A. HEISKANEN and HELMUT MORITZ, *Physical Geodesy* (1967); and MARTIN HOTINE, *Mathematical Geodesy* (1969). Also notable is the *Geodetic Reference System 1967*, a special publication of the *Bulletin geodesique* of the International Association of Geodesy (1970).

(U.A.U.)

Earth, Geological History of

To survey earth history requires an understanding of the vastness of geological time. The year is hardly an adequate unit for measuring geological time. A span of 4,600,000,000 years, the currently accepted age of the earth, is almost beyond comprehension, and earth history is therefore divided into eras, the eras into periods, and the periods into epochs.

The first era, the Precambrian, comprises almost 90 percent of geological time, from the time of origin of the earth about 4,600,000,000 years ago to the beginning of the Paleozoic Era, about 570,000,000 years ago, when evidence of living things first becomes plentiful in the rock record. The geological history of Precambrian time is very incomplete. The succeeding 570,000,000 years, down to the present, are much better known than the earlier times and can be divided into three eras, namely the Paleozoic, Mesozoic, and Cenozoic, which are collectively referred to as the Phanerozoic. During the Paleozoic Era, which lasted about 345,000,000 years, the most abundant animals were marine invertebrates. During the Mesozoic Era, which lasted about 160,000,000 years, dinosaurs and other reptiles were abundant. The Cenozoic Era, comprising the last 65,000,000 years of earth history, is the time when mammals and broadleaf trees became important. The basis for reconstructing Phanerozoic history has been the succession of rock formations and their contained fossils.

The eras of geological time

This article is intended as a broad overview of earth history, from the origin of the planet to the present. For more detail on any specific aspect of earth history, the interested reader should see the several related articles. Specifically, see EARTH, STRUCTURE AND COMPOSITION OF; ATMOSPHERE, DEVELOPMENT OF; OCEANS, DEVELOPMENT OF; and PRECAMBRIAN TIME for the earliest aspects of earth history, including the probable physical, chemical, and biological conditions that prevailed. See ROCK DEFORMATION; MOUNTAIN-BUILDING PROCESSES; SEA-FLOOR SPREADING; and CONTINENTAL DRIFT for discussions of earth movements of several types, including those of relevance to continental formation and distribution. See SEDIMENTARY ROCKS; IGNEOUS ROCKS; and METAMORPHIC ROCKS for treatment of the nature and formation of these basic constituents of the earth's crust; see FOSSIL RECORD; STRATIGRAPHIC BOUNDARIES; GEOLOGICAL TIME SCALE; and DATING, RELATIVE AND ABSOLUTE for information on the means of interpreting the record of the rocks and the record of life through time and the means of subdividing geological time. See also articles on the eras, periods, and epochs of geological time—*e.g.*, PALEOZOIC ERA, LOWER; JURASSIC PERIOD; PLEISTOCENE EPOCH.

FACTORS INVOLVED IN EARTH HISTORY

Earth movements. Rocks that contain fossils do not occupy the position they had when the rocks first formed. Formations containing sea shells may be found on the summits of some of the highest mountains, yet the sea never was that high. The rocks containing the shells were deposited as sediments in the sea, and the sediments then became compacted and consolidated to form rock. Subsequently, earth movements uplifted the rocks to their present locations, sometimes thousands of feet or even miles above sea level.

The earth movements that accomplish such changes are slow. A foot of uplift in a thousand years is not exciting; many parts of the world are more active than that. Yet that movement, if continued for only 10,000,000 years, can raise a mountain range 10,000 feet above sea level.

Displacement and uplift by faulting

Geologic processes that build mountain ranges and later destroy them by erosion can be observed today. The earth movements that raised mountains generally progressed as repeated small movements of the same kind as those accompanying modern earthquakes. In 1959, at Hebgen Lake, west of Yellowstone Park in Wyoming, in a matter of moments the bed of the lake was tilted 20 feet (6 metres) northeast. Houses and highways on the northeast shore were submerged, whereas boats and docks on the opposite southwest shore were stranded 20 feet above the new shore. Half of this displacement was taken up by a fault (fracture of the Earth's crust along which movement occurs) with a 10-foot displacement. Highways crossing the fault were displaced, and a barn over the fault was broken in two parts, one 10 feet higher than the other. The geological record indicates that the world's great mountains—the Himalayas, Alps, Andes, and Rockies—were broken and their parts uplifted by small displacements like those at Hebgen Lake, repeated over long periods of time.

Former environments. An important aspect of earth history is, of course, the environment that prevailed during the deposition or erosion of rocks in former times. Reconstructing the kinds, magnitude, and intensity of former geological processes from ancient deposits is the subject of paleogeography (*q.v.*). It is generally accomplished by recourse to the dictum that the present is the key to the past, meaning that past processes and their effects were similar to those processes and effects that are observable today. Modern coasts provide an example of the environmental factors involved.

Coastal facies and environments

A succession of different kinds of environments and sedimentary deposits occurs along most coasts. Inland are stream valleys with floodplain deposits of stream-transported gravel, sand, and silt. These sediments, referred to as alluvial or fluvial, contain the remains of land animals and plants or freshwater shellfish and finfish. Approaching the coast, this freshwater environment gives way to an estuarine environment where the water may be brackish. No longer is there much gravel, for streams entering the estuary are too sluggish to transport coarse sediment. The channels are of sand, silt, and mud. In marshes and swamps, the wet ground prevents oxidation and decomposition of the plant matter, which then collects as peat. Here the species of shellfish and finfish are those conditioned to brackish water and to tidal fluctuations. Plants around the shores of the estuary are those that can tolerate 1 or 2 percent salts in the water.

Deposits that represent such different environments are referred to as facies; the stream deposits constitute one facies, and this grades laterally into the estuarine facies. The estuarine facies, in turn, grades to the shore or littoral facies, which may include shore deposits, beach dunes, and offshore sediments (marine muds). Each facies has a distinctive composition and texture (lithology), and each has a distinctive fauna and flora.

Record of the rocks. Ancient rock formations record successions of facies along the shores of ancient seas that

once extended onto various parts of the continent. The gravel, sand, and silt of the fluviatile environment becomes rock, known as conglomerate, sandstone, and siltstone, respectively. The mud, sandy mud, and peat in the

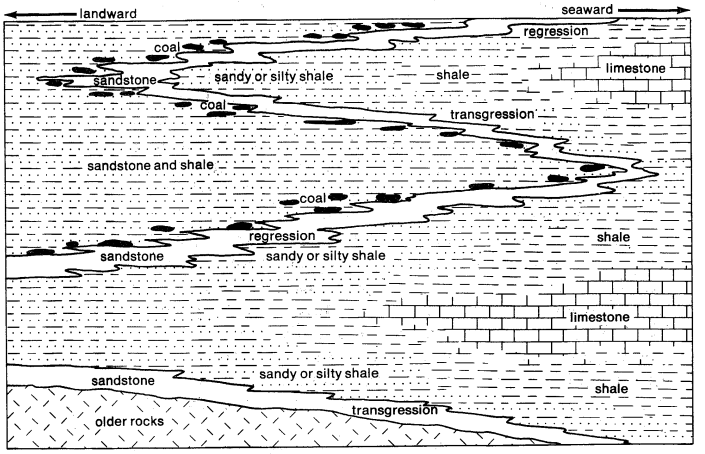

Figure 1: Environmental changes (facies) across a shifting, ancient shoreline. Floodplain deposits of sandstone and shale (left) containing fossil land animals and plants identify the old coastal plain. These grade seaward to estuarine deposits containing coal beds, and these grade to sandstone representing the ancient beaches. The diagram shows two transgressions and two regressions.

estuarine environment is transformed to shale, sandy shale, and coal. Sandstone representing former beach deposits grades into shale and sandy shale containing marine fossils; the latter represent former offshore marine muds. Where the water is warm, as in tropical latitudes, calcium carbonate may be precipitated, and this forms limestone, another indication of former environments.

Where earth movements cause coasts to subside and enable the sea to advance onto what had been land, the different environments become shifted landward, and the facies characteristic of seaward environments overlap earlier deposits characteristic of landward environments. Where coasts are stable and the influx of sediments from the land is considerable, the facies characteristic of landward environments extend seaward and overlap earlier deposits representing the seaward environments (Figure 1).

Transgression, regression, and stratigraphic succession

An advance of sea over the land is referred to as marine transgression; a retreat of the sea caused by uplift of the land or by accelerated influx of sediments is referred to as regression. Figure 1 illustrates two transgressions and two regressions. The continuity of the sedimentation may be interrupted by uplift accompanied by erosion. Such breaks in the geologic record are referred to as unconformities (Figure 2).

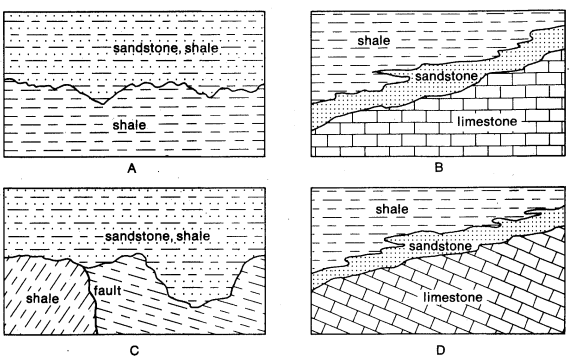

Figure 2: *Examples of unconformities.*
(A) Change from shale to sandstone and shale, slight erosion on top of shale. (B) Limestone surface eroded, buried by sandstone and shale. (C) Shale folded and faulted buried by sandstone and shale. (D) Limestone tilted and eroded before marine sandstone and shale deposited.

Younger sedimentary deposits must initially overlie older ones in accord with the principle of superposition. This provides the basis for studying the sequence of sedimentary rocks. The physical changes recorded by a succession of strata are accompanied by biological changes recorded by the fossils in those sediments. These biological changes are of two kinds; one relates to changes in environments (facies), and the other records the evolution of life forms through time.

Whereas stratigraphic succession is the basis for chronology, the subdivision of the sedimentary formations into units of geological time is defined by the fossil record for each of the eras and periods. The succession of paleontologic changes is the basis for correlating the rock formations and the episodes of geological history they record.

Igneous and metamorphic rocks

In addition to sedimentary rocks, the earth's crust consists of igneous rocks, which once were molten (*e.g.*, lava), and metamorphic rocks, which are produced by the alteration of pre-existing rocks by great heat or pressure.

Temperatures and pressures in the earth increase greatly with depth. The melting point of rocks such as granite, at atmospheric pressure, is around 1,200° C (2,200° F), and such temperatures are reached a few miles down. The rocks are not generally melted because of the great confining presssures, but earth movements can relieve the pressure locally and cause the rock to melt. When this happens, the molten mass becomes squeezed upward as an intrusion into the overlying rocks. The intrusions cut discordantly through the overlying rocks to form what are called stocks, or if an intrusion continues to the surface it may form a volcano and erupt. Stocks clustered closely together (such as the extensive granites of the Sierra Nevada and Coast ranges of Canada and Alaska) are called batholiths.

Igneous and metamorphic rock facies are somewhat like those in sedimentary rocks. An igneous mass, for example, may change greatly between two locations because of different reactions with the host (intruded) rocks, different rates of cooling that control the kinds and sizes of minerals that crystallize from the melt, differences in fluidity or rates of injection that affect the shapes of the intrusive masses, and differences in fluidity that may allow early-formed heavy minerals to settle and leave behind a melt with a composition different from that of the parent mass.

Metamorphic rocks have different facies depending on the degree of alteration and commonly exhibit changes with distance from a site of intensive deformation.

Geological dating. Correlations based on superposition and paleontology have been greatly extended by dating rocks by their radioactivity. The principle of radiometric dating is disarmingly simple.

A radioactive element decays to a daughter element (isotope) at a constant and known rate that is referred to as the half-life, the time required for one-half of the originally present (parent) element to decay to the daughter element. Knowing the decay rate, measurement of the ratios of the parent and daughter elements provides the age. The chief difficulty in applying the methods to rocks and minerals or to surface deposits and soils is the necessary assumption that there has been no depletion or enrichment of either isotope.

Radiometric-dating methods

Three methods widely used for determining radiometric ages involve uranium (and thorium)–lead, potassium–argon, and radiocarbon.

The method utilizing the ratio of uranium to lead and thorium to lead involves three pairs of isotopes occurring together and having different decay rates, as follows:
uranium-238–lead-206,
half-life 4,500,000,000 years;
uranium-235–lead-207,
half-life 700,000,000 years; and
thorium-232–lead-208,
half-life 13,500,000,000 years ± 500,000,000 years.
This method has the advantage of utilizing three different decay ratios, and when the three rates indicate comparable ages the probabilities are enormous that a

satisfactory age has been determined. The method is largely restricted to igneous and metamorphic rocks and is particularly useful in dating Precambrian events.

The potassium–argon method involves the transformation of potassium-40 to argon-40 and to calcium-40 with a half-life of 1,310,000,000 years. A great advantage of this method is the abundance and wide extent of potassium-bearing minerals in the earth's crust, including some sedimentary rocks. This enables absolute dating of paleontologic and stratigraphic successions.

The radiocarbon method involves the transformation of carbon-14 to nitrogen-14 with a half-life of about 5,500 years. With this half-life the method is restricted to dating deposits younger than about 50,000 years, those of the Holocene Epoch and latest Pleistocene time.

Other methods have been used for estimating ages of certain geologic events, such as retreat of waterfalls, salinity of the oceans, rates of weathering, rates of deposition of sediments, and rates of soil formation. These are not dependable, however, because the assumed rates probably have changed over the period of time being estimated.

The earth's interior. Geophysical data, including the velocity of earthquake waves and density or gravity measurements, indicate that the earth consists of concentric shells that decrease in density outward from its centre. At the centre is a core with a radius of about 3,400 kilometres (2,000 miles). The inner part is judged to be solid and the outer part has the properties of a highly viscous liquid. This core has a density of about 12 and is thought to be a mixture of iron and nickel. It is 15 percent by volume and 32 percent by weight of the earth.

Mantle, crust, and Mohorovičić Discontinuity

A sharp structural discontinuity separates the core from the next outer shell, the mantle, and the density drops abruptly to less than 5.5, which is less than the density of iron (7.9). The density of the mantle decreases outward to about 4.5 at a depth of about 900 kilometres (550 miles) and to about 3.5 at the Mohorovičić Discontinuity, which marks the base of the outermost shell, the crust. The mantle comprises 84 percent of the earth's volume and 67 percent of its weight. The crust has an average density of less than 3.0 and is about 5 kilometres (3 miles) thick under the oceans; it thickens to 30 to 50 kilometres (20–35 miles) under the continents. The crust has a lower layer termed sima (a contraction for silica–magnesium) with a density about that of basalt (2.8–2.9); the upper layer termed sial (for silica–aluminum) has a density about that of granitic rock (2.65–2.75). The crustal layer under the oceans is mostly basaltic; under the continents it consists of both basaltic and granitic layers. The crust makes up less than 1 percent of the earth by volume and about 0.4 percent by weight.

Structure of the continents. The continents are rafts of light rock floating on the denser mantle. Each continent consists of a core of highly metamorphosed sialic rocks, which outcrop as nuclei of the continents, referred to as continental shields. Cores and shields are composed of the oldest pre-Paleozoic rocks forming the continents. Around each shield is a stable platform of such pre-Paleozoic rocks overlapped by thin Paleozoic or younger sedimentary rocks (Figure 3) largely of marine origin and showing evidence of former submergence. Along the outer edges of these platforms are unstable mobile belts where the crust has been subject to broad downwarping to produce structural troughs known as geosynclines. These troughs were invaded by the sea and great thicknesses of marine sediments were deposited in them. The sediments commonly aggregate 35,000 to 45,000 feet (10,600–13,600 metres) thick, whereas those deposited on the stable platforms surrounding the shields are mostly less than 5,000 feet (1,500 metres) thick.

Role of geosynclines in earth history

In general, these marginal geosynclinal troughs consist of two belts. The outer belt seemingly was very mobile and was bordered by arcs of volcanoes; in it were deposited coarse clastic sediments (sediments made up from fragments of pre-existing rocks), lavas, and sediments derived from volcanic ash and lavas. This belt is referred to as the eugeosynclinal belt. Parallel to it and adjoining the stable platform is another geosyncline containing little volcanic material and much less coarse sedimentary deposits; thick deposits of limestone and other carbonate rocks are included in this miogeosynclinal belt, however.

The geosynclines sank as the sediments were deposited in them, as if the weight of the sediments contributed to pushing these mobile parts of the crust downward. Although the sediments in the geosynclines may be as thick as 45,000 feet (13,600 metres or 9 miles), the troughs never were that deep. The facies represented by the sediments mostly indicate moderately shallow water. Evidently the sinking progressed as the sediments accumulated.

During the history of a particular geosyncline, the sides of the trough at times would become compressed, and the rock strata in the trough would be folded. Where folding progressed beyond the limit of strain of the rocks, they broke by faulting. Most geosynclines record several episodes of such folding and faulting, especially in the eugeosynclinal belt. These episodes commonly but not invariably are accompanied by volcanism and intrusions of various kinds of igneous rocks.

After eight to ten miles of sediment had been deposited in most geosynclines, the sinking ended, and the sediments became strongly folded, faulted, and uplifted to form mountains. What had gone down now came up. These kinds of structural movements terminating geosynclines or interrupting their development have been termed orogenies; they are mountain-building episodes in the Earth's history.

Orogenies

BEGINNINGS OF EARTH HISTORY

The primitive earth. Most theories about the origin of the earth assume it began in a gaseous state, evolved through a liquid state, and finally became partly solid. Some theories assume that the solar system and the earth began as a dust cloud with the composition of interstellar gas. Such a cloud would have contained only 1 percent of most of the terrestrial elements, with a remainder of hydrogen and helium in equal amounts. As the dust-cloud particles aggregated, perhaps electrostatically, gravity would have caused further aggregation.

Some theories assume that the earth began in a hot state and has been steadily cooling; other theories assume that the earth began cold and grew warmer as a result of compression and subsequent radioactive decay of its interior constituent elements. It is generally supposed that the dust particles of the heavy terrestrial elements would gravitate toward the centre of the mass and that the light elements, especially hydrogen and helium, could escape again to outer space. As aggregation progressed the heavier terrestrial elements gravitated toward the centre and the lighter ones toward the top. The original gaseous mass differentiated into liquid and gaseous phases, and these in turn differentiated into solid and liquid phases. Some calculations suggest that these changes could have

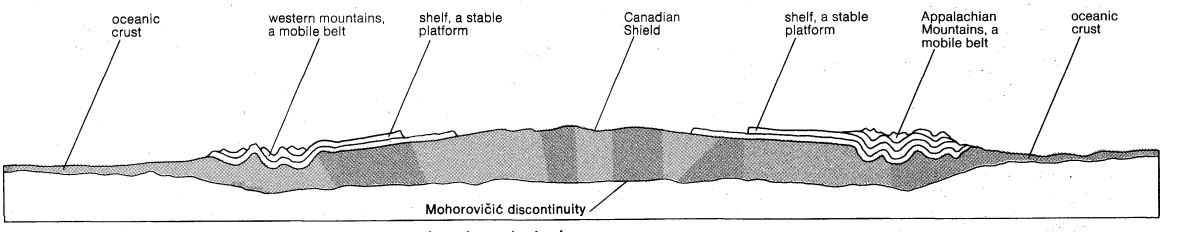

Figure 3: Cross section of North America illustrating the principal structural elements of a continent.

occurred quickly, in as little as a few thousand years. In any event, the formation of a solid crust can be taken as the beginning or zero time in geological history. Judging by the age of the oldest meteorites, of moon rocks, of terrestrial lead, and by calculations about the rate of retreat of galaxies, this occurred about 4,600,000,000 years ago. The earlier history is referred to as the astronomical period of earth development.

Differentiation of core, mantle, and crust

During the astronomical period of earth history the processes of differentiation into core, mantle, and crust began. The iron–nickel core is thought to have begun forming by the gravitating of liquid iron with nickel toward the centre of the mass. Outside of this, a shell of metallic silicates and sulfides collected, later to become the mantle. The lightest constituents, the silicate phase, rose to the top and formed the crust. Some of the hydrogen in the proto-atmosphere dissolved in the molten iron and was retained in the earth, but much of the hydrogen and most of the inert gases were lost to outer space. When the crustal layer first solidified, there is thought to have been little or no atmosphere. The atmosphere developed later by the escape of various gases from the earth's interior.

Primitive atmosphere, organisms, and soils. Perhaps the first crust on earth was like that on the moon and had a composition similar to stony meteorites. As this crust cooled and solidified it further differentiated into a comparatively dense sima layer and an overlying, lighter sialic layer. Such differentiation may have contributed water vapour to the atmosphere, but the early atmosphere must have been cloudy; the water could not fall as rain until the temperatures had dropped below 100° C (212° F). This stage can be referred to as the proto-atmosphere.

When the rains came, weathering and erosion began. Water running off the high ground formed the first streams, and where it collected in basins there formed the first lakes and seas. The abundance of chlorine, bromine, iodine, boron, and sulfur in the oceans and the comparative scarcity of these elements in the sialic crust has been interpreted as a relic of the proto-atmosphere. There still was no living matter, and weathering was entirely by physical-chemical processes.

There must have been some free oxygen in the primitive atmosphere, but most of the oxygen in today's atmosphere is thought to be the product of photosynthesis by plants that have lived since life on earth began. When life arrived on the land, the biochemical processes of soil development could begin, but the soils must have been primitive compared to the well-layered ones that develop under higher types of vegetation. This was the period of protosoils.

Assuming that the solid crust formed 4,600,000,000 years ago, the proto-atmosphere may have lasted for 250,000,000 years and protosoils may have lasted for a similar time span. These periods of the primitive earth must have lasted less than 1,000,000,000 years because granitic rocks as old as 3,500,000,000 years have been dated from the African and European shield areas.

PRECAMBRIAN HISTORY

Continental shields. Each of the continents has a core of Precambrian rocks extensively exposed over a large part of the continent and reduced by erosion to low relief. These are the continental shields, in which the rocks are complexly folded, faulted, and metamorphosed. The rocks composing them are mostly granite and gneiss; infolded and infaulted with them are metamorphosed volcanic and sedimentary rocks in belts that represent remnants of Precambrian geosynclines. The earliest geosynclines probably formed when the earth was less than 1,000,000,000 years old. There was sufficient water to cause rains and to form seas, and the runoff on the land was sufficient to cause erosion.

The Canadian Shield

The core of North America outcrops in the Canadian Shield, which extends over nearly 3,000,000 square miles. Topographically and structurally the Canadian Shield is a vast saucer that rises outward from an area beneath Hudson Bay and Foxe Basin. The shield was submerged by shallow water at times during the Paleozoic, but the flat-lying beds show no subsequent folding.

The Precambrian rocks are mostly below 1,000 to 1,500 feet (300–450 metres) in altitude but exceed 2,000 feet (600 metres) in some places. Their surface slopes away from the shield and forms a platform to the south and west under a cover of thin and nearly flat-lying Paleozoic and Mesozoic formations. To the southeast the shield ends abruptly at a deep trough, a geosyncline, in the Precambrian formations; this trough contains thick Paleozoic formations that are intensely folded and faulted.

The outstanding feature of the shield is its tremendously long, complex, and only partly understood geological history. Some of the rocks are dated at more than 2,000,000,000 years old, which is nearly four times longer than all of Phanerozoic time. The shield was eroded to low relief before the Paleozoic and was inundated by shallow seas intermittently during the Paleozoic. The shield probably was emergent during the Mesozoic and Cenozoic. It was covered by a continental ice sheet during the Pleistocene Epoch.

The rocks in the Canadian Shield are practically without fossils, and the stratigraphic succession must be based largely on radiometric dating of intrusive igneous rocks. These intrusions accompanied intense folding and faulting, and the resulting metamorphism caused sufficient recrystallization in the folded rocks to cause them to yield the same radiometric age as the intrusions that cut them. Age relations in the Canadian shield therefore are grouped on the basis of radiometric ages of granitic intrusions.

On this basis three major periods of intrusion and associated folding and other deformation have been distinguished; their names and ages are Grenville 1,000,000,000 years; Hudsonian 1,800,000,000 years; Kenoran 2,500,000,000 years. Hudsonian foldbelts occur in the Churchill, Bear, and Southern Superior Provinces; Kenoran foldbelts in the Superior and Slave Provinces (Figure 4). There must have been other periods of folding and igneous activity in addition to those named because it is unlikely that the intervals, which are as long as the entire Phanerozoic, were without folding and faulting. Present information permits dividing the Canadian Shield into the structural provinces shown in Figure 4.

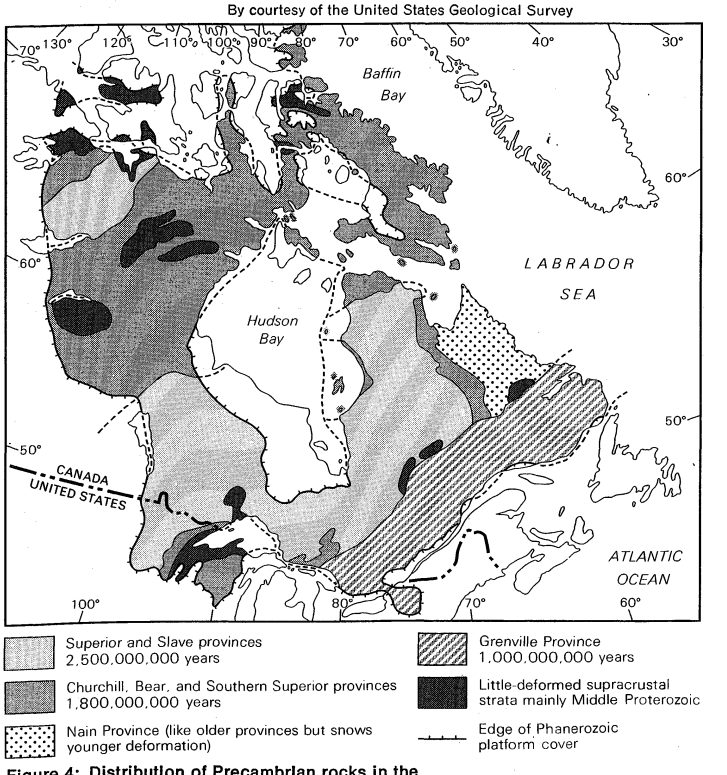

Figure 4: Distribution of Precambrian rocks in the Canadian Shield.

The rocks in the Superior and Slave provinces record major development of granite about 2,500,000,000 years ago. Antedating the granite, and largely engulfed by it are thick, tightly folded beds of basaltic lava, volcanic ash, banded iron formations, and graywackes (a poorly sorted sandstone that is characterized by rock fragments in an abundant, clay-rich matrix). The oldest graywacke contains fragments of granite and clearly indicates existence of a granitic terrain older than the one dated at 2,500,000,000 years ago. These dates suggest that the continental crust in North America 3,500,000,000 years ago was transitional between the primitive basaltic crust and the thick, extensive granitic crust that exists today. Before the end of Precambrian time the continents were well formed.

Precambrian rocks also are exposed in the eastern United States in the Piedmont Province and Blue Ridge and in the central and western United States in uplifts at the Ozark Plateau, central Texas, Rocky Mountains, southern Basin and Range Province, and some California coast ranges. Some of these rocks have been assigned radiometric ages as great as 2,500,000,000.

The Baltic Shield

Rocks of the Baltic Shield record at least four episodes of deposition of coarse clastic sediments, lavas, and tuffs, alternating with episodes of folding, faulting, and intrusion of granite. The early sedimentary rocks are like those in the ancient basins of Canada; basaltic lavas occur together with sandstone, shale, and graywacke from granitic and basaltic terrain and banded iron formations. The younger rocks include dolomite. Rocks as old as 1,800,000,000 to 2,000,000,000 years contain graphitic schist and traces of bitumen; this carbon suggests organic matter and living organisms.

The Precambrian rocks extend southward and southeastward under the plains of northern Europe and form a platform, capped by thin Paleozoic formations, very similar to the platform under the central United States. The eastern part of the Baltic Platform ends at the Urals; southward it is overlapped by Mesozoic formations.

Angaran, African, and Indian shields

A third continental core in the Northern Hemisphere is exposed in the Angaran Shield in central Siberia between the Yenisey and Lena rivers. Precambrian rocks forming this shield extend westward under the platform of the west Siberian Lowland and end at a mobile belt marked by the Ural Mountains. This shield is a high plateau, higher on the average than the Canadian or Baltic shields.

The Southern Hemisphere has shields in Africa, India, Australia, South America, and Antarctica, and all are plateaus. The African Shield, by far the largest, includes the entire continent except for narrow belts of folded rocks at the northwest and southern margins. Over much of Africa the shield rocks are overlain by thin, flat-lying Phanerozoic sedimentary formations, like those on the platform in the central United States. Africa, like the Canadian Shield and its platform, has remained comparatively stable since the beginning of the Paleozoic. This shield not only is largest but is the highest today; extensive areas are above 1,000 metres (3,280 feet) altitude. Perhaps the core of this continent is the thickest. In the Transvaal, granite dated at 3,200,000,000 years intrudes rocks that obviously are older and undated.

Of special interest among the rocks of the African Shield are those of the Witwatersrand formations, which consist of more than 24,000 feet (7,400 metres) of conglomerate, feldspathic sandstone, quartzite, slate, and lavas. These formations contain the world's largest known deposits of gold.

The Indian Shield, comprising nearly all of peninsular India, consists of a complex of gneisses, metamorphosed volcanic rocks, and granite. At least three Precambrian orogenies occurred, but this shield, like the others, has been stable during the Phanerozoic. The northern margin of the shield ends at Paleozoic and younger geosynclines marked by the Himalayas and the plain of the Ganges. The western part is capped by one of the world's great basalt fields, the Deccan Traps.

Precambrian glaciations. Among the conglomeratic formations of the shields are some tillites, heterogeneous rocks derived from glacial till. The boulders, faceted and striated, are in a fine-grained matrix. Associated with some of the deposits is banded slate that may have originated from varved (banded by annual layers) lake deposits. Tillite has been found in all of the shields, but only a few deposits are well dated. At least three stages of glaciation are indicated by deposits as shown in Table 1.

Table 1: Location and Age of Precambrian Glaciations

location	approximate age (years)
Uppermost Precambrian (Beltian Series), Wasatch Mountains, Utah	750,000,000
Uppermost Precambrian (sparagmite sandstone) on Baltic Shield in northern Norway	750,000,000
African Shield in Katanga, Angola, lower Congo, and South Africa	750,000,000
Australian Shield has banded slate thought to be seasonal (varved) banding	750,000,000
Canadian Shield (cobalt formation in the Huronian [Animikie] Series)	2,000,000,000
African Shield (Transvaal System)	2,000,000,000
Australian Shield (Broken Hill area)	2,000,000,000
African Shield (Witwatersrand Series)	2,600,000,000

Precambrian life. The first organisms probably appeared at the time of the first seas. Oxygen, still deficient, increased as photosynthesis developed. The first organisms releasing oxygen would be oxidized (burned up) by it unless the oxygen could combine with mineral matter. Supposedly this was ferrous iron, and its oxidation could have produced the banded iron formations that are widespread in Lower and Middle Precambrian rocks. These unique rocks are not found in younger formations. They consist of alternating layers of iron-rich and iron-poor silica and represent rhythmically banded, chemically precipitated sediment.

Banded iron formations and bluegreen algae

The last episode of banded iron formation was 1,800,000,000 to 2,000,000,000 years ago, and signs of bluegreen algae are associated with it. Thereafter, with much or most of the iron oxidized, oxygen was added to the atmosphere. Younger iron formations consist of red beds, the sediments of which are individual grains coated with iron oxide. The oldest thick and extensive red beds in the Precambrian are about 2,000,000,000 years old.

With the first appearance of red beds, calcium and magnesium carbonate (dolomite) occurred in abundance for the first time in marine sediments. The seas may then have developed a salinity comparable to that of today.

The younger Precambrian sedimentary deposits, notably the calcareous ones, contain concentric limy structures thought to have been formed by colonies of algae. Sponge spicules and the impressions of a jellyfish have been found, and some beds have burrows looking very much like worm burrows. The animals of those times did not have shell or skeletal material that would survive burial, and consequently there are almost no fossils.

This virtual absence of fossils, though, should not be construed to mean the absence of living organisms. The abrupt appearance of abundant fossils of animals with hard parts at the beginning of the Paleozoic requires considerable and diverse ancestry. An indirect record of the ancestral floras and faunas is provided by the carbon content of black shale and slate and by bedded deposits of graphite in some of the formations.

Eocambrian formations and the first trilobites and shelled invertebrates

The beginning of the Paleozoic has been defined by the first appearance of trilobites and associated fauna of shellfish, including linguloid brachiopods and ostracods. In many parts of the world, however, a thick series of essentially nonfossiliferous sedimentary formations conformably underlie the earliest Paleozoic beds that contain the fossils. These formations are physically part of the Paleozoic, but they are Precambrian on paleontological grounds because of the absence or primitive nature of contained fossils.

In the southern part of the Appalachian Geosyncline these Late Precambrian or Eocambrian formations consist of 7,500 feet (2,300 metres) of shale, sandy shale,

feldspathic sandstone, and conglomerate. Northward and westward the formations thin and are only about 2,500 feet (760 metres) thick in Maryland and southern Pennsylvania; they are absent in New York.

Eocambrian formations also are represented in the Paleozoic geosyncline west of Grand Canyon. In the Death Valley region they comprise 8,500 feet (2,580 metres) of nonfossiliferous dolomite, claystone, and quartzite. Eastward, the formations thin by overlap and are not represented under the Paleozoic formations on the continental platform at Grand Canyon.

Mineral resources. Some of the world's most important mineral deposits are in Precambrian rocks. Among them are the world's largest iron deposits (Canadian, Baltic, Amazonian, and Guianan shields, and in the Ukraine, U.S.S.R.); the world's largest gold deposits on the African Shield and other important gold deposits on the Canadian Shield and in Western Australia; and the world's largest nickel and cobalt deposits on the Canadian Shield.

Other major deposits include: copper on the Canadian Shield and in England; tin in England; uranium on the Canadian and African shields; platinum in Canada and the U.S.S.R.; chromium in South Africa and the U.S.S.R.; manganese in India, West Africa, and Brazil; lead and zinc in New Jersey, Idaho, British Columbia, and New South Wales; graphite in Korea and Siberia; mica in the U.S.S.R. and India; and talc in northeastern and southwestern United States.

Absence of fossil fuels

Equally notable are the mineral deposits that are lacking, especially the fossil fuels—coal, oil, and gas. There may have been such deposits in Late Precambrian time, but the intense metamorphism that has altered those old rocks has destroyed any fossil fuels that may have existed, except traces represented by deposits of graphite and the carbonates.

PALEOZOIC HISTORY

Stability of shields and mobility of geosynclines. During the Precambrian the shields included mobile geosynclines containing seaways that were bordered by mountainous uplifts. The mobile belts were subject to folding, faulting, volcanic activity, and intrusion of granite. By the beginning of Paleozoic time, the shields had become stable parts of the granitic crust forming the continents, and their complicated rock structures were eroded to low relief. The stable areas included the shields and the structural platforms bordering them. The platforms, and to a lesser extent the shields, were overlapped by shallow seas during the Paleozoic; both areas were subject to warping, but there was no more strong folding, faulting, or igneous activity.

Along one or more sides of each of the shields, unstable mobile belts formed deep troughs during the Paleozoic. In each such geosyncline, sediment accumulated to thicknesses of six to ten miles as the troughs sank, and these sediments thin against and overlap the platforms bordering the shields (Figure 5). Curiously, most of the sediment in the geosynclines was derived not from the shields but from mountains in the unstable mobile crust outside the geosynclinal belt; the sediments were mostly from mountains that no longer exist and were transported toward the shields.

This poses a double problem. Not only have the mountains been lost but if they were approximately symmetrical, there has also been lost that half of the sediments that must have been eroded from the far side. The problem can be relieved, perhaps, by assuming that the lost mountains were asymmetrical and represented a turned up edge of the continent. It is also possible that island arcs (*q.v.*) were present, having formed along the zone where sea-floor spreading caused underthrusting of the continental margins.

Early Paleozoic geosynclines and shelves. Just before the beginning of Cambrian time, a geosynclinal trough had formed along the west, south, and southeast sides of the Canadian Shield and along the northwest side of the Baltic Shield. The geosyncline in Europe is named the Caledonian. With the beginning of Cambrian time the geosynclines deepened. Similarity of fossils in the Caledonian and northeast Appalachian geosynclines suggests a connection across what now is the Atlantic Ocean.

The Caledonian and Tethys geosynclines

In North America and northwestern Europe, the Late Precambrian and earliest Cambrian deposits are mostly clastics—sandstone and shale—whereas the later Cambrian deposits are mostly limestone.

In the Anti-Atlas Mountains of northwest Africa the base of the Cambrian is within a thick limestone sequence. The faunas in these formations are related to those in the Cambrian of Asia Minor and eastern Asia. This marks the beginning of a long-lasting east–west trending geosyncline known as Tethys; the Mediterranean Sea is a descendant.

Ordovician formations in the Caledonian Geosyncline in Wales are of the eugeosynclinal types, but calcareous deposits of shallow seas overlapping the platform extend toward the Baltic Shield. Around the core of North America, Ordovician formations include shallow-water carbonate formations on the platform, miogeosynclinal formations bordering the platform, and eugeosynclinal facies away from it. The miogeosynclinal formations are largely marine carbonate and shale; the eugeosynclinal facies are mostly clastic, consisting of sandstone and black shale (Normanskill and Deepkill shales) with lavas, volcanic ash, and other volcanic derived sediments.

During the Silurian Period subsidence continued. In North America the seas on the platform divided into basins where evaporation increased the salinity and led to the precipitation of salts. In the British Isles the Early Paleozoic geosyncline filled with sediment, with shale accumulating in the inner basin and calcareous and sandy deposits along the margin. The volcanism that had occurred during the Ordovician almost ceased.

The Caledonian Geosyncline ended with an episode of strong folding in Devonian time. Tethys and the North American geosynclines also were subjected to folding during the Devonian, but those geosynclines persisted.

Early Paleozoic folding and igneous activity. Both in North America and along the Caledonian Geosyncline, rather steady subsidence during the Cambrian caused the sea to transgress on the platforms. There is little evidence of folding or of igneous activity in those mobile belts during the Cambrian. In the middle European (Czechoslovakia) and Mediterranean (Morocco) geosynclines, however, during the early stages of Tethys, there was volcanism and deposition of graywackes, and there was folding in Central Asia and Australia.

Throughout the world during the Ordovician and Silurian, there were repeated episodes of folding and volcanism. This deformation and igneous activity attained a

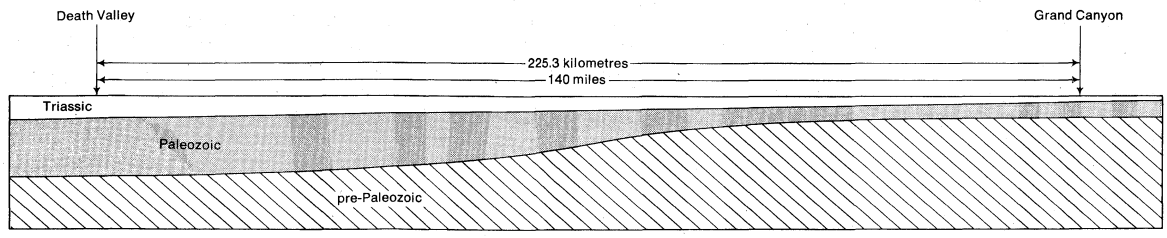

Figure 5: Thinning of sediments upon a stable shield area, illustrated by a cross section from Death Valley to the Grand Canyon. The vertical and horizontal scales are the same.

climax during the Devonian. Much of the granite in eastern North America formed at this time.

Late Paleozoic geosynclines and shelves. In North America, after the Devonian, the eugeosynclinal part of the Appalachian Geosyncline ended. The north part of the geosyncline divided into three deep troughs, each of which received distinctive sediments during the Mississippian and Pennsylvanian. In the central Appalachians the Mississippian is represented chiefly by clastic sediments derived from erosion of Devonian formations that had been uplifted to the east. Farther south and west these grade to limestone. During the Pennsylvanian (Upper Carboniferous) and Permian, deltaic or coastal plain deposits including coal beds spread westward across what had been the geosyncline and onto the platform to the west. In western North America the Cordilleran Geosyncline continued to deepen and received marine sediments as late as Permian time.

The Variscan and Uralian geosynclines

The European geosyncline is called the Variscan. In England, Mississippian (Lower Carboniferous) formations are largely limestone; in Scotland they are limy sandstone. Major folding at the end of the Mississippian produced Late Paleozoic mountains, and the great European coal deposits formed in the basins around them. Central Europe was unstable at this time, and episodes of folding are recorded by numerous unconformities. A geosyncline at the site of the Ural Mountains had begun deepening by Silurian time; in it accumulated 10,000 feet (3,000 metres) of Mississippian deposits, 2,000 feet (600 metres) of Pennsylvanian, and 7,000 feet (2,200 metres) of Permian.

The Late Paleozoic seas reached their greatest extent during the Mississippian. Thereafter, as sediments were deposited faster than the troughs sank, coastal plain deposits completed the filling of the geosynclines. These deposits and their coal beds are the outstanding feature of the Late Paleozoic; indeed, this part of earth history is referred to as the Carboniferous Period.

Late Paleozoic deposition on the platforms in central Europe and southwestern United States ended in the Permian when the salt beds were deposited. In Europe, these beds (Zechstein) include the famous Stassfurt Salts. The formations, 3,000 feet (900 metres) thick, extend across most of the north German plain. Potassium salts at the centre of the basin are surrounded by a belt of sodium chloride which in turn grades outward to salt-free clastic deposits. Important deposits of potassium and other salts formed also in the Permian basins in western Texas and southeastern New Mexico and in Pennsylvanian basins in western Colorado and eastern Utah.

Late Paleozoic folding and igneous activity. At least five major episodes of folding occurred during the Late Paleozoic. The first was at the end of the Devonian. After Middle Mississippian time regression became general, and the seas became more and more restricted. In Europe, folding occurred at the end of the Mississippian. Folding was renewed during and after the Permian. Similar folding terminated the Appalachian and Cordilleran geosynclines in North America.

Late Paleozoic tillites

Paleoclimates. Tillites are known in Devonian and Permian formations. The Devonian occurrences are in South America and South Africa. By contrast, the marine Devonian in North America, Europe, Southeast Asia, and Australia contains coral limestone, which suggests a relatively warm environment. Possibly the continents have shifted so that what is now the South Atlantic Ocean near 20° west longitude and 40° south latitude was at the South Pole. The north part of the Pacific Ocean would have been at the North Pole. The Equator, in this reconstruction, would have been near the south coast of Australia, extending through the Arabian Peninsula, central Europe, and eastern North America, and diagonally back across the Pacific to Australia.

Permian tillite is widely distributed in southern South America, southern Africa, India, and Australia. The deposits are associated with a distinctive flora (*Glossopteris* flora) that is indicative of a cool climate. The Pennsylvanian and Permian fern forests of Europe and North America, source of the rich coal deposits there, are suggestive of a warm climate. Permian climatic conditions were therefore somewhat like those of the Devonian.

Paleozoic life. One of the most remarkable events of geological history is the abrupt appearance, at the beginning of the Cambrian, of animals representing all of the major phyla. The suddenness with which they appear in the record is especially impressive because, as already noted, in many geosynclines there was continuous deposition of sediments from the Late Precambrian into Paleozoic time. In the midst of this continuous sedimentation a striking change in population occurred. The large numbers of animals with complex morphology that suddenly appear in the geologic record must have been preceded by a long period of evolution of the living forms, but the Precambrian rocks contain no such record.

To be preserved as fossils, animals must have hard parts —shell, bone, or tests. The seas that advanced into the Late Precambrian geosynclines must have contained an abundant and varied fauna of morphologically complex forms without hard parts, and something happened during an early stage of those seas to enable the animals suddenly to develop shells or tests. Most of the first hard parts seem to have been of chitin, but by Middle Cambrian time most animals were utilizing calcium carbonate. Perhaps it was increasing CO_2 (carbon dioxide) in the atmosphere passing some critical threshold that made certain complex carbohydrates available for animal use in manufacturing chitin at first and calcium carbonate later.

Known Cambrian fossils are from marine deposits. Freshwater and terrestrial animals and plants appear later in the Paleozoic, but this may be due to the fact that the Cambrian record is not complete. The Cambrian fauna is dominated by trilobites, arthropods that shed their chitinous exoskeletons during growth. Brachiopods with simple phosphatic shells also appear in the Cambrian; later in the Cambrian shells of calcium carbonate developed. Another Cambrian animal, the archaeocyathid, may have been related to the corals or sponges.

Diversification of life after Cambrian time

During the Ordovician, trilobites and brachiopods became more numerous and more diversified; cephalopods and gastropods also became abundant. Ordovician black shale contains planktonic (floating and swimming forms) animals known as graptolites. These also are present in the Silurian but then decline. The first vertebrates, in the form of fishes, appear in the Ordovician but do not become abundant until the Devonian.

Devonian marine formations are dominated by brachiopods, bryozoa, and corals that are numerous and varied; trilobites and graptolites greatly decline. The first known forests are Devonian, although some land plants are known from the Silurian. Amphibians first appear in the Devonian.

During the Mississippian, stalked echinoderms, crinoids, are abundant, as are bryozoa and thick-shelled brachiopods. During the Pennsylvanian, great forests of fern trees growing in swamps gave rise to extensive coal deposits. Amphibians further evolved, and by Permian time there were reptiles. During the Permian, forests changed from the fernlike forms to plants related to conifers, and these became dominant during the Mesozoic. Among the important marine shells of the Pennsylvanian and Permian are the calcareous protozoa, fusulinids.

Extinctions, or near extinctions, at the end of the Paleozoic include the colonial, rugose, and tabulate corals and the chief groups of Paleozoic plants, the seed ferns and scale trees.

Mineral resources. The Paleozoic rocks and the most important mineral deposits in them are largely of sedimentary origin. Most notable are the fossil fuels—coal, oil, and gas. The principal coal deposits of the world are of Late Paleozoic (Carboniferous) age. Oil and gas resources constitute about 15 percent of the world's total; this is considerably less than the known occurrences in Mesozoic or Cenozoic rocks.

Evaporites yielding potash, sodium, and other salts are major resources in Silurian and Permian formations. Sedimentary iron formations are important in the Appalachian Geosyncline and in European platform deposits.

Metalliferous deposits in Paleozoic rocks locally are important, but many or most of these are due to post-Paleozoic emplacement or enrichment.

MESOZOIC HISTORY

During the Mesozoic, the shields continued to be stable cores of the continents. They had been submerged by shallow seas during the Paleozoic, but when they emerged they remained so until the second half of the Mesozoic. During the Cretaceous the platforms bordering the shields again were shallowly submerged.

Some parts of the continental margins that had been mobile during the Paleozoic became stable platforms during the Mesozoic. Along the Atlantic and Gulf coasts of North America, for example, Cretaceous and younger formations rest on a smoothly bevelled platform of folded and metamorphosed Paleozoic formations.

Triassic stratigraphy and paleogeography. Geosynclines generally were more restricted during the Triassic than during the Permian, but Tethys persisted from the western Mediterranean to eastern Asia, as did the geosyncline along the west side of North and South America.

On the platform Permian evaporites became buried by fluviatile sandstones and conglomerates around the edges of the depositional basins and by marine siltstone with beds of carbonate, anhydrite (calcium sulfate), and rock salt in the inner basin. As the basins became connected with the open sea, limestone was deposited. The Triassic ended with deposition of deltaic beds, in part coal-bearing, followed by brightly coloured, shallow water, marine clay, and sandstone grading upward into the Jurassic.

Alpine Triassic formations

At the present site of the Alps, Triassic formations are 10,000 feet (3,000 metres) thick. They are almost entirely marine, in contrast to the generally land-derived deposits on the platform to the north. The western Tethys (Alps) Geosyncline grew from south to north. Marine Triassic deposits appear first in the south; correlative deposits in the north Alps are marginal continental deposits. As the marine deposits transgressed northward across these continental deposits, reefs began forming in the southern part of the geosyncline. During the Middle Triassic the sea floor in the geosyncline became covered by carbonate deposits, partly of coral and partly of calcareous algae.

Renewed uplift and folding again restricted the sea and led to weathering of the exposed formations, and these became buried under conglomerate, sandstone, and shale as the sea again advanced. The sea reached its maximum extent during the Late Triassic, when thick bedded limestone and dolomite were deposited.

In North America, a geosyncline developed along the western edge of the continent, and more than 25,000 feet (7,700 metres) of eugeosynclinal sediments were deposited in it, derived by erosion of mountains that lay to the west, in what now is the Pacific Ocean. To the east were discontinuous miogeosynclinal basins. Farther east, in what is now the area of the Rocky Mountains and Great Plains, was a continental platform where less than 1,000 feet (300 metres) of sediments accumulated, largely of continental origin. Beyond, to the northeast, was the Canadian Shield, much of it still covered by Paleozoic formations. Triassic geosynclinal deposits also occur along the length of the Andes in South America.

Triassic deposits in the Appalachian and Himalayan belts

In eastern North America, the Triassic is represented by continental red beds with associated dikes, sills, and lava flows of diabase. The red beds, consisting mostly of conglomerate, sandstone, and shale a few thousand feet thick, were deposited as alluvial-fan and river-floodplain deposits in basins formed by faulting. The sills and lavas in the red beds form some prominent topographic features in the eastern United States, including the Holyoke Ridges in Massachusetts; East and West Rock at New Haven, Connecticut; the Palisades of the Hudson; Watchung Ridges in northern New Jersey; and Cemetery Ridge at Gettysburg, Pennsylvania.

In Asia, peninsular India continued to be stable, but continental Triassic sandstone and shale were deposited in linear, downfaulted basins. Marine Triassic in the mountains of Baluchistan and the Himalayas are generally conformable with the underlying Permian. The Lower and Middle Triassic formations are mostly shale, whereas the Upper Triassic is mostly limestone. The deposits are many thousands of feet thick and represent the eastern continuation of Tethys, which continues eastward to Burma and Laos, where the structural trend turns southward.

In peninsular India and on the shields of Africa and South America, continental Triassic and underlying Late Paleozoic formations are much alike and contain closely related floras, the *Glossopteris* flora. Plant species are so closely related as to suggest that the three widely separated areas were connected, probably by being juxtaposed and subsequently separated as the continents drifted apart.

Jurassic stratigraphy and paleogeography. The record of the Jurassic Period, like the Triassic, is best known in Europe, where it was named for the Jura Mountains. The Tethys Geosyncline was extended westward in the region of the western Alps. To the north and northwest, in Germany, France, and England, partly marine and partly continental platform deposits were formed. The Jurassic sea overlapped beyond the limits of the Triassic sea, and the sediments deposited on the platform north of the geosyncline extended across the eroded, folded mountains of Paleozoic formations.

Early Jurassic formations in Europe are mostly dark shale. The Middle Jurassic formations are mostly brown sandstone and oolitic limestone, and the Late Jurassic are mostly limestone.

Formation of salt domes and diapirs

The Jurassic generally was a period of structural quiet in Europe, but two important structural developments occurred. On the north German plain, the Permian salt deposits became squeezed upward in salt plugs. Thick deposits of salt are plastic, and under the load of Triassic and Jurassic deposits, the light density salt was squeezed upward in masses shaped like teardrops. As the salt rose, the beds at the sides were dragged upward. The rising masses of salt, known as salt domes (*q.v.*) and diapirs, are analogous to air bubbles rising in dough. The upward rise probably began in the Triassic; it continued during the Cretaceous.

The other important Jurassic structural development in Europe was in the Alpine Geosyncline, where the broad downwarp became interrupted by submarine, anticlinal ridges. Uplift of the ridges caused submarine sliding; mountainous masses, known as nappes, slid as much as five kilometres into the synclinal basins. The anticlinal ridges divided the geosyncline into northern and southern troughs, which extend eastward as the Carpathian and Dinaride geosynclines. They in turn rejoin in the geosyncline extending through Asia Minor and along the Caucasus Mountains.

Tethys continued eastward along the site of the Himalayas, where the Jurassic formations are largely carbonates conformable on those of the Triassic, although the upper part of the section is shale grading upward to sandstone in the Cretaceous. Farther east the geosyncline divides irregularly.

In North and South America, a Jurassic geosyncline extending the length of the Pacific coast of both continents consisted of a eugeosyncline on the west and miogeosyncline on the east. The sediments were derived from mountains to the west in what now is the Pacific Ocean. In California, 30,000 feet (9,200 metres) of Lower and Middle Jurassic sediments were deposited. A second trough was in western Utah. Eastward the formations thin to 1,000 feet (300 metres) or less on the platform at the site of the Colorado Plateau and Rocky Mountains, and they thin out against the shield.

Cretaceous stratigraphy and paleogeography. The Cretaceous Period was named for the chalk beds that outcrop in northwest Europe, but chalk is by no means the characteristic Cretaceous rock.

Tethys continued to develop and was extended northward along the site of the Pyrenees. Shallow seas lay to the north and wrapped around the Baltic Shield. In the Alps, Cretaceous formations aggregate about 9,000 feet (2,700 metres) thick; on the platform to the north they are up to 3,000 feet (920 metres) thick but thin against

the shield. Toward the west in the geosyncline the deposits are calcareous; northeastward they are shaly and sandy. In the Bavarian–Austrian foothills are deposits consisting of sandstone, breccia, siliceous limestone, and chalk derived by erosion of ridges within the geosyncline and the accumulation of sediments in rapidly subsiding troughs north of the ridges. These deposits, termed flysch, are sparsely fossiliferous but are believed to range from Early Cretaceous to older Tertiary in age.

Cretaceous transgressions and regressions of the seas

In Europe, the Early Cretaceous began with a stage of regression followed by major transgression that ended when there was folding in the eastern Alps and northwest Germany. This folding was followed by renewed transgression at the beginning of Late Cretaceous time, and again the transgression was interrupted by folding in the Alps, Dinarides, and northwest Germany. Following this, the Cretaceous sea reached its maximum extent in latest Cretaceous time, and this stage was terminated by folding of the Alps and Apennines at the end of the Cretaceous and beginning of the Tertiary.

In North America, a Lower Cretaceous geosyncline in northern Mexico and southwestern United States received as much as 15,000 feet (4,600 metres) of sediments. A similar but smaller geosyncline in the Great Plains in Canada received 5,000 feet (1,500 metres) of sediments. A third one, in northwest California and westernmost Oregon, Washington, and British Columbia, received a maximum of 25,000 feet (7,700 metres) of sediments.

Marine transgression continued during the Upper Cretaceous, and the Gulf of Mexico became connected with the Arctic Ocean. The trough of this geosyncline extended northwestward across Texas and the transcontinental arch to the site of the Rocky Mountains and then northward along the Rockies to the Arctic. A maximum of about 15,000 feet (4,600 metres) of sediments was deposited in this trough. A second trough along the Pacific Coast continued to develop and received up to 10,000 feet (3,000 metres) of sediments.

Mesozoic folding and igneous activity. Early Mesozoic deformation occurred during the Triassic in eastern North America. During the Middle Jurassic, granite batholiths were emplaced along the Pacific Coast of North and South America. Folding is not necessarily accompanied by granitic intrusion, but granitic intrusions are accompanied by folding. Radiometric age determinations of granitic rocks in the Sierra Nevada suggest the occurrence of at least five intrusive episodes there: Early and Middle Jurassic, Middle and Late Jurassic, Late Jurassic, Early Cretaceous, Late Cretaceous. If age determinations were available for rocks along the length of the Pacific Coast, continuous Mesozoic igneous and structural activity along the Pacific edge of the continents probably would be revealed.

Deformation of Tethyan deposits; continental drift

Tethys, which was well formed by the Late Paleozoic, persisted without much deformation until the end of the Turonian Stage of the Cretaceous, when the geosynclinal sediments, together with part of the crystalline basement, were folded and uplifted to form the core of the western Alps. Similar uplift and folding in the northeastern Alps produced the troughs that received the marine flysch deposits.

At the end of the Mesozoic Tethys was folded and uplifted, as was the Upper Cretaceous geosyncline that extended along western North America from the Gulf of Mexico to the Arctic Ocean.

In the Paraná and Uruguay River valleys in South America are vast quantities of basalt that were erupted during the Jurassic. In South Africa extensive dikes and sills of basalt have been interpreted as accompanying the breakup of the equatorial continent (Gondwanaland) that included lands of the Southern Hemisphere. The breakup occurred during the Cretaceous; this dating is suggested by the occurrence of Cretaceous sediments (overlain by Tertiary and Quaternary) resting on basalt in the South Atlantic Ocean.

Mesozoic life. Mesozoic plants and animals differ greatly from those of the Paleozoic. Whereas Paleozoic trees are giant ferns, Triassic plants include groups still extant, such as conifers. Broadleaf trees became abundant during the Cretaceous and probably contributed greatly to the evolution of those mammals and birds that depend on nuts and fruits of such plants.

Mesozoic life: the age of reptiles

The Mesozoic commonly is known as the age of reptiles because of the dinosaurs, which survived only to the end of the Mesozoic. Most Triassic dinosaurs were small; Jurassic dinosaurs included some weighing many tons. In Cretaceous time the horned dinosaurs appeared.

Birds first appear in the Jurassic. Mammals appear in the Triassic but were small and remained so until the end of the Mesozoic.

As early as Triassic time modern forms of corals, clams, and gastropods become common. The most distinctive Mesozoic marine forms are the ammonites, whose rapid evolution and wide extent have provided the basis for the finest chronologic subdivision of the geologic column. They underwent three great extinctions, first in the Late Permian, from which only one stock survived; again in the Late Jurassic; and finally at the end of the Mesozoic, when total extinction occurred. Subdivisions of the Mesozoic are based on evolutionary changes in the ammonites. The end of the Mesozoic may be further characterized as having no species of invertebrates or vertebrate animals surviving to the present.

Of equal or perhaps greater importance in earth history is the massive extinction of microscopic forms of marine plankton at the end of the Mesozoic. Of 44 taxa of calcareous microscopic plankton, 34 did not survive from the Mesozoic to the Cenozoic. Another large group that became extinct were the rudistids, a group of benthonic (bottom-dwelling) pelecypods thought to have lived in shallow water.

Why these massive extinctions during so brief a span of geologic time? An explanation based on predators seems inadequate. Excessive radiation caused by some cosmic event does not seem to fit with the survival of the land flora or the extermination of some benthonic forms that would have been shielded from radiation by water. A change in ocean chemistry may have exterminated part of the microscopic marine fauna and flora and so reduced the rest that the loss of this population deprived other populations of their food supplies. The problem resembles that of the seeming population explosion at the beginning of the Cambrian; an understanding of one might lead to better understanding of the other.

Mineral resources. Principal mineral resources in Mesozoic rocks include oolitic iron in Jurassic formations in England, France, and Germany, which makes the Jurassic deposits the most important Phanerozoic source of iron. Fossil fuels are major. Coal in the Cretaceous in western North America is second only to the Pennsylvanian. Oil and gas from the Cretaceous in Texas, California, the Great Plains, the Wyoming Basin, and Venezuela is second in value only to production from Cenozoic fields. Major deposits of uranium are in Triassic and Jurassic platform deposits on the Colorado Plateau.

Copper, tin, silver, and gold deposits are associated with the Late Mesozoic granite intrusions, including the Mother Lode deposits in California that caused the 1849 Gold Rush. In Africa, diamonds occur in volcanic pipes of Jurassic or Cretaceous age.

CENOZOIC HISTORY

The Cenozoic Era, comprising the last 65,000,000 years of earth history, is divided into the periods and epochs listed in Table 2.

Massive extinction of biota at the end of the Cretaceous led to the rise and dominance of mammals, modern shellfish, deciduous trees and other flowering plants. Geosynclines that had formed during the Mesozoic were ended by folding and uplift. The high mountain chains of the world are largely Cenozoic for this reason. Also, the continents and oceans assumed their modern shapes during Cenozoic time. The last 2,500,000 to 3,000,000 years witnessed climatic changes sufficient to cause several major glaciations; produce lakes in the deserts of the southwestern United States; led to substantial shifts in the bio-

Table 2: Division of the Cenozoic Era by Period and Epoch

period		epoch	approximate age of time boundary
Quaternary		Holocene (Recent)	began about 10,000 years ago
		Pleistocene	began about 2,500,000 years ago
Tertiary	Neogene	Pliocene	began 7,000,000 years ago
		Miocene	began 26,000,000 years ago
	Paleogene	Oligocene	began 38,000,000 years ago
		Eocene	began 54,000,000 years ago
		Paleocene	began 65,000,000 years ago

ta, such as the southward migration of North Sea species of shellfish into the Mediterranean; and other changes in soils and ground conditions.

End of Tethys in Europe and growth of the Alps. Uplift of the Alps had begun during the Cretaceous and it continued into the Paleocene and Eocene. A depression north of the uplift received flysch deposits and these overlapped northward as the trough and Alpine thrust sheet advanced northward onto what had been platform.

Flysch and molasse deposits and subsequent deformation

This Early Tertiary deformation greatly restricted the Tethys Sea, and the low areas became buried by as much as 12,000 feet (3,700 metres) of Oligocene and Miocene clastic deposits derived by erosion of the newly formed mountains by northward flowing streams. The deposits, known as molasse, include conglomerate and sandstone in alluvial fans that grade northward to alluvium, which in turn grades northward to lake or brackish water deposits. The molasse overlaps and extends northward beyond the marine flysch. The flysch was involved in this folding and so were the more southerly and early formations of the molasse. South of the uplift the molasse also overlaps and extends beyond the flysch.

Finally, during the Pliocene and Quaternary, the Alps were uplifted by broad arching, and the sea was expelled. The Alps owe their great altitude to this very late uplift, and they owe their spectacular landforms to later sculpturing by Pleistocene glaciers.

The platform north and northwest of the Alps was largely land at the beginning of the Tertiary. Marine transgression reached a maximum in middle and late Eocene time and again during the early and middle Oligocene. The Paris Basin was a bay. After Middle Tertiary time regression occurred, and the platform emerged.

Tethys has not completely ended. It still exists as the Mediterranean Sea, and the earth movements that reduced Tethys continue in the form of regional earthquakes and the active volcanism in Sicily and Italy.

End of Tethys in Africa and Asia. On the south flank of the Tethys Geosyncline in northwest Africa, marine transgression was followed by folding and uplift during the Eocene and at the end of the Oligocene. Two straits connected the geosyncline with the Atlantic Ocean, one in southern Spain and one in the Atlas Tellien (Tell Atlas) of northern Africa.

East African rift system and Himalayan development

Most of the rest of Africa remained stable during the Cenozoic, but East Africa developed a unique, extensive system of rift valleys (*q.v.*) resulting from block faulting. The fault valleys extend from Lake Nyasa to the Red Sea, the Gulf of Aqaba, and the Dead Sea and join the south flank of the Tethys Geosyncline at the head of the Jordan River Valley. The rifting may have started as early as Cretaceous time, but most of the displacement is Cenozoic, and some is as young as Pleistocene. It is today a belt of moderately active seismicity.

In India, at the eastern end of Tethys, uplift and folding of the Himalaya Mountains began toward the close of the Eocene and reached a climax during the middle Miocene, when there was much folding, thrust faulting, and intrusion of granite in the mountain belt. South of the Himalayas a trough separated the mobile geosynclinal belt from the stable shield of peninsular India, and in it was deposited 15,000 to 20,000 feet (4,600–6,200 metres) of upper Miocene to lower Pleistocene fluviatile and lacustrine sediments (Siwalik Series). These formations are folded in the Siwalik Hills, for which they were named, at the south foot of the Himalayas and probably extend southward under the Indo-Ganges Plain.

On the shield of peninsular India, during latest Cretaceous and earliest Tertiary time, the plateau basalts (Deccan Traps) were erupted. The lavas cover 200,000 square miles and are up to 5,000 feet (1,500 metres) thick.

The belt of Tertiary Himalayan folding turns southward in Burma and continues southeastward through the islands of Indonesia. There was folding during the Miocene, and the continued activity in the mobile belt is reflected in the seismically active belt of volcanoes in western Sumatra, southern Java, and the lesser islands to the east. Southwest of this belt is a structural trough, and south of that there was Miocene folding, but volcanoes were absent. North of the volcanic belt, in Malaysia and parts of Borneo, a platform existed on rocks that had been folded during the Paleozoic and Mesozoic.

Volcanism and earthquakes around the Pacific. The belt of active earth movement and volcanism noted in Indonesia turns northward in the western part of the Pacific Ocean and forms long island arcs that are convex toward the ocean basin at the Philippine Islands, Japan, the Kurile Islands, the Kamchatka Peninsula, and the Aleutian Islands. A second earthquake belt with active volcanoes extends southwestward through the Solomon Islands and New Hebrides. New Zealand is on the projection of this arc. On the opposite side of the ocean, along the coast of North and South America, earthquakes are frequent and volcanoes are active or have been recently. Around all of the Pacific the depth of the earthquake centres is least toward the ocean basin and greatest toward the bordering continents, as if the continents were drifting toward the ocean basin.

The island arcs that rim the Pacific

Volcanoes surrounding the Pacific Ocean have erupted some basalt but greater amounts of more siliceous rocks, and this has been attributed to melting of continental sialic rocks as well as basaltic material from the lower part of the crust or even from below it. By contrast, volcanoes within the ocean basin, like those in Hawaii, are entirely basaltic. Gravity, seismic, and other evidence suggests that the Pacific is underlain almost entirely by basalt. The Paleozoic and Mesozoic geosynclines along the Pacific side of North and South America, however, received sediments derived from mountainous landmasses of sialic composition that were located in what is now the Pacific Ocean. One theory holds that North and South America have been drifting westward, and the lost mountains have foundered and have been overridden by the westward drifting continents. Whatever the cause, the opposite sides of the Pacific Ocean, both youthful, are very different structurally.

Structural development of North and South America. Like the other continents, North and South America rose above sea level during the Cenozoic, and only the edges were transgressed by the sea. Many of the Cenozoic formations on these continents are terrestrial deposits derived by erosion of the mountains that were uplifted at the end of Cretaceous and beginning of Tertiary time.

Development of the Andes and Rocky Mountains

In South America, Early Tertiary marine sediments of Eocene (?) and Oligocene age were deposited in the upper basin of the Amazon River. According to one theory, the embayment extended eastward from the Pacific coast of Peru; the lower Amazon at that time would have been an elevated plain draining westward. When the Andes were uplifted in Middle Tertiary time the outlet to the Pacific was closed, and the basin, filled with Tertiary sediments, spilled eastward to the Atlantic. Uplift of the Andes in Peru (peaks above 20,000 feet [6,200 metres]) continued to Late Pleistocene time. The mountains are probably still rising, as indicated by frequent strong earthquakes, fresh fault scarps, and volcanic activity.

During the Cenozoic, the Isthmus of Panama was submerged intermittently, and at such times the two Americas were separated. When the continents were connected the vertebrate faunas mixed; they developed independently when the two continents were isolated.

In North America, at the end of the Cretaceous and be-

ginning of the Tertiary, the Rocky Mountains rose from what had been the Upper Cretaceous geosyncline. In Early Tertiary time the Great Plains and foot of the Rocky Mountains were near sea level. The drainage was disintegrated and collected in basins such as the Green River Basin, Powder River Basin, San Juan Basin, and others. In Oligocene time the basins overflowed, and as the region became uplifted during the Middle Tertiary, drainage eastward off the Rocky Mountains built broad alluvial plains that extended to the central United States. By Late Tertiary time the drainage, collected in a few valleys, could join the Mississippi River system. Since then, as uplift continued, the drainage system has become incised into the older Tertiary fans. Drainage westward off the mountains reached Grand Canyon, and the Colorado River was initiated in Miocene time.

Along the Pacific Coast of North America small deep basins formed during the Cenozoic (*e.g.*, the Los Angeles and Ventura basins) and became filled with sediments several miles thick. During the Cenozoic, the Mesozoic granite batholith of the Sierra Nevada was faulted on the east, uplifted, and tilted west. To the north, the Cascades began in the Early Tertiary as a series of shield volcanoes, and in the Late Tertiary and Quaternary on top of this volcanic ridge were built the magnificent volcanic cones of the High Cascades.

East of the Cascades is one of the world's great plateau basalts, the Columbia Plateau. Most of the lavas were erupted during the Middle Tertiary, but there were sporadic earlier eruptions, and the volcanism has continued to the Quaternary. At the east end of the volcanic field, at Yellowstone National Park, the volcanic activity is recent enough to maintain the celebrated hot springs and geysers.

The eastern edge of North America had been submerged during the Cretaceous and very gradually emerged during the Cenozoic. The Atlantic coastal plain formations rest on a platform of folded and faulted Paleozoic and Triassic rocks.

The Americas are thought to be drifting westward into the Pacific and away from Europe and Africa. The rate of drift may be as great as two centimetres a year, which would be enough to span the Atlantic since Late Mesozoic time.

Pleistocene glaciations. The Pleistocene Epoch lasted about 2,500,000 years and has been called the Glacial Period or Ice Age because at several times ice caps formed in polar regions. The resulting ice sheets formed continental glaciers that spread into temperate latitudes. In North America the ice covered all of Canada and advanced southward into the United States as far as Long Island and the Ohio and Missouri rivers. In Eurasia, ice caps formed on the Baltic Shield, the west Siberian lowland, and the Angara Shield and spread southward across the northern European and western Siberian plains. Local ice caps formed also in the mountains beyond the continental glaciers.

Extent of ice sheets

To develop glaciers requires not merely low temperatures but also adequate precipitation. Mountains in Alaska and eastern Siberia had local alpine glaciers but no continental ice cap because the precipitation was not sufficient. Parts of the cold north slope of Alaska, for example, today receive less than five inches of precipitation yearly.

The last glaciation reached its maximum extent some 20,000 to 25,000 years ago and since then has melted back to the position of the present ice caps on Greenland, Antarctica, and some high mountains. The last glaciation was recent enough to have profoundly affected the landforms both directly and indirectly. Drainage systems were disrupted, sea level rose and fell, lakes expanded and contracted, and relics of such changes exist today. The permafrost, or permanently frozen ground of the far north, is one example. See PLEISTOCENE EPOCH for a detailed treatment of this ice age in earth history.

Development of modern fauna and flora. During the Cenozoic the big animals have been mammals. Marsupials and insectivores appeared during the Cretaceous; most of the other orders appeared during the Early Tertiary. Elephants are known in the earliest Tertiary deposits in Italy. The early forms were small; they reached maximum size during the Pleistocene, when mammoths and mastodons were abundant.

The development of the grasses and the seed- and nut-bearing trees and shrubs during the Cenozoic probably was both a cause and an effect of the proliferation of the mammals. Grasses appear in the Middle Tertiary, and about that time horses and camels changed from browsing leaves to grazing (shown by the evolution of their teeth).

At the beginning of the Cenozoic the vegetation covering the land appeared much like that of the present, but the geography of the plants was very different and grasses did not become abundant until the Miocene.

Changes in the marine invertebrate faunas during the Cenozoic can be expressed in terms of percentages of species that have survived to the present. Practically no Mesozoic species survive. Less than 5 percent of the Eocene species survive, and about 15 percent of the Miocene species, 35 percent of Pliocene species, and 95 percent or more of Pleistocene species still survive. Moreover, with changes in temperature of the ocean water caused by the glaciations, cold-water forms have alternately migrated southward and retreated northward.

Marine invertebrate faunas

Earliest man in the world dates to the beginning of the Pleistocene. The earliest remains are from the Lower Pleistocene in Africa where the Australopithecinae (*Australopithecus, Paranthropus, Zinjanthropus*) have been found. In the Middle Pleistocene appears Java man (*Homo* or *Pithecanthropus erectus*), Peking man (*Homo* or *Pithecanthropus pekingensis*), and Heidelberg man (*Homo heidelbergensis*). Neanderthal man (*Homo neanderthalensis*) is found in Upper Pleistocene deposits. Modern man (*Homo sapiens*) dates from the last glaciation.

Mineral resources. Cenozoic formations, especially in the Near East, Caribbean region, and United States, contain more than half of the world's oil and gas. Notable deposits in the United States are the fields along the Gulf Coast and in California, and the oil shale deposits in the Eocene Green River Formation on the Colorado Plateau. Other fossil fuels include coal in Japan and vast deposits of lignite on the Great Plains in Canada and the United States. Other deposits in sedimentary rocks include bromine, borax, and other salines in lake beds in the Wyoming Basin and southwestern United States, phosphate in Late Tertiary formations in Florida, and bauxite in Arkansas. Practically all sand and gravel in the world is from Cenozoic deposits, and in addition there are widespread deposits of diatomaceous earth, perlite, pumice, clay, and peat.

Principal Cenozoic metallic ore deposits are associated with igneous intrusions that accompanied the folding and uplift of the Cenozoic mountain ranges. They include tin in Bolivia and copper and silver in the Andes; chromite in Asia Minor; mercury in the Paleozoic rocks at Almadén, Spain; porphyry copper ores in the Basin and Range Province of western North America (including Butte, Montana); molybdenum at Climax, Colorado; gold and silver at numerous districts in western North America; and gold placers, especially those at the west front of the Sierra Nevada in California, in Alaska, and in Australia.

Earth, Gravitational Field of

The gravitational field, or gravity, of the Earth is manifested as the force acting on a free, unsupported body, causing it to move in the general direction of the Earth's centre. The speed of the body is not uniform; it increases with time and distance, the rate of change in speed being called acceleration. Acceleration is a measure of the Earth's gravitational field and is denoted in the literature by the symbol *g;* it represents one of Earth's fundamental mechanical properties (see EARTH, MECHANICAL PROPERTIES OF). The Earth's gravity is not fixed but varies from place to place on the surface, as well as in the Earth's interior. It is expressed as an increase of velocity per second; and, because velocity is measured in units of centimetres per second or feet per second, acceleration is stated in centimetres per second per second (denoted as cm/sec^2) or feet per second per second (ft/sec^2).

The average gravitational field at the Earth's surface is 979.76 cm/sec^2, or 32.144 ft/sec^2. The main variation of this acceleration is with latitude, or distance from the Equator. At the Equator it averages about 978.03 cm/sec^2; at the poles, about 983.22 cm/sec^2. There are other variations of about ±.04 cm/sec^2, which are also of interest: they indicate variations of density within the Earth that are of scientific importance, and they affect measurement systems designed to obtain accurate locations, such as geodetic control surveys and artificial-satellite-tracking networks. The expression "study of the Earth's gravitational field" is conventionally used to mean the study of the properties of the Earth's interior as inferred from the gravitational acceleration at the surface. This type of study is the subject of this article, which includes the definition of terms used to express the field, measurement of the Earth's field, and the geological and geophysical interpretations that can be made.

The study of the Earth's gravitational acceleration to infer its effect on measuring systems and its relation to other modes of expressing the field is physical geodesy (see EARTH, FIGURE OF). Other related articles include GRAVITATION; EARTH, STRUCTURE AND COMPOSITION OF; RIFT VALLEYS; OCEANIC RIDGES; MOUNTAIN-BUILDING PROCESSES; ROCKS, PHYSICAL PROPERTIES OF; EARTH, MECHANICAL PROPERTIES OF; and EARTH AS A PLANET.

DEFINITION OF GRAVITY

According to Newton's second law of motion, the force between two bodies is directly proportionate to the product of their masses and inversely proportionate to the square of the distance between them. A body of mass (symbolized as m) at the surface of the Earth is attracted as though all the mass of the Earth (M) were concentrated at its centre. The force of attraction between the body and the Earth (F) will be equal to the product of a constant of proportionality (G) and the masses of the body (m) and Earth (M), divided by the distance between the body and the Earth (R) squared. This can be written in equation form as $F = GmM/R^2$, in which R is the separation distance (*i.e.*, the radius of the Earth), m and M are the masses of the body and the Earth, and G is the constant of proportionality (called the universal gravitational constant). A free body acted upon by this force is accelerated toward the centre by an amount (g) equal to the force divided by its mass—that is, $g = F/m$—or, substituting the value of force from the former equation, the acceleration of gravity is equal to the gravitational constant times the Earth's mass divided by its radius squared; *i.e.*, $g = GM/R^2$, which is seen to be independent of the mass of the body. As this equation shows, from the acceleration of any mass relative to the Earth, the Earth's total mass and something about its mass distribution can be determined.

Hydrostatic figure of the Earth. If the Earth were a perfectly homogeneous sphere, then the acceleration at every point on its surface would be GM/R^2, in which G is the gravitational constant (6.67×10^{-8} cm^{3}gm^{-1} sec^{-2}), M is the Earth's mass (5.97×10^{27} grams [6.6×10^{21} tons]), and R is its mean radius (6.37×10^8 centimetres [2.09×10^7 feet]). The major departure from this gravitation law arises from the rotation of the Earth. The rotation of the Earth on its axis adds a component to the acceleration at its surface through centrifugal acceleration (approximately 3.36 cm/sec^2 [0.11 ft/sec^2] at the Equator but zero at the poles). This centrifugal acceleration causes an additional effect on gravity by distorting the shape of the Earth, which is not rigid, thus changing slightly the distance of the surface from the centre of mass. A homogeneous fluid sphere would be distorted into an ellipsoid of revolution, with a slight flattening at the poles. The Earth has an appreciable increase in density toward the centre, so that its equivalent rotating fluid figure (called its hydrostatic figure) would differ slightly from an ellipsoid. The shape of an ellipsoid is conventionally expressed by its flattening (f) expressed as the (dimensionless) ratio of the difference between the equatorial radius (a) and the polar radius (b) to the equatorial radius, or $f = (a - b)/a$. The flattening (f) of the hydrostatic figure of the Earth is 1/299.8, which is a reference figure for geophysical purposes.

Effects of Earth's rotation

Reference ellipsoid and standard gravity. Because the hydrostatic figure differs by only a few metres from an ellipsoid, it is mathematically convenient to use one as a reference figure. The ellipsoid that best fits the observational data has a flattening of 1/298.25 (this difference from the hydrostatic figure implies stresses in the Earth); nevertheless, the ellipsoid that is used as the basis for referring gravity measurements has a flattening of 1/297, because this value was the best estimate when the International Union of Geodesy and Geophysics adopted a standard formula in 1924. This formula for standard gravity (denoted by the Greek letter gamma, γ) is equal, in centimetres per second per second, to 978.049 times a correction factor composed of sine terms of the Earth's latitude (symbolized by the Greek letter phi, ϕ):

$$\gamma = 978.049\,(1 + 0.0052884 \sin^2 \phi - 0.0000059 \sin^2 2\phi).$$

This formula applies to gravity at sea level. Besides giving an incorrect variation with latitude, the equatorial value ($\phi = 0$) of gravity of 978.049 cm/sec^2 is too high and 978.032 cm/sec^2 is now believed to be a better estimate. Because many data have been expressed in terms of the 1924 standard and because the difference has no significance for most applications of gravity data, the standard will probably never be changed.

Gravitational attraction decreases with altitude, and so gravity values at an elevation above sea level are customarily corrected to apply at sea level. These corrected observations are called free-air gravity values, because the mass of Earth material between the observation station and sea level directly below is neglected. A free-air gravity value thus represents the gravity at sea level (g_0) and is equal to the gravity at the observation station (g_h) plus a numerical factor, 0.3086×10^{-3} times the elevation (h) in metres of the station above sea level; *i.e.*, $g_0 = g_h + 0.3086 \times 10^{-3}\, h$ cm/sec^2.

Gravity above sea level

When the crustal Earth matter between the observation station and sea level is taken into account, a correction for its gravitational attraction must be considered. The effect of such matter can be approximated by assuming that it is an infinitely broad slab having the same thickness as the elevation. The gravity value corrected for sea level in this manner is called the Bouguer gravity (see below *Bouguer anomaly*) value, after Pierre Bouguer, a mathematician and hydrographer of 18th-century France. The Bouguer gravity value (g_B) is equal to gravity at the elevation of the observation station (g_h) minus a factor 0.04815 times density (symbolized by the Greek

letter rho, ρ) of the material slab times the elevation (h) in metres: $g_B = g_h - 0.04815\rho\, h$ cm/sec^2.

Gravity anomalies. *Free-air anomaly.* The quantity symbolized by Δg represents the difference between the free-air gravity value (g_0) and the standard gravity value (γ) cited above, or $\Delta g = g_0 - \gamma$, and is known as the gravity anomaly. It is measured in units of the gal, a conventional term for the acceleration unit of one centimetre per second per second, named in honour of the Italian Galileo. Because the gravity anomaly Δg is always less than 0.5 cm/sec^2 and usually less than 0.1 cm/sec^2, the unit customarily used is the milligal, 0.001 cm/sec^2.

The sea-level surface to which the gravity anomaly refers is known as the geoid (Figure 1). The geoid represents a surface that is everywhere at right angles to the direction of gravity. Over the oceans the geoid coincides with the mean (a statistical average, taken midway between two extreme values) sea level. Hence, its continuation on the land is inside the Earth.

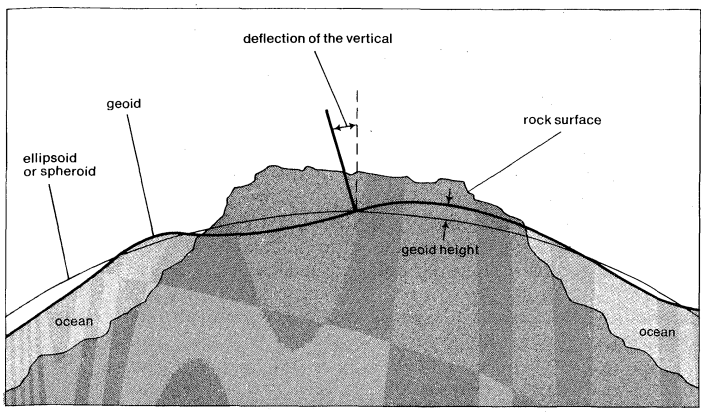

Figure 1: Deflection of the vertical from the geoid to the spheroid (see text).

Bouguer anomaly. When the mass of the Earth material between the observation station and the geoid is taken into account the anomaly is referred to as the Bouguer gravity anomaly, Δg_B. It is equal to the Bouguer gravity value minus the standard gravity value (γ), or $\Delta g_B = g_B - \gamma$; that is, $\Delta g_B = g_h - .04815\rho\, h - \gamma$, in gal units. The error caused by the flat-slab assumption in the Bouguer anomaly is usually less than one milligal; in mountainous terrain, however, it may amount to more than 50 milligals. A topographic correction must be applied, therefore, in which the differential attractions of mountains higher and valleys lower than the gravity-observing station are computed from a topographic map.

The free-air gravity anomalies (Δg) normally have a positive correction with height above sea level in a given region, because of the attraction of the extra matter. The Bouguer anomalies (Δg_B), however, have a much more pronounced negative correlation with elevation, as though the rocks had a density significantly less than what they are observed to have (the value of ρ used in the equations), 2.5 to 2.8 grams per cubic centimetre. The hypothesis therefore arose that in the topography beneath sea level there is a compensation of equal mass per unit area but of opposite sign.

Isostatic anomalies. Gravity anomalies corrected for a compensation in a manner similar to the topographic correction are known as isostatic anomalies. Isostasy literally means "equal standing." There are two principal types of isostatic correction, the Pratt–Hayford and the Airy–Heiskanen. As shown in Figure 2, the Pratt–Hayford correction assumes that the compensation is accomplished by horizontal variations in density (symbolized by ρ) down to the level of equal pressure, whereas the Airy–Heiskanen correction assumes that it is accomplished by variations in the thickness of a layer of constant density. The Pratt–Hayford correction was originally suggested in the 19th century by John Henry Pratt, an English archdeacon and amateur scientist, and later developed in detail by a United States civil engineer, John Fillmore Hayford; and the Airy–Heiskanen correction was first proposed in the 19th century by an English astronomer, George Biddell Airy, and later developed by the Finnish geodesist Weikko Aleksanteri Heiskanen.

The two types of isostatic correction

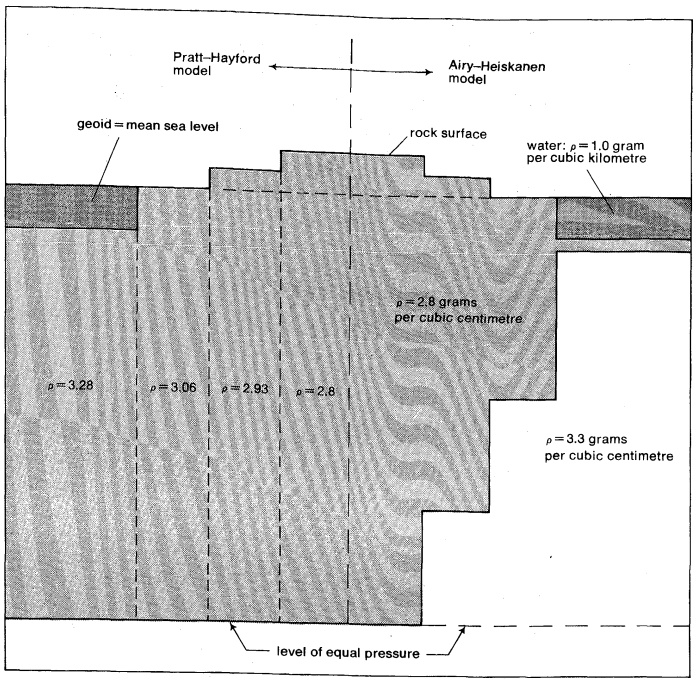

Figure 2: Pratt–Hayford model and Airy–Heiskanen model of isostasy (see text).

By adjusting the depth of compensation, the systematic correlation of isostatic gravity anomalies with elevation can be removed. For Pratt–Hayford anomalies, the depth to the level of equal pressure is usually 60 to 120 kilometres (37.5 to 75 miles). For Airy–Heiskanen anomalies, the crustal thickness corresponding to zero elevation above sea level is usually 20 to 40 kilometres.

Because the crust does have some strength, in the real Earth the isostatic compensation is regional. A regional gravity anomaly reduction correction was devised by a Dutch geophysicist, F.A. Vening Meinesz. In this system the compensation of each topographic feature is distributed over a specified radius. Other, more elaborate types of gravity anomaly have been proposed, but the free-air and Bouguer anomalies are those most commonly used.

Harmonic analysis of gravity. Any variation of a quantity over the surface of a spherical or nearly spherical body, such as the Earth, can be expressed mathematically as the sum of terms known as spherical harmonics. The expression is particularly convenient for theoretical manipulation, in which the gravity anomaly is the radial gradient of the gravitational potential (change of potential with radial distance; potential is related to gravity in that it represents the work required to move a unit mass to infinity against the force of the Earth's gravitational attraction). When spherical harmonics are used, the conventional expression for gravity field is the potential, which varies with latitude and longitude. The dimensionless coefficients C_{lm} and S_{lm}, in which the indices l and m take successive integer values until the potential reaches the approximation desired, are conventionally used to represent gravity as an alternative to the spatial representation by anomaly Δg or geoid height (displacement distance of geoid from reference ellipsoid). The most important coefficient is C_{20} ($l = 2$, $m = 0$), known as the oblateness. The oblateness is the consequence of the distortion of the Earth by its rotation, the gravitational equivalent of the flattening (f). The order of magnitude of coefficient C_{20} is 10^{-3}; of all other coefficients, 10^{-6} or less.

Oblateness

MEASUREMENT OF GRAVITY

There are three principal systems for measuring the gravitational acceleration of the Earth, namely, gravimetry,

astrogeodesy, and artificial-satellite orbit perturbations. Because each system measures the gravitational field differently, a different expression of the field is appropriate for each.

Gravimetry. The gravimetry system measures the gravitational acceleration (g_h) directly. The instruments used are of three distinct types: (1) the timing of the free fall of an object in a vacuum, (2) the timing of the period of a pendulum, which is inversely proportional to the square root of gravitational acceleration, and (3) the measurement of the force exerted on a mass by the tension on a spring required to hold it at a null point (point at which the operative forces balance and hence cancel). Of these instruments, those timing the free fall can measure the absolute value of the gravitational acceleration most accurately; but it is a difficult experiment, performed in only a few laboratories around the world. Type (3), the spring balance (called a gravimeter), is the most sensitive for measuring small differences in gravity from place to place, less than about one cm/sec^2, or 1,000 milligals. Gravimeters are, however, subject to systematic errors such that they require calibration over a greater range of values. Type (2), the pendulums, are less sensitive than gravimeters but are more stable; they are less accurate than free-fall devices but are more portable. Because of these various instrumental characteristics, the entire gravimetric system is a combination of absolute measurements at a few laboratories that are connected to north–south calibration lines by pendulums that measure differences up to about five gals. East–west reference ties of less than one gal difference by gravimeter make up the remainder of the network that serves as a control for field measurements by gravimeter.

Gravimeters have been developed that are extremely portable on land, and the effort spent in using one is actually less than that expended on a survey to obtain the elevation h, a preliminary to the free-air reduction to sea level. Pendulums were taken to sea in a submarine for the first time in 1923. Since then, considerable development in stabilizing devices has made possible measurements in surface vessels and in aircraft, the principal source of inaccuracy often being the navigation to obtain latitude and longitude.

Pendulum measurements at sea

From gravimetry, the free-air anomaly over a large portion of the world is known with varying detail. There still remain, however, large areas without measurements, particularly in the oceans of the Southern Hemisphere (see GRAVITATION).

Astrogeodesy. The vertical is the direction of the force of gravity, perpendicular to the geoid, as indicated by the solid line in Figure 1. The direction of the vertical with respect to the coordinate axes defined by the fixed stars (called inertial coordinates) can be measured by theodolites; *i.e.*, in effect, telescopes that have attached sensitive level bubbles and accurately divided circles. These inertially referred directions can be corrected to directions referred to Earth-fixed coordinates by radio time signals that in effect give the Greenwich sidereal time, the angle between Earth-fixed and inertial coordinate axes.

The normal is the direction of the perpendicular to the reference ellipsoid, as indicated by the dashed line in Figure 1. The normal can be considered as the horizontal coordinates in a system referred to the ellipsoid. Differences in horizontal coordinates from place to place are measured by methods, called triangulation and traverse, that use theodolites in conjunction with such distance-measuring instruments as tapes or electronic devices.

The difference in angle between the vertical and the normal is the deflection of the vertical, which is the same as the slope of the geoid with respect to the ellipsoid. The displacement of the geoid from the reference ellipsoid is known as the geoid height (N). It and the gravity anomaly (Δg) are both expressible in terms of a disturbing potential; that is, the difference in potential between the actual Earth and the reference ellipsoid. The geoid height may then be obtained by integrating the slope variations in the geoid over the anomaly wherever astronomic and geodetic measurements are available. Such measurements have been made over much of the major continents but were not in the early 1970s possible over the oceans. (See EARTH, FIGURE OF; SURVEYING.)

Artificial-satellite orbit perturbations. If the Earth were a homogeneous sphere and there were no atmosphere, Sun, Moon, or planets, then an artificial satellite would move in a perfect ellipse in an unvarying plane. The main difference of an actual satellite orbit from the hypothetical ellipse is represented by the oblateness factor C_{20}, the major effects of which are to cause rotations of a few degrees per day of (1) the plane of motion about the polar axis, called the precession of the node, a node being the point at which the plane of motion intersects the Equator; and (2) the ellipse within the plane, called the precession of the perigee, the point of closest approach. In addition, the satellite oscillates about these steady precessions at rates that are various combinations of the rates of rotation of the node, the perigee, the satellite itself, and the Earth. These oscillations, or perturbations, are of less than five kilometres (three miles) in amplitude and are caused by the other variations in the Earth's gravitational field. Because their effects depend very much on the wavelength of the oscillation and the satellite's direction of motion, for satellite-orbit analysis these variations are best expressed by the spherical harmonic coefficients C_{lm}, S_{lm}.

Effect of oblateness on artificial satellites

Photographic and tracking networks around the world enable the determinations to be made within about two metres (seven feet) of the amplitudes of systematic oscillations in certain selected satellite orbits. This accuracy is sufficient to determine 100 to 200 of the gravitational coefficients C_{lm}, S_{lm} (see EARTH, FIGURE OF; MECHANICS, CELESTIAL).

Results of gravity measurements. Figure 3 shows the Earth's gravitational field expressed in terms of the free-air anomaly. This field is a determination made in 1970 by E.M. Gaposhkin and K. Lambeck of the Smithsonian Astrophysical Observatory from a combination of satellite-orbit perturbations and gravimetry.

Figure 4 is an example of a more limited regional survey made by gravimeters in northern California and northeast Nevada. Here the Earth's gravitational acceleration is expressed in terms of the Bouguer anomaly, as is customary. It is evident from Figure 4 that there is a considerable amount of local variation of the gravitational field as well.

INTERPRETATION OF GRAVITY DATA

Isostasy. The dominant fact about the variations of the Earth's gravitational field is that they are much smaller than would exist if the topography were rigidly supported on a homogeneous interior. This fact was first noticed in the Andes and was later confirmed in the Himalayas: the mountains always showed less attraction than calculated. The explanation for this mildness of gravity variations is assumed to be some sort of isostatic compensation for the topography, such as the alternatives sketched in Figure 2.

Evidence of isostasy appears in Figure 3 because there is no apparent correlation of the free-air gravity anomalies with the topography of the continents and oceans. By statistical analysis, the correlation of free-air anomalies with topography is negligibly small for features of more than 4,000 kilometres (2,500 miles) in extent. For smaller features, the correlation is positive but still much less than would prevail if the topography were rigidly supported.

Evidence of isostasy also appears in Figure 4; the Bouguer anomalies are most negative at places where the topography is highest, along the mountains of the Sierra Nevada Range between Sacramento, California, and Reno, Nevada.

Isostasy is apparently a consequence of the evolution of the Earth's crust coupled with the mechanical weakness of rocks. During the 4,600,000,000 years of Earth history, those topographic features that chanced to be associated with some sort of density compensation have persisted, whereas those that constituted an excess or deficiency were reduced by creep of the rocks in response to the stresses caused by these loads. The rate of this creep

Origin of isostasy

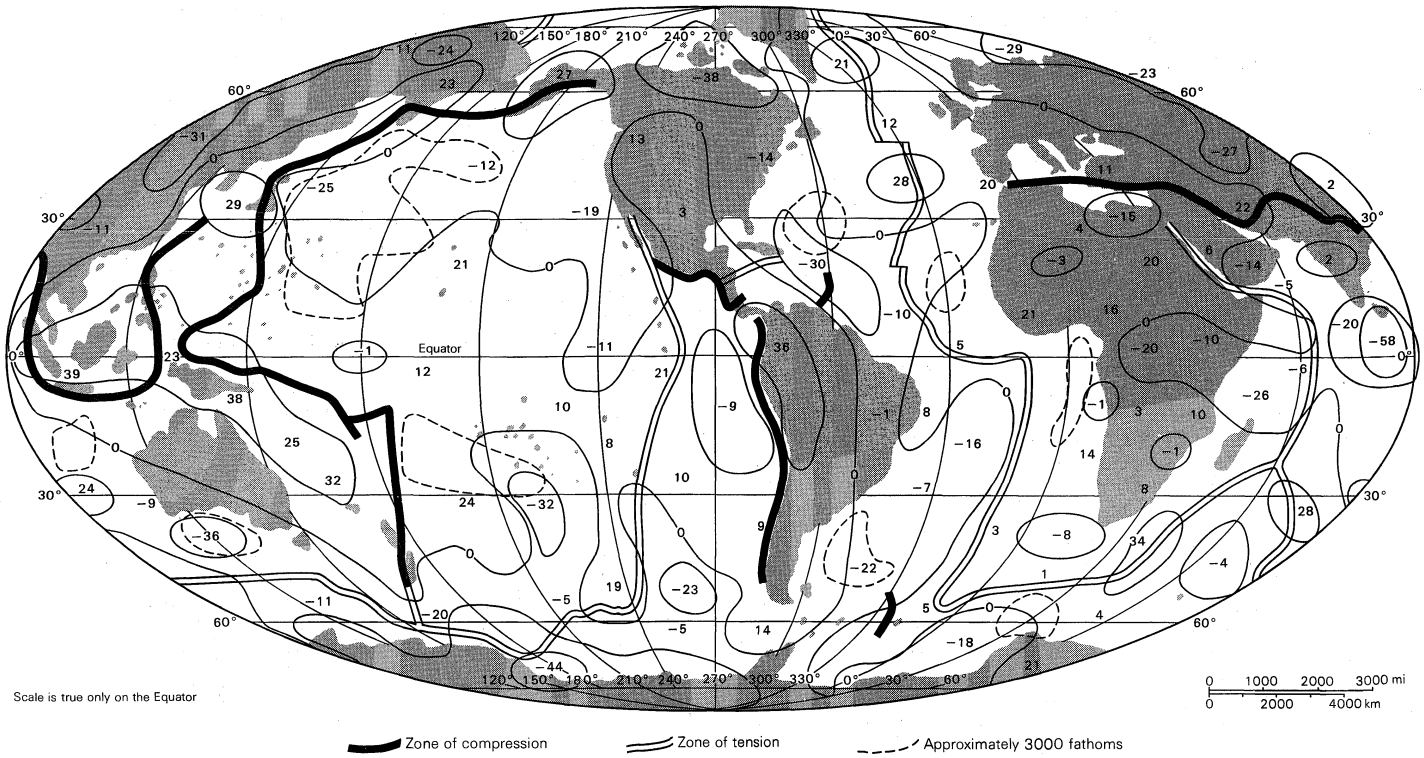

Figure 3: World gravity distribution, showing free-air anomalies in milligals.
After E.M. Gaposhkin and K. Lambeck in W.M. Kaula, *Science*, vol. 169, p. 983 (September 4, 1970); American Association for the Advancement of Science

is directly proportionate to the extent of the load: large features are rapidly obliterated, but small ones of less than 100 kilometres (60 miles) extent can remain for several 10^8 years.

The finds of seismology indicate that the Airy–Heiskanen hypothesis of isostasy probably prevails. The depth to the Mohorovičić Discontinuity (named after a Croatian geologist, Andrija Mohorovičić), the rather sharp interface between crustal rocks (density about 2.8 gm/cm^3) and mantle rocks (density about 3.3 gm/cm^3), is positively correlated with topography. However, there are also many areas in which variations in rock type indicate that a form of Pratt–Hayford compensation exists.

Because isostasy is mainly a consequence of the passive adjustment of rocks in the Earth to stresses, the concept tells little about the primordial forces that have shaped the Earth's crust. Though isostasy is a general characteristic that must be taken into account, it is far short of a full explanation of the variations in the Earth's gravitational field.

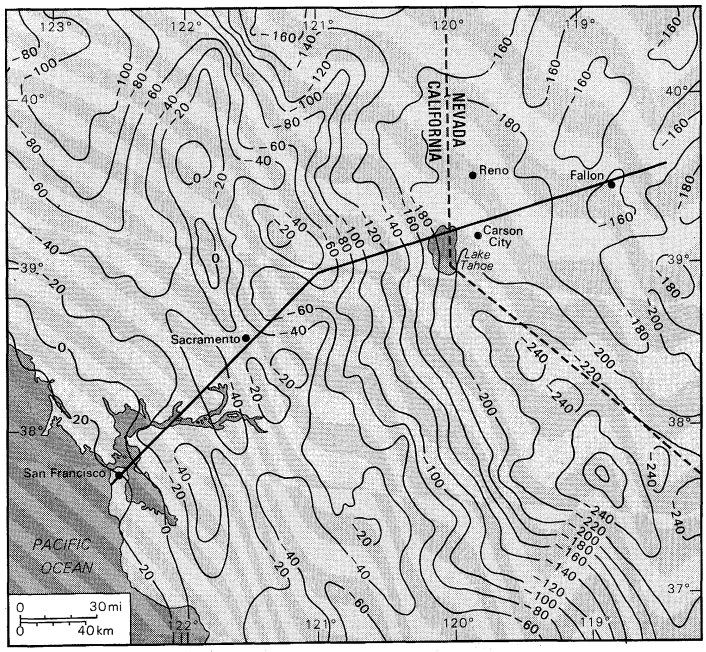

Figure 4: Gravity distribution in the region including the San Francisco to Fallon, Nevada, transect.

Local irregularities: geophysical prospecting. Variations in the gravitational field on a scale of kilometres are necessarily associated with densities and structures of rather shallow rock inferred from the surface geology.

Sometimes erosion and sedimentation will result in the concealment of geologic features uncorrelated with surface geology. In these circumstances, accurate gravimetric surveys have aided in the finding or evaluation of mineral resources. The indications of a gravimetric survey may be direct, as when an ore body consists of a mineral distinctly denser than its surroundings, or indirect, as when certain geologic structures trap economically exploitable deposits.

The use of gravimetry for prospecting requires measurement within plus or minus 0.05 milligal. The interpretation is usually complicated by the need to remove regional trends resulting from deeper seated variations. The ambiguity of the results is normally such that in promising cases further investigation is undertaken by seismological techniques that reveal greater detail. Hence, gravimetry performs mainly a reconnaissance function.

Regional irregularities: crustal structure. Most scientific use of gravimetry has been to investigate structures on a scale of tens to hundreds of kilometres. At the shorter end of this scale, the gravimetry can be most readily correlated with variations in rock type. Toward the longer end of the scale, the gravimetry can be correlated with variations in seismic velocities associated with both natural and artificial sources. These variations in seismic velocities are caused by variations in rock density, which is positively correlated with velocity, or by variations in the depths of interfaces between rocks of different densities.

Correlation of gravimetry with seismic velocities

As an example, Figure 5 is an interpretation of the Bouguer gravity anomalies along the section cut by the line from San Francisco to Fallon, Nevada, in Figure 4. This section crosses five distinct geologic provinces.

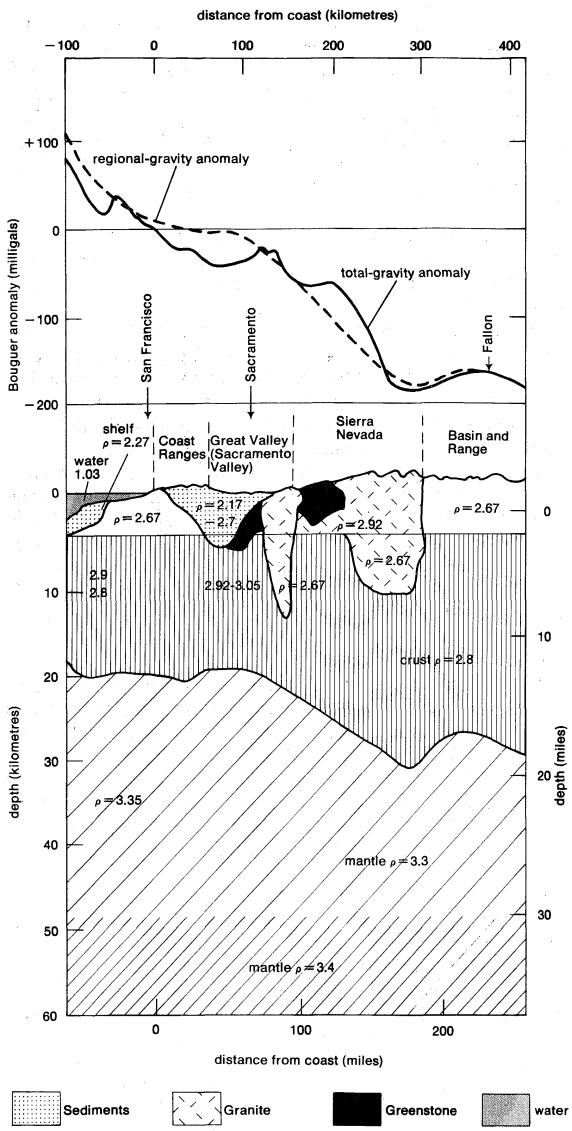

Figure 5: Gravity anomalies and inferred subsurface configuration and density distribution, along the San Francisco to Fallon, Nevada, transect.

From G.A. Thompson and M. Talwani, *Science*, vol. 146, pp. 1539–49. Copyright 1964 by the American Association for the Advancement of Science

From left to right, they are: (1) the Pacific continental slope of North America; (2) the California Coast Ranges, a complicated young, active mountain belt at an angle to the coast; (3) the Great Valley, a heavily sedimented region; (4) the Sierra Nevada, a great block tilted about 2° westward; and (5) the Basin and Range Province, a region of recent faulting, warping, and extension.

The dominant feature of Figure 5 is the inverse correlation of the Bouguer anomaly with topography, mainly a manifestation of isostasy. Variations about this trend of tens of kilometres in extent are explicable by geologic data extrapolated to less than five kilometres' (three miles') depth. Variations below the regional trend are associated with the light sediments of the continental slope and the Great Valley; anomalies above the trend are associated with belts of greenstone, metamorphosed volcanic rocks of high density. Larger variations are explicable by seismological data that reveal low-density rocks of the granitic Sierra Nevada and oscillations of the Mohorovičić interface between crust and mantle. Finally, a portion of the overall trend must be ascribed to a variation in density in the upper mantle itself. Such a variation, together with the shallower than usual Mohorovičić Discontinuity, is characteristic of a region of recent mountain-building activity.

Other types of regional irregularities have been explained by gravity anomalies, always in combination with geologic and seismic data, sometimes in combination with heat-flow or magnetic-anomaly data. Examples include (1) trench and island arcs, which have a sharp negative gravity anomaly over the trench and a more moderate but widespread positive anomaly over the islands; (2) oceanic rises, which have sharp local variations in gravity correlated with a rugged sea bottom but only a mildly positive regional character; and (3) areas of postglacial uplift, which are predominantly negative, as well as regions of sedimented basins (negative), granitic batholiths (negative), and volcanic belts (positive) similar to those occurring in the above-described example. (See RIFT VALLEYS; OCEANIC RIDGES; and MOUNTAIN-BUILDING PROCESSES.)

Large-scale irregularities: global tectonics. Not until 1970 had the determination of the major variations in the gravitational field become accurate enough to show distinct correlations with other global tectonic phenomena (those associated with crustal deformations), for which determinations from paleomagnetic, seismological, and other data have evolved rapidly since 1963. The main features of this global tectonic pattern are shown in Figure 3 by belts of tension, along which crustal material comes up and spreads out, mainly ocean rises; and belts of compression, along which crustal material is thrust back into the mantle, mainly trench and island arcs and mountain belts.

Features correlated with gravity anomalies

The most important correlation of the global gravity field is that large regions of positive gravity anomaly are regions of current geologic change, as measured by the amount of volcanism, earthquakes, heat flow, and mountain building. The one great exception to this rule is the East Asian portion of the Alpide Belt, the compressive belt extending from the Mediterranean to Indonesia in Figure 3. This region is unique in that it is the only case of compression resulting from abutment of two continental masses, in contrast to the usual case of a continent and an ocean basin; apparently, the great thicknesses of low-density crust are too buoyant to be thrust down into the mantle.

The principal regions of negative gravity anomaly are either areas of postglacial uplift, in which the great glaciers of the Ice Age melted away about 10,000 years ago, or basins: topographic lows characterized by thick sediments, no seismic activity, and low temperatures, as inferred from heat-flow measurements and seismic velocities. Ocean basins are marked on Figure 3 by dashed lines corresponding to the 3,000-fathom- (5,500-metre-[18,000-foot-]) depth line.

Correlations of the gravity field with other global tectonic phenomena are enhanced if the variations expressed by fifth and lower degree (corresponding to the maximum value of l that is used) spherical harmonics (*i.e.*, of more than 4,000-kilometre [2,500-mile] extent) are subtracted from the gravity. This fact suggests that part of the field may be caused by the lower mantle, perhaps the core–mantle interface.

The increasing indications that the major tectonic activity in the Earth moves at rates of one to ten centimetres (0.4 to four inches) per year and that the upper mantle contains a zone of relatively low viscosity, or resistance to flow, require that explanations of broad variations in the gravity field be in terms of a dynamic flow system. Probably the greatest effects of this system on the gravity field arise from the behaviour of the lithosphere, the layer of mechanical strength 50–80 kilometres (30–50 miles) thick that includes the crust, in response to flows in the asthenosphere, the low-viscosity zone 80–400 kilometres (50–250 miles) deep.

BIBLIOGRAPHY. The Earth's gravitational field is part of the study of the solid Earth; modern undergraduate texts on this topic include ARTHUR N. STRAHLER, *The Earth Sciences*, 2nd ed. (1971); and JOHN VERHOOGEN *et al.*, *The Earth: An Introduction to Physical Geology* (1970). Texts specifically treating the gravitational field are G.D. GARLAND, *The Earth's Shape and Gravity* (1965); and A.H. COOK, *Gravity and the Earth* (1969). More advanced treatises are by W.A. HEISKANEN and F.A. VENING MEINESZ, *The Earth and Its Gravity Field*

(1958); and HAROLD JEFFREYS, *The Earth*, 5th ed. (1970). Excellent collections of articles on recent investigations of the solid Earth are P.J. HART (ed.), *The Earth's Crust and Upper Mantle* (1969); and E.C. ROBERTSON (ed.), *The Nature of the Solid Earth* (1971). More technical books on specific aspects are W.M. KAULA, *Theory of Satellite Geodesy* (1966); MILTON B. DOBRIN, *Introduction to Geophysical Prospecting*, 2nd ed. (1960); and GUY BOMFORD, *Geodesy*, 2nd ed. (1961).

Earth, Heat Flow in

Heat flow in the Earth is generally described as the rate of heat conduction per unit time and per unit area to the Earth's surface. Units in which heat flow is measured are small in terms of everyday experience: the heat flow unit (HFU) is 10^{-6} calories per square centimetre per second. The average value for the Earth's crust is about 1.5 HFU and is roughly the same for the continents and the ocean floors. Heat flowing at this rate would take about a year to melt a layer of ice only six millimetres thick. The heat received from solar radiation is 2,000 to 3,000 times as great. Yet heat derived from within the Earth during geological time has played an important role in forming the surface features of the Earth.

Early observations of the Earth's heat

The origin of the Earth's interior heat has long been a subject of inquiry. Volcanic eruptions led ancient scholars and alchemists to many and varied speculations on the mystical sources of subterranean fire. In Britain, Robert Boyle in the 17th century made one of the first significant inquiries into the subject of heat flow, however, and, when the first mines subsequently were dug deep into the Earth, it became apparent that a thermal gradient exists—*i.e.*, that the temperature of the Earth increases with depth. In the deepest modern mines, the temperature is so high that air-conditioning equipment must be installed to prevent miners from being roasted.

Truly accurate underwater measurements of heat flow were first made in the 1950s, and only in the 1960s, with the construction of more advanced electronic instrumentation and greater availability of suitable oceangoing vessels, were heat flow measurements made routinely on the ocean floor. Geothermal heat-flow measurements for the Earth's surface are by no means complete.

The thermal history of the Earth is intimately connected with the problem of the origin of the Earth. Similarly, information about the Moon's thermal history should prove valuable in explaining the origin of that satellite. Apollo heat-flow measurements, for example, have indicated a heat-flow value for the Moon about one-half that of the average heat flow for the Earth. Such a heat-flow value implies that most of the present heat emanation from the Moon results from the decay of radioactive isotopes with long half-lives. (The half-life of an element is the amount of time required for half of a given amount of that element to be changed into other elements or isotopes through radioactive decay.) It seems likely that very little of the present lunar heat flow stems from retention of initial temperatures during the period of the Moon's formation.

This article treats the origin of the Earth's heat, its transmission from the interior to the Earth's surface, and certain geological aspects of heat flow. For further information on the Earth's origin and internal constitution, see EARTH, GEOLOGICAL HISTORY OF and EARTH, STRUCTURE AND COMPOSITION OF. For coverage of the elements within the Earth and their radioactive decay, see ELEMENTS, GEOCHEMICAL DISTRIBUTION OF and DATING, RELATIVE AND ABSOLUTE. Articles treating the principal geological aspects of heat flow include SEA-FLOOR SPREADING; CONTINENTAL DRIFT; ORE DEPOSITS; MOUNTAIN-BUILDING PROCESSES; GEYSERS AND FUMAROLES; VOLCANOES; IGNEOUS ROCKS; and ROCK METAMORPHISM, PRINCIPLES OF. For additional information on the heat transmissibility of rocks of several kinds, see also ROCKS, PHYSICAL PROPERTIES OF.

SOURCES OF THE EARTH'S HEAT

There are several possible sources of heat flow in the Earth. These include the original heat of the matter that formed the Earth; the heat produced by the decay of radioactive isotopes within the Earth; gravitational contraction of the Earth as it solidified; tidal heat of friction produced by movement of materials inside the Earth under the influence of gravitational attraction of other heavenly bodies; chemical reactions within the Earth; and electromagnetic interaction with the solar wind, which is a stream of electrons and protons discharged from the Sun.

Of these possibilities, the most significant are the heat involved in the formation of the Earth and the heat produced by the decay of radioactive isotopes within the Earth.

Theories of Earth formation

Original heat of the Earth. One theory of Earth formation holds that the Sun was formed by condensation of interstellar matter. After its formation, a far-reaching cloud of gases and dust particles remained outside it. Gradually, as small particles in the cloud collided with larger ones, they coalesced to form still larger particles. As these bodies grew larger, they acquired more smaller particles through gravitational attraction. Tremendous amounts of heat were generated because the kinetic energy (energy of motion) of the smaller particles striking the large ones was converted into heat. As the surrounding cloud was exhausted of its matter, fewer collisions could occur and less heating took place. Heat was radiated from the Earth's surface, thus leading to the formation of a solid crust by cooling.

Another theory, which is actually a variant of that cited above, involves first the condensation of the gaseous cloud surrounding the Sun, forming bodies (protoplanets) that possess gaseous atmospheres. As the Sun formed, its heat dissipated most of the gases in the atmospheres of these protoplanets, leaving the planets in somewhat their present forms. Again, gravitational compaction and friction from particle collisions are held to have heated the Earth.

Any theory of Earth formation necessarily involves the gradual loss of initial heat through time. This heat loss thus constitutes a possible and plausible component of the Earth's heat flow.

Heat produced by radioactive decay of elements. At some stage in its development, the Earth almost certainly contained large pressures and large quantities of heat, which caused much melting to occur in its interior. Because they crystallize at lower temperatures than iron, silicon, or magnesium compounds, molten radioactive elements were forced upward as the denser materials settled toward the core under the influence of gravity. Heat produced by the decay of radioactive isotopes was brought to the surface by conduction. If some radioactive rocks of the crust were wedged too far down to lose heat to the surface by conduction, the heat given off as they decayed would raise the temperature in their locality sufficiently to melt the surrounding material and so let them rise eventually to a point nearer the surface. Thus heat generated by radioactivity would flow away from its source quickly enough to prevent further melting. As molten materials solidified, crystals would form. Any fluid remaining during this process would carry heat upward by convection. The crystals then would solidify in such a way as to force upward any remaining fluid. In this way a sort of stability would be maintained; the mantle would then be at a temperature below the melting point of any of its components. The solid crust would extend downward just far enough to carry away heat of radioactivity.

The first mentions of radioactivity as a source of the Earth's heat flow were made in England by two physicists, Ernest Rutherford and Robert John Strutt, 4th Lord Rayleigh. In 1906 Rayleigh showed that the amount of heat produced by radioactive decay of radium in the Earth's crust is enough to account for the entire flow of heat from the Earth.

Recent observations and calculations indicate that approximately 80 percent of the Earth's heat flow is due to radioactive decay, whereas the remaining 20 percent is derived from the original heat of the Earth. Naturally occurring radioactive substances with a very long half-

life that are sufficiently concentrated to produce a significant amount of heat are uranium-235, uranium-238, thorium-232, and potassium-40. Uranium, thorium, and potassium are found in measurable amounts in all rocks.

TRANSMISSION OF THE EARTH'S HEAT

Thermal conductivity of rocks. In order to determine the heat flow from the Earth, the thermal conductivity of the rocks in an area of interest and the temperature gradient, or thermal gradient, in this area must be measured. The thermal conductivity of a substance is a measure of the rate at which the substance conducts heat, and the thermal gradient is the rate at which temperature increases with depth.

Rate of heat transmission

Heat is conducted through the Earth at an extremely slow rate. At a few feet below the ground, daily temperature variations are hardly felt. The effects of changing seasons may be felt after a lag of about a year at a depth of approximately 100 metres (330 feet). Thermal conduction, in fact, is such a slow process that heat energy from radioactive decay taking place below a depth of a few hundred kilometres would take more than 4,600,000,000 years—the presently accepted value for the age of the Earth—to reach the surface.

Thermal conductivity of solids, although not very dependent on pressure, decreases somewhat as temperature increases. This is not always true: at high temperatures the thermal conductivity of many materials that do not conduct electricity increases greatly with increasing temperature. That is, it increases proportionally as the third power of the absolute temperature; the dominant heat-transfer process in this case is radiation.

Thermal gradients in the Earth. Thermal gradients in the continental crust show a wide variation, even in areas far removed from volcanic activity. These variations are due largely to differences in the thermal conductivity of various types of rock. The thermal conductivity, however, tends to be low where thermal gradient is high, and vice versa, so that their product, the heat flow, remains constant.

Numerous heat-flow measurements have been made on the ocean floor, and large variations are known to exist. Some of these variations were probably caused by local heat sources such as intrusions of magma or other volcanic events in the vicinity of midoceanic ridges.

Heat transfer is generally a slow process, but it may occur more rapidly under appropriate conditions. The existence of high temperatures approaching melting points in the Earth's mantle (the zone beneath the crust) can reduce the thermal gradient required to transfer a given amount of heat, because radiative heat transfer exceeds conductive transfer under these conditions.

The Earth is thought to have a solid inner core surrounded by a molten outer core. If the material in the outer core is in a state of convective motion, then the thermal gradient in it must be higher than the adiabatic value (that is, the value if no exchange of heat is assumed). Also, because the inner core is solid, the thermal gradient must be lower than the gradient at the melting point; this results because the outer core temperature is higher than the melting point and because the inner core temperature is lower than the melting point temperature. The strong temperature dependence of radiative transfer tends to stabilize internal temperatures.

Heat flow in continental and oceanic regions. Although radioactive rocks are not distributed in the same proportions in the continental and oceanic crust, continental and oceanic heat-flow values are equal within errors of measurement. This surprising equality of the continental and oceanic values implies that radioactivity, the source of most heat, must be similar in magnitude under continents and oceans. This, in turn, implies that the upper mantle is significantly hotter under the oceans than under the continents.

The difficulty with the above implications lies in the requirement the argument imposes on the density of the oceanic mantle, namely, that it must be less dense than the continental mantle because of its greater temperature. The concept of a warmer oceanic mantle also implies that it contains some of the lighter elements that the continental mantle no longer holds and, again, is thereby less dense. If the oceanic mantle were indeed less dense, the shape of the geoid (the surface within or around the Earth that is everywhere perpendicular to the direction of gravity and coincides with mean sea level in the oceans) would be affected. It has been suggested that some type of dynamic balance in the convecting upper mantle may account for the equality of oceanic and continental heat flow.

Reliability of heat-flow data. The surface temperature of the Earth has an annual oscillation that can be neglected at depths greater than 20 metres, but it must be considered an important correction in calculations of properties near the surface. Aside from this theoretical consideration, heat-flow data are affected by instrumental error and local conditions. Heat-flow measurements generally lose no more than 10 percent of their accuracy through instrumental errors.

Effects of topography and water circulation

A topographically rough ocean floor may cause variable water movements near the ocean floor. These movements could cause a variation in the rate of heat exchange in the ocean floor and thus produce variations in the effective temperature of the ocean floor. Generally, however, the correlation of heat flow in the oceans with topography is low, and global analysis shows little correlation of heat flow with topography.

The values of thermal gradients, especially those in shallow holes, may be affected by subsurface water circulation. Water flows in tunnels or in water-bearing seams are easily recognized, but the effect of slow movements of water in aquifers (bodies of highly porous, permeable rock through which water may flow) is not as easily seen. Water movement caused by other mechanisms such as salinity convection may also affect heat transfer in water near the bottom of the sea.

Surface conditions will exhibit change at the edges of lakes or oceans. Also, the effects of glaciation on the Earth's surface temperature may be preserved at depths commonly reached by boreholes. In some deeper holes, effects of changes from as far back as 1,000,000 years ago may be of importance and must be properly accounted for in any calculations.

The correlation between gravity and heat-flow data is not yet well established, since not enough is known yet about the gravity field, the heat-flow field, and any relation between them. Also, gravity readings are determined by the present distribution of the Earth's mass, whereas heat-flow readings may lag gravity readings by millions of years because of the slowness of the thermal conduction process.

Relatively high values of heat flow are associated with oceanic ridges (*q.v.*), the values showing a gradual decrease with distance from the crest of the ridge. It is possible that upward-flowing mantle currents form vertical sheets, intersecting the Earth's surface along the crests of the ridges. These upwelling mantle currents would explain the high heat-flow values and the production of great quantities of basaltic magma that occurs along the loci of the ridges.

GEOLOGICAL ASPECTS OF HEAT FLOW

The age of the Earth: Kelvin's problem. In the 19th century, a physicist, William Thomson (Lord Kelvin), assumed that the Earth formed as a hot gas that condensed and cooled. Kelvin assumed an initially molten crust that solidified from the outside inward. The thermal gradient in the crust was determined by the temperature difference across it, decreasing with the thickness of the crust. Accordingly, the thermal conductivity of the crust fixed the heat flow and the rate of solidification. In the 1890s Kelvin calculated the amount of time necessary for the Earth to reach a state, after solidification, in which the heat flow would have its present value between a maximum of 400,000,000 and a minimum of 20,000,000 years. The discovery of radioactive heat sources in the Earth invalidated Lord Kelvin's calculations, however. The presently accepted value for the age of the Earth is, as noted above, about 4,600,000,000 years.

Convection currents in the Earth. The lack of any significant correlation between heat flow and gravity may be explained better by convection in the Earth's mantle than by conduction, which, as mentioned before, is an extremely slow process. It has been calculated that abnormal readings in the heat flow and gravitational fields are consistent with convection currents with velocities of several centimetres per year.

Sea-floor spreading and continental drift

Sea-floor spreading (*q.v.*), a process in which new sea floor is created at ocean ridges, also points to the possibility of thermal convection. The theory of continental drift (*q.v.*), which holds that all the present continents once formed one large continent, finds some support in the theory of sea-floor spreading, since it seems that the rate at which the continents are separating can be measured (see further ROCK MAGNETISM).

The mechanism of thermal convection is thought to be set in motion by sources of great heat in the mantle and the consequent difference in temperature between the mantle and the base of the crust. The heat at great depths causes some material to become less dense than that surrounding it; this material is thus forced upward. The convection currents thus may rise upward from the bottom of the mantle, cross under the crust, and then return downward, flowing within a huge cell with dimensions as great as the radius of the Earth.

Arguments against the existence of thermal convection in the upper mantle are based on continental structure and on mechanical properties of the mantle. If continental structure should extend to depths of hundreds of kilometres, that would pose a serious obstacle to any large-scale horizontal convection (and to continental drift). Also, convection might homogenize the upper mantle, and so differences between oceanic and continental structure might no longer exist. The mantle should behave like an ultradense liquid for convection to occur. The calculated viscosity necessary for such convective motion is so high, however, that heat flow about 10 times as great as that presently observed would be required to initiate convective currents. Therefore, convection covering the entire mantle seems doubtful. No satisfactory theory based on convection yet formulated explains the Earth's thermal constitution.

Metamorphism of rocks. Metamorphism is the structural and mineralogical change of solid rocks caused by pressure and temperature conditions differing greatly from those prevailing at the time of their formation. Rock texture may be changed either by recrystallization or by alteration of the rock's chemical composition through the formation of new minerals.

Several types of metamorphism exist; those in which heat plays a dominant role are contact metamorphism, regional metamorphism, and plutonic metamorphism. Contact metamorphism is caused when changes are induced in rocks by the thermal effect of intrusive igenous rocks (rocks formed deep within the Earth's crust by cooling molten material). Regional metamorphism is caused by a combination of the thermal effects and pressures involved in orogeny (the forming of mountains). This is the most important type of metamorphism and is effective over areas of hundreds of square kilometres. Plutonic metamorphism is associated with great depths, great hydrostatic (equal in all directions) pressures, and extremely high temperatures.

Mountain building and formation of ore deposits. According to the contraction theory of Earth formation, as the molten planet cooled and the crust solidified, heat loss from the interior caused contraction and compressional stresses in the crust. The stresses produced folding and belts of fold mountains in weak spots in the crust. According to the continental-drift theory, however, all the continents were once joined together in one large protocontinent. When the protocontinent was broken up and the continental blocks migrated toward their present positions, the friction generated by their motion caused them to buckle, forming fold mountains. Finally, according to the convection-current theory, convection currents are responsible for folding of the Earth's crust. The more recent concept of plate tectonics holds that the Earth's crust and upper mantle consist of six major segments of plates that abut and intersect on the surface. Mountain systems result from the collisions at plate boundaries, which are also associated with earthquakes, magmatism, and heat flow. Ore bodies are bodies of rock containing a concentration of one or more chemical elements sufficient to allow profitable mining. Development of ore bodies occurs near or in igneous rock intrusions, often during mountain building.

Plate tectonics and heat flow

Volcanism and geothermal power. Volcanism is the geological process involving the activities of magma and lava. The high heat-flow readings obtained in the mid-oceanic crests are probably related to recent volcanism. Generally, the energy discharge associated with volcanic eruptions is transported mostly in the form of the thermal energy of the ejected material. The energy transported by the motion of the ejected material is not of significantly large magnitude, however. An estimation of the size of the Earth's crust can be used to gauge the share of heat flow caused by volcanism; this amounts to only about 1 percent of the Earth's total heat flow. Useful energy can be extracted from naturally occurring hot water and steam associated with volcanism. Power is obtained by releasing the hot water or steam through drill holes, then channelling it through pipes to a turbine-generator unit. Several analyses have been made of the cost of geothermal power; each concluded that it is indeed competitive with conventional means of electric-power generation. The first large-scale modern use of natural heat sources began in Italy in 1904, and some 50,000 homes in Iceland are heated by natural sources. Several other countries (notably Japan, the Soviet Union, and New Zealand) have similar geothermal-power operations, and exploration for more sources of geothermal power continues throughout the world (see further GEYSERS AND FUMAROLES).

BIBLIOGRAPHY. The subject of the Earth's heat flow is in a constant state of flux due to the relative recency of many of the data. Consequently, most references are contained within a rather specialized literature (*e.g.*, the *Journal of Geophysical Research*) and only a few textbooks or general works can be cited here. The interested reader should consult P.J. HART (ed.), *The Earth's Crust and Upper Mantle* (1969); W.H.K. LEE (ed.), *Terrestrial Heat Flow* (1965); and JOHN VERHOOGEN *et al.*, *The Earth* (1970). The first two works cited contain many additional references of relevance; the last presents a general treatment of many of the topics presented in this article.

(A.L.La.)

Earth, Magnetic Field of

The Earth is surrounded by a magnetic field, within which it behaves as if it were a ball of magnetized iron with north and south magnetic poles. The field is bigger than those of Venus and Mars; Mercury possibly has none; and only Jupiter has been shown to possess, like Earth, an appreciably intense dipolar magnetic field.

The discovery of the magnetic field of the Earth was dependent in part on the fact that a freely suspended lodestone (the mineral magnetite or maghemite, an iron oxide), which is naturally magnetized, seeks to align itself in a northerly direction everywhere on the Earth. Thus, the lodestone was man's earliest magnetic compass. In the 13th century a French engineer, Petrus Peregrinus, suspended an iron needle over various parts of a lodestone; the needle responded in different directions, which, when plotted as lines, converged to points on opposite ends of the lodestone. These points he called poles. In his *Epistola de magnete* he wrote about the attraction of the poles of heaven upon the poles of lodestone. Peregrinus also described compasses in which a magnetized needle attached to a stick was floated on water or was mounted on a pivot. In the Middle Ages, these man-made magnetic compasses were widely used by mariners for navigation, and it was known in the first half of the 16th century that a needle of a magnetic compass does not point exactly toward the North Pole. An English scientist, William Gilbert, summarizing all existing knowledge about magnetism in 1600 when he dis-

Naming of the magnetic poles

pelled the idea that lodestone and compass needles are attracted by the Pole Star or some other object in the heavens. From an experiment with a spherically shaped piece of lodestone, he concluded that the entire Earth is a great magnet with its two magnetic poles situated in regions near the geographical poles (Figure 1).

In the sense of exact science, however, a full understanding of the distribution of the Earth's magnetic field was not achieved until a German physicist, Carl Friedrich Gauss, published "Allgemeine Theorie des Erdmagnetismus" in 1838, in which his mathematical analysis showed that more than 95 percent of the Earth's magnetic field originates within the Earth's interior, and only a small remaining portion comes from outside sources.

Theoretical studies on possible physical mechanisms of an inside source of the Earth's magnetic field have developed only recently. Scientists agree, however, that the inside source is not one or more large aggregates of magnetic material but an electric-current system that most likely exists within the Earth's core and is caused by the flow of electric charges. Modern theoretical treatments of the origin of the Earth's magnetic field are concerned with possible mechanisms of generating and maintaining electric currents within the core, where there is a

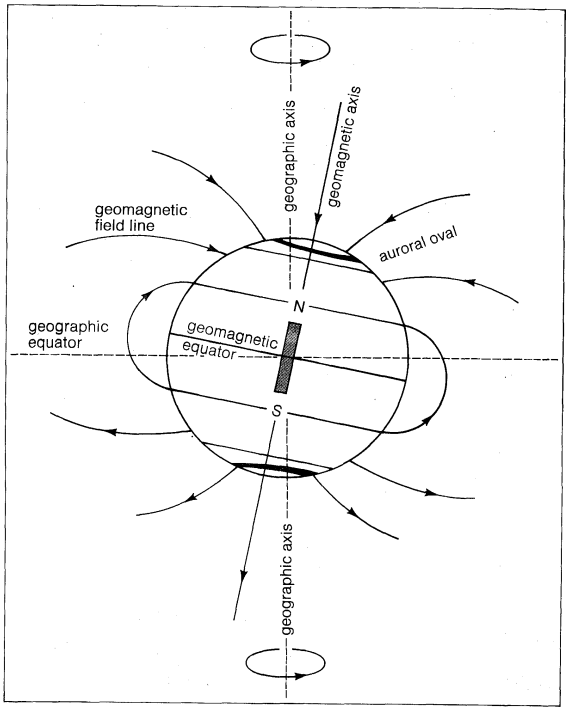

Figure 1: Distribution of the geomagnetic field in the space surrounding the Earth in terms of a hypothetical bar magnet, labelled N and S to correspond to the north and south geomagnetic poles, respectively.

circulation of material. It is well known that the Earth's magnetic field is gradually changing with time in its intensity as well as in its distribution pattern. Paleomagnetism, which deals with the behaviour of the Earth's magnetic field through geological time, has shown that the Earth's magnetic field has been frequently reversed. Any theory of an internal source, therefore, must be consistent with agelong variations of the Earth's magnetic field during historic, prehistoric, and geologic time.

Magnetism produced in ionosphere

On the other hand, the fraction of the Earth's magnetic field produced by outside sources is now understood to be an important representation of the electromagnetic activities in the Earth's upper atmosphere. Balfour Stewart, a Scottish physicist, first proposed that the daily varying part of the Earth's magnetic field can be ascribed to electric currents flowing in the Earth's upper atmosphere. The currents flowing in the atmosphere were identified later as the ionosphere by Kristian Birkeland, a Norwegian physicist, who concluded that electrically charged particles impinging on the polar upper atmosphere give rise to displays of auroras and to simultaneous magnetic storms. Until recently, outer space beyond the Earth's atmosphere was believed to be an almost perfect vacuum. Recent measurements of the physical effects on vehicles in outer space, however, have clearly indicated that the solar corona extends beyond the Earth's orbit, the space between the Sun and the Earth being filled with plasma gas (an ionized gas that, because it consists of equal numbers of positive ions—nuclei of atoms, mostly hydrogen—and electrons, is electrically neutral), called the solar wind. Although the particle density of the solar-wind plasma is only five to ten particles per cubic centimetre (one cubic centimetre equals 0.061 cubic inch), the macroscopic effect of the plasma on the Earth's magnetic field is still significant because of the very large spatial scale of phenomena concerned.

During a period of low solar activity (quiet Sun), the solar wind flows radially outward from the Sun at speeds of 300–500 kilometres (186–311 miles) per second. Electrons and positive ions in the solar wind are repelled by the magnetic field of the Earth as they approach the Earth until they reach a region where the kinetic pressure of the solar wind and the pressure of the Earth's magnetic field are in equilibrium. Near the Earth the magnetic field is compressed and neutralized in an outward direction, and thus the magnetic field is confined within a limited space surrounding the Earth. The limited space and its outer boundary are called the magnetosphere and the magnetopause, respectively, of the Earth (Figure 2).

Because the solar wind blows outward from the Sun, the magnetosphere on the dark side of the Earth is elongated along the direction of solar wind, the elongated shape resembling the tail of a comet. The tail of the Earth's magnetosphere, called the geomagnetic tail, has been observed to extend over a distance greater than 2,000 times the Earth's radius.

Although the Earth's magnetic field prevents charged particles of the solar wind from penetrating into the magnetosphere, some of them do, nevertheless, diffuse into it from the magnetopause. In some cases, electrically neutral particles (such as the neutron component of cosmic rays), which can get into the magnetosphere because they are not influenced by magnetic fields, decay into electrons and positive ions within the magnetosphere. These charged particles (mostly electrons and protons) are trapped by the magnetic field and are confined to the magnetosphere. A circular belt of these trapped charged particles surrounding the Earth is called a radiation belt or a Van Allen belt.

Van Allen belts

Though the magnetic field of the Earth, generally called the geomagnetic field, has been long valued as a direction indicator, it is now realized that the magnetic field plays a much more important role for man as the protector of the Earth from a continuing lethal attack of solar charged particles.

This article treats of the Earth's main magnetic field, its

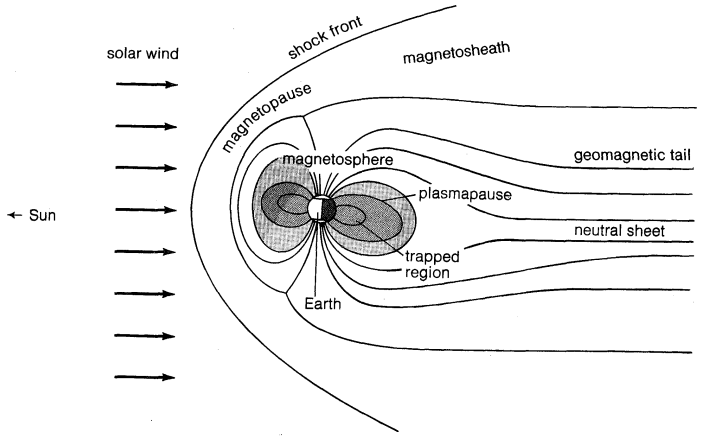

Figure 2: Distribution of the geomagnetic field in space surrounding Earth (see text).

transient and short-term fields, including telluric currents (those electric currents on or near the Earth's surface), and includes theories of the origin of the geomagnetic field. For further information on the Earth's interior, see EARTH, STRUCTURE AND COMPOSITION OF; for a discussion of paleomagnetism, see ROCK MAGNETISM; and for relevant information on the interaction of the Earth's magnetic field with the solar wind and allied atmospheric phenomena, see AURORAS; IONOSPHERE; VAN ALLEN RADIATION BELTS. See also COMPASS; MAGNETISM.

EARTH'S MAIN MAGNETIC FIELD

Elements of the geomagnetic field. The intensity, or strength, of a magnetic field at a given point is defined as the force exerted on a unit north pole positioned at that point. Fields are sometimes called field lines, because the number of lines per unit area and their direction pictorially represent the intensity and direction of the magnetic field. The geomagnetic-field strength, or intensity, at any point on the Earth's surface is customarily specified by means of the rectangular components, X, Y, Z, of the total intensity, F, defined as follows: X is the component along the horizontal northward direction, Y is the horizontal eastward component; Z is the downward component, all in the geographical coordinates, as illustrated in Figure 3. Another common way of specifying the geomagnetic intensity is by means of the magnetic elements, symbolized by H, D, and I, defined as follows: H is the magnitude of the horizontal component, considered to be positive whatever its direction and called the horizontal intensity; D is the azimuth of the horizontal intensity, reckoned positively from the geographic north toward the east and called the magnetic declination, or, by mariners, the magnetic variation, of the compass; I is the angle made by the direction of the total magnetic intensity with the horizontal, reckoned positive when the direction of the intensity inclines downward and called the magnetic dip, or the magnetic inclination. A horizontal line along the magnetic horizonal intensity, H, is called the magnetic meridian. The components of the intensity (X, Y, and Z) and the magnetic elements (D, I, and H) have a simple trigonometric relationship, as shown in Figure 3.

The same specification of magnetic elements can be used for describing the vector quantity (magnitude and direction) of the geomagnetic intensity at a position not too much above the Earth's surface that is observed from an aircraft or orbiting satellite at low altitude; say, 100–300 kilometres (60–190 miles). To specify the geomagnetic intensity observed at a point far from the Earth—for example, on a space vehicle just inside the magnetopause—another set of coordinates, referring to the ecliptic plane of the Earth (plane of the Earth's orbit), has been frequently used. The intensity components, designated as X', Y', Z', are defined as follows: X' is the Sunward (*i.e.*, directed toward the Sun) component, Y' is the component perpendicular to the direction of X' lying in the ecliptic plane, and Z' is the northward component.

World magnetic surveys and magnetic observations. A three-dimensional vector of the geomagnetic intensity at any point can be determined by measuring any three magnetic elements independently of one another. In the case of magnetic surveys on land or sea, a combination of measurements of the two angles, magnetic declination (D) and inclination (I), and one intensity component, such as the magnetic horizontal intensity (H), the total geomagnetic intensity (F), or the downward component (Z) of the geomagnetic intensity, has been generally adopted. The two angles are measured because an angle can be determined to a much higher accuracy than can a magnetic-intensity component. Recent progress in atomic and nuclear physics, however, has resulted in great improvement in the precise measurement of weak magnetic intensities, and, as a result, a combination of three rectangular magnetic-intensity components is now frequently used in determining the geomagnetic intensity; in particular, on board space vehicles.

Magnetic observations

At the present time, the geomagnetic intensity is being measured by magnetic surveys at a great number of points on land, over oceans, in the air, and in outer space. Over the whole surface of the Earth there are about 140 permanent magnetic observatories at which certain combinations of three magnetic elements are continuously recorded; and it is significant that the value of the geomagnetic field is observed to change appreciably with time. Magnetic fields are measured in gauss units (a field of one gauss is produced at a distance of one centimetre [0.39 inch] from a straight wire in which a current of five amperes—3×10^{19} electrons per second—is flowing; for comparison, the field in the vicinity of a magnetized needle is a fraction of a gauss, whereas the field between the poles of a horseshoe magnet may be hundreds or thousands of gauss). The total geomagnetic force at the geographical Equator and near the poles of the Earth amounts to approximately 0.3 and 0.7 gauss, respectively. The total geomagnetic force, however, changes even within a day's time, with a range of 0.0002 gauss at the Equator and 0.0005 gauss at the poles. One hundred-thousandth of one gauss, called a gamma ($1\gamma = 0.00001$ gauss), has been adopted as the unit for specifying the strength of geomagnetic forces. It may be stated, therefore, that the geomagnetic intensity has a daily variation of about 20 gammas and 50 gammas in amplitude, respectively, near the Equator and the poles, even during the period of a quiet Sun. In addition to the temporal variations, such as the daily variation, the seasonal variation, and sporadic disturbances, the annual mean of the geomagnetic force is subjected to a nonperiodic secular variation, amounting to several gammas per year. To represent the world distribution of any geomagnetic element on a chart, therefore, the temporal variations must be eliminated, and the value of the geomagnetic element concerned must be reduced to a certain common period of time (such as a year) by reference to the secular variation chart of the element. Figure 4 illustrates a world magnetic chart of the magnetic declination (D) on the Earth's surface in 1965.

At the magnetic poles, which are defined as the points on the Earth's surface where the geomagnetic intensity is vertically directed, there is no horizontal intensity, and consequently the magnetic declination is indeterminable. The north magnetic pole, where the geomagnetic intensity is exactly downward (*i.e.*, the magnetic inclination, or dip, $I = +90°$) is located in northern Canada; the south magnetic pole, in which $I = -90°$, is located almost diametrically opposite near the Antarctic coast at about 140° east in longitude. The horizontal component of intensity (H) reaches its maximum magnitude of about 0.3 gauss (3×10^4 gammas) at a magnetic inclination of $I = 0$ (roughly along the geographical Equator) and vanishes at the two magnetic poles. The vertical magnetic intensity (Z) takes maximum positive and negative values of about 0.7 gauss in magnitude at the north and south magnetic poles, respectively, whereas it becomes zero along the line of zero magnetic inclination ($I = 0$). The

line of $I = 0$ surrounding the Earth is called the magnetic equator. World charts showing the distribution of the magnetic elements D, H, Z, F, and I on the Earth's surface are compiled for every five-year epoch.

If it is assumed that there is a bar magnet at the Earth's centre as shown in Figure 1, in which the axis of the bar magnet is inclined about 11° of arc from the Earth's geographical axis so that a pole of the magnet is directed toward northern Canada, then the distribution of all magnetic elements of the magnetic field caused by the hypothetical magnet will resemble those of the real geomagnetic field, at least on and near the Earth's surface. In this case, the magnetic moment (a constant of any bar magnet is its magnetic moment, the product of distance between its north and south poles and the pole strength) of the hypothetical magnet corresponding to the geomagnetic field at the present time would be 8×10^{25} gauss-centimetres^3. Such a hypothetical bar magnet is called the centred geomagnetic dipole. The poles of the centred geomagnetic dipole are exactly opposite one another on the surface of the Earth and are called the geomagnetic poles. The location of the geomagnetic north pole in 1965 was 78.5° north in latitude and 69.1° west in longitude. A great circle along which the vertical (Z) intensity component of the hypothetical magnetic field is zero is called the geomagnetic equator. The great circle of the geomagnetic equator deviates somewhat from the magnetic equator, which itself is not a great circle.

Geomagnetic poles and equator

Although the geomagnetic field can be approximately represented by the magnetic field of the centred geomagnetic dipole, there still remain residual magnetic fields when the centred dipole field is subtracted from the real geomagnetic field. The residual fields are called the geomagnetic regional anomalies. It has been demonstrated that these regional anomalies can be accounted for by clockwise and counterclockwise vortices of electric currents, which are hypothetically located at the Earth's core beneath the centres of regional anomalies.

Surveys for the geomagnetic-field distribution within the magnetosphere by means of space-vehicle magnetometers have not yet been completed; nevertheless, the general feature of the configuration of lines of the geomagnetic field, summarized from a large number of observations, is illustrated in Figure 2. Attention must be paid, in the Figure, to the observed fact that the geomagnetic field in the sunlit side is markedly compressed by the solar wind, whereas that in the dark side is markedly elongated, and that such a difference or a change in the field-line configuration is dependent upon the local time of the field-line meridian and not upon the location of the field line on the Earth. In accordance with the rotation of the Earth, the outer lines of geomagnetic intensity that have their roots on the Earth's polar regions are compacted within the sunlit side of the magnetosphere but are dragged far away behind the Earth as they enter into the night-side space; these outer lines of geomagnetic intensity are, thus, periodically subjected to a vast daily change in configuration.

The inner lines of force, which have their roots in lower latitudes of the Earth, on the contrary, are always closed, regardless of whether they are on the sunlit side or the night side, although their shapes are changed to a certain extent: they can be considered as stable lines of intensity. It is evident that charged particles, such as electrons and protons, trapped by these stable inner lines of force, can survive much longer than those that interact with the changing outer lines. This trapping is regarded to be the main cause for the Van Allen radiation belts, which consist chiefly of a high population of electrons and protons.

Variations in the main magnetic field. It has been known for many years that the geomagnetic field is subjected to a secular variation, gradually varying with a rate of several gammas per year for the magnetic-intensity elements. During the last 150 years, since the measurements of the magnetic elements of the Earth were first initiated, the magnetic moment of the geomagnetic dipole has been continuously decreasing; for instance, it is now 8×10^{25} gauss-centimetres^3, but in 1838 it was 8.6×10^{25} gauss-centimetres^3. It also has been noticed that some centres of the regional anomalies in the geomag-

netic field are drifting westward with an average speed of about 0.2° of arc per year. This observed characteristic of the geomagnetic secular variation is known as the westward drift of the geomagnetic regional anomalies. An increase or a decrease of the strength is more markedly observed, however, for some other regional anomalies. Each regional anomaly seems to be drifting westward with either growth or decay of its strength.

Knowledge of the geomagnetic secular variation can go back further into prehistoric or geologic times with the aid of rock magnetism. The science that deals with the geomagnetic field in these distant times is called paleomagnetism; a similar science that deals specifically with geomagnetism in prehistoric times is called archaeomagnetism.

Rock magnetism and paleomagnetism

In archaeomagnetism, the direction and intensity of the geomagnetic field at a certain site at a certain past time can be determined by measuring the direction and intensity of magnetization of igneous rocks or baked earths, provided that these materials have maintained the initial magnetization (called remanent magnetizations) they acquired when they were formed in the presence of the old, but now changed, geomagnetic field. The chief results of archaeomagnetic studies for the past 8,000-year period are as follows: the distribution mode of the geomagnetic field during this period is substantially the same as its present mode; that is to say, the geomagnetic field during the period also can be represented approximately by that of the present geomagnetic dipole. The moment of the geomagnetic dipole has changed slowly during the period, having been 1.5 times the present value about 2,000 years ago and 0.8 times the present value about 4,000 years ago. The observed decrease in the intensity of the geomagnetic dipole for the last 150 years is considered to be a continuation of its decrease during the last 2,000 years. On the other hand, the secular variations of declination (D) and inclination (I) during the last 8,000 years seem to imply that the westward drift of regional anomalies has continued with a speed of 0.2°–0.4° per year during the period also.

The same method of determining archaeological geomagnetic fields by use of remanent magnetization of natural rocks can be applied to much older geologic times. The results of paleomagnetic research by means of a large number of rocks collected from various continents indicate that the geomagnetic field in geologic times also can be substantially approximated by the geomagnetic dipole field. In dealing with the geomagnetic dipole field in the last 100,000,000 years, it is found that the geomagnetic north pole was located within two circular areas of about 30° in radius either at the geographic North Pole or the geographic South Pole; seldom was the geomagnetic north pole located in the temperate latitudes between the two polar areas. The geomagnetic field in geologic times, in other words, was approximately the same as it is at present, or almost perfectly reversed with respect to the Equator, and the time interval for a reversal of the field must have been small compared with the time during which the geomagnetic-field polarity was either normal, as it is at present, or reversed.

The phenomena of the geomagnetic-field reversals for the last 6,000,000 years have been thoroughly studied. During this geologic period, the average lifetime of a geomagnetic-field polarity, either normal or reverse, was 230,000 years, but individual lifetimes varied appreciably and may be ascertained to a close approximation by probability theory.

The magnetic moment of the geomagnetic dipole for the same geologic period is found to be $(9.1 \pm 3.3) \times 10^{25}$ gauss-centimetres^3 (the figure after the plus-or-minus sign represents the standard deviation) for both the normal and the reverse polarities. It may be concluded, therefore, that the geomagnetic field took either the normal or the reverse polarity, which now appears to be in a quasi-steady state, having an average magnetic moment of about 9×10^{25} gauss-centimetres^3. In several instances, the time interval for transition between the two polarities has been estimated to be less than 10,000 years.

The geomagnetic field in remote geologic times is more complicated, and there is a hypothesis associated with it called polar wandering. The age of the oldest geomagnetic field ever estimated from terrestrial rocks goes back 2.5×10^9 years, and the geomagnetic field has, therefore, been subjected to repeated polarity reversals for at least 2.5×10^9 years. The average moment of the geomagnetic dipole throughout this period remained at the same approximate magnitude as at present. The position of the geomagnetic pole, however, was not located within the geographical polar regions 10^9 years ago and before but was near the geographical Equator. It seems likely that the geomagnetic-pole position has gradually moved from the equatorial zone to the polar region during the past 10^9 years, regardless of whether the geomagnetic field had a normal or a reverse polarity.

Polar wandering

There is a problem related to the polar-wandering hypothesis: Although the conclusion that the geomagnetic-pole position has moved from the equatorial zone to the polar region is supported by experimental data derived from rock samples of different continents, the routes of the polar wandering according to data from different continents are not alike. The route of the polar wandering derived from North American data, for instance, is systematically different from that derived from European data. If it be assumed, however, that there was no Atlantic Ocean between North America and Europe 100,000,000 years ago and that the Atlantic Ocean floor has continued to spread since then, the discrepancy between the two routes becomes understandable, and it is in part for this reason that the hypothesis of continental drift has been reintroduced.

TRANSIENT AND SHORT-TERM GEOMAGNETIC FIELDS

Solar and lunar daily magnetic variations. It has been observed that the geomagnetic field at any point on the Earth's surface is subjected to a quasi-regular daily variation of from ten to 30 gammas. The vertical intensity decreases around local midday in the Northern Hemisphere, whereas it increases around midday in the Southern Hemisphere. The declination takes the maximum and minimum values in the local mornings and afternoons, respectively, in the Northern Hemisphere, whereas daily variation of the declination is reversed in the Southern Hemisphere. Variations in the geomagnetic field are small in the dark time compared with those in the sunlit time. In the local summer, the daily variation is enhanced; it is reduced in the local winter. It thus becomes evident that the geomagnetic daily variation is primarily controlled by the position of the Sun at the observing site.

Applying Gauss's method of analysis (*i.e.*, dividing a magnetic field into outside and inside sources), it is found that two-thirds of the daily varying component of the geomagnetic field is caused by a source outside the Earth's surface, while the remaining one-third is caused by a source inside. The location of the outside origin has been determined by measuring the vertical distribution of the daily varying field with sounding rockets at various sites over the Earth. The results have indicated that the outside source is caused by horizontal electric currents flowing in a region between 105 kilometres and 130 kilometres (65 and 81 miles) in altitude; namely, through the lower part of the Earth's ionosphere. As expected, the intensity of the electric current in the lower ionosphere is observable only in the sunlit time, and the current intensity in the dark time is unobservably weak. The total electric current in the sunlit time is of barely sufficient magnitude to account for the outside-origin part of the daily geomagnetic variation observed on the ground.

To account for the inside source, which contributes one-third of the daily geomagnetic variation, it is assumed that the primary outside source produces a flow of electric current in the Earth's electrically conductive interior by a process of electromagnetic induction. This, in turn, generates a magnetic field that varies in intensity and frequency with the primary outside source and is consistent with Gauss's mathematical representation.

The horizontal wind in the upper atmosphere has been observed directly by the use of sounding rockets and indirectly by observing, for example, the flow of ionized

clouds (clouds consisting of positively and negatively charged particles) generated by incoming meteors. The results of such measurements have shown that a strong wind speed of from 50 to 100 metres (164 to 328 feet) per second is always blowing in an observed altitude range of 80–300 kilometres (50–186 miles) and the direction of wind is subjected to a fairly systematic daily variation. When an air mass containing charged particles moves in the presence of a magnetic field, an electric field is created in the air mass; it is perpendicular to the direction of motion and to the magnetic intensity and is represented by the vector product $E = v \times F$, in which E is the electric-field intensity, v is the velocity, and F is the magnetic-field intensity. If the air mass is electrically conductive, with electric conductivity (σ), then an electric current (j) will flow through the air. The flow of current will be equal to the product of the conductivity and the field intensity (E), namely, $j = \sigma E$. The electric current produces a magnetic field, and, in accordance with changes in the intensity and direction of the electric current, the resultant magnetic field also should change. The system consisting of the parameters (v, E, and σ) is usually called the ionospheric dynamo.

Ionospheric dynamo

In the sunlit time, the neutral atoms and molecules in the ionosphere are partly ionized into electrons and positive ions by the solar ultraviolet radiations and X-rays, which have high ionizing energy, and, as a result, the ionized part of the ionosphere becomes electrically conductive. During dark time, there is scarcely any ionization of the ionospheric particles; instead, the electrons and ions ionized during time of sunlight tend to recombine with each other to become neutral particles once more; thus, the electrical conductivity of the ionosphere in the dark time is much reduced compared with its sunlit-time magnitude.

Because the ionospheric wind is caused mostly by the tidal force of the Sun, there should not be an appreciable difference in its velocity between the day and night. The electrical conductivity of the ionosphere, however, is much smaller in the dark time than in the sunlit time, and this condition can be regarded as the principal reason why most of the daily variation of the geomagnetic field, caused by the product of conductivity and velocity, takes place in the daytime.

Effects of the Moon

The Moon's gravitational force, on the other hand, also gives rise to a tidal current in the ionosphere, just as it does in the ocean water, and consequently a lunar ionospheric dynamo also exists. If the time variation in the geomagnetic field is carefully analyzed, therefore, a periodic change during the lunar semidiurnal period is clearly observed. Evidently, the lunar geomagnetic variation is attributable to a lunar-tidal electric-current system in the ionosphere, which is caused by the lunar-tidal current, and the resultant electric current is the product of the electric conductivity of the air mass times the vector product of its velocity and the magnetic-field intensity, or $j_L = \sigma(v_L \times F)$, in which j_L is the electrical current due to the lunar-tidal current, σ is the conductivity, v_L is the velocity of the lunar-tidal current of air, and F is the magnetic intensity in the ionosphere. It is obvious that the lunar geomagnetic variation also is appreciable only on the sunlit hemisphere, where the ionospheric electric conductivity is high. In general, the lunar geomagnetic variation has a much smaller amplitude than the solar daily one, being only about one or two gammas in magnitude.

Magnetic storms and substorms. Occasionally geomagnetic disturbances of large amplitude take place, in particular when the Sun is active. The behaviour of such a geomagnetic disturbance observed in temperate latitudes is characterized by a sudden increase in the horizontal intensity, followed several hours later by its sharp depression of 50–200 gammas and a gradual recovery of the depression at a later stage. Such a geomagnetic disturbance is called a magnetic storm. In such a case, a satellite outside the magnetopause always records a marked increase in the speed of the solar wind or an increase of the number density of plasma particles in the solar wind. A satellite located near the magnetopause on the sunlit side will record that parts of the magnetosphere become compressed and contracted. The magnetopause is located at a distance of ten to 12 Earth radii from the Earth during an ordinary, quiet period but will become contracted on the Sunward side to a distance of five to seven Earth radii in case of a magnetic storm. It is evident, then, that a geomagnetic storm is primarily caused by a sudden increase of the solar-wind kinetic energy, which in turn is induced by solar activity. The increased kinetic (gaslike) pressure of the solar wind compresses the magnetosphere toward the Earth more so than ordinarily, resulting in an initial sudden increase of the geomagnetic field. Several hours after the initial increase in the geomagnetic field, it is observed that plasma particles at a distance of four to six Earth radii from the Earth that are within the magnetosphere begin to move so as to give rise to westward moving electric currents (composed of protons), whereas the electrons flow in an eastward direction. The magnetic field caused by their motion is mainly responsible for an observed marked depression of the geomagnetic field, called the main phase of a magnetic storm. The westward electric current of protons, called the equatorial-ring current, is maintained by the increased solar-wind energy, because the compressed magnetospheric plasma particles are continuously influenced in their motion by the geomagnetic field, which is increasingly more intensive toward the Earth. When the kinetic energy of the solar wind recovers to the ordinary state, the maintenance of the equatorial-ring current ceases, and the magnetic storm begins to go into its gradual recovery phase.

In regard to a detailed physical mechanism for the generation of equatorial-ring currents, no unanimous conclusion has yet been reached among specialists. Comprehensive experimental and theoretical studies on this problem are being carried out on the basis of numerous observations taken on satellites and on the ground.

When a magnetic storm is in progress, tremendous disturbances of various aspects are observed in the Earth's north and south polar regions. The most fantastic of these disturbances in the polar regions is the display of a phenomenon called an aurora (*q.v.*). Auroras are seen mostly in special zones surrounding the north and south geomagnetic poles, lying within an angular distance of 25°–30°. These zones are specifically called the auroral zones (see Figure 2). Recent studies of the distribution of auroral displays have indicated that auroral zones are not exactly circular in form with a geomagnetic pole at the centre but rather are of an oval shape, and, for this reason, the term auroral oval is sometimes used.

Auroral zones

Simultaneously with an auroral display, a sharp and substantial change in the geomagnetic field is observed in and near the auroral ovals, its magnitude often exceeding 1,000 gammas. The duration of such a sharp geomagnetic disturbance varies in time from 30 minutes to three hours and is called a polar magnetic substorm. Because the shape of a change in the geomagnetic horizontal force with time in the case of a polar magnetic substorm has a depression or bay shape, polar magnetic substorms are often called geomagnetic bays. There is a high degree of correlation between the auroral display and the magnetic substorm with respect to time of duration, place of appearance, and magnitude.

A polar magnetic substorm is accompanied not only by an auroral display but also by other, simultaneous electromagnetic phenomena, such as an unusual increase in the density of electrons in the ionosphere, an emission of X-rays from above, an emission of very low frequency radio waves, and so forth. All of these simultaneous phenomena indicate that a shower of electrons is impinging along the geomagnetic-intensity lines from outside toward the auroral-oval ionosphere. From these observed data, the energy of impinging electrons has been estimated to be between 10^8 and 10^{10} electron volts (some laboratory devices can accelerate electrons to these energies). One electron volt is the energy that a charged particle such as an electron acquires when it is accelerated by an electric potential of one volt, which means that electrons can penetrate into the Earth's atmosphere down to 80–120 kilometres (50–75 miles) in altitude. The

source of a polar magnetic substorm can thus be identified as strong electric currents that flow through the auroral-oval ionosphere and become anomalously conductive because of the ionization of upper-atmosphere gas by impinging electrons. There is a question as to why and how the electromotive force that drives the electric currents is produced in the auroral oval ionosphere. Some clarification has been achieved from satellite-borne observations. The following appear significant: The polar magnetic substorms occur mostly at night and frequently at times around local midnight. In the night side within the magnetosphere, electrons and protons tend to drift eastward and westward, respectively, in the outside of the plasmapause (see Figure 2), implying that plasma flows, moving inward from the geomagnetic tail into the stronger geomagnetic field, drift in accordance with a law that states that the force acting on a charged particle is in a direction at right angles to the direction of motion of the particle and the direction of the magnetic field within which it is moving. The force acts in one direction for a positive charge and directly opposite for a negative charge. In vector notation, one has the cross product of the velocity and field vectors, or $ev \times F$, in which e denotes a positive electric charge for a proton or a negative electric charge for an electron, v denotes the velocity vector, and F denotes the magnetic-field intensity vector.

Just before a breakup of a substorm accompanied by an auroral display, the number densities of electrons and protons in the neutral sheet (see Figure 2) of the geomagnetic tail suddenly decrease. It is likely that these particles are pushed forward in a direction toward the Earth, with the result that the population of electrons and protons in the space outside the plasmapause may suddenly increase.

One possible explanation for the occurrence of substorms is as follows: As the result of a certain trigger action, plasma gas in the night-side magnetosphere flows toward the plasmapause, where electrons and protons separately drift in opposite directions, producing two regions of electrostatic charge, negative in the dawn side and positive in the dusk side; these regions may then accelerate charged particles of the plasma toward the Earth, because the charged particles can move only along the lines of geomagnetic force. A closed electric circuit is thus formed, starting from the positively charged region in the magnetosphere, along geomagnetic-field lines and the auroral-oval ionosphere of high conductivity, and coming back to the negatively charged region along lines of the geomagnetic field. In brief, a breakup of a substorm accompanied by an auroral display and other, simultaneous phenomena can be regarded as an electric discharge along lines of the geomagnetic field between the magnetosphere and ionosphere. The discovery of the trigger phenomenon that produces such an electric discharge is one of the goals of the main research projects of magnetospheric physics. Studies so far suggest that the magnetic field concomitant with the solar wind plays a principal role in the trigger action. The observed magnetic field in the solar wind amounts to five to ten gammas in intensity, and its direction is sometimes approximately northward and at other times approximately southward. The solar-wind magnetic field is due to electric-current vortices within the wind mass, which were generated when the wind moved away from the Sun's magnetic field. When the solar-wind magnetic field is directed northward, it is repelled by the geomagnetic field of the magnetopause over the northern and southern polar regions of the Earth. But, on the contrary, when the solar-wind magnetic field is directed southward, a part of the field will be connected with the geomagnetic field of the same region, because the directions of both magnetic fields there are parallel and therefore connectable. The solar-wind magnetic field and the geomagnetic field are thus sometimes repelled away from each other and at some other times connected with each other. It is a statistical fact that a polar substorm takes place when the magnetic field of the solar wind turns southward.

The trigger phenomenon

If the foregoing theory of the physical mechanism of polar magnetic substorms is true, then a polar magnetic substorm accompanied by an auroral display and other related phenomena ought to occur simultaneously, both in the northern and southern polar areas, which has been corroborated so far by observation. The simultaneous occurrence of polar magnetic substorms is called the geomagnetic conjugate relationship.

Electromagnetic induction and telluric currents. All kinds of transient variations in the geomagnetic field observed on the Earth's surface are caused by the changing of the outside and inside sources.

As was pointed out earlier in relation to the daily geomagnetic variation, the inside source of field variations affects magnetic storms, substorms, and other transient magnetic variations, and they are attributable to the transient electric currents that are electromagnetically induced within the Earth's interior by the primary magnetic-field variations of the outside sources. The magnitude of the inside-source component is about half that of the outside one in most cases, and the variation of the former is systematically subjected to that of the latter in accordance with Maxwell's equations for electromagnetic induction. Experimentally, the potential difference between two separate points on the Earth's surface has been measured at various places. The potential differences thus measured, the so-called electric fields, consist of a steady component and a transient variation component. The steady component is caused by geological conditions that form a certain kind of electric cell owing to local differences in the electrochemical compositions of materials. The transient variation component, expressed in terms of an electric field, is approximately related to the geomagnetic field, as given by Maxwell's equation for electromagnetic induction.

In actual cases, electric currents are caused by the electric field within the Earth (even the uppermost part of the Earth has a finite electric conductivity). Thus, the relationship between the electric and geomagnetic fields is modified by an effect of the induced current. If the electrical conductivity is sufficiently small, as in the case of igneous rock, for example, then the electric current can be expressed as the product of the conductivity and electric field, and Maxwell's relation between the electric and geomagnetic fields holds approximately. The electric currents thus induced within the Earth are generally called telluric currents.

Telluric currents

With an increase in temperature, the electrical conductivity within the Earth increases sharply with increased depth. Analyses of transient geomagnetic variations of various periods in terms of the electromagnetic induction within the Earth have shown that the distribution of the Earth's electric conductivity is dependent on the geocentric distance. The results of such studies have shown that the average electric resistance is about 10^6 ohms per centimetre from the surface down to 400 kilometres (250 miles), where the resistance decreases sharply to about 10^3 ohms per centimetre; it also gradually decreases to 0.1 ohm per centimetre near the surface of the Earth's core.

The lateral distribution of electric conductivity near the Earth's surface, on the other hand, is not uniform at all but varies from place to place, even within a continent. This heterogeneous distribution of the conductivity results in anomalies of the induced currents in the uppermost part of the Earth, particularly for geomagnetic variations of short period.

ORIGIN OF THE GEOMAGNETIC FIELD

Main geomagnetic field and its secular variation. The origin of the main geomagnetic field, presumed to exist within the Earth, has long been a great mystery in the Earth sciences. It is evident that the Earth cannot be a permanent-type magnet because of the high temperature of the Earth's interior, and, therefore, electric currents that are responsible for the main geomagnetic field, with its secular variation, must be maintained somewhere inside. There is almost no possibility that these currents flow through the Earth's solid mantle, which extends between the Earth's crust and core, whose outer boundary is about 2,900 kilometres (1,800 miles) beneath the

Earth's surface. The electrical conductivity of the mantle is so low, being 10^{-3} to 10 (ohm-centimetres)$^{-1}$, that the maintenance of necessary electric currents would require an electrical-generator system of fantastically high power. It has long been believed, therefore, that a system equivalent to a powerful electric generator and consisting of a circulating electrically conductive metallic fluid may exist within the Earth's core.

Any theoretical model of the main geomagnetic field must be able to account for its frequent reversals in geologic times as well as its general behaviour at present. No theory has ever been proposed to account quantitatively for the observed various aspects. A number of hypotheses explain the origin of the geomagnetic field, but many of them are unable to account for even the present geomagnetic field. A U.S. geophysicist, Walter M. Elsasser, in 1939 proposed that a thermoelectric electromotive force in the core might give rise to the electric current responsible for the geomagnetic field. He assumed that some thermal convections are maintained within the core by the energy supply from radioactive substances and that the rising and sinking parts of the core's fluid caused by the convections may correspond to the hot and cold junctions of a hypothetical thermojunction system, provided that the core material changes with its radius. The thermoelectric force that might thus be produced could drive the electric currents within the core. Quantitative examination of this possibility, however, has indicated that the hypothesis is hardly acceptable because of the small magnitude of the electric current. Another possibility was suggested in 1954—namely, that a stray magnetic field accidently impressed within the Earth could be amplified by the Hall effect (in the Hall effect, a secondary electric current, and, hence, magnetic field, is produced when an electric current moves at right angles to the magnetic-field lines) of the lower mantle near the core's boundary. Although this Hall-effect hypothesis cannot be ruled out in principle, no favourable evidence has ever been given to support it.

Twisted-kink theory

In 1950 a possible mechanism to maintain the geomagnetic field, now called the twisted-kink theory, was proposed. It is based essentially on the magnetohydrodynamics of a highly conductive core. In this model, bundles of magnetic-field lines are assumed to be present as stray magnetic fields in the Earth's core, and the magnetic field corresponds, giving rise to the dipole-like magnetic field outside the core. Because the fluid within the core may be subjected to an appreciable differential rotation and the fluid is highly conductive, the bundles of field lines may be dragged and stretched by the fluid motion, and some of the bundles would become unstable under the strong twisting motion, eventually forming loops (kinkings) of field lines. Once such loops of magnetic-field lines are formed in the differentially rotating fluid, some of them could be separated from the original field lines, and the separated ones could be stretched out by the fluid motion to become approximately parallel to the original bundles of field lines. Thus, these magnetohydrodynamic processes could result in an enhancement of the original stray field by changing the fluid-motion energy into the magnetic-field energy. The instability of a twisted bundle of magnetic-field lines has been mathematically studied. It is not clear, however, whether these processes are sufficiently regenerative. The twisted-kink theory is acceptable, in a qualitative way, for explaining maintenance of the present geomagnetic field, but its quantitative aspects have not yet been worked out.

Another theoretical model to account for the origin of the geomagnetic field is the so-called dynamo theory, which is based essentially on electromagnetic induction processes within a moving and highly conductive fluid of the core, and is akin to the twisted-kink theory. Because the dynamo theory is pertinent to both the maintenance of the geomagnetic field and its secular variation behaviour, a discussion of it in some detail follows.

Dynamo theory of the geomagnetic field. The basic idea of the dynamo theory was advanced in a paper on the magnetic field produced by a rotating sphere. This notion of a self-exciting dynamo was later re-examined in terms of a disk dynamo, consisting of the following elements: a conducting disk rotating about its axle and a solenoid (a coil of wire in the shape of a cylinder; an electric current passing along the wire will produce a magnetic field parallel to the coil's axis) concentric with the axle in which one terminal contacts the rim, or periphery, of the disk and the other terminal contacts the axle. When the disk rotates about the axle in the presence of a magnetic field parallel to the axle, a radial electric field is induced in the disk between its centre and periphery, and the generated electromotive force between the periphery and centre will drive an electric current through the solenoid. The solenoid will produce a magnetic field, thus enhancing the initial magnetic field. The decrease in energy of the disk is thus transformed into an increase of magnetic-field intensity. An experimental demonstration of the disk dynamo may be impossible to achieve under laboratory conditions, inasmuch as a disk of ten centimetres (3.9 inches) in radius in a circuit of ten ohms electric resistance would have to rotate about 10,000,000 times per second to reach a steady state of no loss in energy and no gain in magnetic field. This situation does not mean, however, that the self-exciting dynamo mechanism is impossible for a rotating body on the scale of the Earth and the Sun. The self-exciting dynamo mechanism is based on the principle of repeated self-excitations of the magnetic field by the addition of a magnetic field generated by the electric current of the dynamo: an analogous mechanism of an electrically conductive rotating disk and solenoid could be present in the Earth's core, where the fluid core materials are perhaps circulated by heat sources or other mechanical forces.

Use of the disk dynamo

Of the various possible patterns of electric-current systems within the Earth's core, one may consider the possibility that two or more dynamos are coupled together. A model of such a two-disk dynamo was proposed by a Japanese geophysicist, Tsuneji Rikitake, in 1958, in which the electric current induced in a rotating disk flows through a solenoid to enhance the magnetic field affecting another rotating disk, and similarly the electric current induced in the second disk enhances the magnetic field for the first. In this two-disk dynamo system, the electric currents in the two solenoids, as well as the angular velocities of the disks, can oscillate, and the currents can even reverse for appropriate initial conditions, whereas, in the single-disk dynamo, the electric current can periodically change on an appropriate initial condition, but it can never reverse.

The models of the single disk or the coupled two disks demonstrate possible processes of electromagnetic induction within the moving conductive substances. In Earth's highly conductive core, on the other hand, there can exist two different types of electric-current systems and their associated magnetic fields. One type is the poloidal magnetic field, which extends from the inside of the core into the outside, its lines of magnetic force making a closed circuit through regions inside and outside the core. Such a poloidal magnetic field can be produced, for example, by a solenoidal-type electric current flowing around the core's rotational axis. The other type is the toroidal magnetic field, which makes a closed circuit of each line of the magnetic field only within the core's boundary. Such a toroidal magnetic field can be produced, for example, in a doughnut-shaped solenoid, within which all lines of magnetic field are necessarily confined. Even if a toroidal magnetic field were present within the Earth's core, it could not be directly observed from its outside because of electromagnetic laws. The geomagnetic dipole field must, therefore, be caused by a poloidal field if it originates within the Earth's core. It may be supposed that a dynamo process caused by fluid motion in the poloidal dipole field $\boldsymbol{B}_0$ generates a toroidal field $\boldsymbol{T}_1$, a similar dynamo process in $\boldsymbol{T}_1$, generating another toroidal field $\boldsymbol{T}_2$, and such a chain process of generating toroidal fields proceeds until a toroidal field $\boldsymbol{T}_i$ is generated. As has been said, these toroidal fields, $\boldsymbol{T}_1$, $\boldsymbol{T}_2$, etc., are not observable as such on the Earth's surface. If, however, a dynamo process of a fluid motion in a toroidal field $\boldsymbol{T}_i$ can produce a poloidal dipole field $\boldsymbol{B}_0$, then a sort of a closed

Poloidal and toroidal fields

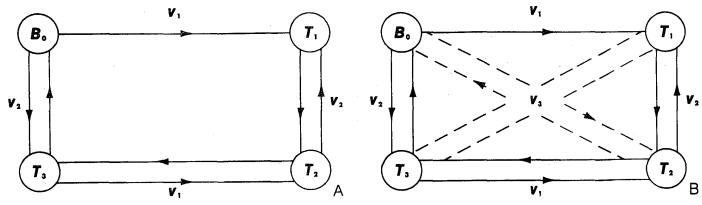

Figure 5: *Four-dynamo theory.*
(A) Chain reactions of dynamo model. (B) Modified dynamo model. See text for explanation of symbols.

chain of dynamo processes starting from B_0 and returning to B_0 again through toroidal field T_1, T_2,———T_1 can be set up.

In 1954 a consistent mathematical model of a limited number of involved dynamo processes was derived in which the fluid motion in the core is assumed to consist of two modes; that is, a zonal flow around the Earth's rotation axis (v_1) and a symmetric convective motion composed of four convection cells (v_2) whose longitudinal symmetricity is expressed as the cosine of 2λ, in which λ denotes the longitude, these motions being confined to the core's interior. The dynamo process between a poloidal dipole field B_0 and the zonal flow v_1 results in a toroidal magnetic field T_1, which is axially symmetric about the rotation axis. The dynamo process between T_1 and v_2 generates a toroidal field T_2 whose longitudinal symmetricity is expressed by the cosine of 2λ. The dynamo action between T_2 and v_1 generates a toroidal field T_3 whose longitudinal symmetricity is given by the sine of 2λ. Finally, the dynamo action between T_3 and v_2 results in a poloidal field of the dipole-like mode B_0, and thus a chain of dynamo processes, $B_0 \rightarrow T_1 \rightarrow T_2 \rightarrow T_3 \rightarrow B_0$, can be apparently completed as far as these four main modes of magnetic field are concerned. It must be noted that each dynamo process generates not only the main mode but also a number of higher harmonic modes of magnetic field having a higher degree of symmetricity as well.

The other possible dynamo processes, between B_0 and v_2, between T_2 and v_2 and between T_3 and v_1, generate, respectively, T_3, T_1, and T_2 types of magnetic field as their main results and associated higher harmonic mode fields in addition. The dynamo process between T_1 and v_1, however, generates only higher harmonic mode fields, and it does not generate a poloidal field of a dipole-like mode. If all the higher harmonic fields are truncated, therefore, the whole picture of the chain reactions of the four dynamo processes may be summarized as that shown in Figure 5A. It has been shown that a system consisting of four dynamos is very likely to have a steady state, insofar as the higher harmonic fields whose degree of symmetricity with respect to lambda are larger than two can be truncated (elimination of higher terms). Assuming that the electrical conductivity of the core is uniformly 3×10^2 (ohm-centimetres)$^{-1}$, the maximum speed of the zonal flow (v_1) has been estimated at about 0.04 centimetres per second. It has been pointed out that the maximum intensity of the toroidal field T_1 may be as large as 480 gauss, whereas the geomagnetic dipole field of 0.7 gauss at the magnetic pole should require only 4.5 gauss intensity at the magnetic pole of the core. Later studies on the possible effect of higher harmonic fields, which were truncated in the earlier model, have indicated that the contributions of these higher harmonic fields to the whole chain system is not negligible, and so it becomes doubtful whether or not the model really does simulate a steady dynamo. Quantitatively, it has been shown that the powers of the four main dynamos are reduced by taking into account the higher harmonic fields, whereas other higher harmonic fields actually increase when still higher harmonic fields are considered. In other words, the energy supplied by fluid motions is not spent mostly in maintaining the closed circuit of the four main dynamos but goes instead to support higher harmonic fields.

Four-dynamo theory

Although the model faces a serious difficulty, workers have shown that certain kinds of dynamo can be maintained in a spherical conductor. In 1958 it was shown that an axisymmetric toroidal magnetic field (T_1), which is generated from an axisymmetric poloidal field (B_0) with a certain appropriate flow in a conductive sphere, can enhance the initial poloidal field by coupling with another appropriate motion, in which all higher harmonic fields are suppressed as minor effects. In brief, it was proved that a dipole-type poloidal magnetic field can be maintained only if an appropriate pattern of fluid motions exists in the Earth's core.

In the same year, it was shown that a dynamo can consist of two rigid conductive spheres embedded in a rigid spherical conductor. It is certain that the self-exciting dynamo system can be maintained if appropriate conditions are satisfied within the earth's core; unfortunately, however, there is no evidence to justify the necessary conditions for the dynamo models in the actual makeup of the Earth's core.

In 1964 a new and important criterion was proposed in regard to the dynamo model, which is based on a realistic flow-pattern model in the core. In the original model, two simple modes of flow were assumed; namely, a zonal flow, which is attributable to a difference of the angular velocity between the fluid core and the solid mantle, and a simple convection pattern, which could be maintained by a possible radiogenic heat (heat due to radioactivity) source in the core in which the longitudinal symmetricity of the convection pattern is expressed as the cosine of two lambda. It was now suggested that a dynamo of this type can hold only when the convection pattern is not as simple as in the original model but consists of two modes whose longitudinal symmetricities are given by both cosine of two lambda and sine of two lambda.

In 1970 another worker, who had worked extensively on a similar model of the modified dynamo, showed that the modified dynamo can reach its steady state even though the higher harmonic fields are taken into account. In this model, a convection flow pattern (v_3) of sine of two lambda in longitudinal symmetricity is newly added to v_1 and v_2 in the original model, in which the v_3 convection is confined to a smaller spherical space whose radius is half that of the core. Thus, the modified four dynamo processes may be summarized as shown in Figure 5B.

In the extensive numerical calculation required to examine this dynamo system, higher harmonic fields up to cosine 6λ and sine 6λ in their longitudinal symmetricities are taken into account. It has been proved that this modified system can maintain the dynamo action and the whole system can reach its steady state. In the modified system also, the intensities of toroidal magnetic fields are large compared with those of poloidal fields of the same degree of symmetricity. In particular, the T_1-T_2-T_3-T_1 triangle of interactions through v_1, v_2, and v_3 plays the most important key role in the maintainance of the whole system. It may be concluded, therefore, that the dipole field B_0 corresponds to the geomagnetic dipole field, and other higher harmonic poloidal fields represent the geomagnetic regional anomalies.

Regional anomalies

Theory of secular variation. The most drastic characteristic of the geomagnetic secular variation may be the reversals of the geomagnetic field that have frequently occurred in past geologic times. The possible mechanism of this phenomenon has not yet been fully interpreted. One model of the geomagnetic field indicates that the dipole field B_0 is a minor field component compared with the major toroidal fields and that its direction can be easily reversed, just as can the perturbation effects of the

main interaction between the major toroidal components. It seems likely, therefore, that the geomagnetic field reversals are caused by such perturbations in the major toroidal field system. This presumption is in agreement with the observed fact that the lifetimes of individual geomagnetic polarities obey statistical laws. In examining the transient processes of the system, a worker in 1970 found that the time required to reach a final steady state from an initial state of no toroidal fields in the system is about 5,000 years. This conclusion seems to favour the estimated time interval for a polarity transition.

Another well-established characteristic of secular variation is the westward drift of geomagnetic regional anomalies. The westward drift phenomenon has been interpreted on the basis of the dynamo theory. If there are convection currents of matter in the core, the conservation of angular momentum requires that the deep interior of the core rotates faster than the outer layer. This means that the outer layer should move westward with respect to the inner part. Furthermore, if the deeper part of the mantle is of sufficient electrical conductivity to result in an electromagnetic coupling between the core and mantle, then the core as a whole and the deeper part of the mantle are tightly connected together. To reach a steady state under these conditions, the angular velocity of eastward rotation is the largest in the deep core, the smallest in the core's outer layer, and in the mantle the intermediate value between these two. Thus, the outermost part of the core apparently drifts westward with respect to the solid mantle and consequently with respect to the Earth's surface. It has been shown that an electric conductivity of one (ohm-centimetre)$^{-1}$ for the deeper mantle is sufficient to cause a westward drift of 0.2° per year of the uppermost layer of the core relative to the mantle. The magnitude of conductivity seems to be reasonable based on other evidence in regard to the Earth's interior.

Growth and decay of the geomagnetic regional anomalies can be interpreted as being caused simply by growth and decay of higher harmonic poloidal fields in the core in the course of transient dynamo processes. It may be concluded, therefore, that all significant aspects of the geomagnetic secular variation can be reasonably understood on the basis of the dynamo theory.

The origin of the geomagnetic field and its secular variation may be reasonably interpreted when they are assumed to be caused by an electromagnetic dynamo action going on in the Earth's core. It must be remarked, however, that the dynamo theory is not yet complete; the dynamo theory so far examined is the kinematic theory, in which the reaction of electromagnetic coupling upon the hydrodynamical fluid motions is ignored. In a complete magnetohydrodynamic (motion of fluids produced by electromagnetic forces) theory, both the electromagnetic coupling and the hydrodynamical motions and their mutual reactions must be simultaneously considered in the form of associated equations of motion. It is practically impossible at present, however, to perform theoretical researches along this line, because even the world's largest computer is barely sufficient to carry out the necessary computations for such work, and then only in a limited way.

Earth, Mechanical Properties of

Mechanics is concerned with the relationship between matter, the forces acting on it, both internally and externally, and the consequent motion of it in its parts or as a whole. Kinds of motion may be translational; that is, in a straight line, vibratory, and rotational. These interrelations are called mechanical properties, which may be invested in the smallest of particles, such as nuclei of atoms, to the largest aggregates of matter—the Earth, Sun, stars, and galaxies.

By knowing how the Earth can deform and recover throughout its volume and by being aware of such fundamental properties as density it is possible to derive useful information on gross phenomena—mountain building, earthquakes, continental drift, internal and external gravitational fields, sources of the Earth's internal heat, and properties of the Earth's core.

The five basic mechanical properties

There are five mechanical properties of the Earth's body that are particularly fundamental to a determination of its behaviour: namely, density, pressure, gravitational intensity, incompressibility, and rigidity. Density refers to mass per unit volume, which varies within the Earth because of the effects of pressure and temperature and because of variations of composition. Pressure refers to the force per unit area inside a body, and incompressibility indicates the extent to which a material resists pressure. Rigidity indicates the resistance of a material to the stresses that tend to distort it, and gravitational intensity is the force per unit mass arising from a gravitational field. These five properties go together as a group, the values of which are derived by an interrelated series of calculations from observational data, and they are by far the most reliably determined mechanical properties of the Earth's interior. Their values provide a firm basis for the investigation of other properties.

A large part of the observational evidence comes from a study of the Earth's response to various external and internal forces, and of the dynamical interplay between the Earth and outside bodies such as the Moon and artificial satellites. For example, the attractions of the Moon and Sun give rise to tides, including bodily tides of the solid Earth, that throw light on the Earth's internal rigidity; observations of the precession of the equinoxes (*i.e.*, a slow change in direction made by the Earth's axis), a consequence of Earth–Moon interaction, contribute toward determining the Earth's moment of inertia (see below for definition) and internal density distribution; observations of artificial satellites contribute to knowledge of the Earth's external gravity field and thence also to the density determination. Examples of internal forces include those associated with earthquakes (*q.v.*), which send mechanical waves throughout the Earth's interior and deliver important numerical information on three of the properties—density, incompressibility, and rigidity at internal points.

In interpreting the observations, the essential aim, as in all science, is to arrive at optimum mathematical model representations of the properties of interest. Scientific method requires models to be the simplest, among the infinity of those possible, that are compatible with the observational evidence on hand at any stage. As evidence grows, models are progressively refined. Models may take the form of mathematical relations, as in equation (1) below, or numerical tables.

Mathematical models

To a close approximation, the Earth is spherically symmetrical, so that the internal distributions of the five mechanical properties mentioned above are closely represented by Earth models, the properties of which vary only with the depth below the surface or the distance from the centre. The deviations from spherical symmetry are important in some problems, however. Reference is made later in this article to the Earth's mechanical behaviour over periods that are comparable with geological time. This is a topic that does not yet compare in precision with the determination of the basic mechanical properties.

The solid Earth (including the oceans) has a mean radius of 6,371 kilometres (3,960 miles) and consists of a crust with an average thickness of about 15 kilometres (about 10 miles), a mantle extending from the crust to about 2,900 kilometres (1,800 miles) in depth, and a core extending from there to the centre (Figure 1). Subdivisions

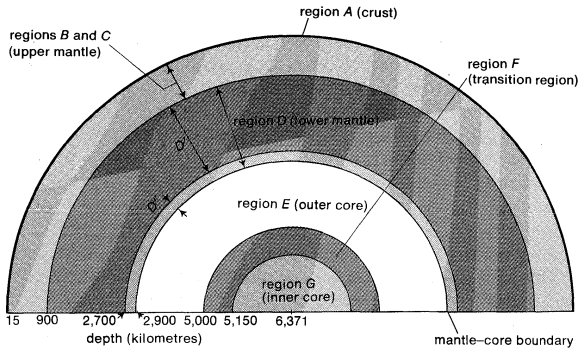

Figure 1: Cross-section of the Earth, showing the principal internal layers.

of the mantle and core will be introduced later. This article is chiefly concerned with mechanical properties below the crust and their large-scale variation throughout the Earth's interior.

PRELIMINARIES ON DEFORMABLE MEDIA

Stress and strain. The Earth consists of deformable matter capable of responding to internal and external applied forces. The forces generate internal stresses that are accompanied by deformation, or strain. Stress may be defined as the force per unit area across an indefinitely small area inside a body, and strain is the proportional change in shape brought about by a stress (see DEFORMATION AND FLOW; and ELASTICITY). In general, six independent components are needed to express the stress at any point. If orthogonal (Cartesian) axes Ox_1, Ox_2, Ox_3 are taken, the six components are commonly expressed in condensed notation as p_{ij}, in which the subscripts i and j take on values 1 through 3—*e.g.*, $ij = 11$, 22, 33, 23, 31, 12. The subscript i refers to the axis Ox_i that is perpendicular to the element of area acted on by the force, and the subscript j refers to the axis Ox_j, to which the component of force is parallel; p_{12}, for example, denotes the component parallel to Ox_2 of the stress, or force per unit area, across a small plane internal interface perpendicular to Ox_1.

The deformation is commonly represented in terms of six strain components e_{ij} (the subscripts i and j take values 1, 2, and 3, as with p_{ij}). Strain relates to the proportionate changes of distances between neighbouring particles when internal movement occurs in a body. The dilatation, denoted by the Greek letter θ (theta), is equal to $e_{11} + e_{22} + e_{33}$, is minus the compression, and indicates the proportionate increase in volume.

Simple stress–strain behaviour. A first task in studying quantitatively the response of a body to applied forces is to select a mathematical model employing stress–strain relations suited to the demands of the observational context. One commonly used set of relations is a generalization of Hooke's law (after an English scientist, Robert Hooke) of elasticity (a perfectly elastic medium is one in which the identical initial form will be assumed after the force of deformation is removed) stating that strain is proportional to stress. Hooke's law relates to the simple case of wires that are stretched under tension; the extension is proportional to the tension.

In the generalized law, the stress (p_{ij}) can be expressed as the sum of two terms, the first being the difference between the incompressibility, also called bulk modulus (k), and two-thirds the rigidity (symbolized by the Greek letter mu, μ), times the dilatation (θ) times a factor δ_{ij}, and the second being twice the rigidity times the strain component (e_{ij})—*i.e.*,

$$p_{ij} = (k - \tfrac{2}{3}\mu)\theta\delta_{ij} + 2\mu e_{ij}, \qquad (1)$$

in which the factor δ_{ij} is equal to 1 or 0 according as $i = j$ or $i \neq j$. The six relations resulting from (1) are the simplest serviceable stress–strain relations for a solid; they relate to the ideal case of a perfectly elastic, isotropic solid undergoing "infinitesimal" strain. The particular case for which rigidity equals zero ($\mu = 0$) corresponds to the ideal perfect fluid, for which p_{ij} always takes the form $-p\delta_{ij}$, in which p is the pressure. Inside solids, p is, strictly, minus one-third the sum of the principal stresses, $-\tfrac{1}{3}(p_{11} + p_{22} + p_{33})$. The stress inside a solid may take the form $-p\delta_{ij}$ as a particular case and is then called hydrostatic.

In contexts in which the model relations (1) are closely compatible with the observations, materials may be classified into "solid" and "fluid" without misunderstanding —solid when the ratio of rigidity to incompressibility (μ/k) is found to be significant (say, about 1 percent, or greater), fluid when the ratio is insignificant.

Deviatoric stress and strength. The stress components (p_{ij}) can be expressed as minus the product of the pressure (p) and the factor δ_{ij}, plus another term (P_{ij}) designated as the deviatoric stress components: $p_{ij} = -p\delta_{ij} + P_{ij}$ (2). When a material is subjected to increasing stress, a stage is reached at which the initial configuration is not even approximately recovered after removal of the stress (see ROCK DEFORMATION; ROCKS, PHYSICAL PROPERTIES OF). For ordinary short-term purposes, the strength of the material is suitably defined as the value of $\sqrt{(3\Sigma\Sigma P_{ij})^2}$ when this stage is just reached. Fracture or flow may subsequently occur. No strengths greater than 10^{10} dynes (a force producing an acceleration of one centimetre per second per second when acting on a mass of one gram) per square centimetre (abbreviated dyne/cm^2) are known, and this value is not likely to be exceeded in the Earth's interior. As seen from the Table, pressure (p) reaches 10^{10} dynes per square centimetre at about 35 kilometres (22 miles) depth and increases continuously with depth, exceeding 3×10^{12} dynes per square centimetre at the Earth's centre. (The pressure of water at the ocean's greatest depths is about 10^9 dynes per square centimetre). Hence, throughout most of the Earth, especially below the outermost few hundred kilometres, all the deviatoric stress components are small compared with the mean of the principal stresses so that $p_{ij} \approx -p\delta_{ij}$. Thus, the stress can be represented as hydrostatic to good approximation inside most of the Earth, even where the rigidity is substantial.

Seismic waves. Forces inside the Earth cause deviatoric stresses to build up to the stage at which the local strength is reached. When the stresses are relieved by fracture, an earthquake occurs (see EARTHQUAKES). Seismic waves are transmitted from the earthquake focus (origin).

Observational checking has shown that the model relations expressed by (1) can be used to good approximation in investigating these waves. The quantities p_{ij}, e_{ij}, and θ in (1) here relate to the comparatively small additional stresses and strains that are superposed, during the wave transmission, on the larger, approximately hydrostatic stresses and compressions already present in the undisturbed state.

***P* and *S* seismic waves**

Seismic waves include two bodily types that pass down into the Earth's interior: the *P* (primary) waves resemble sound waves and cause the material particles to vibrate in the direction of wave advance; the *S* (secondary) waves cause particles to vibrate transversely; that is, at right angles to the direction of wave advance (see WAVE MOTION). The speed α of primary waves is given to good accuracy by the relation, speed squared is equal to density (denoted by the Greek letter rho, ρ) divided into the sum of incompressibility and four-thirds the rigidity, and the square of the speed β for transverse waves is given by the ratio of rigidity to density; *i.e.*,

$$\alpha^2 = (k + \tfrac{4}{3}\mu)/\rho \qquad (3a)$$

$$\beta^2 = \mu/\rho. \qquad (3b)$$

Solid regions transmit both *P* and *S* waves; fluid regions transmit only *P* waves, the rigidity μ and hence the *S*-wave velocity being negligible. Seismic surface waves travel around the Earth's surface with amplitudes that die out more or less rapidly with depth. Earthquakes also excite free oscillations of the Earth in which large proportions of the whole Earth may be vibrating at one and the same time.

Observations of all these waves and oscillations have been applied in working out the Earth's internal mechanical structure.

Deviations from simple stress–strain behaviour. The model stress–strain relations given by (1) are not adequate for all Earth contexts. For example, they do not give a suitable description of deformations over geological time. When these relations are inadequate, the terms solid and fluid cease to be precisely defined terms, and it becomes better in general to classify material in other ways. Deep in the Earth, where compressions are large, the infinitesimal theory has for some purposes to be replaced by finite-strain theory, in which the stress–strain relations are not linear as in the relations in (1). When accumulated deviatoric stresses are relieved by flow or fracture, further theory again is required. The various complications, which are far from being fully resolved, bear especially on questions of the long-term mechanical behaviour of the Earth and are considered below in the section *Anelasticity in the Earth*.

THE BASIC INTERNAL MECHANICAL PROPERTIES

The key item in determining the main mechanical properties of the Earth in its present state is the determination of the distribution of the density (ρ). The distributions of the properties pressure (p), incompressibility (k), rigidity (μ), and gravitational intensity (g), are then readily derived.

Mean density and the moment of inertia of the Earth. The most precisely determined constraint on possible density distributions in the Earth is the mean or average density, estimated as 5.5 grams per cubic centimetre by the English physicist Henry Cavendish in 1798 (abbreviated g/cm^3) and now assessed as 5.517 g/cm^3.

A second powerful constraint on possible density distributions is the moment of inertia, an index of the degree of concentration of denser matter in a body toward its centre. For a sphere of uniform density and of mass M and radius R, the moment of inertia (I) is 0.4 MR^2. A value for the Earth's mean moment of inertia became available in the 19th century when it was calculated by French mathematicians, who, starting in 1743, combined a variety of observational evidence using ingenious mathematical steps. The evidence included numerical data on the universal constant of gravitation (G), the Earth's mean radius (R), mass (M), axial angular velocity, and on the precession of the equinoxes. The mathematical steps involved an analysis of the Earth's internal and external gravitational fields and theory on the Earth's ellipticity of figure (see EARTH, GRAVITATIONAL FIELD OF). Stresses inside the Earth were treated as hydrostatic. Initially, this was because geologists had thought the Earth to be wholly fluid below a thin crust. Although the Earth is now known to be solid (in the ordinary sense) for five-sixths of its volume, the hydrostatic theory can still be justified, up to a point, because of the relative smallness of the deviatoric stresses.

Moment of inertia

The 19th-century estimate of the moment of inertia was 0.3336MR^2. Because the coefficient 0.3336 is appreciably less than the value 0.4, which applies to a sphere of constant density, it followed that the deep interior of the Earth is much denser than the outer part. Along with studies of meteorites, this led to the suggestion that the Earth contains a fairly dense core. In 1963 the Earth's moment of inertia was calculated independently of the internal hydrostatic theory from artificial satellite observations. A reduced value of 0.3308MR^2 was obtained, implying that the deviatoric stresses inside the Earth's mantle are somewhat more significant than had earlier been supposed.

When the value of the moment of inertia first became fairly reliably known, provisional models of the Earth's density variation were formulated. Two such models gave the density increasing steadily from two to three grams per cubic centimetre at the surface to 10 to 12 grams per cubic centimetre at the centre. These values were accepted until the 1930s. Early in this century, simple models allowing for a core also began to appear; these models give approximately the same density range.

Data from seismic bodily waves. Analyses of records of bodily seismic waves have yielded tables giving the travel times of P and S waves along seismic rays in terms of the angular distances covered. Subsequent mathematical processes have yielded values of the P and S velocities α and β throughout the mantle and of α throughout the core. Through the equations (2) and (3), the values of α and β supply values of the physical quantities k/ρ and μ/ρ throughout the mantle and of $(k + \frac{4}{3}\mu)/\rho$ throughout the core. This is important information that must be fitted by the internal distributions of density, incompressibility, and rigidity.

Evidence from natural earthquakes is supplemented from analyses of seismic waves from artificial explosions. Chemical explosions supply information on structure near the Earth's surface and nuclear explosions on the whole interior. Although always smaller in energy than the larger natural earthquakes, explosions have a cardinal advantage in investigating the Earth's interior in that their locations and times of origin are knowable in advance and to high precision.

Explosions of nuclear devices have been important in another way; efforts to detect them have resulted in the establishment of seismological array stations and the application of the mathematical theory of communication in gathering and interpreting the records. An array station in Montana consists of 525 substations, all equipped with similar seismographs, spread over 25,000 square kilometres (10,000 square miles). This development is increasing the precision with which the primary and secondary wave, velocities α and β, and hence the ratios k/ρ and μ/ρ can be determined in the Earth's interior.

Seismograph array stations

In 1906 the British scientist R.D. Oldham showed from analysis of P-wave data that the Earth has a core. In 1909, Andrija Mohorovičić, a Croatian seismologist, gave the first evidence that the wave velocities α and β increase sharply across the boundary, now called the Mohorovičić discontinuity, which separates the crust from the mantle. The detection of S waves throughout the mantle about this time showed that the entire mantle behaves as a solid in its response to stresses produced in seismic waves.

A remarkable calculation by the German-born geophysicist, Beno Gutenberg, in 1914, placed the mantle–core boundary at 2,900 kilometres (1,800 miles) in depth. In 1936 the Danish seismologist Inge Lehmann showed that the P-wave velocity increases fairly sharply deep down in the core, requiring the core to be divided into a (so-called) outer core and an inner core (of radius about 1,200 kilometres [700 miles]).

By 1939, fairly reliable travel-time tables (here called the JB tables) of bodily seismic waves had been evolved by the geophysicists Sir Harold Jeffreys and K.E. Bullen, and by Beno Gutenberg and an American seismologist, C.F. Richter, leading to much further detail. Among other things, Jeffreys calculated distributions of the velocities α and β corresponding to the JB tables, estimated the core radius as 2,898 $\pm$ 3 kilometres (1,800 $\pm$ 2 miles), and gave evidence of a transition zone separating the outer core proper from the inner core. Over a period of years starting from 1926, Gutenberg put forward evidence of a low velocity layer (characterized by decreases of α and β with depth) over a limited range of depth inside the outermost 200 kilometres (150 miles) of the mantle.

Bodily wave data gathered since 1939 have suggested or required several modifications to the JB travel-time tables and the distributions of α and β. The modifications are mostly small and are taken into account in the accompanying Table. Recent bodily wave data have also contributed important evidence on lateral variations of structure—*i.e.*, differences in structure extending down to some 400 kilometres depth below different geographical regions.

Data from seismic surface waves. Starting from the application of an early theory of two English physicists, Lord Rayleigh (William Strutt) and A.E.H. Love, a large number of investigators (notably, Jeffreys, Robert Stone-

ly, Maurice Ewing, and Frank Press) have derived valuable additional information on the properties ρ, α, and β in the outer part of the Earth by analyzing records of seismic surface waves. The results assist in the fine delineation of upper mantle structure, including lateral variations.

Evidence from tidal observations. In 1862 Lord Kelvin (William Thompson) showed from an analysis of tidal observations (see TIDES), including bodily tides of the solid Earth, that the mean rigidity of the Earth (in response to stresses of tidal periods) is about twice that of ordinary steel. When estimates were made later of the rigidity in the mantle, it became possible to estimate the mean rigidity of the core. In 1926 Jeffreys inferred in this way that the core is mostly fluid, a result also indicated by the failure to detect S waves below the mantle. This result was substantiated and elaborated by the Japanese scientist H. Takeuchi in 1950. The calculations establish that the outer core is fluid but fall short of pronouncing on the fluidity or solidity of the small inner core. Thus, in effect, observational values of k/ρ and μ/ρ are separately available down to nearly 5,000 kilometres (3,000 miles) depth.

Fluidity of outer core

Density gradient in the Earth. Density gradients $d\rho/dz$ (rates of change of density with depth z) inside the Earth can be estimated with the help of the equations:

$$d\rho/dz = \eta G m\rho/r^2\phi, \quad (4)$$

$$\phi = \alpha^2 - 4\beta^2/3 = k/\rho, \quad (5)$$

$$\eta = dk/dp - g^{-1}d\phi/dz. \quad (6)$$

In these equations m denotes the mass inside a sphere of the Earth of radius r. In deriving equations (4) and (6), hydrostatic stress and spherical symmetry are assumed, and the theory of gravitation is used.

The special case of equation (4), in which the coefficient η (Greek letter eta) is equal to unity (one unit), innate in early geophysical theory of the French mathematicians Adrien-Maria Legendre and Pierre-Simon Laplace, was applied by the American geophysicists E.D. Williamson and L.H. Adams in 1923 using seismological data on α and β to determine the parameter ϕ. But this case (often called the Williamson–Adams equation) gives only that contribution to density gradient that arises from pure adiabatic compression—that is, compression without heat exchange—and is seriously inadequate in some parts of the Earth. The Legendre–Laplace theory was generalized by Bullen to the equations (4)–(6) as shown; the coefficient η takes account of deviations from adiabatic temperature gradients and of variations of chemical composition and phase inside the Earth. The utility of equation (6) lies in the fact that, for much of the Earth's interior, numerical bounds (limits) can now be set for the quantities dk/dp, g, and $d\phi/dz$, enabling η and hence $d\rho/dz$ to be assessed to useful precision.

In applying equation (4), independent evidence is required on the density ρ' just below the crust. The value of ρ' was assessed by Williamson and Adams as 3.3 grams per cubic centimetre on the basis of petrological evidence and comparisons of seismological data on α and β with experimental data of rocks. Any error in this value is unlikely to exceed 0.2 gram per cubic centimetre and is unimportant in the estimation of densities in the deeper interior.

Derivation of Earth models. During 1936–42, the foregoing principles were applied to construct what Bullen called A-type models, using the data on α, β, and the Earth's moment of inertia available at the time. Significant variations of chemical composition or phase (see EARTH, STRUCTURE AND COMPOSITION OF) were shown to exist inside the mantle, with corresponding departures of the coefficient η from unity. Down to about 5,000 kilometres (3,000 miles) depth, these models gave the density distribution within 5 percent or less and correspondingly reliable distributions of the properties k, μ, p, and g. Further down, only lower bounds could be set for the density, the minimum value at the centre being 12.2 grams per cubic centimetre. Improvements since 1942 have been mainly of the character of successive approximations starting from the A-type models.

A nomenclature, since widely used, was introduced during this work to delineate internal layers of the Earth (see Figure 1): A for the crust; B, C, and D for regions of the mantle; and E, F, and G for the core. The regions B and C together constitute the upper mantle, extending down to about 900 kilometres (550 miles) depth; D is the lower mantle; E and G relate to the outer and inner core proper and F to a possible transition zone between. Some modifications, chiefly in the form of subdivisions of layers, will be indicated below.

The A-type calculations revealed an interesting property of the incompressibility k. In contrast to ρ and μ, both k and its pressure gradient dk/dp showed at most quite small changes at the mantle–core boundary, leading to the idea that incompressibility varies fairly smoothly with pressure throughout the whole of the Earth's lower mantle and core. This hypothesis was fortified by later evidence from finite-strain theory and experiments on the behaviour of rocks at high pressure.

From the evidence on the compressibility, the inner core was inferred by Bullen in 1946 to be solid, the jump in P-wave velocity from outer to inner core being associated through equation (3a) with a jump in the rigidity. The presence of significant rigidity in the inner core is now supported by a variety of indirect evidence, including thermal and geomagnetic evidence. Until 1972 means had not been found to detect the rigidity directly (*i.e.*, seismically), but recent investigators now claim to have detected S waves in the core. Their results would indicate a rigidity of at least 1.0×10^{12} dynes/cm^2, a value greater than that of ordinary steel.

Attempts to measure core rigidity

The findings on the rate of change of rigidity with pressure (dk/dp) led to a subdivision of the region D into

D' and D'' (see Figure 1). The region D'', which occupies the lowest 200 kilometres (100 miles) of the mantle, is an abnormal region in which the seismic velocity gradients (rates of change of velocity with depth) $d\alpha/dz$ and $d\beta/dz$ become zero or negative. Through the relations (4)–(6), the evidence on dk/dp showed that either the density gradient is markedly greater in the region D'' than in D', or there is a marked fall in rigidity inside D'', or possibly both.

Various implications of the evidence on compressibility were incorporated in Bullen's Earth model B of 1950, including a preliminary estimate of the Earth's central density.

Evidence from free Earth oscillations. On May 22, 1960, there occurred in Chile a great earthquake that, indisputably for the first time, excited free oscillations of the whole Earth, with a period of up to an hour. Analyses of observatory records (following pioneering work of the American geophysicist Hugo Benioff on the instrumental side) have since yielded reliable estimates of more than 100 separate free Earth oscillation periods (fundamental and overtone). Each period estimate adds, in effect, one new constraint on the possible distributions of ρ, k, and μ in the Earth. Early analyses confirmed the reliability of the A-type and B models within the estimated accuracy. Subsequently, the oscillation data have been applied in an endeavour to refine the previously existing Earth models.

Further evidence bearing on the density distribution. P.W. Bridgman and F. Birch, two American scientists, provided much experimental data on the behaviour of rocks and metals at high pressures and temperatures. Birch also developed a simplified version of finite-strain theory for application to the Earth's interior. In 1952 he estimated thermodynamical contributions to the Earth's density gradient, postulated empirical relations connecting density with P-wave velocity for materials of assigned atomic weights, provided some additional evidence on the variation of compressibility and its derivative (dk/dp) in the Earth, and formulated trial equations of state connecting density, compressibility, and pressure. His results have usefully confirmed some of the findings from other sources on the internal mechanical properties of the Earth, especially the mantle, and have supplied additional detail on a number of points (see ROCKS, PHYSICAL PROPERTIES OF).

During 1961–63, Birch used data from shock-wave experiments involving transitory pressures up to several million atmospheres to infer an upper bound of about 13 grams per cubic centimetre for the Earth's central density. Through equations (4)–(6), Bullen showed that, using the latest data on P-wave velocities, any value of the central density less than 14.7 grams per cubic centimetre would require the inner core to be solid with the rigidity mildly increasing in depth. These results gave a measure of new support to the presence of solidity in the inner core.

Solidity of inner core

Distribution of ρ, k, μ, p, g, and other factors. Representative values of the density and related properties of the Earth's interior, as inferred from the evidence given above, are shown for selected depths in the Table and Figures 2 and 3. The values relate to a spherically symmetrical Earth model and hence are global averages for the depths given. They are based principally on a procedure in which an A-type model was progressively modified to fit recent evidence and accord fairly well with results derived by other methods.

Some of the main features exhibited in the Table are: the jump in density (5.6 to 9.9 grams per cubic centimetre) at the mantle–core boundary (at a depth of about 2,900 kilometres [1,800 miles]); the currently favoured value of 13 grams per cubic centimetre for the central density; the fairly smooth variation of the incompressibility throughout the Earth; the steady increase of the rigidity μ throughout most of the mantle; estimates of rigidity in the inner core; and details on pressure and gravity. The values of Young's modulus E and Poisson's ratio σ are derived from those of k (incompressibility) and μ (rigidity) by simple standard formulas (see ELASTICITY).

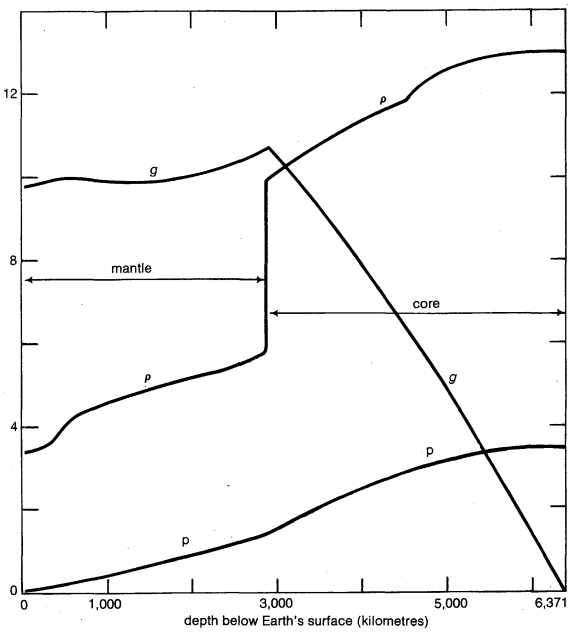

Figure 2: Variation of the density ρ (in grams per cubic centimetre), gravitational intensity g (in 100 centimetres per second squared), and pressure p (in 10^{12} dynes per centimetre squared) throughout the interior of the Earth (see text).

A broad description of the internal layering is as follows. The conventional crustal region A is taken as averaging 15 kilometres (about 10 miles) thick with a mean density of 2.84 grams per cubic centimetre. The region B (15–350 kilometres [10–200 miles] in depth) is subdivided into B' and B'' by a boundary (not closely determined) at 60 kilometres (40 miles) depth, at which small diminutions in β and μ probably occur. The average value of the coefficient η inside region B is noticeably less than unity and would correspond to the presence of a high temperature gradient (which somewhat offsets the rate of density increase due to pure compression). In the region C (350–900 kilometres [200–600 miles]), in which the coefficient η is greater than unity, there are significant changes in chemical composition or phase. The subregions C' and C'' are separated by a boundary at 650 kilometres (400 miles) depth, where there are small but fairly sharp changes in the density gradients. The changes from C'' to D are gradual, so that the boundary at 900 kilometres (600 miles) is not closely determined. The subregion D' (900–2,700 kilometres [600–1,700 miles]) appears to be nearly chemically homogeneous with η approximately equal to unity. Inside the subregion D'', the coefficient may be as high as three units. The outer core proper (region E) extends to about 4,500 kilometres (2,800 miles) in depth and may deviate a little, but not far, from chemical homogeneity in the upper part. The inner core proper (region G) has a radius of about 1,200 kilometres (800 miles). The intermediate zone F may include one or more transition regions (see EARTH, STRUCTURE AND COMPOSITION OF).

DEPARTURES FROM SPHERICAL SYMMETRY

Oblateness. The outstanding departure from spherical symmetry is the Earth's oblateness of figure—that is, flattening at the poles (see EARTH, FIGURE OF; EARTH, GRAVITATIONAL FIELD OF)—a consequence principally of the Earth's axial rotation. The measure of oblateness is ellipticity, which is equal to the ratio of the difference between the equatorial radius and polar radius (about 26.5 kilometres) to the equatorial radius. The ellipticities of surfaces of constant density and pressure within the Earth diminish steadily from the surface inward, ranging from 0.00335 at the outside surface, to about 0.0025 at the mantle–core boundary, to about 0.0024 near the centre. Allowances for oblateness have to be made in a variety of problems—*e.g.*, in deriving seismic travel-time tables.

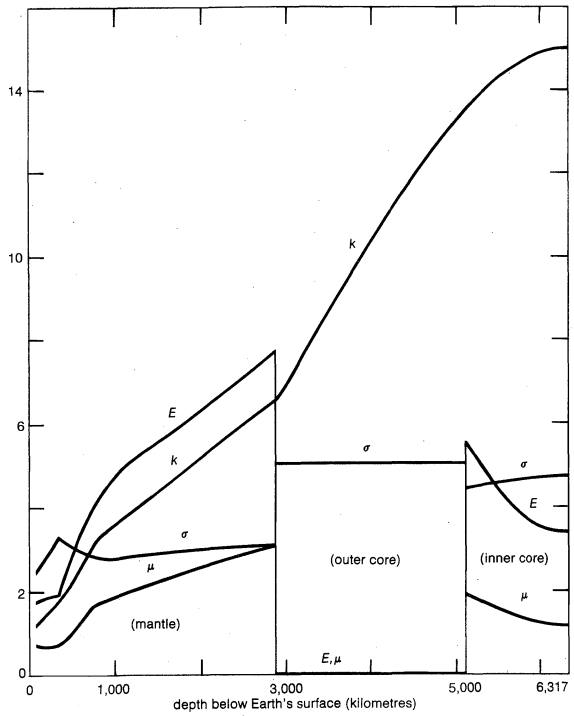

Figure 3: Variation of the principal elasticity variables throughout the interior of the Earth: k is incompressibility, μ is rigidity, and E is Young's modulus (each in units of 10^{12} dynes per centimetre squared); σ is Poisson's ratio (in units of 0.1; see text).

Lateral variations. The remaining departures from spherical symmetry occur predominantly in the crust and upper mantle. The depth to the Mohorovičić discontinuity is about 35 kilometres (about 20 miles) in continental shield areas, nearly 70 kilometres (40 miles) under some mountain chains, but only about ten kilometres (about five miles) in oceanic regions. Lateral variations associated with these crustal differences persist for some distance down into the mantle, becoming undetectable at 400–600 kilometres (250–400 miles) depth. The variations chiefly involve small differences in the rates of change of rigidity and density under different geographical regions, and they complicate the task of determining the P and S seismic velocities to close accuracy.

Distribution of deviatoric stresses

The distribution of deviatoric stresses below the Earth's surface is far from symmetrical. This is indicated by the predominant occurrence of major earthquakes in limited zones, mainly near the boundary of the Pacific Ocean Basin and on a belt running through the East Indies to the Mediterranean. Other phenomena such as mountains and certain sequences of geophysical importance are likewise unsymmetrically distributed; for example, sequences of ocean troughs, shallow earthquakes, gravity anomalies, large earthquakes, island arc systems, volcanoes and earthquakes of deep focus.

Isostasy. The visible inequalities at the Earth's surface in general produce much less disturbance in the gravitational intensity (g) than would be the case if they were simple (positive or negative) loads. Thus, elevations of the surface are "isostatically compensated" to greater or less extent by reduced density for some distance below—depressions by increased density. Isostasy is not complete, and gravity anomalies remaining after theoretical allowance for isostasy contribute further evidence on deviatoric stresses existing at present. Isostasy to some extent counterbalances some of the mechanical effects of crustal asymmetries.

ANELASTICITY IN THE EARTH

The results given above relate mainly to properties of the Earth at its present stage of evolution and ignore anelasticity (departures from perfect elasticity), and they provide a basis—in a sense supply "boundary conditions"—for investigating mechanical aspects of the past evolution of the Earth. The investigations bear on possible large-scale happenings in the past (see MOUNTAIN-BUILDING PROCESSES and CONTINENTAL DRIFT) and involve, fairly crucially, difficult questions of the anelasticity and strength of the Earth's materials.

There is evidence that all materials show some creep (gradual movement of material after the removal of applied deviatoric stress) even under quite small deviatoric stresses (P_{ij}) when the stresses are sufficiently long sustained. This carries the consequence that the strength of a material may depend not only on the P_{ij} but also on the time during which the P_{ij} are applied. Over geological time, creep may be substantial. The perfect elasticity stress–strain relations, equations (1), then cease to be an adequate model and have to be amended to allow for anelasticity. To some extent, this applies even for times well short of geological time. The mechanics of anelasticity are so complicated that, while some limited quantitative inferences of geophysical interest can be made, many conclusions in this field are qualitative and circumstantial and fall well short of the precision of the earlier results.

Damping of seismic waves. Evidence on anelasticity in response to stresses with periods up to an hour comes from the observed damping of bodily and surface seismic waves and free Earth oscillations. The results are commonly expressed in terms of the quantity Q defined so that the damping factor is the exponential of minus 2π divided by Q, $\exp(-2\pi/Q)$, for one wavelength; thus, $1/Q$ is a measure of the dissipation of the wave energy. It has been estimated that the order of magnitude of Q is 400 in the average crust, 100–200 in the upper mantle, and 1,000–2,000 at greater depths. (These estimates are simplified; *e.g.*, they ignore dependence of Q on the wave period.) The evidence suggests that Q is a minimum at about 70 kilometres (40 miles) depth, a point that bears on strength in the upper part of the mantle.

Damping of Eulerian nutation. The Eulerian nutation, an oscillation of the Earth's axis now known to have a period of about 14 months, appears to be damped with an amplitude reduction factor of 1/e in about 15 years (see EARTH, FIGURE OF). There are problems in assessing the damping accurately and determining its mechanism. It is likely but not certain that the damping is associated with energy dissipation inside the Earth's mantle. The observations have been used to supply evidence on anelasticity in respect of stress periods of the order of some years.

Region of energy damping

Suggested laws of imperfect elasticity. The model relations (1) are equivalent to a pair of relations expressing that (a) the pressure is equal to minus the product of incompressibility (k) and dilation (θ),

$$p = -k\theta; \tag{7}$$

and (b) the deviatoric stresses (P_{ij}) are equal to twice the product of the rigidity (μ) and the deviatoric strains (E_{ij}, defined analogously to the P_{ij}),

$$P_{ij} = 2\mu E_{ij} \tag{8}$$

In general, anelasticity is significantly observed only under deviatoric stress, so that only the relations (8), which for convenience will be abbreviated to $P = 2\mu E$, have to be modified.

Simple modifications are obtained by adding to both sides of the equation $P = 2\mu E$ terms that involve the rate of change of stress (dP/dt) or strain (dE/dt). An example is the model set of relations

$$P + \tau dP/dt = 2\mu E + 2\nu dE/dt, \tag{9}$$

involving the parameters μ, τ, and ν. Particular cases of this model are the firmoviscous model for which the parameter τ equals zero, and the elasticoviscous model for which μ is set equal to zero in (9). Between them, these models exhibit in a general way such properties as sudden change of strain (as in perfect elasticity) following sudden change of stress, creep or plastic flow under sustained stress, and elastic afterworking after removal of stress, with a possible permanent set. The elasticoviscous

model gives approximately perfect elastic behaviour under rapidly changing stress, and viscous fluid behaviour under slowly changing stress. Analysis of the models shows that mechanical properties such as rigidity and viscosity are not in general determined by a single parameter but depend on combinations of parameters and markedly on the period of the applied stress. The above models are too simple to agree with observational evidence in fine detail, but they are useful in special limited geophysical contexts.

Models designed to suit wider geophysical contexts are more complicated. An example is the Jeffreys model, based on an earlier model of C. Lomnitz, which for constant deviatoric stresses (P) takes the form (involving the four parameters μ, q, a, and α):

$$2\mu E = P\{1 + (q/\alpha)\,[(1 + at)^{\alpha} - 1]\}. \qquad (10)$$

This model takes account of certain laboratory evidence and data on the damping of seismic waves and nutation. When α is equal to unity, equation (10) is equivalent to the elasticoviscous model. But Jeffreys requires α to be near 0.2, a difference that has far-reaching effects. After testing this model against certain evidence on the mechanical properties of the Moon, Jeffreys concluded that it is also applicable on the geological time scale.

Completely different approaches involving more complicated theory have been made from considerations at the microscopic level, through solid-state and lattice theory and related experimental evidence. A difficult problem in these approaches is to ascertain the parameters that are likely to be important in the macroscopic Earth context. Notwithstanding considerable progress, there is as yet no comprehensive, widely accepted quantitative representation of the Earth's anelasticity.

Attempts have been made to assess viscosity in the Earth's mantle using such evidence as the Fennoscandian uplift (if attributed to deglaciation) and the excess of the Earth's ellipticity as revealed through analyses of satellite orbits over the value calculated on the hydrostatic theory. The assessments are of the order of 10^{21} poise (a unit of viscosity, dyne-second per square centimetre) and upward (the viscosity of castor oil is 10 poise and glass 10^{13} poise).

In interpreting these results, it should be noted that the reference to viscosity in the Earth context assumes rather over-simple stress–strain relations.

RESPONSE OF THE EARTH TO STRESSES OF LONG DURATION

The presence of anelasticity in the Earth affects possible large-scale movements in two ways. First, it permits the possible flow of materials that behave as ordinary solids under stresses of limited duration. Second, it causes mechanical energy to be dissipated. For large-scale flow to be maintained, this dissipation has to be overcome by sufficiently large independent sources of energy release. Also, the forces arising from the energy release have to be appropriately directed.

Sources of energy. The possible sources of energy are dynamical, thermodynamical, gravitational, and chemical, including energy latent in particular phases of materials. Of these, the thermodynamical and gravitational are the primary sources of any positive supply of energy that can be expected to be maintained over geological time. The available gravitational energy includes energy connected with lateral variations of density in the upper mantle and possible small departures from monotonic variation with depth of the "uncompressed" density (*i.e.*, the density when reduced to zero pressure). The thermodynamical energy includes energy changes that may be associated with cooling inside the Earth (resulting also in further gravitational energy being made available) and energy from heat sources (radioactivity; see EARTH, HEAT FLOW IN).

If sufficiently detailed evidence on the sources of energy and on anelasticity were available, mechanical principles could be applied to infer large-scale past movements inside and on the Earth. As yet, the usual procedure is the other way around—to set up hypotheses of past movements on independent grounds (in which much of the evidence is of a nonmechanical type) and then test against the mechanical evidence.

Mountain building and continental drift. The most evident large-scale Earth movement is the intermittent elevation of mountains (see MOUNTAIN-BUILDING PROCESSES). The long-standing theory of mountain building assumes thermal contraction in the outermost 700 kilometres (400 miles) of the Earth as the primary source of energy, though another theory assumes thermal expansion arising from internal heat sources. The formation of a major mountain system involves horizontal displacements of the order of 50 kilometres (30 miles).

The 1960s and 1970s brought a revival of interest in the hypothesis of continental drift, another type of assumed large-scale movement that had (on grounds mainly somewhat different from the present) been strongly advocated by the German meteorologist Alfred Wegener in 1912–27. The evidence for drift, which is diverse (see CONTINENTAL DRIFT), takes account of observations of paleomagnetism, details on the spreading of ocean floors in the vicinity of midocean ridges, as well as older geological and paleontological evidence on the edges of continents supposed to have been once in contact. Many geophysicists conclude that there is now strong evidence that continents have steadily drifted apart since the beginning of the Mesozoic Era, about 200,000,000 years ago, without serious distortion of the coastlines originally in contact. Followers of this view associate many phenomena with continental drift; for example, mountain building, the asymmetric distribution of earthquake sources, earthquake focal mechanisms, the present distributions of island arcs, and ocean deeps.

Apart from some controversies about some of the evidence used in its support, the hypothesis of drift faces difficulties on the question of mechanism. The only proposed mechanism that has not been quickly ruled out envisages the continents as being carried like rigid plates on top of convection currents assumed to exist some distance below the crust. The comparatively small value of the attenuation parameter Q used in assessing energy dissipation, the probable reduction in the seismic S velocity, the probably high temperature gradient, and the probably abnormally low density gradient inside the outermost 100–200 kilometres (50–100 miles) of the mantle are brought to bear as evidence for convection.

No satisfactory mechanism of convection that meets all the quantitative requirements has yet been found, however, and most attempts to do this have been grossly simplified. Arguing on the basis of the model equation (10), Jeffreys has asserted in fact that convection currents cannot occur on the scale envisaged. They could occur if the parameter α could be taken as equal to unity (corresponding to the elasticoviscous model) or greater, but Jeffreys regards as crucial his assessment that the constant α is much less than unity. Until the question of mechanism is solved to general satisfaction, it appears premature, in spite of current enthusiasms, to regard continental drift as established. In the meantime, work on the question is proceeding apace.

BIBLIOGRAPHY. Due to the intricacies of the subject, there are few nontechnical books that can be recommended. The following, though not all nontechnical, contain much matter that can be understood by the lay reader: HAROLD JEFFREYS, *Earthquakes and Mountains*, 2nd ed. (1950); SCIENTIFIC AMERICAN, *The Planet Earth* (1957); BENJAMIN F. HOWELL, JR., *Introduction to Geophysics* (1959); DAVID R. BATES (ed.), *The Planet Earth*, 2nd ed. rev. (1964); THOMAS F. GASKELL (ed.), *The Earth's Mantle* (1967); and HITOSHI TAKEUCHI, *Debate About the Earth* (1967). More advanced books are: WALTER H. MUNK and G.J.F. MACDONALD, *The Rotation of the Earth* (1960); K.E. BULLEN, *An Introduction to the Theory of Seismology*, 3rd ed. (1963); HITOSHI TAKEUCHI, *Theory of the Earth's Interior* (1966); S.K. RUNCORN (ed.), *International Dictionary of Geophysics*, 2 vol. (1967), and *The Application of Modern Physics to the Earth and Planetary Interiors* (1969); MICHELE CAPUTO, *The Gravity Field of the Earth* (1967); WILLIAM M. KAULA, *An Introduction to Planetary Physics* (1968); FRANK D. STACEY, *Physics of the Earth* (1969); and SIR HAROLD JEFFREYS, *The Earth*, 5th ed. (1970); J. TUZO WILSON (ed.) *Continents Adrift* (1973).

Earth, Physiography of

The term physiography has evolved through several different meanings. Today it generally signifies the description and genetic interpretation of the relief features of the Earth's surface. Sometimes it is offered as a synonym of geomorphology, but the latter stresses the dynamic, climatic, and structural aspects of landforms, whereas physiography is reserved mainly for the descriptive treatment of the Earth's surface features.

In an areal treatment of the Earth's surface features, a scale of magnitudes (size of features in terms of factors of ten) can be discerned. Several classification schemes have been developed and they can be combined and modified as follows:

Orders of magnitude of Earth features

First order features. The primary form of the globe, namely an idealized spheroid, is characterized by a shortening in the polar axis (7,899 miles, or 12,713 kilometres) and by an equatorial bulge (maximum diameter 7,927 miles or 12,756 kilometres). Satellite data have demonstrated a minor component of triaxial, "pear-shaped" symmetry indicating that the Northern Hemisphere is about 50 feet (15 metres) higher at the pole than predicted, and about 25 feet (8 metres) lower in the middle latitudes. In the Southern Hemisphere the polar area is 50 feet (15 metres) lower than predicted and the mid-latitudes are 25 feet (8 metres) higher. The Earth's surface area is subdivided geometrically into 360 degrees of longitude and 360 degrees of latitude; a degree of latitude is 362,780.4 feet (110,575.4 metres) at the Equator and about 1 percent more at the pole. The polar circumference is 24,860 miles (40,007 kilometres), whereas the equatorial circumference is 25,326 miles (40,757 kilometres).

Second order features. The Earth's surface is subdivided into continental masses (mean elevation: 2,755 feet or 840 metres; area: 148,100,000 square kilometres) and oceanic depressions (mean elevation: −12,500 feet or −3,810 metres; area: 361,900,000 square kilometres). Seven continents are recognized: Europe, Asia, Africa, Australia, North America, South America, and Antarctica. Four oceans are recognized here: Arctic, Atlantic, Pacific, and Indian oceans. (Some classifications group the Arctic with the Atlantic, and others distinguish a Southern or Antarctic Ocean.) The areal order of magnitude of the average ocean is 10,000,000 square kilometres (13,861,000 square miles).

Third order features. The continents and oceanic depressions are further divided into positive topographic (relief) features; namely, mountain systems on the land and rises or ridges undersea. Maximum elevation on land is 8,848 metres (29,028 feet; Mt. Everest), and maximum depression of the sea floor is 11,033 metres (36,198 feet; Mariana Trench). The principal youthful mountain systems of the world are (discontinuously) in two belts, the Circum-Pacific, and the Alpide or Mediterranean-Himalayan systems. All other mountains are more subdued and dismembered or are isolated relics of ancient and deeply eroded systems. The principal oceanic topographic highs are the system of mid-ocean ridges. This forms a spine that bisects the Arctic, Atlantic, and Indian Oceans, extends around the Antarctic region, and passes through the eastern Pacific, where it dies out in the Gulf of California. This is the largest single topographic feature in the world and is approximately 40,000 miles (64,000 kilometres) long. Negative relief features of the same magnitude are lacking elsewhere on the Earth, because it is broken up into large numbers of plains, depressions, and basins. The areal order of magnitude of the major structural units is 1,000,000 square kilometres (380,000 square miles).

Fourth order features. The secondary mountain systems, mountain chains, volcanic provinces, and plateaus, alternating with plains and basins, are features of the 4th order. With a slightly different nomenclature, similar divisions exist in the ocean. The areal order of magnitude is 100,000 square kilometres (38,000 square miles).

Fifth order features. A "tract" of land distinguished by a single rock type, a single volcano, a major ridge or escarpment, or a major valley is a 5th order feature. The areal order of magnitude is 1,000 to 100 square kilometres (380 to 38 square miles).

Sixth order features. A "site," hill, gorge, cave, cliff, or beach is at this level. The areal order of magnitude is 10 square kilometres to 10 square metres (3.8 square miles to 100 square feet).

Seventh order features. A large boulder to a grain of sand are at this level. The areal order of magnitude is 1 square meter to 1 square millimetre (10 square feet to 0.001 square inch). Smaller particles, such as a speck of dust, and those down to the level of molecules, atoms, and electrons, do not concern the topic of physiography.

This article treats the general physiography of the Earth, provides more specific coverage of the configurations of the several continents and oceanic depressions, and indicates some of the factors that govern the observed configurations. For further detail on continental features, see MOUNTAIN RANGES AND MOUNTAIN BELTS; PLATEAUS AND BASINS; VOLCANOES; HILLSLOPES; DESERTS; and JUNGLES AND RAIN FORESTS. Oceanic features are treated in CONTINENTAL SHELF AND SLOPE; ISLAND ARCS; and OCEAN BASINS. See also EARTH, FIGURE OF; and EARTH, GEOLOGICAL HISTORY OF for discussions of relevant geodetic and geological concepts. See further LANDFORM EVOLUTION for treatment of the change in Earth features through time.

HYPSOGRAPHY OF THE EARTH'S SURFACE

As noted under the second order features, there is a clear distinction between continents and oceans in terms of mean elevation, and furthermore a cumulative height frequency curve shows two distinct (bimodal) peaks, one between mean sea level and +1000 metres (3,000 feet), which intersects the coastal plain and continental shelf surface, and the other between −4000 and −5000 metres (−13,000 and −16,400 feet), the mean level of the deep sea floor. The former occupies more than 21 percent of the Earth's surface and the latter 22 percent of the surface. Although 5.5 percent of the Earth (and 7.5 percent of the ocean area) is represented by continental

shelf (0 to −200 metres [0 to −660 feet]), the depth range −200 to −1000 metres (−660 to −3,000 feet) only corresponds to 2.9 percent of the Earth, emphasizing the steepness of the continental slope.

Distribution of land and sea. Oceans cover 70 percent of the globe. Clearly, the continents and oceans of the world are not evenly distributed (Table 1). They are roughly antipodal, displaying a certain regularity. The Northern Hemisphere has the larger proportion of land (30 percent; in round figures 100,000,000 square kilometres [38,000,000 square miles]); and the Southern Hemisphere the smaller (19 percent; approximately 48,600,000 square kilometres [18,700,000 square miles]). Yet the Antarctic continent coincides symmetrically with the south polar region, in contrast to the north polar area, which corresponds to the Arctic Ocean. This curious symmetry prompted the tetrahedral theory proposed in 1875 by Lowthian Green, which depicted the four oceans as lying on the four faces of a tetrahedron. There would be three nodes in the Northern Hemisphere, 120° apart, along latitude 20° N (in The Sudan, Yucatan, and south of Japan, respectively) and a fourth at the South Pole. It was argued that the tetrahedron is the geometric figure with the maximum surface area for a given volume, in contrast to the sphere, which has a minimum area for a given volume. If the Earth had, on cooling, contracted from a perfect sphere it would tend toward the tetrahedral slope. Although no available data support this theory (and both the contraction and cooling theories have been rejected by numbers of authorities), the symmetry remains unexplained.

The tetrahedral theory of land-sea distribution

A second feature of importance concerns the shape of continents or major structural units. Several continents tend toward a triangular form—broad to the north and pointed to the south: North America, South America, Africa, the Indian subcontinent, and smaller structural blocks such as the Sinai Peninsula. In general the great fracture patterns (lineaments) tend to follow NW to SE and NE to SW patterns, except in the Pacific where they tend to be E to W. Several theories, in terms of a geological history of crustal shearing, have been proposed to explain the situation. In 1891 Wilhelm Prinz, a Belgian astronomer, in his torsion theory, compared the intersecting lineaments with the Martian "canals" and suggested that the southern continents had drifted farther eastward than the northern ones, thus anticipating in a remarkable way the theory of continental drift (*q.v.*). His delineation of the E–W belt of maximum mountain-building has now been identified with the equatorial zone of 100,000,000 years ago (displaced now due to polar wandering).

Lineaments and the torsion theory

Other theories to explain the shapes of continents and the major lineaments involve polar migration and various related phenomena.

Symmetry. There is an elegant symmetry to be seen in certain terrestrial features. The parallel shapes of the west coast of Africa and the east coast of South America were first observed by Roger Bacon. The form of the Atlantic Ocean, particularly now that the existence of the Mid-Atlantic Ridge is known, is quite remarkable, although the Antillean (Caribbean) Arc and the analogous Scotia Arc represent paired asymmetric re-entrants in the oceanic depression. The Indian Ocean floor shows a totally different pattern; its mid-ocean ridge is roughly central, but it splits in the south into a Y-shape, and in the northwest it diverges into the Aden–Red Sea Rift System. The major fracture systems of the Atlantic are E to W, but those of the Indian Ocean are N to S. The Pacific in contrast is much less symmetric, although there is a certain parallelism between the Samoa Angle and the Panama Angle and a bisymmetry to the NW and SE. The mid-ocean ridge, however, is displaced completely to the east.

On a smaller scale there is an elegant symmetry displayed by the sides of the Red Sea and the matching escarpments and highlands of the Eastern Desert of Egypt and The Sudan, and those of the Hejaz and Yemen. This type of symmetry is to be seen throughout the rift valley

Table 2: Areas in Elevation Steps; Totals, Volumes and Mean Altitudes

system of Africa and elsewhere in the world where a simple fracturing with central collapse seems to have taken place; *e.g.*, the Rhine Graben of Germany.

Average elevation of continents. If the mean elevation of each continent is plotted on a height-area curve, all of the points for the continents fall on a uniform curve except Antarctica, which is more than four times higher than expected (Table 2). Clearly this departure is related to the accumulation of its ice sheet, which today covers about 23,500,000 square kilometres (9,100,000 square miles). The uniform relations of the non-glacier-covered continents would seem to be related to the nature of fluvial gradation (erosion by running water), but the phenomenon does not appear to have been subjected to critical analysis. The mean hypsometric gradient (altitude–area relation) for Antarctica is closely matched in shape by Greenland, even though its ice area is only 2,500,000 square kilometres (960,000 square miles), about 9 percent that of the Antarctic mass.

Isostasy and land elevation

The elevation of the continents is in part a function of isostasy (natural buoyancy), which requires the Earth's crust to be thicker in areas of relatively less dense rocks, and vice versa, thus insuring that the Earth's crust in general is in hydrostatic equilibrium. If the entire crust were of the same composition, the elevation would correspond to an ideal spheroid, but during the course of geologic history the continents have been segregated as masses of lighter specific gravity (average about 2.7), whereas the crust of the ocean floors consists of denser materials (average about 3.3). The continental crust is characterized by rock of approximately granitic or granodioritic composition (silica-alumina rich, termed sial) and the oceanic crust is marked by basalt or peridotite rocks (silica-magnesia rich, termed sima). According to the concept of isostasy, the sial must float higher than the sima, and according to the hypsographic curve, the actual difference in mean level is about 4,000 metres (13,000 feet). The reason that mountains stand higher than the rest of the continent is because in their formation they develop deep roots of light (granitic) crustal material that enables them to float even higher than the average continental elevation.

Most of the Earth's crust is approximately in hydrostatic equilibrium in this way, so that when erosion occurs and rivers transport large quantities of weathered material away from the upland areas to be deposited in the oceans, there is a tendency for the hinterland to rise isostatically, and for the adjacent ocean floor to sink. Uplifted terraces that represent old river valleys or coastlines testify to the uplift, and deep oil drilling on the continental shelf demonstrates that it has become progressively downwarped through time. The rates of uplift and downwarping vary according to relative relief but average 0.1 to 1.0 millimetre (0.004 to 0.04 inch) per year.

Plainlands and shield areas

Very ancient plainlands, as in the interiors of North America, Central Asia, Africa, Brazil, and Australia (the ancient geological "shields"), have reached an approximate equilibrium; they have very little relative relief, tend to be stable, and suffer a minimum of erosion. Even in the ancient shields, however, the equilibrium is easily upset by an event such as an ice age. The load of ice depresses the crust in a ratio of about 1:3 (the respective specific gravities of ice and rock) and after glaciation has passed, the ice melts and the crust tends to return to its former position. This is never completely achieved because the glaciation leaves behind loads of boulders and other debris, which retard the isostatic readjustment. There may also be permanent modification to the subcrustal mass distribution. In any case, the major continents are marked by numbers of broad, dish-shaped depressions, many of which appear to be the sites of former glacial depressions. Hudson Bay and the Baltic Sea fit this model; in Africa, the Taoudenni, Chad, Congo, and Kalahari depressions seem to represent the sites of Paleozoic (570,000,000 to 225,000,000 years ago) ice ages.

Coastlines. Not counting islands, the continental coastlines of the world measure approximately 312,000 kilometres (193,000 miles; see Table 3). Many aspects of the physiography are directly related to the proximity of the ocean (Table 4). These include climate (oceanicity versus continentality), stream profiles, cyclic salt transport (and thus lake and soil salinity), and other phenomena.

Table 3: Coastlines of Continents*

continent	area (000,000 km²)	coastal length (km)
Europe	9.32	37,200
Asia	41.48	70,600
Eurasia	50.70	107,800
Africa	29.20	30,500

From the point of view of geological structure, the coastal plains of the world are in continuity with the continental shelves. The widest coastal plains usually match the widest shelves. The present mean sea level approximates a medial line between the respective inner and outer limits of the two. This appears to be in part a function of isostasy, which tends to raise the interior as it is eroded and depress the shelf as it is loaded by sediment. Both features are, however, additionally modified by the glacio-eustatic rise and fall of world sea level that has marked the advance and retreat of glaciers during the last 2,000,000 years, the Quaternary Period, marked by the Great Ice Age. The Ice Age was not a single event but was marked by repeated advances and retreats and in fact is not yet over; the next glacial advance is predicted within a few thousand years (see CLIMATIC CHANGE). The areas of the continental shelves (as shown by Table 5) and of the coastal plains vary remarkably from continent to continent. In Africa, for example, the coastal plains (below 200 metres [660 feet]) represent about 10 percent of the total area, the shelves only 4 percent. For Europe, in contrast, the coastal plains represent over 55 percent and the shelves nearly 30 percent. This relationship is attributed to geologic history. In the case of Africa, the bulk of the coastline is a zone of fractures that originated at the time when continental drift split the former "megacontinent" of Gondwanaland apart, separating Africa from South America, Antarctica, India, and Australia; the last critical fracturing occurred about 100,000,000 years ago. Europe, too, was affected by drifting when it split off from North America, but this was more than 200,000,000 years ago and affected only the Atlantic courses. The other coasts of Europe are marked either by the drowning of broad shelf areas, notably to the north, or by mountain-building (orogenic) processes, along the Mediterranean borders with only minor segments of drift-fractured coasts.

Coastal classification and continental drift

A very broad classification of the world's coastlines, therefore, names the orogenic coasts the "Pacific type," and the fractured coasts the "Atlantic type." These designations are only just labels, of course, for examples of each type are found in all parts of the world. Nevertheless, the general pattern applies as follows:

1. Pacific Type—Circum-Pacific coasts: western borders of the Americas, Aleutians, Japan, Philippines, New

Table 4: Continentality—Distances from Oceans

continent	distance from coast (km)		regions near ocean (percent)	regions far from ocean (percent)
	average	maximum		
Europe	340	1,550	62	38
Asia	780	2,400	61	39
Africa	670	1,800	53	47
Australia	350	920	55	45
North America	470	1,650	58	42
South America	550	1,600	56	44

Guinea, New Zealand; Indonesian Arc; Crete and other Mediterranean shores; Caribbean Arc and Scotia Arc.

2. Atlantic Type—coasts of Atlantic (except as stated above), northwestern Mediterranean, most of Indian Ocean borders, Tasman Sea coast of Australia, and certain other western Pacific marginal seas.

This physiographic classification, as indicated above, has its roots in geologic structure and history. Throughout the Paleozoic Era (570,000,000 to 225,000,000 years ago), what is now the South Pole, the "Gondwana Pole," lay over Africa, and what is now the North Pole lay in the mid-Pacific. Polar migration accompanied by continental drifting has split "megacontinents" in the Northern and Southern hemispheres, leaving them with Atlantic type coasts. The continents spread much farther apart in the Southern Hemisphere than in the Northern Hemisphere. At the same time, an ancient Mediterranean Sea (Tethys) was crushed along the latitudinal Alpide (Alpine) Belt, and an E–W belt of mountains was produced.

PHYSIOGRAPHY OF THE CONTINENTS

Europe. The principal orographic and regional feature of Europe is the Alpine System, which embraces not only the Alps of France, Switzerland, Austria, and Italy, but also the structurally related or continuous ranges that include the Pyrenees and Betic belts of Spain, the Apennines of Italy (and Sicily), the Carpathians, Dinarides, Rhodope, and Hellenide chains of eastern Europe.

The stable Precambrian (older than 570,000,000 years) shield region of Europe is exposed in the Fennoscandian sector (Norway, Sweden, Finland, and northwestern U.S.S.R.), and the same stable block forms the deeper foundations of the Russian Platform, only outcropping locally in the southwestern Ukraine.

Older Paleozoic belts of folded rocks, the Caledonides, are today topographically much reduced. They form the western border of the Fennoscandian Shield and extend to Scotland and northern Ireland. Younger Paleozoic foldbelts, the Hercynides, are found preserved in isolated areas of western Britain and Ireland, the Spanish Meseta, Corsica and Sardinia, the French Massif Central, Brittany, the Ardennes, central Germany, and Bohemia. Distributed between, or overlapping, these numerous structural blocks, there are basins and flatlands in great number, for the most part still accumulating sediment today; examples include the London Basin, Paris Basin, North German Plain, the Hungarian (Pannonian) Plain, and the Po Plain.

European glaciation and present appearances

A key factor in determining the landscape has been the Quaternary history of multiple glaciations, which scoured and grooved the surface of the northern highland areas from Scandinavia to the British Isles, as well as the younger mountain belts of the Alps, Pyrenees, and Carpathians. The northern lowlands are thus widely characterized by moraine landscapes and broad sandy outwash plains. Particularly in the eastern parts of Europe and Asia, widespread plains were coated in loess, a wind-blown dust derived from the glacial meltwater regions, giving them a characteristically rounded, gentle topography.

Large numbers of lakes dot the former glaciated regions. Outside of the latter, there is only one large lake in Europe, Lake Balaton (230 square miles [590 square kilometres]), situated in the Hungarian Plain. The major rivers are the Danube, the Rhine, the Vistula, and the Volga. Extensive marshes also occur in the glaciated lowlands, notably the Pripet Marshes and others in Russia and Finland.

Asia. The world's largest continent, Asia, is geologically and geographically closely tied to Europe and the two are often treated as Eurasia. The great Alpine System of youthful mountains continues eastward through Anatolia in a series of double arcs, splitting well apart in Iran to form the Elburz in the north and the Zagros in the south. The ranges reunite in Afghanistan and northern Pakistan in the Hindu Kush and Pamirs, passing around a hairpin bend to form the Himalayan arc on the south and into the Karakorum and Kuen Lun chains to the north. Rejoining in Yunnan, these chains continue south through Burma, and then in a more interrupted manner through the island arcs of the Sunda and Banda islands (Indonesia), where they are joined by the Circum-Pacific belts. Throughout this mighty mountain system, the most important on the globe, there is a systematic pattern of divergence and convergence, surrounding nuclei of interior high plains or plateaus: Anatolia, Iran, Tibet, Indochina. The entire eastern border of Asia from the Verkhoyansk ranges of Yakutia to Chukotski Peninsula (with connections to Alaska) also consists of youthful mountain belts, but of the Circum-Pacific System. They extend southward as island arcs through Kamchatka to the Kurile Islands and Sakhalin, to Japan, Taiwan, the Philippines, Borneo, the Celebes (Sulawesi), and Halmahera, where they join the Australasian belts of New Guinea and New Zealand.

The old crystalline shields of Asia are multiple—the most important is the Angara Shield of Siberia (with its Anabar nucleus), largely overlapped by subhorizontal younger formations, leading to extensive plateau landscapes. In the Soviet east, there is the Kolyma Block; in southeastern China, the Sinian Block; and south of the Alpide zone, the "subcontinental" shields of peninsular India and Arabia.

Interior basins and their drainage

Fold belts of ages comparable to the Caledonian and Hercynian belts of Europe extend from the Urals to the Altai and others in Central Asia, continuing through China to the Pacific coast and into Korea. Between all these ranges are numerous large interior basins. Between the Urals and the Angara Shield lie the West Siberian Lowlands and to the south the plains of Kazakhstan, and the Kara-Kum depression of Turkmenia and Uzbekistan. In Sinkiang there are the Tarim and Dzungaria basins. In Mongolia there is the Gobi depression. Smaller depressions in China include the Szechwan Basin and the Yellow Sea lowlands. South of the Alpide belt, the Indian Shield is separated from the mountains by the Indo-Gangetic depression and in a similar way the Zagros are separated from the Arabian Shield by the Mesopotamian-Persian Gulf depression.

Asia possesses many areas of interior drainage and inland seas and lakes: the Caspian Sea, Aral Sea, Lake Balkhash, and Lake Baikal (the world's deepest lake, containing more water than all of the North American Great Lakes together). In Iran, Tibet, Sinkiang, and northwestern China, there are innumerable ephemeral, saline lakes; an example is Lop Nor, the borders of which are variable and bear traces of more extensive lake floors indicating formerly moister climates. Unique among the salt lakes is the Dead Sea, the surface of which is −392 metres (−1280 feet).

Extensive deserts occur in Arabia, notably the Rub'al-Khali, in northwestern India (Thar Desert), and in Mongolia (Gobi). The great rivers of Asia are the Ob, Yenisey, and Lena flowing to the Arctic Sea; the Amur, Huang Ho, Yangtze, and Mekong flowing to the Pacific; the Ganges, Brahmaputra, Indus, Tigris, and Euphrates, which flow to the Indian Ocean; and some small streams, such as the Orontes and Meander (Büyür Menderes Nehri), flowing into the Mediterranean and thence into the Atlantic. All four oceans are thus fed by the rivers of Asia.

Africa. Youthful fold mountains in Africa are limited to parts of the Atlas, a continuation of the Betic-Sicilian

sector of the Alpide System. Most of the continent consists of an immense Precambrian crystalline shield, subdivided into broad basins: Taoudenni, Chad, Congo, Upper Nile, Kalahari, and Karroo depressions. The shield is impressively split along its entire eastern margin, by rifts from the Red Sea, Aden, Ethiopia, and East Africa southward to Natal. Only in the Cape Ranges (Capides) are there some Paleozoic mountains, now greatly reduced in relief.

African deserts and jungles

Africa is marked on the one hand by its great deserts, the Sahara in the north, passing into the Libyan and Arabian deserts, and the Kalahari in the south; and on the other hand by its great tropical forests and jungles, notably in West Africa and the Congo. High savanna-covered plateaus extend over most of the subtropical latitudes as well as the high, terraced landscapes of East Africa. During the last ice age much of Africa was reduced to a desert, and traces of old sand dunes, now tree-covered, are widely traceable, even crossing over the Congo both from the south and from the north. Great rains then set in, reaching a peak around 12,000 years ago, leading to torrential floods along the Nile and the growth of lakes to enormous size. The ancestral Lake Chad, for example, was at least ten times larger than today. High terraces reflect former stronger precipitation feeding the East African lakes: lakes Victoria, Rudolf, Tanganyika, and Nyasa (Malawi). The great rivers of Africa, the Nile, Senegal, Niger, Congo, Zambezi, Limpopo and Orange, nearly dried up during the glacial maximum, and some became lost in swamplands, for example, in the Sudd (Nile), in the middle Niger and in the Okavango Swamps of the Kalahari depression.

Australia. Youthful mountain belts are absent from the Australian continent but run through the great Australasian subcontinental islands: New Guinea–New Caledonia–New Zealand, where Mt. Cook reaches 12,349 feet (3,764 metres) elevation. The high mountains of central New Guinea were crowned by a small ice cap during the last glaciation and New Zealand was extensively glaciated.

The (West) Australian Shield occupies two-thirds of the continent and is marked by broad savannas or sandy deserts (Simpson and Victoria deserts). Like Africa, traces of former sand ridges cover much of the northern part of the country, though now they are largely tree covered. Innumerable ephemeral salt lakes dot the interior, marking former river systems now dried out and truncated by drifting sand. Most important is the Lake Eyre Basin, which is below sea level, being fed by ephemeral rivers—Coopers Creek and the Diamantina.

A subdued Paleozoic mountain belt forms the Great Dividing Range and Australian Alps along the eastern margin of the country. Only a small area around Mt. Kosciusko (7,316 feet [2,230 metres]; the highest mountain in Australia) was glaciated, but in Tasmania to the south there was an extensive ice cap. Major rivers are the Murray and the Darling; in the tropical north there are the Fitzroy and the Catherine.

Canadian Shield, fold belts, and structural features

North America. The youthful mountains of North America belong to the Circum-Pacific system, extending through Alaska and British Columbia to form the Rocky Mountains and the Coast Ranges of the western United States, and the Sierra Madre Orientale and Occidentale of Mexico. In Guatemala, the fold belts swing eastward to form the discontinuous island arcs of the Caribbean—Jamaica, Cuba, Hispaniola, Puerto Rico, and the Leeward Islands.

The old crystalline nucleus of the continent is the Canadian Shield, which breaks up in the north to form the Canadian Arctic Archipelago and Greenland. Before continental drifting during the geologic past, Greenland fitted snugly against Labrador and Baffin Island.

Wrapped around the margin of the shield in the east there are the subdued mountains of the Paleozoic fold belts, the Appalachians, which in Newfoundland show evidence of having originally been connected to the Hercynian and Caledonian belts of Ireland. To the northwest of the Canadian Shield there is another old fold belt (the Franklin Geosyncline) extending through Banks and Ellesmere islands. A narrow belt of northeast Greenland extends this system and seems to have been originally separated by drifting from Spitsbergen, Norway, and Britain.

Marginal to the shield there are numerous large interior basins and plains, typical of the Prairie Provinces of Canada and the Midwest of the U.S. There are broad coastal plains only in the Atlantic states and on the Gulf Coast (which continue into Mexico). To the interior of the western fold belts there are interior plateaus and depressions structurally comparable with those of Iran and the Alpide Belt. Most important are the Great Salt Lake Basin of Utah, the Colorado Plateau, and the Basin and Range Province of Nevada and adjacent states that continue southeastward through Chihuahua to form the central plateau (altiplano) of Mexico. Extensive lava plains (of flood basalt) mark the landscape of the northwestern states, punctuated along its western border by youthful volcanoes in the Cascade Range. The volcanic belt is picked up again from southern Mexico to the Central American states.

Extensive glacial sheets covered much of North America (more than any other temperate continent) during the last ice age, leaving an immense number of closed drainage systems and major lakes. In the Rocky Mountains, numbers of pluvial (ice age) lakes formed (notably lakes Bonneville and Lahontan), just as in Africa, near the end of each glacial stage. Their sites are marked today by abandoned terraces. Major river systems in North America include the Mississippi (with its tributaries the Missouri, Illinois, Ohio, and others), St. Lawrence, MacKenzie, Athabasca, Churchill, Yukon, Fraser, Columbia, Snake, Colorado, Rio Grande, Hudson, and Susquehanna.

South America. The Circum-Pacific youthful mountain system extends, as the Andes, along the entire western border of South America, swinging easterly in Venezuela to join the Caribbean Arc in Trinidad, and again in the far south, in Tierra del Fuego, to join the Scotia Arc that takes in South Georgia, the South Shetlands, and South Orkneys to join the Antarctic Peninsula in Grahamland. Interior high plateaus, comparable to North America's, form the altiplano regions of Peru and Bolivia, marked in the same way by large lakes; *e.g.*, Lakes Titicaca and Poopo, that were once much more extensive.

Relation of South Americar and African features

The Precambrian shield region lies to the east and is almost continuous but customarily is divided into three parts: the Guianan Shield in the north, the Brazil Shield in the centre (and much the largest), and the Patagonian Shield in the far south. They are separated by transverse basins (respectively, those of the Amazon and the Rio de la Plata) that merge along the inner foot of the Andes with a continuous belt of piedmont depressions. Traces of the older, Paleozoic fold belts in South America are not as clear as on other continents, having been largely overwhelmed and incorporated in the younger Andean folds. A subdued branch in Argentina, however, swings eastward from near Córdoba to south of Buenos Aires, and it seems likely that this is a continuation of the South African Cape ranges in the pre-continental-drift history (earlier than about 200,000,000 years ago).

The great interior deserts of the other continents are largely absent from South America, although a well known arid coastal region is represented by the Atacama Desert of northern Chile and southern Peru. The great rivers all flow to the Atlantic—the Orinoco, Amazon, Paraná, and Paraguay (converging on the Rio de la Plata).

Antarctica. The Antarctic continent is largely ice covered because the Quaternary ice age continues unabated, but there are sufficient projecting mountains and nunataks (isolated peaks) to discern the general structure of the continent. The Circum-Pacific youthful fold belts continue through the Antarctic Peninsula into Marie Byrd Land (West Antarctica), but they were apparently separated by continental drifting from their original connection to New Zealand.

Three quarters of Antarctica consists of the ancient Pre-

cambrian shield terrain of East Antarctica, on which is situated the South Pole. Some 2 to 3 kilometres (up to about 10,000 feet) thickness of continental ice covers the basement (bedrock) here, which is isostatically depressed. When the ice eventually melts the continent will rebound somewhat from the removal of the load. Thus, though some parts of the basement floor are below sea level today, they would not remain an archipelago after deglaciation.

Between the East Antarctic Shield and the fold mountains of the western part there is a belt of depressions with scattered hills, extending from the Ross Sea to the Weddell Sea. This is largely a rift zone, as indicated by the presence of volcanoes (Mt. Erebus, 12,450 feet [3,795 metres]) near McMurdo Sound. The lower parts of the depression are covered by extensive ice shelves.

THE EARTH'S OCEANIC REGIONS

Although oceanic regions cover 70 percent of the Earth's surface, very little was known about the floor of the ocean until the "Challenger Expedition" of the last century brought back a series of wire soundings that showed there were depths in the ocean at least as great as the Himalayas are high. Only with modern echo sounding techniques have the sea floors become well known.

Mid-ocean ridge system, deep-sea trenches, and other submarine landforms

Principal oceanic features. Just as the continents are united by the continuity of the youthful Alpide and Circum-Pacific fold mountain belts, there is a united "suture" around the globe in the form of the Mid-Ocean Ridge: the site of a high seismic (earthquake) activity, high heat flow from the Earth's interior, and youthful injections of basaltic lava. Its central rift is the site of the splitting apart of the ocean floor that is now referred to as sea-floor spreading (*q.v.*) and is going on at a rate ranging from 1 to 5 centimetres (0.4 to 2 inches) per year. Numerous transverse fracture zones displace the ridge distances of 50 to 500 kilometres (30 to 300 miles).

Topographically the ridge is a broad swell, 1 to 3 kilometres (0.6 to 1 mile) in elevation, 2,000 to 4,000 kilometres (1,200 to 2,500 miles) wide, and 55,000 to 65,000 kilometres (34,000 to 40,000 miles) long. It extends from the termination of the Verkhoyansk Range in eastern Siberia, crosses the Arctic Ocean, bisects the Atlantic Ocean, turns east to bisect the Indian Ocean, one branch disappearing into the Aden–Red Sea rift and the other continuing south of Australia, to cross the southeastern Pacific, and disappears into the Gulf of California.

The structural margins of continents do not terminate at the coastline, but are continued in the continental shelves. They pass at the break in slope (usually between 100 and 200 metres [300 and 600 feet] depth) into the continental slope, with a declivity of 3 to 6°. Below about 1,500 metres (5,000 feet) this passes into the continental rise, with a much more gentle slope, about 1:1,000.

Between the rise and the mid-ocean ridge there are relatively flat or low hilly regions at depths of 3,000 to 5,000 metres (9,800 to 16,000 feet). The flat areas are the abyssal plains and the hummocky sectors are called the abyssal hills. Deep rifts, often parallel to island arc sectors, are called deep-sea trenches or troughs (the less extreme ones).

Most of the ocean floor falls into one of these three major categories: mid-ocean ridge, continental margins, and abyssal depressions. Apart from these, there are certain less regular features—continental borderlands, oceanic rises and aseismic ridges, oceanic plateaus, and seamounts (a flat-topped seamount is a guyot). Certain erosional features (submarine channels and canyons) also characterize the shelf, slope, and rise areas.

Summary of oceanic physiography. The principal features of each ocean are described below.

Arctic Ocean. The Mid-Ocean Ridge crosses the sector north of Spitsbergen to the New Siberian Islands, separating the Nansen Basin on the south from the Eurasia Deep, which underlies the North Pole. Parallel to these in the trend of longitudes 40° W and 140° E (a great circle) is the Lomonosov Ridge, separated in turn by the Makarov Deep from the Alpha Ridge. From here almost to the Alaskan side is the broad Canada Basin, with smaller embayments in the Hyperborean Basin and Beaufort Deep, separated respectively by the Chukchi Cap and the Beaufort Plateau.

Atlantic Ocean. Bisecting the ocean symmetrically is the Mid-Atlantic Ridge; its northernmost sector is called the Reykjanes Ridge. In the Northern Hemisphere, to the west lie (from N to S) the Labrador Basin, Newfoundland Basin, North American Basin (with the Puerto Rico Trench), and the Guiana Basin. In the east there are the West Europe Basin, Iberia Basin, Canaries Basin, Cape Verde Basin, Sierra Leone Basin (with Romanche Trench), and Guinea Basin. In the Southern Hemisphere, on the west lie the Brazil Basin and Argentine Basin, and on the east the Angola Basin, Cape Basin, and Agulhas Basin. In the Southern Ocean sector south of the ridge (here called Atlantic-Antarctic Basin), the Sandwich Trench is in the west, adjacent to the Scotia Arc.

Principal ridges and plateaus on the west side are the Greenland-Iceland Rise, Labrador Rise, SE Newfoundland Rise, the Bermuda Rise, the Blake Plateau, the Pará Rise, the Rio Grande Rise, and the Falkland Plateau. On the east side are the Iceland-Faeroe Ridge, the Biscay Rise, the Azores Rise, the Azores Plateau, the Canary Island Rise, the Cape Verde Plateau, the Sierra Leone Rise, the Liberia Rise, the Guinea Ridge, Walvis Ridge, and Cape Rise.

Marginal seas to the Atlantic include the Greenland, Norwegian, North, Baltic, Mediterranean, and Black seas in the north and east, with the Gulf of Mexico and Caribbean Sea on the west, and the Scotia Sea and Weddell Sea in the extreme south.

Indian Ocean. The Mid-Indian Ridge bisects the ocean in an inverted Y pattern, with a deflection to the northwest as the Carlsberg Ridge. To the West are the Somali Basin, Mascarene Basin, and Madagascar Basin, with the Madingly Rise, Mascarene Plateau, Madagascar Ridge and Agulhas Plateau. East of the Mid-Indian Ridge are the Oman Basin, Arabian Basin, Ceylon Basin, Java Trench, Bali Trough, Timor Trough, and the Wharton Deep, North Australia (Argo) Basin, Cuvier Basin and West Australia Basin, South Australia Basin, and Diamantina Trench. Positive features include the Chagos-Laccadive Plateau, the Ninetyeast Ridge, Cocos Rise, Christmas Rise, Karma Rise, Roo Rise, Exmouth Plateau, Wallaby Plateaus, Broken Ridge, and Naturaliste Plateau. South of the mid-ocean ridge are the Valdivia or Enderby (eastern Atlantic–Indian-Antarctic) Basin, Kerguelen Basin, and the Wilkes (Indian-Antarctic) Basin. High features include the Crozet Rise, Amsterdam-St. Paul Plateau, Kerguelen Plateau, Banzare Plateau, and Gribb Plateau.

Marginal seas to the Indian Ocean include the Red Sea, Gulf of Aden, Persian Gulf, Andaman Sea, Timor Sea, Arafura Sea, and Gulf of Carpentaria.

Pacific Ocean. The mid-ocean ridge in the Pacific embraces a number of sectors—the southern one is the Pacific-Antarctic Ridge, the centre sector merges with the East Pacific (Easter Island) Rise, and the northern one with the Albatross Plateau. The Main or Central Pacific Basin has not been subdivided for the most part but occupies a vast area of the North Pacific, extending westward to a zone of trenches that borders the "Andesite Line" island arcs, including the Aleutian Trench, Kuril Trench, Japan (and Bonin) Trench, Mariana Trench, and Yap Trench; from north of New Guinea and the Bismarck Archipelago, the British Solomon Islands to Tonga, there are no trenches and the border is poorly defined. Instead, there are a series of *en echelon* troughs (including the Vitiaz) within the margin of the Melanesian Borderland. South of about 20° S is the South-western Pacific Basin. Two small basins near the western limits are identified as the West Caroline Basin and East Caroline Basin.

To the east of the mid-ocean rise, from north to south, are the Middle America Trench (Acapulco Trench and Guatemala Trench), and off South America the Peru-Chile Trench, with several intermediate basins, the Guatemala Basin, South-eastern Pacific Basin, Bellingshausen (Pacific-Antarctic) Basin, and Balleny Basin.

Numerous ridges occur in the Pacific; in the east there are the Cocos Ridge, Carnegie (Colón-Ecuador) Ridge, San Felix-Juan Fernandez Ridge, and South Chile Ridge, Emperor Seamounts, Marcus-Necker Rise, Christmas Island Ridge, Marquesas Ridge, Tuamotu Ridge, Society Ridge, Austral Ridge, Tokelau Rise, Phoenix Rise, Samoa Ridge, Ellice Ridge, Marshall-Gilbert Rise, Caroline-Solomon Rise, Ontong-Java Rise, and Eauripik-New Guinea Rise, Magellan Seamounts. In the southwest are the Chatham Rise and New Zealand Plateau, the Macquarie-Balleny Ridge, South Tasmania Ridge, and Mill Rise.

Marginal seas to the Pacific include the Bering Sea (with the Aleutian Basin), Sea of Okhotsk, Sea of Japan, the East China Sea, Yellow Sea, South China Sea, Philippine Sea (with Nansei Shoto or Ryukyu Trench and Philippine or Mindanao Trench), the Sulu Sea, Celebes (Sulawesi) Sea, Flores Sea, Savu Sea, Banda Sea, Ceram Sea, and Molucca Sea. In the Southwest Pacific are the Bismarck Sea, Solomon Sea (with New Britain Trench and San Cristobal Trench), the Coral Sea (with Coral Sea Basin, Queensland Plateau, New Hebrides Basin and Trench), Tasman Sea (with Lord Howe Rise, Norfolk Ridge, Norfolk Trough, Three Kings Basin and North Cape Rise), and Fiji Sea (with Melanesian Border Plateau, Pandora Basin, South Fiji Basin, Fiji Plateau, Lau Ridge, and many smaller features).

BIBLIOGRAPHY. Books of a general nature on this subject include: R.W. FAIRBRIDGE (ed.), *Encyclopedia of Oceanography* (1966), containing many articles on the oceans, their basins, and the general physiography of the submerged portions of the Earth, *Encyclopedia of Geomorphology* (1968), presenting separate articles on the many types of landforms that occur on the Earth and thus comprise its physiography; and R.F. FLINT, *Glacial and Quaternary Geology* (1971), covering the final molding of the Earth's surface by glacial events and processes during the Pleistocene Epoch. Fundamental data on the topography of the Earth is given in the article "Die Erdoberfläche" (the Earth's surface) by E. KOSSINNA in B. GUTENBERG (ed.), *Handbuch der Geophysik*, vol. 2 (1933).

(R.W.F.)

Earth, Structure and Composition of

An understanding of the constitution and origin of the Earth is derived from a synthesis of knowledge from many fields, including the basic sciences of physics, chemistry, and mathematics and such derivative fields as geology, geophysics, geochemistry, astronomy, and cosmogony. Progress in the earth sciences requires the rigorous application of fundamental sciences combined with a broad approach that enables the relationships between results obtained from several fields to be recognized and integrated.

Until about 1950 the fundamental fields of solid earth science were seismology and geology. The principal internal provinces of the Earth had been characterized from the determination of the way in which the velocities of compressional (*P*) waves and shear (*S*) waves varied with depth (Figure 1); compressional waves are characterized by volume, and hence density, changes and by particle motion in the direction of travel of the wave; shear waves are distortional secondary or transverse waves. Through calculations based on the constraints of moment of inertia (the tendency of matter to remain at rest or in uniform motion in the same straight line unless acted upon by an external force) and mass (the property of a body that causes it to have weight in a gravitational field), a close approximation to the distribution of density (Figure 2), pressure, and elastic properties throughout the entire interior had been derived. Geologists had been concerned primarily with reconstructing the history and evolution of the crust, a task in which they had been extremely successful. Progress in understanding the chemical and mineralogical nature of the mantle and core had been less successful.

Advances in data resources

Because of advances in several fields, this situation changed drastically after 1950. Studies of the abundances of elements in the Sun, in meteorites, and in deep-seated terrestrial rocks, together with new concepts regarding

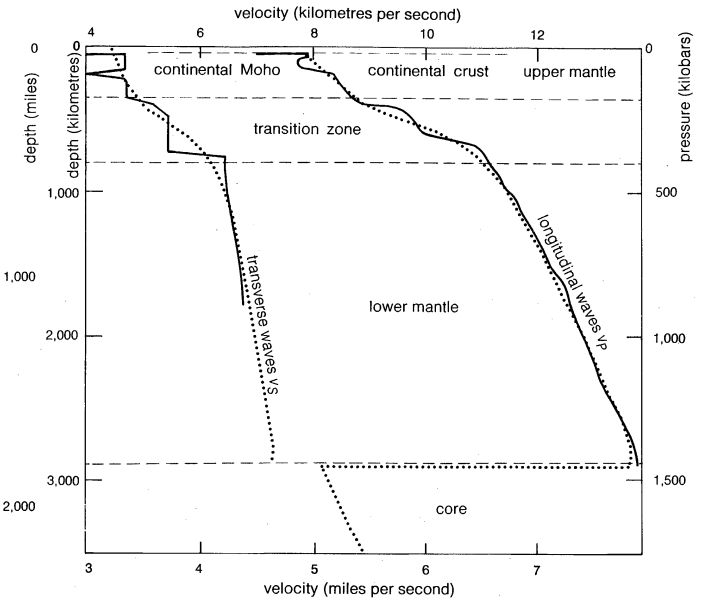

Figure 1: Seismic *P*- and *S*-wave-velocity distributions (v_P and v_S) and principal subdivisions of the Earth. Dotted lines show earlier data and full lines modern values. Subdivision of core occurs at 5,080 kilometres.

the origin of the Earth, placed important limitations upon the chemical composition of the Earth. Expanding geochemical research provided greater understanding of the distribution of elements within the Earth. Advances in knowledge of the elastic properties of silicates and oxides permitted the formulation of equations of state that were applicable to conditions in the Earth's deep interior and were employed to infer the occurrence of major phase transformations in the mantle. Development of experimental high-pressure–high-temperature techniques permitted the stability fields of mantle minerals to be studied at pressures corresponding to depths up to 600 kilometres (370 miles). Use of analogue systems provided information about the probable behaviour of silicates throughout the entire mantle. Developments in experimental petrology (study of the origin and natural history of rocks) made it possible to study under controlled conditions the physical chemistry of the processes within the Earth's interior that generate basaltic, andesitic, and other magmas (mobile rock materials from which igneous rocks form by solidification). Shock-wave methods resulted in the experimental determination of equations of states of silicates, oxides, and metals at pressures and temperatures up to those at the Earth's centre.

New developments in seismology, particularly the use of arrays of instruments and of nuclear explosives as sources of Earth vibrations, together with interpretation of surface-wave and free-oscillation data, resulted in greatly improved data on seismic-velocity distributions, including regional variations. That information, in turn, added further understanding of other important physical properties, such as density. Parallel advances were made in other branches of geophysics—*e.g.*, heat flow, gravity, electrical and magnetic properties, rheological properties (related to the flow of materials) and tectonophysics, which is concerned with forces responsible for movements and deformations in the Earth's crust. Manned exploration of the Moon and retrieval of lunar-surface samples, combined with space-probe studies of Mars and Venus, stimulated studies of the relationships between the Earth and other members of the solar system.

In the period between 1950 and 1970, agreement was reached on the answers to many long-standing fundamental questions regarding the Earth's internal constitution, and methods and techniques for the solution of other problems were developed. Development of theories of sea-floor spreading and plate tectonics (*i.e.*, study of broader structural features of the Earth) provided an integrated theory of the behaviour of the crust as recon-

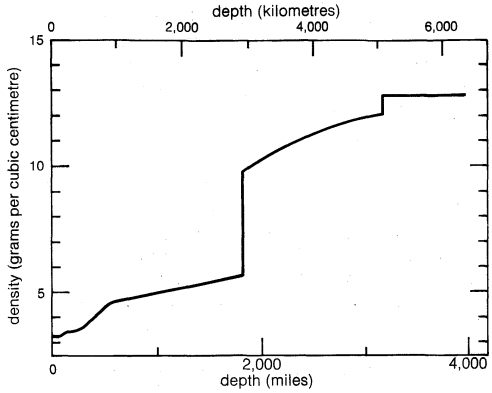

Figure 2: Density distribution within the Earth assuming that the upper mantle is composed of pyrolite.

Table 1: Dimensions and Properties of the Earth

Equatorial radius (a)	6,378.2 km
Polar radius (c)	6,356.2 km
Mean radius (r)	6,371 km
Volume V	1.083×10^{27} cm^3
Mass M	5.977×10^{27} gm
Mean density M/V	5.517 g/cm^3
Moments of inertia	
About polar axis (C)	8.043×10^{44} gm cm^2
Mean	8.025×10^{44} gm cm^2
Coefficient of moment of inertia $\left(\frac{C}{Ma^2}\right)$	0.3309
Equatorial gravity (g_e)	978.032 cm sec^{-2}
Ratio $\frac{\text{mass of Sun}}{\text{mass of Earth}}$	3.33×10^5
Ratio $\frac{\text{mass of Earth}}{\text{mass of Moon}}$	81.3
Mean distance from Sun	1.49×10^8 km
Mean distance from Moon	3.844×10^5 km
Mass of atmosphere	5.1×10^{21} gm
Mass of oceans	1.4×10^{24} gm
Mass of crust	2.4×10^{25} gm
Mass of mantle	4.1×10^{27} gm
Mass of core	1.9×10^{27} gm

structed by geologists, in terms of the dynamics of the mantle (see CONTINENTAL DRIFT; SEA-FLOOR SPREADING).

Three major regions of the Earth

Distribution of seismic velocities with depth divides the Earth into three principal regions: crust, mantle, and core (Figures 1 and 2). The crust is about 40 kilometres (25 miles) thick in continental regions and is highly heterogeneous, composed largely of rocks varying in composition between granite and basalt. Beneath the deep oceanic basins, the crust is about five kilometres (three miles) thick on the average and is believed to be predominantly of basaltic composition. The seismic *P*-wave velocities in the crust mostly vary from six to seven kilometres (about four miles) per second. Below the crust lies the mantle, which extends downward for 2,900 kilometres (1,800 miles). In most regions the crust is separated from the mantle by the Mohorovičić Discontinuity, or Moho, a narrow zone over which the seismic *P*-velocity increases suddenly to about 8.2 kilometres per second (5.1 miles per second). The mantle is solid—not liquid—and thus transmits both *P*- and *S*-waves. It is believed to be dominantly composed of magnesium silicates, with lesser amounts of iron, calcium, and aluminum, and is divided into a number of layers characterized by different types of mineral assemblages. At a depth of about 2,900 kilometres (1,800 miles), a major seismic discontinuity occurs. Below that level, *S*-waves are no longer transmitted, and *P*-wave velocity decreases from 13.7 to eight kilometres (8.5 to five miles) per second. The region below this discontinuity is known as the core and is believed to be predominantly composed of metallic iron in the molten state. At a depth of 5,080 kilometres (3,160 miles), a small increase of *P*-velocity occurs. This marks the boundary of the inner core that may be solid as the result of freezing of the iron under the high pressure existing (about 3,200,000 atmospheres).

This article treats the physical and chemical properties of the Earth's crust, mantle, and core, the structure of the Earth that is deduced from these properties, and the probable course of development of the Earth. For further information on the Earth's composition, see MINERALS; IGNEOUS ROCKS; METAMORPHIC ROCKS; SEDIMENTARY ROCKS; and ELEMENTS, GEOCHEMICAL DISTRIBUTION OF. For detail on the Earth's physical properties, see EARTH, MECHANICAL PROPERTIES OF; EARTH, MAGNETIC FIELD OF; EARTH, GRAVITATIONAL FIELD OF; EARTH, HEAT FLOW IN; and EARTHQUAKES. See also GEOCHEMICAL EQUILIBRIA AT HIGH TEMPERATURES AND PRESSURES; HIGH-PRESSURE PHENOMENA; and PHASE CHANGES AND EQUILIBRIA.

PHYSICAL PROPERTIES AND ZONAL STRUCTURE OF THE EARTH

Velocities of seismic P- and S-waves. Some important general physical properties of the Earth are given in Table 1. Variation of these properties within the Earth will be discussed in the following sections. The fundamental observational data required are the times of travel of seismic waves from sources (earthquakes, nuclear explosions) to seismometers spread over a wide range of distances. From these data, travel-time curves are constructed. In general, the farther the seismometer is from the source, the deeper the seismic rays penetrate into the Earth, carrying information about the integrated velocity variations along their paths. By analysis of the basic travel-time data, the variations with depth of *P* (compressional) and *S* (shear) waves are obtained (Figure 1). The fundamental seismic structure of the Earth was thereby explained before 1940, and the results provided the basis for subdivision of the Earth into crust, mantle, and core. In addition, the mantle was divided into three regions: upper mantle, transition zone, and lower mantle, each with a characteristic velocity–depth structure. Also, two distinct regions of the core were recognized.

Improvements in techniques of measurement

After World War II, a number of important advances were made, including the employment of improved long- and short-period seismometers and arrangements of seismometers, signal-filtering techniques, nuclear explosives as seismic sources (eliminating uncertainties in source location and times), and surface-wave-dispersion techniques, combined with data reduction by large electronic computers. Increased accuracy and separation of signals, including the use of second arrivals, resulted in important refinements of the existing velocity–depth curves. In particular, regional differences between velocity distributions beneath major geologic provinces were established; the widespread existence of a minimum in seismic velocities under oceans and active continental regions at depths of approximately 70–150 kilometres (40–90 miles) was confirmed; and the existence of at least two important seismic discontinuities in the mantle at depths of about 400 and 650 kilometres (250 and 400 miles) was established. Evidence of minor discontinuities and fine structure in the lower mantle and in narrow transition zones between core and mantle and between the outer and inner core was also obtained. The mean variation of *P*- and *S*-wave velocities with depth in the Earth and the principal internal subdivisions is shown in Figure 1.

Density distribution. In any region of the Earth that is chemically uniform, knowledge of the seismic *P* and *S* velocities immediately yields through what is called the Williamson–Adams equation the rate at which density varies with depth within the particular layer. In the 1930s it was demonstrated that, when this equation was applied in conjunction with the moment of inertia and mass of the Earth and with the density at the top of the mantle as estimated from other geologic-geophysical considerations, the density variation in most regions of the Earth could be defined within narrow bounds. Refinements have been proposed, based upon improvements in seismic-velocity distributions and determinations of the periods of the Earth's free oscillations; the most important modifications have been consideration of minimum average density between 70 and 150 kilometres (40 and 90 miles) and of the occurrence of rapid increases in density associated with the seismic discontinuities at 400 and 650 kilometres (250 and 400 miles). Whether the

mean density of the outer mantle is closer to 3.3 or 3.5 grams per cubic centimetre is not known, but the former value is probably the more nearly correct one. The density distribution within the Earth is shown in Figure 2.

Electrical conductivity. Magnetic storms caused by solar activity induce electric currents in the mantle. These currents in turn induce secondary magnetic fields at the Earth's surface. It has been demonstrated that the rate of decay of these secondary magnetic fields yields information on the electrical-conductivity distribution within the mantle. Most interpretations have had certain key features in common: an outer zone of relatively low conductivity extending to depths of a few hundred kilometres followed by a rapid increase in conductivity by factors of 100 to 1,000 at depths around 400–700 kilometres (250–450 miles). Additional considerations show that this rapid increase must flatten off at greater depths. When a more thorough understanding of the electrical conductivity of mantle minerals is obtained, the inferred conductivity distribution will be of value in determining the temperature distribution within the mantle.

Conductivity distribution within the mantle

Temperature distribution. Temperature distribution within the Earth is a function of heat flow within materials of varying composition and is related to the ultimate sources of heat within the Earth. These sources include residual heat from the time of the Earth's formation, heat from tidal friction (due to the gravitational interaction of the Sun, Moon, and Earth) and the braking effect of the Earth's rate of rotation, and energy emitted by radioactive decay of elements within the Earth. Radioactive decay can release substantial amounts of heat. It has been estimated that radiogenic heat production from granitic rocks in the Earth's crust is about 2.6×10^{-13} calories per gram per second, and that from basaltic rocks, which underlay most of the oceanic areas, about 3.8×10^{-14} calories per gram per second, on the average. The temperature distribution within the Earth is of critical importance to many aspects of geophysics, but at many depths it has not been determined, especially for those greater than about 400 kilometres (250 miles). Down to about 100 kilometres (60 miles), the approximate temperature distribution may be calculated from the theory of heat conduction, using as boundary conditions the amount of heat observed to be conducted to the surface of the Earth, the thermal conductivities of rocks, and the depth distributions of the heat-producing radioactive elements: uranium, thorium, and potassium. Between 100 and 200 kilometres (60 and 120 miles), the principal considerations are imposed by the experimentally observed melting behaviour of mantle silicate minerals at high pressures combined with knowledge that temperatures in this region must be high enough to explain the production of widespread basaltic magmas throughout geological time. Further limitations upon temperature are imposed by the necessity of explaining the occurrence of the low-velocity zone, believed to be caused by a small degree of partial melting.

Theories of heat distribution for greater depths must take into account not only the inferences that the outer core is mainly composed of liquid metallic iron and that the boundary between outer and inner core is caused by the freezing of iron but also large differences in estimates of the melting point of iron at very high pressures. These considerations suggest that the temperature at the base of the mantle may be about 3,000° C (5,400° F), whereas at the centre of the Earth the temperature may be in the vicinity of 4,000° C (7,200° F). The uncertainties in these estimates are probably ±1,000° C (2,000° F).

Rheological properties. Most rheological (flow) properties of materials such as viscosity, plasticity, strength, and creep rates are dependent upon the degree of proximity to melting temperature. The evidence on temperature distribution within the Earth and experimental data on the effect of pressure upon the melting temperatures of silicates imply that their melting point is approached most closely at depths between about 70 and 200 kilometres (40 and 120 miles). Accordingly, this zone could be expected to be the "weakest" in the Earth and one of high mobility that might take an important part in the dynamics of the mantle, continental drift, and adjustment mechanisms of isostasy, in which pressures from all sides are equal. Evidence suggests that this is indeed the case. The outermost cool shell, or lithosphere, some 70 to 100 kilometres (40–60 miles) thick, possesses substantial long-term strength and appears to slide relatively freely in the form of a series of large rigid "plates" over the underlying weak asthenosphere. Below 200 kilometres (120 miles), the melting-point gradient appears to increase more rapidly than the actual temperature gradient; in other words, the high-temperature material in the lower mantle is well below the melting point and probably has a much higher viscosity, or creep strength, than the region between 70 and 200 kilometres.

CHEMICAL AND MINERALOGICAL COMPOSITION OF THE EARTH

The continental crust. The thickness of the continental crust as defined by the depth to the Mohorovičić Discontinuity is usually between 35 and 45 kilometres (20 and 30 miles). Seismic *P*-velocities in the upper crust are usually between 5.8 and 6.4 kilometres (3.6 and four miles) per second and are believed to increase generally with depth; velocities in the vicinity of 6.6 to 7.2 kilometres (4.1 to 4.5 miles) per second are commonly inferred for the lower crust in stable regions. Higher velocities are found in some regions, however, particularly in those that have been the site of active mountain-building activity during the last 100,000,000 years. The nature of the downward velocity increase is not settled; in some regions there is evidence for a seismic discontinuity—the Conrad—whereas in others the increase is probably continuous.

Seismic *P*-velocities of 5.8 to 6.4 kilometres per second in the upper crust correspond to those of acidic igneous and metamorphic rocks and have led to the inference that below a veneer of sedimentary rocks, which may or may not be present, the upper crust or basement complex has an average composition approaching that of a granitic rock, more specifically granodiorite. This view is supported by the close agreement between both geological observations and geochemical estimates of the mean chemical composition (see Table 2). A granodiorite rock consists principally of the minerals quartz, feldspar, mica, and amphibole. Gravity investigations also lead to the conclusion that the upper crust has a density of approximately 2.70–2.75, which is consistent with the inferred composition.

Table 2: Chemical Compositions of Continental Shield Crystalline Surface Rocks and Pyrolite Model
(in weight percent)

component	A*	B†

*Continental shield crystalline surface rocks; composition A after Poldervaart. †Pyrolite model; composition B after Ringwood.

Large regions of the lower crust are characterized by *P*-velocities in the range 6.5–7.2 kilometres (four to 4.5 miles) per second, velocities similar to those of basalts, dolerites, and gabbros, and for many years it had been widely accepted that the lower crust is indeed composed of such rocks. Recent experimental investigations, however, demonstrate that gabbroic rocks are not thermodynamically stable under the pressure (five to ten kilobars)

and temperature (300°−700° C, or 400°−1,300° F) conditions of the lower crust. The experimental results, in conjunction with inferred densities and seismic velocities, suggest two classes of rocks for the lower crust: (1) in highly evolved regions, such as shields, the lower crust is probably highly heterogeneous and comprised on the average of groups of rocks of intermediate chemical composition (in granulitic or eclogitic metamorphic facies) that have been altered in composition, texture, or structure, by changes in pressure, heat, or chemical environment; (2) in crustal regions that have had a simpler and lower temperature history, the lower crust may consist dominantly of common rock-forming minerals called amphibolites.

Two classes of rocks in the lower crust

The mean chemical composition of the entire continental crust in most regions probably approaches that of the intermediate volcanic rock andesite, which is the most abundant volcanic rock erupted in many island arc regions. Geochemical investigations indicate that the crust is the result of extremely efficient chemical and magmatic differentiation processes that must have affected much of the mantle. It is estimated that between 30 percent and 60 percent of the uranium and barium originally present in the entire Earth has since become concentrated in the crust. This type of concentration is also displayed by some other elements and is in part attributable to large radii or ionic charge or both that inhibit the ready entry of such elements into the major minerals that comprise the mantle.

The ages of continental crustal rocks display a more or less continuous distribution from the present time to about 3,000,000,000 years. A few older ages beyond that figure—up to 3,800,000,000 years—have been recorded; but no rocks have been found with ages between 3,800,000,000 and 4,700,000,000 years, the estimated age of the Earth. Conditions on the Earth during the first 1,000,000,000 years of its history evidently differed in important respects from those in latter times. Increasing evidence suggests that the crust has formed more or less continuously from the mantle over geological time by magmatic differentiation processes and that perhaps this differentiation process did not commence until about 3,800,000,000 years ago.

Crustal profile of deep oceanic basins

The oceanic crust. The average crustal profile in deep oceanic basins consists of about 0.5 kilometre (0.3 mile) of sediments underlain by a layer of 1.5 to 2.5 kilometres (one to 1.5 miles), which has a compressional-wave (*P*-) velocity of about five kilometres (three miles) per second and is believed to represent a series of submarine flows of basalt characterized by substantial porosity. Next below is the main oceanic crustal layer with a thickness of about five kilometres (three miles) and mean *P*-velocity of 6.7 kilometres (4.2 miles) per second. Two hypotheses have been proposed about the nature of this layer: one holds that it consists of partly serpentinized peridotite; the other, that it consists of basalts, gabbros, and other mafic (composed largely of magnesium silicates) igneous rocks. Both concepts explain the observed seismic *P*-velocities, but the first does not satisfactorily explain the sharpness of the suboceanic Mohorovičić Discontinuity. In addition, the observed Poisson's ratio (ratio of the fractional transverse contraction to the longitudinal extension of a body under tensile stress) of serpentine (0.38) is much higher than that of the oceanic crust (0.27), which is, however, similar to that of mafic rocks. Most scientists favour the hypothesis that the oceanic crust consists of mafic igneous rocks, most likely a heterogeneous mixture of basalts, dolerites, gabbros, amphibolites, and greenschists.

According to the theory of sea-floor spreading, the oceanic crust is generated at midoceanic ridges (see Figure 4) and migrates away from the ridges for great distances, ultimately reaching oceanic trenches where it subsides and is consumed in the mantle. The crustal generation process consists of the partial melting of primary mantle material beneath midoceanic ridges forming basaltic magmas and leaving behind residual peridotite. The subsurface structure near the axes of ridges probably consists of a complex and highly heterogeneous mixture of mafic and ultramafic (peridotitic) rocks. Because of the relatively high temperatures that greatly weaken the crust in these regions, the large, highly dense peridotite bodies subside back into the mantle as the crust moves away from the ridge axis, and ultimately a relatively sharp boundary between crustal mafic rocks and mantle ultramafic rocks is established. This boundary constitutes the Mohorovičić Discontinuity.

The Mohorovičić Discontinuity. Beneath most stable continental regions the Mohorovičić Discontinuity is marked by a rapid increase in *P*-velocity, from 6.5 to seven kilometres (four to 4.4 miles) per second characteristic of the lower crust to values of eight to 8.4 kilometres (five to 5.2 miles) per second characteristic of the upper mantle. The detailed structural nature of the transition is not well understood and probably varies widely from place to place. In some regions, there is evidence of reflections from the Moho, indicating that the transition boundary is relatively sharp (about 0.3 kilometre, or 0.2 mile wide). In other regions, there is evidence of the existence of a transition zone. It is widely believed that in most regions, a large part of the increase of velocity from about seven to 8.2 kilometres (4.4 to 5.1 miles) per second occurs within a depth range probably less than five kilometres (three miles) thick. Observations of near vertical reflections and critical reflections combined with lack of evidence of the presence of a positive-velocity gradient in the main oceanic crust layer indicates that beneath deep oceanic basins the Mohorovičić Discontinuity is usually a relatively sharp feature, less than one kilometre (0.5 mile) thick and sometimes less than 0.3 kilometre (0.2 mile).

The nature of the Moho—two hypotheses

Two hypotheses regarding the nature of the Moho have been widely discussed. The first maintained that the Moho was caused by an isochemical phase transformation of a gabbroic (pyroxene + plagioclase) lower crust into an eclogitic (jadeitic pyroxene + garnet) upper mantle. As eclogite has a density of about 3.5 grams per cubic centimetre, or some 15 percent greater than that of gabbro, it could provide the required seismic velocity for the upper mantle. This hypothesis attracted attention largely because of the possibility that a phase change at the Moho, involving the reversible transformation of gabbro to eclogite, could be responsible for vertical movements of the Earth's crust and other tectonic phenomena. The second hypothesis maintained that the Moho represents a sharp change in the chemical makeup of the material above and below the Moho—from an intermediate or mafic lower crust into an ultramafic mantle composed of peridotite (olivine + pyroxene). Peridotite, with a density of 3.3 grams per cubic centimetre, could also provide the observed mantle seismic velocities.

The phase transformation hypothesis was ultimately tested by means of laboratory investigations of the gabbro–eclogite transition. The experiments indicated that a transitional mineral assemblage (garnet granulite) intervened between the stability fields of gabbro and eclogite. As gabbro became transformed through garnet granulite to eclogite, pressures ranged from three to 12 kilobars, with densities and seismic velocities distributed throughout this zone. Furthermore, gabbros with only slightly different chemical compositions displayed very large differences in the pressures required to cause transformation. Considering the foregoing characteristics of the gabbro–eclogite transformation, it is impossible to explain the relative sharpness of the Moho in most continental and oceanic regions. Observed relationships between surface-heat flow and crustal thickness were also contrary to expectations based upon the phase transformation hypothesis. In most continental and oceanic regions where it is clearly defined, the Mohorovičić Discontinuity cannot be explained in terms of a reversible chemical change from gabbro to eclogite; it is accordingly considered that the discontinuity is caused by a difference in chemical composition between crustal rocks and the underlying mantle rocks. The composition of the mantle rocks is discussed below.

The upper mantle. Seismic velocity distributions (see Figure 1) provide the basis for subdividing the mantle

The three regions of the mantle

into three regions. The upper mantle extends to a depth of 400 kilometres (250 miles) and is characterized by regional differences in velocity profiles and by generally low-velocity gradients except in the vicinity of the low-velocity zone beneath oceans and some geologically unstable regions. The transition zone extends downward from about 400 to 1,000 kilometres (250 to 600 miles) and is characterized on the average by rapid increase of velocity with depth. There are at least two major seismic discontinuities, at depths of about 400 and 650 kilometres (250 and 400 miles). The lower mantle extends between 1,000 kilometres and 2,900 kilometres (600 and 1,800 miles) and is characterized by relatively gentle and uniform increases of velocity with depth, although high-resolution seismic studies provide some evidence of minor irregularities in this region also. On the basis of seismic velocities, this threefold subdivision of the mantle is likely to reflect corresponding variations in other physical and chemical properties and must be explained in terms of the physicochemical properties and thermodynamic stability of the minerals present.

Compressional-wave velocities. Seismic *P*-velocity in the uppermost mantle usually falls within the range 8.2 (±0.2) kilometres, or 5.1 (±0.1) miles per second. This property, together with certain broad petrological and mineralogical limitations, indicates some combination of olivine, pyroxene, garnet and, in restricted regions, amphibole. The two principal rock types carrying these minerals are peridotite (olivine-pyroxene) and eclogite (pyroxene + garnet). Both types may carry some amphibole. These relationships have given rise to the alternative hypothesis that the upper mantle is of peridotitic or eclogitic composition; choice between these alternatives would require accurate knowledge of the density of the upper mantle. The densities of peridotitic rocks, which might qualify as major upper mantle constituents, are close to 3.3 grams per cubic centimetre, whereas eclogites with seismic velocities of 8.2 kilometres (5.1 miles) per second possess densities close to 3.5 grams per cubic centimetre. Geophysical evidence on the density of the upper mantle is, however, somewhat conflicting. Interpretations of gravity observations combined with the theory of isostasy (which holds that all large portions of the Earth's crust are balanced as though floating on a denser underlayer) are considered to favour a density closer to 3.3 than 3.5 grams per cubic centimetre, and thus the less dense peridotitic composition. Observations demonstrating that in the oceanic upper mantle seismic velocity varies substantially with azimuth or orientation also support the peridotite conclusion, because such a phenomenon (anisotropy) is characteristic of many peridotites but much less pronounced, or absent, in eclogites. Some estimates of density of the upper 200 kilometres (120 miles) of the mantle, obtained by inversion of free-oscillation data for the Earth, on the other hand, indicate a density of about 3.5 grams per cubic centimetre, suggestive of eclogitic composition; but conflicting results have been obtained by the method.

Conflicting geophysical evidence on density

Composition of the upper mantle. Geological and petrological observations provide more definitive information. An important indication of the composition of the upper mantle is provided by the study of xenoliths (inclusions) in kimberlite pipes, cylindrical igneous bodies. In Africa and Siberia, where the pipes have been studied most intensively, they carry numerous xenoliths of crustal rocks that they are known to have intruded during rapid upward emplacement. Such pipes also contain many inclusions of rocks not known to occur in the vicinity, particularly peridotites and eclogites. It is generally believed the latter xenoliths are from the mantle and represent a random sample of mantle rock types that have been intersected by the pipes. The occurrence of diamonds (evidently formed under great pressures) in the pipes and in some of the inclusions implies that the pipes are derived from depths of at least 150 kilometres (about 90 miles); occurrence of other high-pressure phases suggests some pipes come from depths as great as 300 kilometres (about 180 miles). In nearly all cases in which sampling has been adequate peridotitic inclusions were found to be much more common than eclogitic inclusions —strong indication that the upper mantle sampled by the pipes is predominantly of peridotitic composition, with eclogite a minor but widely distributed constituent.

Alpine-type peridotites

Investigations of the occurrence and origins of large bodies of so-called Alpine-type peridotites emplaced in the Earth's crust are a second source of information on the composition of the upper mantle. Peridotite rock intrusions, some covering several thousand square kilometres, have been found in New Caledonia, New Guinea, the Philippines, Cyprus, Greece, British Columbia, and many other localities. Alpine-type peridotites are characteristically intruded close to the axis of maximum deformation along mountain-building belts and island arcs. It is known that intrusion is frequently controlled by major faults, which may extend for hundreds of miles and almost certainly extend into the mantle.

Dredging on the mid-Atlantic and mid-Indian oceanic ridge systems has also revealed widespread occurrences of peridotites. Great thicknesses of these rocks have been discovered in fracture zones that offset the mid-Atlantic Ridge.

The nature and significance of Alpine-type peridotite occurrences have been considerably clarified by development of the theories of sea-floor spreading and plate tectonics. The outcrop of large bodies of peridotites along midoceanic ridges, combined with geophysical observations of mantle-type seismic velocities at shallow depth beneath some ridge localities, strongly indicates that such peridotites represent actual mantle material intruded to high levels. Similarly, detailed mapping of peridotite and associated gabbro and basalt occurrences in New Guinea, Cyprus, and Greece provides evidence that relatively complete sections of oceanic crust and underlying peridotitic mantle have been overthrust into the crustal environment. Other peridotite occurrences are believed to have originated at midoceanic ridges and been carried into their present localities in island arcs (*q.v.*) and continental margins by the migrating sea floor.

The occurrences of many Alpine-type peridotites, as interpreted in the light of plate tectonic theories, provide strong indication that these rocks are representative of the uppermost suboceanic mantle, whereas there is no comparable evidence that eclogites have comparable significance. Eclogites are rare compared to peridotites and occur in very small bodies. According to the results of detailed studies, many eclogites found in the crust have been formed there by metamorphism of mafic rocks and do not represent tectonic slices of the upper mantle.

Basaltic magmas have been erupted abundantly over both oceanic and continental regions of the Earth's surface throughout geologic time. The source of basalt is believed to be the upper mantle, of which a fundamental property is, clearly, that it should be capable of yielding basalt magmas when subjected to suitable partial melting processes. Because they are generally so low in potassium, uranium, thorium, barium, strontium, lanthanum, and other trace elements—as well as in the major elements of sodium, calcium, and aluminum—the compositions of Alpine peridotites cannot yield basalt magmas by partial melting. Rather the compositions are strongly suggestive of refractory residues remaining after partial melting processes in which basaltic magmas have been produced.

From such considerations it can be concluded that below the residual layer of Alpine-type peridotite must exist a more primitive rock that is capable of yielding basalt magmas by partial melting, leaving behind a residual unmelted peridotite. The composition of this hypothetical primitive material, called pyrolite, must lie somewhere between the compositions of peridotite and basalt. Several types of evidence indicate that the primitive composition is closer to that of peridotite and is perhaps not far from a mixture of three parts peridotite to one part of basalt (see Table 2). The exact nature of the composition is not known, however, and it is thought that it may vary substantially from place to place. Experimental investigations on the crystallization of basaltic magmas at high pressures and the formation of basalts by partial

melting of pyrolite have led to a generally consistent interpretation of physicochemical relationships between types of basalt and their complementary peridotites.

The above considerations lead to the concept of a chemically zoned upper mantle consisting of a layer of residual peridotite underlain by pyrolite. Beneath oceans the peridotite layer is believed to be about 70 kilometres (40 miles) thick; beneath highly evolved continental regions such as Precambrian shields the thickness would be closer to 150 kilometres (90 miles).

Low-velocity zone. In many oceanic regions, the upper 70 kilometres (40 miles) of the upper mantle exhibits an *S*-wave (shear-wave) velocity of about 4.6 kilometres (2.9 miles) per second. Below this "lid," velocity decreases rather sharply, reaching a minimum of about 4.3 kilometres (2.7 miles) per second at about 100 kilometres (60 miles). This zone of decreased velocity extends to about 150–200 kilometres (90–120 miles), and a corresponding low-velocity zone is also believed to occur for *P* (compressional) waves. The low-velocity zone is more strongly evident in some regions of recent mountain-building activity, as in the Alps. In other active regions (*e.g.*, Japan, or the Basin and Range Province of the United States) the 70-kilometre (40-mile), high-velocity lid may not be present, and the low-velocity zone may extend upward to the Moho. Beneath stable continental areas such as Precambrian shields, a low-velocity zone is probably not present for *P*-waves, and the *S*-minimum is much less pronounced, occurring at greater depths.

A number of possible causes of the oceanic and tectonic low-velocity zones have been considered, and it is believed that the observed magnitude of the velocity change together with the inferred velocity gradients indicates a small degree of partial melting in the region. The presence of as little as 1 percent of liquid in the form of thin films along grain boundaries would cause a marked decrease in both *P* and *S* velocities and also the increase in attenuation of seismic waves that is also observed. Experiments lead to the suggestion that partial melting is caused by the effect of water, believed to be present in the mantle in amounts of about 0.1 percent. At depths less than 70 kilometres (40 miles) the water is principally held in the mineral amphibole; at greater depths, however, amphibole becomes unstable because of the high pressure, and the water is liberated as a free phase. As a result, the temperature at which melting begins is lowered by 200°–400° C (350°–700° F), and a small amount of interstitial melt occurs between 70 and 150 kilometres (40 and 90 miles). Below that depth other minerals capable of incorporating water in their structure become stable, and hence the water-vapour pressure is reduced, so that melting does not occur.

Partial melting in the low-velocity zone has important implications for the dynamic behaviour of the mantle; the low-velocity zone is a region of very low mechanical strength and high mobility. The less pronounced *S*-wave low-velocity zone beneath Precambrian shields is not attributed to partial melting; it is believed to be the result of the temperature gradient in the region, which is not, however, critical enough to affect *S*-waves.

Phase transformations in the upper mantle. An important property of rocks near the pyrolite composition is that they may crystallize in four distinct mineral assemblages characterized by the coexistence with olivine of amphibole, plagioclase, aluminous pyroxenes, and garnet. These mineral assemblages have different physical properties, with densities and seismic velocities varying by about 4 percent; accordingly, their distribution has a significant effect upon the fine structure of the upper mantle. The stability ranges of the different types of pyrolite have been determined, leading to a general understanding of the conditions governing their occurrence.

Mineral assemblages and structure

Garnet pyrolite is stable in the upper mantle beneath Precambrian shields; pyroxene pyrolite probably occurs as a relatively thin layer in the uppermost mantle beneath oceanic and tectonically active regions, and it transforms into garnet pyrolite at depths of 60–100 kilometres (35–60 miles) beneath these regions. Garnet pyrolite is characterized by the highest velocity and density and remains stable between depths of approximately 70 and 350 kilometres (40 and 200 miles); no further phase transformations occur in this region. Regions of occurrence of plagioclase and amphibole pyrolites are limited in the uppermost suboceanic mantle; plagioclase is restricted to conditions of low pressure and high temperature such as, for example, immediately beneath midoceanic ridges.

The transition zone. The region of the mantle between 400 and 1,000 kilometres (250 and 600 miles) below the Earth's surface is called the transition zone and is characterized in general by an exceptionally high rate of increase in seismic velocities with depth and has at least two major seismic discontinuities (see Figure 1). It was demonstrated in 1936 that the density in the transition zone increased much more rapidly with depth than would be expected in a uniform self-compressed layer. A detailed study of the elastic properties of the mantle in 1952 led to the conclusion that the abnormal changes of elastic properties and density in this zone were probably caused by a series of major phase transformations; that the principal minerals of the upper mantle (olivine, pyroxenes, and garnets) were not stable under the high pressures existing, and that those minerals transformed into a new set of denser polymorphs in which the atoms were more closely packed and different in crystal structures.

A series of experimental investigations between 1956 and 1966 confirmed 1952 inferences that olivines, pyroxenes, and garnets were unstable at high pressures, transforming into denser polymorphs. A systematic study of these transformations in silicates using both direct, static, high-pressure techniques (up to 200 kilobars), and indirect methods utilizing thermodynamic studies provided indications of the probable series of phase changes occurring throughout the transition zone.

Assuming that the transition zone composition is similar to that of the upper mantle (pyrolite), a number of transformations are to be expected (see Figure 3). Near 400

From A.E. Ringwood, *Earth and Planetary Science* Letters (1972), 14, pp. 233-241

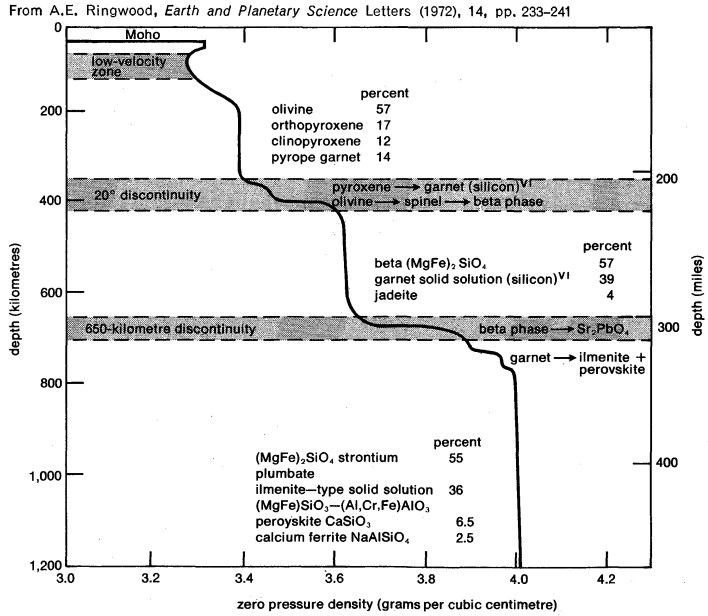

Figure 3: Mineral assemblages and densities given by pyrolite model in outer mantle.

kilometres (250 miles), two major transformations occur: (1) the pyroxene component of the upper mantle becomes unstable and transforms to a new type of garnet structure, in which about one quarter of the silicon atoms are surrounded by six atoms of oxygen; (2) at slightly greater depths, olivine transforms into a spinel-like structure. These transformations would result in an increase of density of about 8 percent and an accompanying increase of about 0.7 kilometre (0.4 mile) per second in seismic velocity, which is in close agreement with observed seismic velocity changes at the 400-kilometre (250-mile) discontinuity.

Two major transformations near 400 kilometres

Between about 450 and 600 kilometres (300 and 400 miles) the rate of increase of seismic velocities is not indicative of further phase transformations. Experimental studies reveal that the spinels and garnets formed near 400 kilometres (250 miles) remain stable through the interval to 600 kilometres (400 miles). Direct techniques are unable to reproduce pressures and temperatures occurring below about 600 kilometres; detailed interpretation of phase changes at greater depth rests heavily upon studies of analogue compounds and shock-wave methods. Such studies reveal that garnets and spinels will transform to denser phases at pressures of about 200–300 kilobars; the spinel phase may transform to the strontium plumbate structure or it may disproportionate (*i.e.*, convert itself into two derivatives) into a mixture of periclase and ilmenite structure. The garnet phase probably disproportionates into a mixture of ilmenite and perovskite structure. Minor phases that are probably present possess the calcium ferrite structure and hollandite structures.

These transformations are unlikely to occur at exactly the same depth. By far the most important transformation would be of magnesium silicate, Mg_2SiO_4 (spinel-like), to the strontium plumbate structure, which may well occur within a relatively narrow depth range and could be responsible for the occurrence of the 650-kilometre (400-mile) seismic discontinuity (Figures 1 and 3). Transformation of garnets to ilmenite and perovskite structures involves the disproportionation and formation of very complex solid solutions, probably smeared out more than the strontium plumbate transformation; it would be coincidental if both were to occur at exactly the same pressure. Apparently, they contribute to a rather complex fine structure between 650 and 1,000 kilometres (400 and 600 miles) that has yet to be resolved by seismology.

From the crystallographic standpoint the principal characteristic of transformations occurring between 400 and 1,000 kilometres (250 and 600 miles) is the replacement of typical upper mantle silicate minerals by a new assemblage of phases in which the structure is octahedral (each silicon atom being surrounded by six oxygen atoms) instead of the original tetrahedral structure (each silicon atom being surrounded by four oxygen atoms). Closer packing of the atoms is primarily responsible for the 20 percent increase in density (referred to zero pressure) associated with the transformations. The mean density of the assemblage of silicate polymorphs with ilmenite, perovskite and strontium plumbate structures, which is thought to occur at depths of 800–1,000 kilometres (500–600 miles), is similar to that of a mixture of oxides of magnesium, iron, calcium, aluminum, and silicon ($MgO + FeO + CaO + Al_2O_3 + SiO_2$), provided the density of SiO_2 is taken as that of the high-pressure, rutile-type polymorph of SiO_2, "stishovite," of octahedral structure.

Increases in densities with transformations

The lower mantle. The general nature of the phase transformations responsible for the large increases in density, seismic velocities, and other physical properties in the transition zone of the mantle, between 400 and 1,000 kilometres (250 and 600 miles), is fairly well understood. Further transformations to denser states of materials in the lower mantle must also be considered possible. Although the rate of increase of seismic velocities in the lower mantle had been considered similar to that to be expected for self-compression of homogeneous material without chemical or phase changes, seismic velocity distributions show regions of anomalously high gradients near depths of 1,000, 1,230, 1,540, and 1,910 kilometres (600, 760, 960, and 1,190 miles). About 15 percent of the total velocity increase between 1,000 and 2,300 kilometres (600 and 1,400 miles) can be accounted for by those regions, and it is possible that minor-phase changes could be the cause. Further phase transformations in the deep mantle over the pressure range of 300 to 1,300 kilobars are not unlikely in view of the number of transformations that occur at pressures of less than 300 kilobars. Nevertheless, the density distribution and elasticity of the deep mantle are considered to permit only small density changes.

Studies of the density distribution of the lower mantle and of shock-wave data on the densities of silicates at comparable pressures indicate the density of the lower mantle to be about 5 percent higher than expected for the pyrolite composition crystallizing as a mixture of phases with ilmenite, strontium plumbate, perovskite, and periclase structures. A possible explanation is, as already suggested, that further minor transformations have resulted in the formation of a mineral assemblage intrinsically denser than the assemblage above it. An alternative explanation is that the lower mantle is characterized by a slightly higher iron/magnesium ratio than the upper mantle and is thus denser. Combined experimental and seismic investigations have developed a generally consistent and satisfying explanation of some of the major physical properties of the mantle in terms of the natures and structures of the minerals present and their stability fields.

When due allowance is made for the effects of phase transformations, the concept of pyrolite composition for the upper mantle explains the observed physical properties of the transition zone and lower mantle; it also suggests that major changes in chemical composition do not occur throughout the mantle. This appears explicable if the mantle had been rather well "stirred" and homogenized during the process of core-segregation early in the Earth's history; strong cosmochemical arguments can, in fact, be made in support of the view that the composition of the entire mantle may approximate that of pyrolite.

Concept of pyrolite composition of upper mantle

Seismic velocities in the lower 200 kilometres (120 miles) of the mantle may decrease slightly with depth, as might be caused by the presence of metallic iron. It has been suggested that the core and mantle may be out of chemical equilibrium and that chemical reactions near the core–mantle boundary may result in precipitation of metallic iron in the region.

The core. The boundary of the core is marked by a major seismic discontinuity close to 2,900 kilometres (1,800 miles), at which *P*-wave velocity drops from 13.7 kilometres (8.5 miles) per second to approximately eight kilometres (five miles) per second and below which *S*-waves are no longer transmitted (see Figure 1). The latter observation implies that the rigidity of the outer core is zero (*i.e.*, that it is liquid), a conclusion that is reinforced by tide investigations and theories of the origin of the Earth's magnetic field. The seismic discontinuity at 2,900 kilometres (1,800 miles) is accompanied by a corresponding discontinuity in density, which changes from 5.7 grams per cubic centimetre in the lowermost mantle to approximately 9.8 grams per cubic centimetre in the outermost core (see Figure 2).

The dominant component of the Earth's magnetic field can be demonstrated to originate within the Earth. Intensity of the field varies from place to place in a rather irregular manner, and in addition there are gradual changes ("secular variation") over periods as short as ten years. The short time scale of these changes makes it improbable that they originate in the solid mantle, and it is believed that their source lies in the liquid region of the core. It has been demonstrated that fluid motions in the core in the presence of an initial magnetic field may lead to a self-sustaining dynamo action, whereby a relatively stable system of electric currents is induced within the core. These currents in turn generate a magnetic field, part of which leaks to the Earth's surface to provide the observed field and part of which interacts with the moving liquid to sustain the dynamo action.

The Earth's magnetic field and the liquid region of the core

Originally, it was proposed that the motions of the liquid outer core were convective in nature, caused by heating from a high concentration of radioactive elements in the inner core. As the required distribution of radioactive elements was improbable on geochemical grounds, however, a modified theory was proposed. It held that convection was driven by cooling at the core–mantle boundary accompanied by freezing at the boundary of the inner core, which liberated its latent heat, thus providing the required energy.

The dynamo theory of the Earth's magnetic field implies that the electrical conductivity of the outer core is very

high and similar to that of a metal, and this property together with the high density suggests that the core may be composed principally of liquid iron. Cosmochemical evidence on the relative abundances of iron in the Sun and in the most primitive chondritic meteorites supports such a hypothesis. The extraterrestrial abundances are similar to the relative abundance of iron in the Earth, providing the core is assumed to consist mainly of iron (see further, EARTH, MAGNETIC FIELD OF).

Composition of the core

All available evidence thus supports the hypothesis that the core is principally composed of metallic iron, but it is probable that additional components are also present. Studies of meteorites and cosmic-abundance tables indicate that the core probably contains about 10 percent of metallic nickel. Careful comparisons of the density and elasticity of the core with those of pure iron, as provided by shock-wave investigations at core pressures, indicate that the density of the core is 10–15 percent less than that of pure nickel–iron under comparable pressure and temperature conditions, whereas the seismic velocity is substantially higher than that of pure iron. Such observations suggest the presence of a third component in the core, capable of decreasing density and increasing the velocity; on geochemical grounds the most likely component is sulfur or elementary silicon. About 20 percent of either in solution in the core would explain the observed densities and velocities, and would have interesting implications for the processes by which the core was formed, and indeed for the origin of the Earth.

At a depth of about 5,100 kilometres (3,200 miles) the seismic *P*-velocity increases by about 10 percent (see Figure 1). That depth marks the boundary of the inner core. From limitations on the density of iron at the centre of the Earth—as indicated by shock-wave data, experiment, and calculations—it can be demonstrated that the inner core is probably substantially rigid, which would imply that it is solid. The inner core may thus be regarded as being caused by the freezing of iron under very high pressures (approximately 3,000–5,000 kilobars).

Detailed seismic studies reveal the presence of a rather complex fine structure at the boundary of outer and inner cores and, further, that at least two seismic discontinuities may occur within a transition zone several hundred kilometres thick. The structure of the transition zone may be a consequence of chemical inhomogeneity and phase changes during the crystallization of a relatively pure iron–nickel inner core from a less pure liquid containing larger amounts of a third component (sulfur or silicon) in solution.

DEVELOPMENT OF THE EARTH'S STRUCTURE AND COMPOSITION

The origin of the Earth is one of the oldest problems of natural philosophy, one that has captured the interest not only of scientists from many different disciplines but also of mankind generally. Although the subject remains controversial in many respects, a great deal has been learned since 1950, largely through the consideration of geochemical and cosmochemical evidence that has accompanied the expansion of knowledge in these fields. A new dimension of data has been added by the retrieval and study of lunar-surface samples.

Theories of the origin of the Earth

Prior to 1950 the most popular theories of the origin of the Earth and other planets were based on cataclysmic events, such as removal of material from the hot Sun by some means; for instance, tidal interactions from a star passing nearby. In addition to the improbability of such processes, it was recognized that many intractable geochemical problems followed from the assumption that the Earth had condensed entirely out of gaseous solar material.

Astronomers had developed theories of star formation by accretion processes in vast interstellar clouds of dust and gas. Such concepts were extended to the Earth, suggesting that it, too, had accreted from dispersed solid matter within a primordial solar nebula. Many of the processes occurring during accretion fall in the realm of chemistry rather than physics, and many of the key boundary conditions that must be satisfied by an acceptable theory of formation of the Earth are geochemical in nature. Several hypotheses have been developed in attempts to satisfy these and other boundary conditions. Three distinct categories can be recognized and are discussed below.

Homogeneous accretion of the Earth. The various theories of formation of the Earth as a result of the accretion of metal and silicate particles in the solar nebula have certain essential elements in common. It is assumed that a flattened solar nebula of dust and gas (mainly hydrogen and helium) first developed some 4,600,000,000 years ago, then passed through a high-temperature stage, during which the dust component recrystallized as a mixture of metallic iron and silicate particles. Some physical fractionation process (magnetic fields is one suggestion) then caused varying degrees of separation of metal particles from silicate particles, so that the metal/silicate ratio varied in different parts of the nebula. (This assumption is necessary to explain the differing densities of the planets.) The metal and silicate particles present at this stage are believed to resemble those found in chondritic meteorites.

The Earth then is assumed to have accreted from the mixture of metal and silicate particles in a localized region of the nebula. Accretion occurred slowly enough (over 10^8 years) so that enough energy was dissipated by radiation to allow formation of the Earth in a cool, unmelted state at a mean temperature of probably less than 1,000° C (1,800° F). Radioactive elements (potassium, uranium, thorium) then slowly heated the Earth until partial melting occurred in the interior, perhaps 10^9 years after accretion. When this stage was reached, the metal particles, which had previously been somewhat uniformly distributed throughout the Earth, then melted and collected together, ultimately sinking and segregating to form the core; differentiation and degassing of the mantle, leading to the gradual formation of the crust, hydrosphere, and atmosphere, accompanied the melting process.

This hypothesis offers no satisfactory explanation for the initial physical fractionation of metal particles from silicate particles within the solar nebula. The accretion of the Earth from an intimate mixture of small metal and silicate particles would have led to a state of local chemical equilibrium (in which the products formed by the reaction themselves react with each other to reform the original reactants) between the two phases. But the Earth's mantle seems to contain too much nickel and other siderophile elements (those that have weak affinity for oxygen and sulfur and go readily into solution in molten iron); it also is too highly oxidized (as shown by the amount of ferric iron present) to have been in equilibrium with metallic iron before the core separated. It is difficult, too, to understand the trapping of water and carbon dioxide in the mantle (subsequently to be liberated into the atmosphere and hydrosphere), because these compounds would be mostly reduced to hydrogen, carbon, and carbon monoxide in the presence of metallic iron at high temperatures. Some recent experimental measurements on the partition of lead between metallic iron and silicates, combined with knowledge of the isotopic composition of lead in the upper mantle-crust system, have shown conclusively that the core must have segregated about 4,600,000,000 years ago, close to the time of accretion of the entire Earth. Formation of the core soon after accretion would have required temperatures far higher than are consistent with the "cool accretion" hypothesis.

Inhomogeneous accretion of the Earth from metal and silicate components. The above considerations have resulted in substantial modifications of the homogeneous accretion hypotheses. One such modification that has received some consideration is the proposal that accretion of the Earth was a sequential process occurring over a wide range of temperatures: iron core first at high temperatures; silicates of the mantle at a later stage; the hydrosphere, atmosphere, and other volatiles at the terminal stage at low temperature. According to this version, silicate components did not accrete upon the Earth until formation of the metallic core was nearly complete, so

Sequential cooling of Earth components

that the core thus became surrounded by a silicate mantle; and at the lowest temperatures, the material condensing or precipitating from the solar nebula became more oxidized and rich in volatiles, including water and carbon dioxide. The latter material was plastered onto the outside of the mantle at the latest stage of accretion and ultimately provided the Earth's atmosphere and hydrosphere.

The early formation of the Earth's core and the lack of chemical equilibrium between the upper mantle and core are accounted for by this hypothesis, which, however, still has many shortcomings. For example, if the Earth's core condensed from the solar nebula at a temperature of about 1,500° C (2,700° F) and if subsequent accretion of the mantle (depleted in the heat-producing radioactive element, potassium) occurred at lower temperatures, then the temperature at the centre of the Earth after accretion was not much higher than 2,000° C (3,600° F). Under the prevailing pressure, the core would have been well below the melting point throughout, and there does not appear to be any way in which subsequent heating of the deep interior could occur at a sufficient rate to cause the melting of the outer core some 2,000,000,000 years later, a rate that would be required to explain the generation of a magnetic field as inferred from the magnetizations of Precambrian rocks.

Furthermore, if the Earth's mantle condensed sequentially from a gaseous solar nebula, the first components to condense would be calcium oxide and aluminum oxide, which should form a seismically distinct layer several hundred kilometres thick near the base of the mantle; there is no evidence of such expected seismic zoning. The upper mantle would be expected to be strongly depleted in calcium, aluminum, and other involatile elements; but the compositions of widespread basalts derived from the upper mantle show that such is not the case.

Single-stage accretion of the Earth from primordial material. In addition to the specific shortcomings mentioned, both of the preceding hypotheses assume that complex chemical and physical fractionation processes occurred in the solar nebula before the Earth accreted. An attempt to avoid these assumptions and difficulties proposes that the terrestrial planets accreted directly from primitive solid material resembling the Type 1 carbonaceous chondrites in a cool solar nebula; that there were no complex high-temperature physical and chemical fractionations in the nebula prior to accretion.

Type 1 carbonaceous chondrites are believed to be the most primitive type of meteorites known and to contain the primordial or solar abundances of most elements, except those that are highly volatile. All of the iron occurs in the oxidized state, which is to be expected under conditions of thermodynamic equilibrium in a nebula of solar composition at low temperature. Furthermore, the meteorites contain about 20 percent of water, up to 10 percent of complex organic compounds, and large quantities of other relatively volatile components. In many respects the compositions of these meteorites resemble those expected for the primitive dust particles in a low-temperature solar nebula.

It has been suggested that the Earth, Mars, and Venus accreted directly from planetesimals of this composition and that, during accretion, carbonaceous compounds reduced the associated oxidized iron to form metallic iron. This process occurred to varying extents on the three planets, and it is believed that the differences in planet densities were primarily caused by differences in oxidation states rather than in the relative abundances of metals. On this model, Mars is more oxidized than the Earth, and Venus is intermediate.

Assuming that accretion of the Earth occurred in a period of a few million years or less, the chemical equilibria in the accreting material were largely controlled by the liberation of gravitational potential energy as the primitive planetesimals fell upon the Earth. This energy amounted to 10,000 calories per gram for the entire Earth, but it was not liberated uniformly. Gravitational energy per gram would have been zero at the start of accretion, increasing as the Earth grew, and reaching more than 15,000 calories per gram during the final stages of accretion. Early stages of accretion would have occurred under relatively cool conditions, permitting the trapping of volatiles and oxidized iron deep within the interior; temperature would have risen during later stages because of the very large amounts of gravitational potential energy dissipated; carbon reacted with oxidized iron to form metal and to complete the degassing that was taking place. The degassing resulted in the formation of a large primitive atmosphere, perhaps one-fifth the mass of the Earth and composed mainly of carbon monoxide and hydrogen, with perhaps about 10 percent of volatilized silicates and metals.

According to this model, the Earth accreted in a state grossly out of chemical equilibrium, the temperature in the outer region exceeding the melting point during the final stages and permitting metallic iron to segregate into large bodies that then sank toward the centre. The process of core segregation is highly exothermic (*i.e.*, formed with the evolution of heat), releasing an additional 600 calories per gram of gravitational potential energy, enough to heat the entire Earth by 2,000° C (3,600° F). Segregation of the core would have been too rapid for complete chemical equilibrium between core and mantle to be attained, and both would have been homogenized by convection after formation of the core.

Model for simple chemical development

The foregoing model appears to be capable of satisfying some important chemical and physical boundary conditions for the Earth's formation, specifically the early formation of the core, implying a high-temperature Earth immediately after accretion and the lack of chemical equilibrium between mantle and core. The hypothesis provides a ready explanation of the densities of Mars and Venus, within the framework of a rather simple chemical development of the solar nebula prior to accretion, but does not provide a satisfactory explanation of how the massive primitive atmosphere was lost from the Earth. A combination of two causes has been suggested for that loss: (1) rotational instability and (2) the effects of intense solar particle radiation when the Sun passed through a very young (T-Tauri) phase. Whether those mechanisms were capable of removing the postulated primitive atmosphere is not yet known; future investigations may be expected to provide a crucial test of the single-stage hypothesis. As a by-product of this hypothesis, it was suggested that the formation of the Moon may perhaps be linked with the loss of the massive, hot primitive atmosphere, that on expanding and cooling the silicate components of the atmosphere would be precipitated to form a ring of planetesimals orbiting the Earth, ultimately becoming unstable and coagulating to form the Moon.

Evolution of crust from mantle. Much geochemical and petrological evidence suggests that the crust has evolved gradually from the mantle. The theory of seafloor spreading, combined with developments in experimental petrology, has begun to provide an understanding of the processes of crust formation.

Pyrolite diapirs (folds of pyrolite produced by a rising, mobile core material; see Figure 4) rise from the low-velocity zone beneath midoceanic ridges and undergo partial melting to produce basaltic magmas and residual peridotite. The basaltic magmas segregate and crystallize to form a heterogeneous oceanic crust composed mainly of basalt, gabbro, amphibolite and greenschists. The oceanic crust and underlying ultramafic (*i.e.*, composed dominantly of magnesian rock-forming silicates) lithosphere moves outward from the ridge, ultimately reaching a trench near an island arc or continental margin. The lithosphere then subsides into the mantle.

A second stage of partial melting of the former oceanic crust, possibly caused by frictional dissipation along a band of earthquake foci known as the Benioff zone, may then occur. Experiments indicate that the products of this second stage of partial melting resemble the dominant volcanic rocks in most island arc regions, the compositions of such rocks being similar to average continental rocks. A parallel differentiation process occurs in the wedge between the Benioff zone and the surface. In this

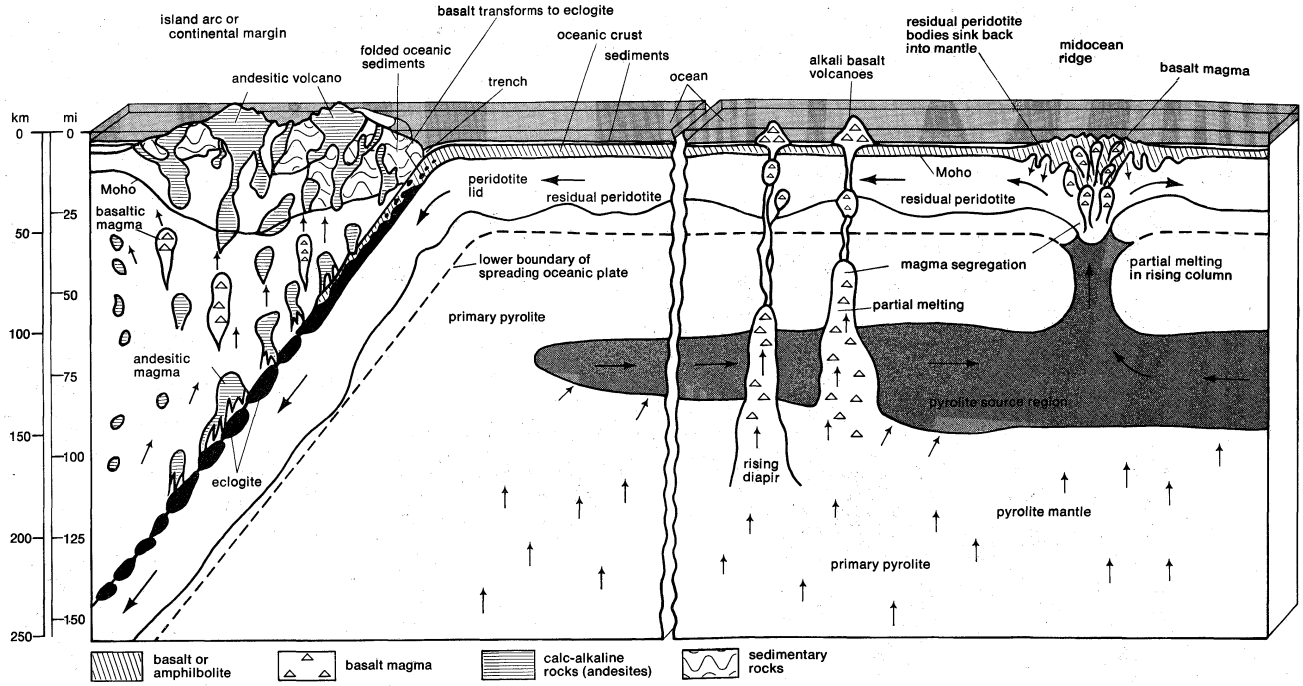

Figure 4: Petrological model of sea-floor spreading, differentiation of the mantle, and crustal evolution.
From A.E. Ringwood, *Geophysical Monograph*

region, water carried down into the mantle in the form of hydrous minerals from the oceanic crust is released by dehydration and enters the overlying pyrolite, lowering the melting point and initiating the production of basalt magmas, which under wet conditions may also differentiate toward andesitic compositions.

It is seen that formation of crustal rocks from the mantle proceeds via two distinct processes characterized by vertical and lateral differentiation, respectively. Vertical differentiation involves partial melting of the mantle and transport of the low-melting components into the crust immediately above. The result is the formation of a residual ultramafic zone in the mantle, a process that has reached its maximum development in Precambrian shield regions. In lateral differentiation oceanic crust is formed at midoceanic ridges; the differentiated mantle and crust is then transported, perhaps for thousands of kilometres, to a trench, where the material sinks into the mantle and remelts at depth to produce andesites.

There is no evidence that crustal rocks were formed during the first 1,000,000,000 years of Earth history, perhaps because the basic sea-floor spreading process did not occur during this period. It is significant that the formation of continental crust entails at least two major stages of petrological differentiation, whereas the formation of oceanic crust is a single-stage process.

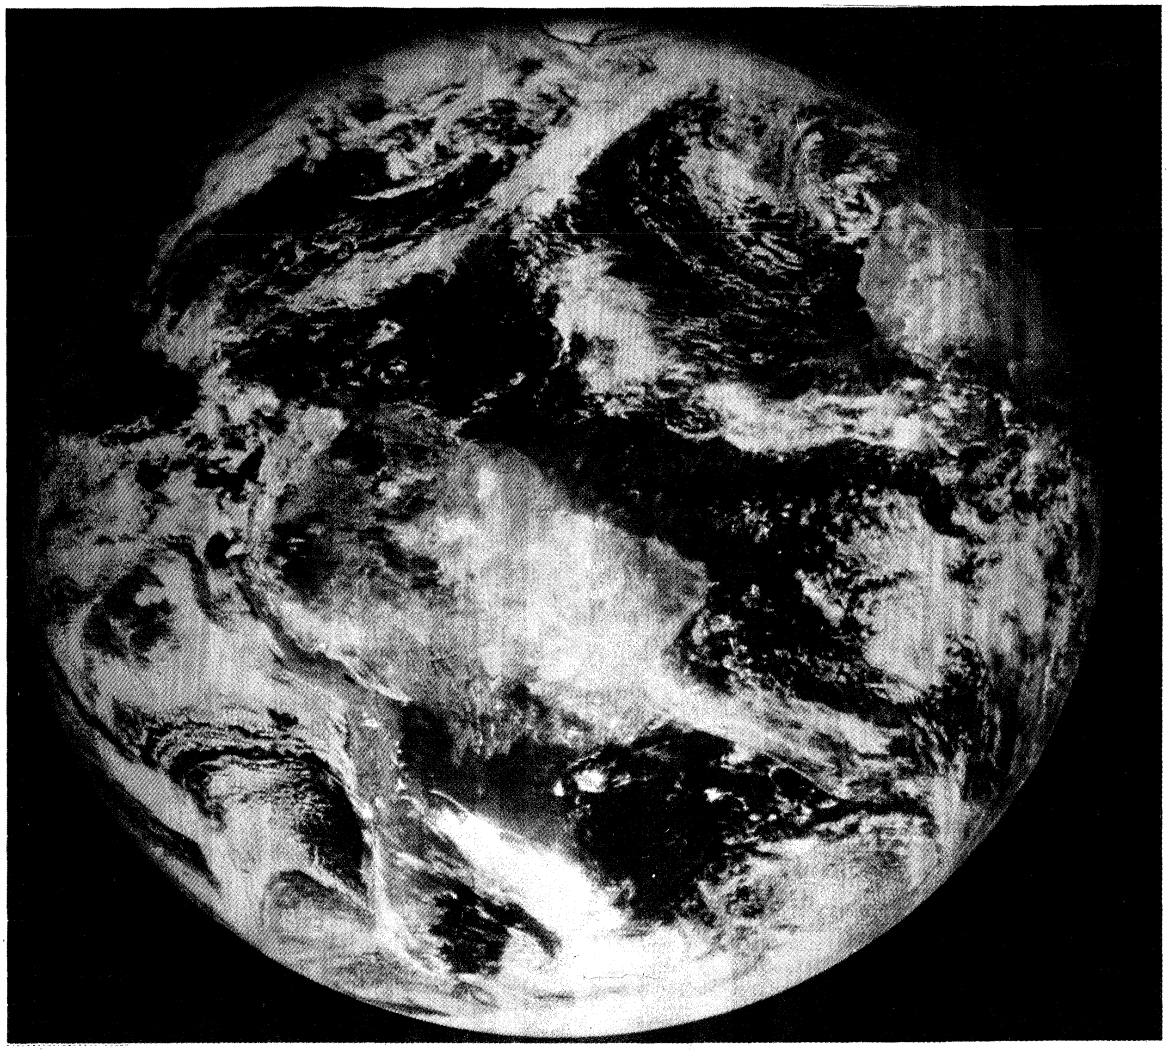
It is apparent from Figure 4 that, petrologically speaking, the sea-floor spreading process may be regarded as being one of irreversible differentiation of an initially homogeneous mantle. The principal products of this differentiation process are the continental crust, on the one hand, and the residual and complementary peridotite and eclogite; on the other. The peridotite and eclogite sinks deeply into the mantle and displaces relatively unfractionated material upward into the low-velocity zone, the immediate source region for the midoceanic ridges. It is improbable that the residual peridotite and eclogite ever participate in further magma generation. It has been estimated that perhaps 30 to 60 percent of the Earth's total uranium and barium has been segregated into the Earth's crust by differentiation processes, and it can thus be argued that a comparable proportion of the Earth's mantle has so far been subjected to the irreversible process of differentiation involved in crustal evolution.

BIBLIOGRAPHY. Useful reviews of the physical properties and internal structure of the Earth are given in the following books: K.E. BULLEN, *An Introduction to the Theory of Seismology*, 3rd ed. (1963); T.F. GASKELL (ed.), *The Earth's Mantle* (1967); P.J. HART (ed.), *The Earth's Crust and Upper Mantle* (1969); B. GUTENBERG, *Physics of the Earth's Interior* (1959); H. JEFFREYS, *The Earth*, 4th ed. (1962); and F.D. STACEY, *Physics of the Earth* (1969). An additional key reference is, "Elasticity and Constitution of the Earth's Interior," *J. Geophys. Res.*, 57:227–286 (1952). The following books contain chapters devoted to several aspects of the chemical and mineralogical composition of the Earth: T.F. GASKELL, *op. cit.;* P.J. HART, *op. cit.;* A. POLDERVAART, *Crust of the Earth* (1955); A.E. RINGWOOD and D.H. GREEN (eds.), *Phase Transformations and the Earth's Interior* (1969); J.S. STEINHART and M.A. TUVE (eds.), *The Earth Beneath the Continents* (1966); and P.J. WYLLIE (ed.), *Ultramafic and Related Rocks* (1967). Papers by S.P. CLARK and A.E. RINGWOOD, "Density Distribution and Constitution of the Mantle," *Rev. Geophys.*, 2:35–88 (1964); D.H. GREEN and A.E. RINGWOOD, "The Genesis of Basaltic Magmas," *Contr. Miner. Petrol.*, 15:103–190 (1967); and A.E. RINGWOOD and D.H. GREEN, "An Experimental Investigation of the Gabbro-Eclogite Transformation," *Tectonophysics*, 3:383–427 (1966), deal with topics less adequately covered in the texts. Principal hypotheses relating to the origin and early evolution of the Earth are advanced in the following references: P.M. HURLEY (ed.), *Advances in Earth Sciences* (1966); H.C. UREY, *The Planets* (1952); F. BIRCH, "Speculations on the Earth's Thermal History," *Bull. Geol. Soc. Am.*, 76:133–154 (1965); A.E. RINGWOOD, "Chemical Evolution of the Terrestrial Planet," *Geochim. Cosmochim. Acta*, 30:41–104 (1966).

(A.E.R.)

Earth as a Planet

The Earth is the third planet in distance outward from the Sun. Many consider the Earth–Moon system to be a unique double planet because the Moon is much larger in comparison with its primary, the Earth, than most other planetary satellites. In the more usual view, the Earth has a single natural satellite, the Moon. Like some other planets of the solar system, the Earth has radiation belts, an ionosphere (part of the atmosphere containing electrically charged particles, or ions), an atmosphere, and a lithosphere, or crust (outer surface); beneath the crust, the deep interior is divided into layers called the mantle and the inner and outer core (see Figure 1). Much more is known about details of the Earth's structure and composition than about those of the other planets because of its accessibility. The Earth has, however, been much changed and differentiated locally because of its active and turbulent history, and,



The Earth from 22,300 miles in space. The National Aeronautics and Space Administration's ATS III satellite transmitted this colour photograph to a ground station at Rosman, North Carolina. It was received at 10:30 AM EST on November 10 from its on-station position at 47° west longitude on the Equator over Brazil. Four continents (portions of North and South America, Africa, and Europe and the Greenland ice cap) can readily be seen, while the Antarctic continent is blanketed under cloud cover. Major weather over the central United States, stretching from the Great Lakes to Mexico, represents a cold front moving eastward. A tropical storm (bottom centre) with a cold front extending into Argentina can be seen.

thus, care is needed in making interpretations. Processes such as volcanism, mountain building, and sea-floor spreading are still going on.

The curvature of the Earth can be demonstrated from ground level in many simple ways—for example, by measurements of Eratosthenes of Cyrene in antiquity (see below). Photographs from rockets in the 1950s clearly showed the curvature of the edge of the Earth (at the horizon), as did later photographs taken from the space vehicle Gemini 4. In the 1960s, for the first time, the Earth was photographed from sufficient distance to show it as a planet, more beautifully coloured and more varied than any other. (See accompanying photograph.) In this picture, cloud patterns show clearly the scale of atmospheric circulation. Below the clouds, the oceans appear blue and the outlines of continents can be seen. The Earth's oceans are probably unique among the planets because of the small temperature and pressure range at which liquid water can occur.

Like other planets, the Earth is approximately a sphere. It spins on its axis (the line joining the points at the surface called the north and south poles) once a day relative to the Sun. This is equivalent to once in about 23 hours 56 minutes 4 seconds relative to the stars (the sidereal day). The sidereal day is shorter than the solar day (24 hours 3 minutes 57 seconds) because the Earth, revolving at the same time about the Sun, must rotate farther, after completing the sidereal day, before the solar day is completed.

This article presents an overview of the Earth as a whole, ignoring the details of its surface features, the oceans, and the atmosphere. Those topics are treated in the articles EARTH, PHYSIOGRAPHY OF; OCEANS AND SEAS; and ATMOSPHERE. For additional information on the Earth's interior, surface configuration, physical properties, and chemical composition see EARTH, STRUCTURE AND COMPOSITION OF; EARTH, FIGURE OF; EARTH, MECHANICAL PROPERTIES OF; and ELEMENTS, GEOCHEMICAL DISTRIBUTION OF. See also the separate articles treating the Earth's gravitational and magnetic fields and its heat flow. The history of the Earth is summarized in the article EARTH, GEOLOGICAL HISTORY OF and the origin and nature of the Earth's principal surface features are treated in MOUNTAIN-BUILDING PROCESSES; SEA-FLOOR SPREADING; CONTINENTAL DRIFT; and OCEANIC RIDGES, among others.

BASIC DATA

Figure of the Earth. The radius from the centre to the poles is not quite the same as that from the centre to a point on the Equator (see the Table), but the concept of the Earth as a sphere is a good approximation. The distance a traveller has to proceed northward in order to make the elevation of the Pole Star increase by one de-

Earth Data

a (equatorial radius)	6,378.188 km (3,963.221 mi)
b (polar radius)	6,356.784 km (3,949,921 mi)
R (mean radius)	6,371 km (3,959 mi)
f (flattening)	0.033523
e (eccentricity)	0.081813
Circumference, equatorial	40,075.51 km (24,902.45 mi)
M (mass)	5.976×10^{27} g
V (volume)	1.083×10^{27} cu cm
Mean density (M/V)	5.517 g per cu cm
Mass ratios: Sun to Earth to Moon	333,400 : 1 : 0.01228
Mean distance from Sun	1.496×10^{8} km (92,900,000 mi)
Earth's speed in its orbit	29.8 km/sec (18.5 mi/sec)
Revolution around Sun	365.25 days
Rotation	23 hr 56 min 4.09 sec
Area	5.096×10^{8} sq km (197,000,000 sq mi)
Land	1.48×10^{8} sq km (57,000,000 sq mi; 29% of Earth)
Highest point	9,521 m (29,028 ft; Mt. Everest)
Lowest point	−10,912 m (−35,800 ft; Marianas Trench)
Lowest point on land	−397 m (−1,302 ft; Dead Sea)

gree is the length of one degree of latitude. The length of a degree of latitude depends slightly on the latitude at which it is measured. This dependence indicates that there is a deviation of the Earth from spherical shape. Sir Isaac Newton was the first to demonstrate that the centrifugal force of the Earth's rotation would tend to make the Earth bulge out at the Equator, giving it the shape of an oblate spheroid (the surface formed by an ellipse when it is rotated about its short axis). Such a surface is flatter near the pole than near the Equator, and one degree of latitude is therefore longer in high latitudes than it is in low ones. Gravity also varies over the Earth's surface, primarily with latitude, being somewhat higher by about 0.5 percent at the poles than at the Equator.

Rotation and precession. Because the Earth revolves around the Sun in 365.25 days, the sidereal day (the exact length of which is 23 hours, 56 minutes, 4.099 seconds of mean solar time) is shorter than the conventional mean solar day by about one part in 365. Astronomical observations show that the Earth is not an ideal timekeeper. The length of the day is subject to certain tiny changes. The most important are (1) a gradual slowing down of the Earth's rotation—*i.e.*, lengthening of the day; (2) small annual or seasonal variations; (3) small irregular variations. The magnitude of the gradual slowing down found from ancient astronomical observations, especially from ancient eclipses and from the more accurate astronomical data available since about 1600, amounts to an aggregated time change of about 30 seconds per century. If this phenomenon is assumed to have existed throughout the Earth's lifetime, the Earth must once have rotated much more rapidly than it does now. The cause of the slowing down has not been established with complete certainty, but most probably it is due to the effect of tidal friction in the oceans. The loss of angular momentum (that is, momentum acquired through rotation) by the Earth is compensated by that gained by the Moon's orbit, which then moves farther away from Earth. The seasonal fluctuations in the length of the day are tiny, of the order of some thousandths of a second per year; they can be explained by changes in the size of the polar ice caps and changes in atmospheric circulation. The irregular changes are equally tiny and can apparently be traced to motions in the Earth's core.

Factors in the changing length of the day

Lacking any external influences, the direction of the Earth's axis of rotation in space would remain the same for all time. Gravitational forces of other members of the solar system, in particular the Moon and the Sun, however, influence the Earth. Because the Earth is flattened, the Moon's gravity tends to tilt the Earth's axis, so that it becomes perpendicular to the Moon's orbit, and to a lesser extent the same is true for the Sun. A spinning body, such as the Earth or a gyroscope, subject to such a force will not, however, yield to it, but the axis of rotation will precess—*i.e.*, move around the surface of a cone in space. This motion of the Earth's axis is known as the precession of the equinoxes (times of equal day and night in spring and autumn). It was discovered by the astronomer Hipparchus in 120 BC and first theoretically explained by Sir Isaac Newton in the 17th century. Precession implies that the pole is not always in the same place among the constellations but moves about; for instance, 12,000 years hence it will coincide with the star Vega. The length of one period of the precession is 26,000 years. The precession makes the Sun's orbit in the heavens (the ecliptic) and its intersection with the celestial equator (the equinoxial points) move in such a direction as always to meet the Sun, at a rate of 50.26″ per year. This change amounts to about 29° since Hipparchus' time; hence the ancient Greek's description of the Sun's yearly path across the constellations no longer fits. The force tending to alter the tilt of the axis is not constant; when the Sun or Moon is crossing the Equator, for instance, it has no effect. The path of the pole is therefore not exactly a circle but contains a superimposed smaller oscillation, the nutation, with a period of 18.6 years and an amplitude of 9.2 seconds of arc. The Chandler wobble, another gyroscopic effect of extremely small amplitude and a period of 436 days, is accompanied by a slight deformation of the Earth's body. The solid body of the Earth undergoes a slight daily tidal deformation caused by the gravitational action of the Moon and Sun, about 25 centimetres (10 inches) at most.

The Chandler wobble

Numerical data. Some quantities relating to the Earth are known with a precision exceeding one part in 1,000,000. Others are known only to within a much lower error limit, and those derived from the latter have corresponding uncertainties. The one most important quantity of the former type is the constant of universal gravitation, $G = 6.67 \times 10^{-8}$ ($cm^3\ g^{-1}\ sec^{-2}$) units, known to about one part in 2,000. The numbers with many digits given in the Table might some day have to undergo revision in the last one or two decimal places, but they are internationally agreed upon as the most likely values.

STRUCTURE OF THE INTERIOR

Data from seismic waves. Two phenomena provide information about the deeper layers of the Earth's interior: seismic waves generated by earthquakes (*q.v.*) and, to a lesser degree, the Earth's magnetic field. There are two main types of seismic waves, the P-waves (primary, because they travel fastest) and the S-waves (secondary, because they travel more slowly and, hence, arrive later at the station than the P-waves). The P-waves are compressional (longitudinal) in nature, whereas the S-waves are shear (transverse) waves. The existence of two types of waves greatly increases the amount of information about the Earth's interior.

Types of seismic waves

The most conspicuous feature of the Earth's interior is the existence of a sharp boundary at which reflection and refraction occur and which encloses the part known as the core; it represents an extremely well-defined discontinuity. The mean radius of the core (ignoring flattening) is 3,470 kilometres (2,156 miles), or nearly 55 percent of the Earth's radius. The most outstanding feature of the core is that it never transmits S-waves. Because the failure to transmit transverse waves is a distinctive char-

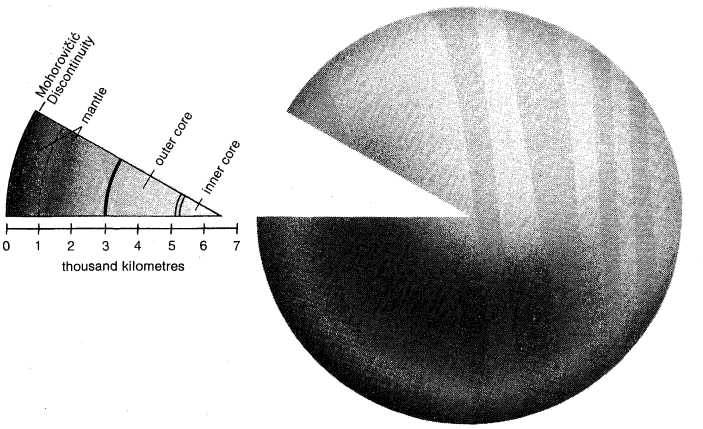

Figure 1: Main layers of the Earth.

acteristic of liquids, it is generally accepted that the core material is in a liquid state, probably mainly of molten iron. Existence of the core was first quantitatively established in 1913. Later studies have shown an additional boundary, somewhat diffuse, which encloses the so-called inner core. Its radius, not precisely known, is about 1,300 kilometres (800 miles). Evidence indicates that the inner core is solid iron (solidified under extreme pressures).

Seismic velocities, density, pressure. In the mantle and the core a progressive stiffening of the material with increasing pressure makes the velocity of seismic waves increase at greater depths. The density distribution cannot be uniquely determined from such data, but certain rather restrictive conditions are imposed on it thereby. A further condition results from a knowledge of the moment of inertia of the Earth about its axis, known with great accuracy from a combination of astronomical and geodetic observations. The moment of inertia about an axis through the centre of a homogeneous sphere, for which m is the total mass and a is the radius, is 0.4 ma^2. Observations show that the moment of inertia of the Earth is 0.334 ma^2, which indicates a rather pronounced increase of density toward the central parts.

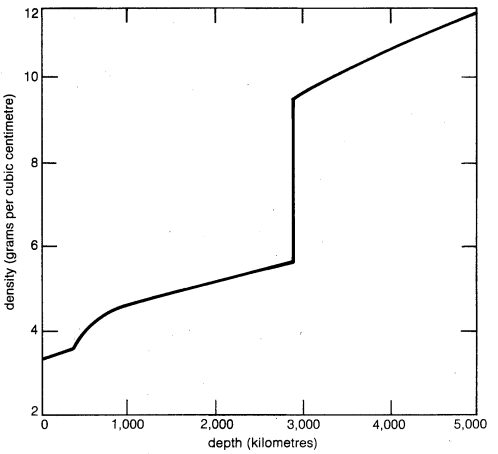

Figure 2: Known density distribution in the Earth down to the limit of the inner core.

The pressure inside the Earth rises rather regularly with increasing depth. In the mantle the rise is at a rate of about 470 atmospheres per kilometre (one atmosphere of pressure equals 14.7 pounds per square inch). The pressure at the boundary of the core is 1,370,000 atmospheres; at the centre of the Earth it is 3,700,000 atmospheres. The strength of gravity is also a function of the depth; it clearly must vanish at the centre. Gravity is remarkably constant throughout the mantle, to within 1 or 2 percent; but, beginning at about the boundary of the core, it decreases steadily to zero.

ORIGIN, COMPOSITION, AND AGE

Formation of the Earth. Astronomers have speculated about the origin of the solar system ever since it was suggested in the 18th century that the stars and planets arose from the condensation of vast gaseous masses filling cosmic space. The formation of the Sun may have occurred much earlier than that of the planets. It is now generally accepted that the planetary system developed out of a disk-shaped mass of gas surrounding the Sun. The original cosmic matter consisted mainly of hydrogen (and some helium), and most of these gaseous components must have been lost to space early from the disk. The less volatile matter condensed, mainly as silicates and metallic iron, these being the prime constituents of present-day meteorites as well as of the interior of the Earth. At the time the gas escaped, the solid matter probably consisted of bodies much smaller than the present planets, because the larger bodies would hold on to a gaseous envelope by gravitation, at least to some of the gases heavier than hydrogen. Most probably, the original solid components were dust grains.

While this picture is crude and speculative in its details, it brings out one crucial point common to all modern theories as distinct from the views held in the 19th century: the original matter from which the planets condensed must have been relatively cold. The temperature in this primary lens-shaped body of gas and dust was probably quite low, because it should readily have been cooled by radiation that could escape in a direction perpendicular to the plane of the disk. When dust congregated to form the Earth, gravitational energy was released and could be transformed into heat, but it is not known what fraction was available for actual heating, because this amount depends critically on the speed of aggregation. If the aggregation was slow, most heat should have escaped by radiation, and this is the most likely case.

Chemical composition. The composition of the Earth's crust can be investigated directly by quantitative chemical analysis of samplings from many rocks. The pioneer in this field was V.M. Goldschmidt, who in the early decades of the 20th century undertook the painstaking task of determining the average proportions of the chemical elements in the Earth's crust. To appreciate the significance of the results it is necessary to compare them with what is known about the chemical composition of cosmic objects other than the Earth. Such objects as meteorites fall upon the Earth from outer space. Meteorites are generally considered to be fragments of a larger solar system body or bodies. Many chemical analyses of meteorites have been made. Next, quantitative determinations of the relative proportions of the chemical elements can be made for the Sun by spectroscopic methods. Finally, though with greater limitations, the same can be done for other stars.

One conclusion long drawn from the vast mass of observations is that the gross chemical composition of matter in the universe is relatively uniform. There might be small variations from one star to the next, but the impression of overall uniformity is strong. Scientists are thus led to think of a definite gross composition of primordial matter from which the Earth and the other planets were formed. The figures given below for the relative proportions (known as cosmic abundances) of the most important elements are from a classical compilation by H. Suess and H.C. Urey (1956). Since the abundances are only relative, they are expressed as the numbers of atoms existing per one atom of a reference substance. The latter is taken to be the element silicon, since rocks consist largely of compounds of silicon. These abundances are as follows:

hydrogen	40,000.0	aluminum	0.09
helium	3,100.0	silicon	1.00
carbon	3.5	phosphorus	0.01
nitrogen	6.6	sulfur	0.37
oxygen	21.5	argon	0.15
neon	8.6	calcium	0.05
sodium	0.04	iron	0.60
magnesium	0.91	nickel	0.03

Remarkably enough, only six of the remaining elements have abundances that lie between 0.001 and 0.0001; all other elements are so rare that they exist only in minutest traces on the cosmic scale.

Location of concentrations of elements in the Earth's layers

On the whole, the lighter compounds are more concentrated in the crust, including oxides and more complex compounds of sodium, magnesium, aluminum, and calcium that form many important constituents of common rocks. Geologists are able to discriminate between rocks of the surface layers and others that have been pushed up from lower layers and should therefore resemble more closely the chemical composition of the Earth's mantle. On the basis of such data it is commonly believed that the Earth's mantle consists primarily of certain compounds (silicates) containing oxygen combined with silicon, magnesium, and iron, three of the most common nonvolatile elements. Sulfur most probably exists in the interior of the Earth in the form of iron sulfide. Geochemical evidence, however, indicates that sulfur is far less abundant on the Earth than the overall cosmic abundance figure given above.

That the core is most probably composed of molten iron is a generally accepted view held for many years; lately the presence of a little sulfur and, in addition, some silicon has been made extremely probable; also there is a small amount of nickel. The view that the core consists of iron fits all the known physical and chemical facts. It is in agreement with the seismic data, and because the melting point of iron at high pressures is much lower than that of the compact silicates, it explains the appearance of a sharp discontinuity at the core's boundary. Iron is by far the heaviest of the common nonvolatile elements; hence it will try to find its way toward the more central parts of the Earth.

Composition of the core

It is at present fairly well established that the inner core consists of solid iron or iron–nickel in almost pure form.

Radioactive age determinations. Geologists early arrived at minimum figures of well over 100,000,000 years for the main part of geological history. The discovery of radioactive decay around 1900 provided an entirely new and much more reliable method for dating events in the Earth's history. Radioactivity consists of the transformation of one species of atomic nucleus into another. In the case of naturally radioactive substances, this transformation occurs spontaneously, and no chemical or physical condition of the environment has any effect on the rate of radioactive decay. In any given interval of time a fixed fraction of the atoms of the mother substance decays into atoms of the daughter substance. Radioactive decay, therefore, furnishes a natural and trustworthy type of clock wherewith to measure the distant past. Only the most long-lived of radioactive substances are useful for dating earlier periods in the history of the Earth (see DATING, RELATIVE AND ABSOLUTE).

The age of the Earth

Attempts have been made to estimate the total age of the Earth under certain plausible assumptions, using data on the relative proportions of lead isotopes in very old rocks and in meteorites. The age arrived at is about 4,600,000,000 years, a figure now well established and believed to be accurate to within a very small percentage of possible error.

MAGNETISM AND TEMPERATURE

Characteristics of the Earth's magnetic field

Earth's magnetic field. The Earth's magnetic field (*q.v.*) has two outstanding characteristics. The first is its irregularity, as seen for instance in the variation of the magnetic declination from place to place, the overall pattern of which is quite complicated. The second is its gradual change in time, a phenomenon well-known to all navigators because the declination of the needle changes continuously. Magnetic maps indicating the declination are seriously in error after a few years and must be redrawn periodically from new observations. This change is known as the secular variation of the Earth's magnetic field. If a variation of 10′ per year continues over, say, 60 years, it corresponds to the considerable change of 10° in declination. The pattern of change is, however, itself variable.

These rapid changes make it clear that the field does not originate in the solid mantle. The magnetic field is caused by electric currents that flow in the fluid, metallic core. The secular variation indicates that the fluid of the core is in motion. This motion carries the electric currents about and thus produces the variation of the field observed at the surface. The details of this variation, rather irregular, may be interpreted as representing so many large-scale eddies in the fluid. From the secular magnetic variation may be obtained a value for the average speed of the fluid iron: 0.03 centimetre per second or about 10 kilometres (six miles) per year. Further development of these ideas leads to the conclusion that the fluid motion not only modifies the electric currents but also can produce and maintain them. This process resembles closely the one that takes place in a rotating generator of electric currents as found in power stations, in which current is produced by the motion of metallic wires past each other. In the core, streams of molten metal are the equivalent of the moving wires. This explanation of the Earth's magnetic field, known as the dynamo theory, has become accepted generally.

Rock magnetism. When a lava melt is solidified in a magnetic field and the field is removed later, the solid rock retains a slight amount of so-called remanent magnetism along the direction in which the original magnetic force pointed. The remanent magnetism is due to small grains of magnetic material (iron oxide) embedded in the rock. It becomes possible to infer from this the direction of the Earth's magnetic field at the time an ancient lava flow occurred. Similarly, sandstones have been shown to retain a small remanent magnetization along the direction of the field in which the material was deposited. The study of rock magnetism (*q.v.*) has been systematically developed, giving information about the character of the magnetic field at earlier times in the Earth's history. There seems to be little doubt that, during the last 500,000,000 years or so that are accessible to detailed geological study, the Earth has had a magnetic field similar to its present one.

Past magnetic reversals

Work on rock magnetism has shown, surprisingly, that apparently the magnetic field has reversed its polarity many times, perhaps hundreds of times during the past history of the Earth—that is, the magnetic south pole became the north pole, and conversely. A detailed explanation of this phenomenon is lacking; it can be said merely that its occurrence is conceivable in terms of the dynamo theory, because a self-excited generator can produce electric current in one direction as well as in the other, depending on its starting conditions. This phenomenon is also seen in some stars.

Temperature and heat transport. There is no direct way of determining the temperature distribution inside the Earth, but it is well-known that the temperature rises in the lower levels of deep mines. The rate at which heat is delivered to the surface is given by the rate at which the temperature rises (the thermal gradient), multiplied by the thermal conductivity, which is a characteristic constant of the material. Thus, by measuring the two last-named quantities, the heat flowing out of the Earth can be determined. The results of heat-flow measurements on the ocean bottom indicate that, even where the oceans are very deep, the heat flow is comparable to that flowing out on the continents. The average thermal gradient in the outermost layers of the Earth is about 25°–30° C per kilometre (70°–90° F per mile) of depth. The average heat flow near the surface of the Earth is about 1.2×10^{-6} calories per square centimetre per second.

Assuming, say, average thermal gradients of 14° per kilometre at some greater depth, the temperature at a depth of 300 kilometres would be about 4,200° C (7,600° F), far above the melting point of any silicate, even at the pressures prevailing at such depth. Hence the temperature must level off; that is, the thermal gradient must radically diminish even at moderate depths inside the Earth. It long has been concluded that most of the heat flowing out of the Earth is produced by radioactivity (mostly from the decay of the uranium and thorium families) and that the radioactive material must now be strongly concentrated in the top layers of the Earth.

It was long believed that most of the radioactive material is in the crust, and because the crust is thick under the continents but thin or almost absent under the oceans, this occurrence would mean that most of the heat flow would occur in continental areas. Heat-flow measurements on the ocean bottom have shown that this view is wrong; it is now usually assumed that heat, especially under the oceans, is also transported by mechanical, convective motions.

In the deeper layers of the Earth it is necessary to rely largely on guesswork, but any assumed distribution is subject to certain conditions. It must remain below the melting point of the simple silicates throughout the mantle, it must be above the melting point of iron in the outer core, and if the inner core consists again of iron the temperature must rise to the melting point of iron at the boundary of the inner core and exceed it inside the latter. The best way to obtain the temperature inside the

Earth is, therefore, to estimate the increase of melting point with increasing pressure. The existing estimates of the temperature in the Earth's interior tend toward relatively low values, perhaps in the neighbourhood of 3,000° C (5,400° F) at the boundary of the core and near 4,000° C (7,200° F) at the centre of the Earth. These estimates, however, may be in error by many hundreds of degrees.

ORIGIN OF THE SURFACE FEATURES

The surface of the Earth shows a remarkable degree of irregular structure. The surface levels cluster around two preferred heights: (1) sea level—most of the areas of the continents and of the offshore continental shelves lie near it—and (2) ocean bottoms, with an average depth of about 5 kilometres (3.1 miles). Levels between these are rare. Another remarkable regularity has to do with the asymmetrical distribution of land and water masses. If a diameter is drawn arbitrarily across the Earth's centre, in more than 90 percent of all cases, one end is on land, the other on the sea. The fact that conclusive explanations, going beyond mere speculation, of such simple regularities cannot be given is indicative of lack of understanding of most of the basic physical and chemical processes that have shaped the surface of the Earth into its present form. The irregularities mentioned are treated in detail in EARTH, PHYSIOGRAPHY OF.

Isostasy. The crust considered as a load on the mantle is less dense; it is specifically lighter than the substratum. Such a load will sink only to a depth at which it is floating freely with respect to vertical displacements; it resembles an iceberg floating in the water with the larger part submerged beneath the surface. According to the principle of isostasy there is a tendency toward vertical equilibrium of the crust. Quantitatively speaking, the total mass encountered on going from the surface down toward the Earth's centre tends to be the same for any point of the surface. Where there is a mountain there seems to be more mass, but isostasy indicates that there must be a deficiency of mass farther down; the mountain has a root consisting of matter less dense than the matter lying under lowlands and the oceans. The root is bigger than the mountain itself; the lighter material extends down to about six times the mean elevation of the mountain.

This idea of isostatic (vertical) compensation was first developed on the basis of gravity observations (see EARTH, GRAVITATIONAL FIELD OF). If ideal isostatic balance prevailed, gravity would be the same over the oceans and continents (apart from variation with geographical latitude). Actually, most mountainous elevations and most oceanic deeps are fairly well compensated isostatically. Deviations, known as gravity anomalies, occur in the regions in which active mountain building occurs, such as the Pacific island areas (*e.g.*, the Japanse islands).

Volcanism and earthquakes

Volcanic activity is concentrated in these same regions, as are earthquakes. Many earthquakes originate fairly near the Earth's surface, but in active regions earthquakes are observed to originate at depths down to 700 kilometres (430 miles). Thus the upper mantle seems to participate to at least this depth in mountain-building.

Deformation of the crust: mountain building. Four agencies have been held responsible for mountain building, either individually or jointly, though it is probable that several (especially the last three) have been acting together.

1. *Contraction*—The Earth resembles a shrunken apple, the mountains and valleys being likened to the wrinkles of its skin. This is the oldest hypothesis, but since the discovery of radioactive heating of the Earth it has been difficult to believe that the Earth has shrunk appreciably in geological times.

2. *Convection*—If the mantle were a viscous fluid heated from below, convective upwelling would occur at a slow rate. If the thermal conditions are right, there must certainly be a tendency toward convection, though the mantle is a plastic solid and not a viscous fluid, and this might make actual patterns look quite different from those of a fluid.

3. *Phase change*—A change in the crystalline structure of minerals, which may occur as a result of either temperature or pressure changes is a phase change. Much evidence shows that at high pressures certain more compact forms of minerals that do not exist at the surface of the Earth are stable. It has been claimed that the Mohorovičić Discontinuity at the bottom of the crust represents such a phase change. Temperature might rise by radioactive heating and this rise could shift the discontinuity downward. Temperature falls again and the discontinuity rises if the heat is carried off by volcanism and other agencies. The tendency toward isostatic equilibrium might then produce fairly large vertical displacements.

4. *Accretion*—Because at increasing depths in the Earth the temperature first rises rapidly and then more slowly, the silicates of the mantle might be closer to melting at a depth of a few hundred kilometres than elsewhere. If melting occurs locally, the material will separate into its lighter components on top and its heavier below. Lighter material might gradually make its way through the overlying layers to the top, and in this manner the amount of crustal material can grow. Volcanism appears to be a process of this kind. The continental blocks of the crust may thus have only gradually accumulated through geological ages. Strong evidence exists that the ocean and the atmosphere are secondary products of accretion—that is, have been slowly formed in the course of the Earth's history from material coming out of the rocks (see OCEANS, DEVELOPMENT OF; ATMOSPHERE, DEVELOPMENT OF).

A more definitive theory of mountain building arose in the 1960s and 1970s. The discovery of the extent and nature of the Earth's mid-oceanic ridges and the fact that sea floor materials became older along paths normal to the ridges led to the concept of sea-floor spreading—that new ocean floor is generated by the upwelling of the mantle along the ridge crests, that it subsequently moves laterally away from the ridges and toward the continents, and that it is eventually subducted or dragged downward back into the mantle along continental margins. These processes are thought to result in both continental drift and mountain building and are further discussed in the article MOUNTAIN-BUILDING PROCESSES.

BIBLIOGRAPHY. The subject of this article is covered by a variety of sciences with a great deal of overlap. There are two major sciences, astronomy and geology, and some minor ones, mainly geodesy, seismology, geochemistry, and geophysics, in its academic rather than its economic context. More detailed bibliographies may be found under the names of the sciences mentioned. In addition, up to about 1965, the subject presented here was almost invariably dealt with in the introductory chapters of treatises on geology, but most of this is definitely obsolete in view of the discoveries of recent years. Therefore, this bibliography is limited to a few relatively recent selected texts arranged in order of ascending technical difficulty.

ARTHUR STRAHLER, *The Earth Sciences*, 2nd ed. (1971), about half of the content deals with matters covered here (nonmathematical); I.G. GASS, P.J. SMITH, and R.C.L. WILSON (eds.), *Understanding the Earth* (1971), some 25 articles by as many authors who are leading experts (readable, nonmathematical); SCIENTIFIC AMERICAN, *Readings in the Earth Sciences*, 2 vol. (1969), an excellent collection containing 74 offprints of articles that appeared in the *Scientific American* between 1948 and 1969—see also current issues of this periodical for further valuable articles; OWEN M. PHILLIPS, *The Heart of the Earth* (1968), introductory for a college science student; FRANK D. STACEY, *Physics of the Earth* (1969), an outstanding text for the advanced undergraduate or beginning graduate student of science with a corresponding mathematics background, including an extensive and carefully selected bibliography; GEORGE D. GARLAND, *Introduction to Geophysics* (1971), a thorough and reliable work that covers several subjects not adequately treated by Stacey; J.A. JACOBS, R.D. RUSSELL, and J.T. WILSON, *Physics and Geology* (1959), a classic text to introduce geology students to the underlying physics with emphasis on those aspects that have direct bearing on large-scale geology; S.K. RUNCORN *et al.* (eds.), *International Dictionary of Geophysics*, 1 vol. and 1 vol. of maps (1967), articles contributed by nearly a thousand authorities, with short bibliographies following the articles.

(W.M.E.)

Earth Movements on Slopes

Hillslopes undergo a permanent development caused by various processes that mold their shape. Of major importance are earth movements that occur under the influence of gravity when the stability of a slope is disturbed either by natural forces or by human interference. Earth movements of the most varied nature depend on the interaction of a number of factors, including the angle of slope, nature of materials, and time.

The great diversity of slope movements can be classified according to the mode and rate of movement, form of the surface of sliding, and the type of earth material moved. The most common downhill movement, almost imperceptible because of its small rate, is called creep, a category that comprises mass movements of a very wide scale, ranging from the creep of slope debris through outward bulging to long-term gravitational slides on mountainous slopes.

Another large group of slope movements includes landslides (landslips), which are rapid movements of earth materials separated from the underlying stationary part of the slope by a definite surface. When the movements occur along a predisposed surface where there is jointing or bedding, the slide is designated as a glide. If a free fall is involved in the movement of blocks of solid rock, the phenomenon is called a rockfall. Slides along newly formed curved surfaces are called slumps, and mass movements involving high-water content are called earthflows and mudflows. On steep mountainous slopes, torrential rains may produce debris avalanches. A special case of flowage and slipping is solifluction; *i.e.*, the movement of a thawed surface layer on the frozen substratum.

Significance to man

Slope movements, which may become a serious economic problem in their extent and recurrence because they often cause great damage to the property and life of men, can be an insurmountable hindrance to human activity. Many disastrous landslides and rockfalls are known to have destroyed whole towns and caused hundreds of deaths. Extensive depreciation of agricultural land, as well as of wooded areas, may also be caused by slope movements. Major slides result in the complete removal or extinction of forest growth; trees are uprooted or become dry. Highways and railways traversing areas susceptible to sliding are not infrequently interrupted by landslides, particularly when the stability of slopes is disturbed during construction. There are cases in which railway lines have had to be abandoned because of permanent danger of sliding movements and consequent high maintenance costs. Slope movements frequently produce serious difficulty during major engineering construction projects, such as tunnels and dams.

Adverse indirect effects of earth movements on slopes include clogging of valleys by landslides that impound temporary lakes that endanger the downstream reaches by flooding after the natural dam has collapsed. Sudden landslides and rockfalls along sea shores also have very disastrous indirect effects. In the Norwegian fjords, for example, landslides often provoke high-water swells up to several tens of metres that are detrimental to the inhabited coast.

Dealt with in this article are the factors that produce earth movements on slopes and the several types of movements that occur in nature. A section on some of the better known historical disasters and their causes also is included. For further information on the types of hillslopes that exist in nature see HILLSLOPES. The strength of rocks and their general resistance to erosion are covered in the articles ROCKS, PHYSICAL PROPERTIES OF; and WEATHERING. Certain aspects of the mechanics of slope failure are covered in SOIL MECHANICS, APPLICATIONS OF.

FACTORS PRODUCING EARTH MOVEMENTS

The variety of landslide types reflects the diversity of factors that are responsible for their origin. Such factors include the character and structure of rocks, the angle of slope, the soil or debris cover, climatic and groundwater conditions, and time.

Debris cover on slopes is generally liable to downslope movements. As mechanical and chemical weathering disturb the cohesion of newly exposed rocks, further material for sliding is continuously supplied. The stability of rocks is also impaired by chemical changes induced by percolating water.

Slopes composed of resistant permeable beds that are underlain by weak, incompetent, impermeable rocks, such as clays, are quite prone to sliding. The underlying clays become saturated with water and are squeezed out by the weight of the hard rocks above. In stratified rocks the contributing factor is the downslope dip of beds. If this slope is undercut by river erosion, then the stability of beds is disturbed, and slipping takes place.

The vegetation cover is also important. The roots of trees maintain stability by their mechanical effects and contribute to the drying of slopes by absorbing part of the groundwater. Deforestation of slopes impairs the water regime in the surface layers and facilitates erosion. The grass mat is gradually worn away so that weathering proceeds more intensively and produces free debris.

Earth movements on slopes are frequently induced by an increase of slope angle. This may be caused by natural or artificial interference; for example, by the undermining of the foot of a slope by stream erosion or by excavation. Exceptionally, the angle of a slope becomes steeper as a consequence of processes such as subsidence or uplift of the Earth's crust. The increase in slope gradient increases the shear stress within the rock mass, and this disturbs the equilibrium.

Effects of earthquakes, groundwater, and climate

Tremors produced by earthquakes also affect the equilibrium of slopes by evoking a temporary change of stress. Some disastrous rockfalls in high-mountain areas (*e.g.*, Peru in 1970) are known to have been caused by earthquakes. In loess (fine-grained silts) and loose sands, shocks can disturb the intergranular bond and thus lower the shear strength. In water-saturated fine sands—those in which water occupies the pore space between all sand grains—and some kinds of clays (quick clays), shocks may result in a displacement or rotation of grains leading to a sudden liquefaction of soil.

The conditions of slopes are greatly affected by groundwater. Flowing groundwater exerts pressure on soil particles that impairs the stability of slopes. In fine sand and silt, groundwater washes out fine particles, and the strength of the slope is weakened by the cavities that are formed. Moreover, soluble cement may be removed and, consequently, the cohesion of rock and the shear strength decreased. If the groundwater is under pressure it acts to uplift the overlying impermeable beds, thus decreasing the stability of slope.

The factors listed above often combine with the influence of climatic conditions, particularly the amount of precipitation and frost activity. Rain and ice meltwater, for example, penetrate into joints (rock fractures) producing hydrostatic pressure, and the increase in pore-water pressure in soils induces a decrease of shear strength.

It has been observed that, under certain climatic conditions, slope movements occur repeatedly in extremely humid years; measurements of rainfall amounts have confirmed that there is a direct relationship between precipitation and frequency of landslides. In Czechoslovakia the monthly rainfall for 70 years of record shows a striking coincidence with the recurrence of slope movements. Systematic examination of such records makes it possible to predict the renewal of slope movements in areas liable to recurrent sliding and to warn of imminent danger.

In clayey rocks, the deleterious effects of atmospheric water are heightened when the rainfall comes after a long dry period: clayey soils are desiccated and shrunken, and water easily penetrates deep into the fissures. The disturbance occurs on the lubricated layer in which the water accumulates.

Among the numerous factors inducing earth movements on slopes, that of time must not be omitted. As the agents change in the course of time, several phases of development occur. These range from the first signs of disturbance of the equilibrium to general loosening of the mass, which is then propelled into motion, travels downslope, and is gradually deposited.

TYPES OF EARTH MOVEMENTS

Rockfalls. Rockfall refers to the abrupt movement of loosened blocks or complexes of solid rocks detached from rock walls. Rockfalls are distinguished by a very high velocity resulting from the free fall. Their size ranges from isolated stones to enormous masses of rock. The stones and blocks that fall build up talus, or debris fans, at the foot of mountain slopes that in some places coalesce into extensive aprons. The slopes of these fan-shaped deposits range from 25° to 40°, depending on shape and form of stone fragments. Floods often carry away the loose material of these fans and deposit it farther downslope.

Origin and occurrence of rockfalls

The origin of rockfalls depends on the morphology of the slopes and on the jointing and fracturing of rocks. Rockfalls are frequent in mountainous areas, particularly in valleys that have been overdeepened by glaciers. Factors contributing to the loosening of blocks are climatic conditions, chiefly weathering, wedging effects of freezing water in joints, hydrostatic pressure of water in open fissures, and pressure of growing roots. The movement can be triggered by the undercutting of steep slopes by erosion or excavation, by earthquakes, or, exceptionally, by thunderbolts.

Hundreds of rockfalls have been recorded from young mountain ranges, such as the Alps, Carpathians, Himalayas, Andes, and Rocky Mountains. One of the largest was the rockfall in the valley of Bartang River, in the Pamir Mountains in 1911. A rock mass of about 4,800,000,000 cubic metres (6,300,000,000 cubic yards) fell and dammed the valley, creating a lake 75 kilometres (47 miles) long and 262 metres (859 feet) deep. When large rock masses drop into a lake or fjord, dangerous huge waves flood the coast. In the Norwegian fjords numerous rockfalls have occurred, and catastrophic results were caused in part by the suddenness of the event.

If a rockfall involves an extremely large mass of rock, the freely falling body detached high from the mountain face may move downslope with a speed of up to 215 kilometres (135 miles) per hour; the blocks are shattered to rock fragments, and the mass movement takes on the character of a flow. Rock streams in the Alps and other high mountains are mostly explained in this way.

Rockfalls are also frequent on rocky shores of lakes and seas, as well as on steep concave banks of erosive river valleys. In these cases the rockfall is an important agency in modelling the cliffs and contributes to the recession of the coastline; the rocks are eroded by waves, the cliff becomes oversteepened, and the upper part of the wall collapses.

Rockfalls also can be responsible for the recession of waterfalls (*q.v.*), particularly when hard rocks overlie less resistant beds. The existence of Niagara Falls, for instance, is threatened by large-scale rockfalls. In 1954 about 185,000 tons of rock collapsed because of undermining by water erosion.

Creep and bulging. The simplest form of creep is the slow, almost imperceptible downslope movement of soil particles and rock debris. Creeping of loose rock fragments is the result of a number of processes, particularly those related to climatic agencies. During the winter months movement is facilitated by the loosening of rock fragments and heaving by frost. Upon thawing in spring, the particles, which have been lifted at right angles to the slope, fall back vertically under the effect of gravity, so that they move a small distance downhill. The creep of slope debris can be compared to plastic deformation occurring in a snow bed on a mountain slope. The rate of movement is greatest near the surface and decreases downward. The expansion of stones by heat and shrinkage on cooling also contribute to the downslope movements, because they are not equal at the upslope and downslope sides of stones. Subordinate effects can be produced by plowing, cattle treading, burrowing by animals, and wedging by plant roots.

Clayey surface layers move slowly downhill by the action of plastic deformation. These movements do not usually develop a discrete slide surface but occur over a wider zone. They are limited to the surface layer, which does not surpass the depth of temperature and humidity effects. Though the deformations amount to only a few millimetres, during the long intervals embraced by geological time they appear as a steady creep of slope deposits.

Creep results in the bending of beds (Figure 1). Friction that is active between the creeping debris and the surface of the bedrock produces a gradual bending of the bed

From Quido Zaruba and Vojtech Mencl, *Landslides and Their Control* (1969); Elsevier, Amsterdam & Academia, Prague

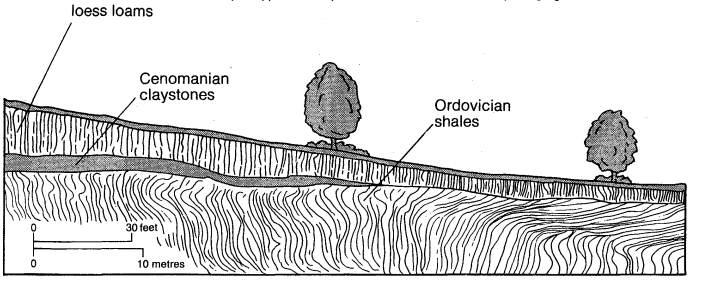

Figure 1: Creep and bending of beds in a loam pit at Prague, Czechoslovakia (see text).

faces cropping out at the surface. The dragged-out and disrupted layers of the bedrock become part of slope deposits, thus increasing their thickness.

Deformation by bulging

In addition to surficial creep, a slow movement disturbing the equilibrium conditions of a slope takes place under suitable conditions at a greater depth below the surface. These earth movements are caused by the squeezing of soft rocks from beneath the more solid overlying rocks. In English literature this phenomenon is designated as bulging; in some countries the result is called a valley anticline. This process involves the plastic flowage of the underlying rocks along a system of surfaces of potential sliding. The instability of the slope is perceptible only during a longer time interval, when the minute deformations have reached measurable values. In the advanced stage these creep phenomena may grade into true landslides.

In some regions the squeezing out of soft rocks in the lower parts of the valley slopes is so widespread that it causes serious economic problems. Bulging was first described from an area of iron-ore mining near Northampton (central England), where valley sides are composed of solid Jurassic limestones and shales (136,000,000 to 190,000,000 years old) that overlie soft Lias clays. Although the beds are nearly horizontal, the near-surface beds of solid rocks are inclined into the slopes, whereas the clays at the foot of the slopes are squeezed upward and contorted. In the initial stage, the bulging appears as a slight anticlinal bend of beds; with advancing deformation the clays are bent into folds, and even small faults may form at the foot of the slope. Although the disturbances extend to several tens of metres in depth, from the geological point of view they are surficial phenomena because they disappear both downward and into the slope where the beds preserve a normal subhorizontal course. This deformation can be interpreted in terms of the upward squeezing of plastic substance from the loaded medium into the unloaded one. The stress that caused the heave of clays results from the difference in the loading of clays in the bottom of the valley and under its slopes.

Figure 2 shows an example of bulging in a river valley near Ostrava (Czechoslovakia). The valley occurs in

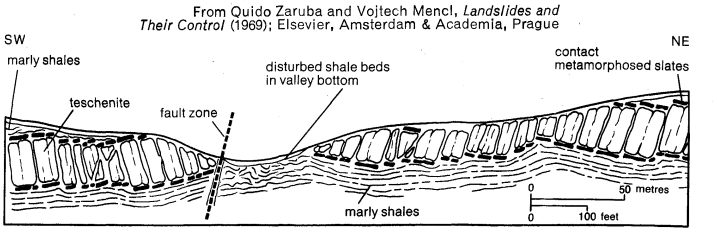

Figure 2: Squeezing-out of marly shales on the valley bottom of the Lucina River, Czechoslovakia.

marly shales of Cretaceous age (65,000,000 to 136,000,000 years old) that are pierced by sills of very firm volcanic rock called teschenite. The section shows that the teschenite body is broken into several blocks by a system of faults running roughly parallel to the valley. The soft shales that are squeezed out by the heavy rock blocks move toward the stream, which gradually carries them away. The main deformations probably occurred about 230,000 years ago, during the Pleistocene Epoch (10,000 to 2,500,000 years ago), because the steps between the blocks are filled with slope debris and loess loam.

The possible development of such deformations under present climatic conditions of the temperate zone has been the subject of much consideration. In general, squeezing of the substratum may occur whenever (1) the soft rocks within a limited area are released from the weight of the overlying rocks, and (2) this release gives rise to stresses, which, even if they do not surpass the shear resistance of plastic beds, may, if they last long enough, result in deformations.

Because the character of motion is essentially like that of creep, some long-term deformation of mountain slopes can be included in this group of earth movements. They consist of movements along planes of separation, such as planes of stratification, schistosity, or jointing.

Many analogous phenomena have been observed in young mountain ranges such as the Alps or Carpathians and occur most frequently on the slopes formed of phyllites, mica schist, and other metamorphic rocks that can be deformed by differential movements.

Movements related to creep can grade into sliding when a slide surface develops in the course of time and the movement is accelerated.

Landslides and debris slides. Landslides include a multiplicity of downslope movements, which, in contrast to creep, occur along well-developed surfaces. A landslide occurs when the stability conditions of the slopes are disturbed either by the increase of shear stress imposed on the slope, or by the decrease in shear strength of the rock building up the slope. The factors and processes that may provoke the change in the state of equilibrium have been mentioned previously.

Slide characteristics

The sliding movements involve bedrock or surficial deposits, but very often both bedrock and its cover are involved. The part of the slope that moves separates from the remaining mass along the plane of least resistance (Figure 3). This slip surface is commonly formed by a bedding, joint, or fault plane. The movements are generally rapid and originate when the planes of separation dip downslope and their continuity is disturbed at the foot of the slope. In stratified rocks with smooth, even bedding planes, the dip of beds is usually the maximum inclination at which the slope is permanently stable. If the beds are undercut by stream erosion, they maintain their position only by friction, which increases with the roughness and unevenness of the bedding planes. Friction can be reduced by climatic factors: freezing and thawing of interstitial water, or by hydrostatic pressure of water in the joints if the free outflow of water is obstructed. Failure can also be provoked by the increase of slope angle, as a result of uplift of the Earth's crust.

From Quido Zaruba and Vojtech Mencl, *Landslides and Their Control* (1969); Elsevier, Amsterdam & Academia, Prague

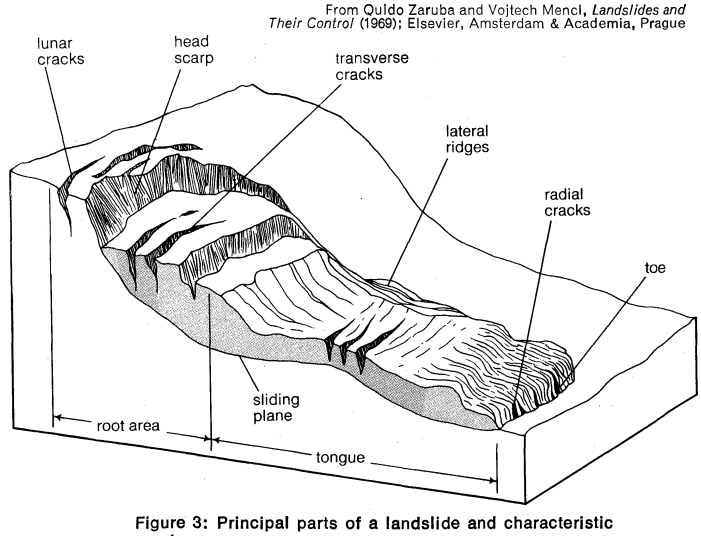

Figure 3: Principal parts of a landslide and characteristic cracks.

Rock slides on bedding planes or other surfaces of separation may be disastrous in mountain areas where, because of great height differences, the movement attains an acceleration nearly equal to that of a rockfall. In steep mountains the conditions are favourable for rock slides, because streams with steep gradients cut readily into the bedrock, and the adjustment of the slopes cannot keep pace with erosion. The stability of slopes is particularly threatened when the dip is toward the valley.

Debris slides—movements of shallow slope debris and weathering materials above the bedrock—are categorized with landslides. Debris slides involve materials of only a few metres in thickness but may cover wide areas in some regions. On disturbed slopes, various stages of slipping are observable, from initial fissuring of the weathered layer up to advanced forms with several generations piled on top of one another. Debris slides generally occur after a heavy rainfall or spring thaw. Rainwater soaking into the soil lubricates the surface bed of the unweathered rock, on which the disrupted top layer slips down. In the other case, during the freezing of the ground the surface layers of debris are enriched by water rising by capillary action toward the surface from the lower unfrozen beds. During the spring thaw the water produces slaking of the surface layer and reduces the internal friction and the stability of slope.

Slumps, earthflows, and debris avalanches. The type of slope failure known as slump is common in homogeneous, poorly consolidated clayey rocks, such as clays, marls, claystones, and clayey shales. Slide-promoting forces are increased by the undermining of the slope by erosion or by excavation or by the overloading of its upper part.

Form and occurrence of slumps

Slumps have a characteristic form. The mass usually tears off along a concave head scarp and moves down a curved slip surface to accumulate at the foot of a slope, spreading laterally. Inside the sliding rock mass some minor scarps originate, so that it is broken into blocks that are tilted toward the slope. In the depressions of the hummocky surface, water accumulates into small lakelets, thus contributing to the instability of the slope. On either side, the mass is squeezed into longitudinal ridges that are often striated. The whole body is cut by cracks of different arrangement. Slumps may gradually increase by backward caving of the head scarp. The movement generally occurs along partial cylindrical surfaces, but the resulting slip surface is somewhat distorted. The depth and shape of a slump adapt to the geological structure of the slope.

Slumps of large dimensions are frequent on river valley slopes and sea coasts. Along some valleys deep slumps occur side by side, and the interlocking alcoves enlarge the slide area laterally. Slide material that weights the foot of the slope may help to restore the equilibrium of the slope, but tongues of the slumps are generally washed away during floods or by waves, and advancing erosion includes further movements. Typical examples of these slump movements are known from the coast of England near Folkestone (Figure 4), and from the valleys of some rivers (Volga, Moskva, Dnepr, and others) in the Soviet Union.

On the lower parts of slopes, slumps frequently grade into flows, the shape of which is controlled by the topography. They move as sheets or streams that fill the erosion gullies or valleys. These movements, called earthflows, debris flows, or mudflows, according to the material and consistency of the mass, represent a separate type of slope movement, one that differs from the slumps because of the higher water content that produces motion of flow type.

Earthflows generally originate in a large basin in the upper part of the slope, where debris and weathering ma-

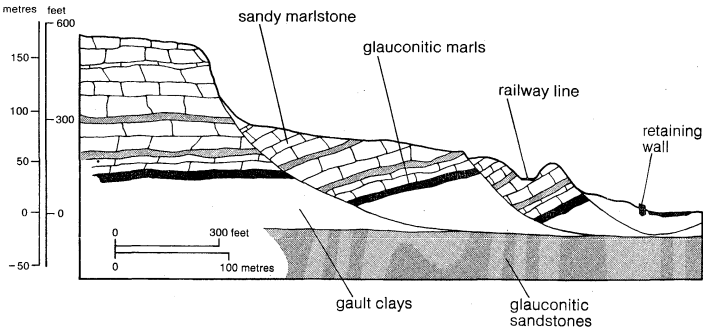

Figure 4: Landslide on the seashore near Folkestone, Kent.

Role of water saturation

terial have accumulated. The movement is usually triggered by heavy rainfall. Interstitial water increases the weight of the debris cover and greatly reduces its shear strength. The loosened mass flows toward the foot of the slope, forming a loaf-shaped bulge. When it flows down a valley, it moves at a rate greater than is achieved over the slope surface, because water-saturated debris packed into a narrow tongue contacts the substratum over a smaller area; consequently, the friction is smaller. When all loose material has been emptied from the source area, the earthflow gradually becomes stabilized and overgrown with vegetation. If part of the debris remains there, heavy rainfall may provoke further movement, and the bulge at the toe will be overridden by younger material.

With increasing velocity earthflows grade into debris flows. Mountainous debris flows are sometimes called avalanches or Muren, a term currently used in the Alpine countries. As a rule, they originate above the timberline in gorges filled with rock detritus. During torrential rains, debris and larger stones travel at a tremendous speed down the stream channels. The material is unsorted, and the ratio of solid particles to water is about 1:1. The rates of flow are so great that moving trains have been trapped and buried beneath debris avalanches. The Muren are very disastrous and often result from too great deforestation of mountain slopes. Scarcity of vegetation is also responsible for much-feared debris and mudflows in arid and semi-arid regions. This group of slope movements also includes volcanic mudflows. Volcanic explosions are usually accompanied by torrential rains that wash ash and ejected material downward as a mushy mass. Debris flows occasionally originate on the slopes of dormant volcanoes that are covered by glaciers. When volcanism recurs, the increase in heat before and during the eruption suddenly melts the glaciers, and the waters bring much debris downhill.

Solifluction. Solifluction is a combined flow and slip movement, which involves the surface layers on slopes in the subarctic region and, to a lesser extent, high mountain regions. The deeply frozen surface layers thaw to only a small depth during a short summer. Meltwater and precipitated water saturate the soil because they cannot percolate into the frozen, impermeable substratum, and the waterlogged bed flows downslope as a dense sludge. Solifluction may occur even on a rather moderate slope, because the soil moves readily on the frozen substratum.

Failure of quick clays

Another somewhat special type of flow movement involves clay sediments of marine origin and is common in Scandinavia and Canada. These sensitive clays, called quick clays in Norway and Leda Clays in Canada, cover flattish areas situated about two hundred metres above sea level. The strength of these sediments progressively decreases because of the decrease of salts in the pore water. The ground and atmospheric water impoverish the salt content by osmotic processes. The decrease in salt concentration in pore water goes hand in hand with the decrease of bond between the clay particles and the bound water, and thus with the decrease in strength. Remarkably, the drop in strength is greatest toward the end of the process. The loss of strength results in a flow movement of unusually great rapidity. The failures of quick-clay slopes are treacherous because they may affect areas that are nearly flat.

One of the largest failures of this type occurred near Verdalen, north of Trondheim, in Norway in 1893. A layer of sensitive clay was laid bare by stream erosion. The liquefied clay, with a volume of 55,000,000 cubic metres (72,000,000 cubic yards), flowed down in 30 minutes. The dense liquid covered an area of 8.5 square kilometres (3.3 square miles) and destroyed 22 farms. The flat terrace in the broad valley of the river Veddalselva is suggestive of absolute safety today, but the monument bearing the names of 111 people who were killed in 1893 testifies to the catastrophic possibilities.

CHARACTERISTICS OF UNSTABLE SLOPES

Slopes disturbed by sliding movements show a characteristic configuration: the head scarp is arcuate with a spoon-shaped depression, and the topography on the downslope side is hummocky and irregular. In active landslides the features are clear cut, whereas in the dormant, temporarily inactive landslides, the forms are effaced by rainwash and erosion or covered by vegetation. An important characteristic is the shape of the slope in cross section. Even a very ancient landslide is recognizable from its convex bulged toe made up of the accumulated slipped mass.

The growth of trees on unstable slopes reveals the presence and age of sliding movements. Trees, which on unstable ground become tilted downslope, tend to return to a vertical position during the period of rest so that the trunks are conspicuously bent. From the younger, vertically growing trunk segments, the date of the last earth movement can be inferred.

For distinguishing the slide areas, the presence of particular plants can be of help. Horsetail (especially *Equisetum maximum*) and horsefoot (*Tussilago*) are good indicators of slopes that are prone to sliding. Horsetails contain 50–60 percent silica and 19–30 percent potash in the ash. This high content suggests the presence of potassium and hydrated silicates in the soil and explains why horsetails thrive on sliding areas formed of potassium-rich (*e.g.*, glauconite-bearing) rocks.

The earth processes and factors that cause slope movements and the characteristics noted are intensively studied because they present serious hazards. Geologists and specialists in soil and rock mechanics endeavour to decipher the reasons for slope instability and to determine how fast and how far the loosened rock mass will move. Although some slope failures will remain unpredictable for a long time, at least those disasters caused by human interference can be avoided.

HISTORICAL DISASTERS

The Hope, British Columbia, rock slide

No warning devices can be effective in the case of a slope failure provoked by an earthquake; the so-called Hope rock slide in the Cascade Mountains, Canada, was such an occurrence. In January 1965 a block of about 140,000,000 tons buried the British Columbia Highway for more than three kilometres (two miles) to a depth of about 90 metres (300 feet). The movement was so rapid that the rock mass buried three cars that were in motion, and some people lost their lives. It is one of the largest slides recorded in North America, involving a volume of 47,000,000 cubic metres (61,000,000 cubic yards). The coarse rock detritus descended from an altitude of about 1,200 metres (3,900 feet) in several surges and was deposited on the valley floor. Muds were driven up the opposite slope, and the effect of the air blast and dust cloud extended far along the valley. Under contributive geological conditions—such as schistosity and jointing parallel to the surface and readily weathering serpentinite and carbonate rocks filling the fissures—the movement was triggered by an earthquake. It is of interest that a much stronger earthquake in 1872 did not threaten the stability of this slope. The earthquake in 1965 proved to be more effective, probably because it had a shallow focal depth and a suitable frequency and orientation of the horizontal shock-wave component.

The largest rock slide known to have occurred in Central Europe occurred near Flims, in the Graubünden Canton, in Switzerland. The stability of the mountain slope, formed by Jurassic marly limestones dipping moderately (7°–12°) toward the Rhine, probably was disturbed during an interglacial stage of the Pleistocene, after the retreat of the valley glacier. A huge block of rock, about 12 cubic kilometres (three cubic miles) in volume, slid down a bedding plane, and the head scarp, called Flimserstein, is still clearly visible. The moving mass must have attained a great velocity because it rose 150 metres (500 feet) up the opposite valley slope. The Rhine Valley was blocked over a distance of nearly 15 kilometres (nine miles), and a lake was impounded. Only when the river had again deepened its channel did the lake dwindle away.

The Mt. Rossberg, Switzerland, rock slide

The disastrous slide that took place on the slope of Mt. Rossberg in Switzerland in 1806 buried the town of Goldau. A complex of Tertiary conglomerates about 20,000,000 years old slid along a bed of bituminous marls dipping 19°–21° downslope. The loosened block was 1,700–2,000 metres (5,600–6,600 feet) long, 300 metres (1,000 feet) broad, and 60–100 metres (200–320 feet) thick. Its total volume was estimated at 40,000,000 cubic metres (52,000,000 cubic yards). In this case, several people were eyewitnesses to the movement. Some saved their lives by jumping over the marginal crack, but within one or two minutes the rock stream had reached a stupendous velocity and destroyed several villages in the valley. Because the slope had always been stable before, the question of the forces that had disturbed its equilibrium was extensively discussed. The origin of the rock slide was explained by three main factors: (1) orogenic forces might have caused a gradual increase in the angle of slope until the coefficient of friction on the bedding plane underlying the loosened block was surpassed; (2) friction may also have been reduced as a result of weathering of rocks on the bedding plane; (3) hydrostatic pressure of water in the bedding joints may have increased after rainy years and caused the uplift of the loosened block. A reinvestigation in 1950 of the reasons for the catastrophe led to the conclusion that it could most plausibly be explained by the increase in the inclination of slope by tectonic movements or by the decrease in the bond between the slide block and the substratum due to weathering.

The catastrophic Vaiont landslide in the Italian Alps in 1963 is analogous. A huge mass of Jurassic limestone of about 260,000,000 cubic metres (340,000,000 cubic yards) slid along a bedding plane into a reservoir, soon after it had been filled for the first time. The greatest damage was produced by a water wave 100 metres (330 feet) high, which overflowed the dam and destroyed and damaged several towns in the Piave Valley.

One of the oldest reports on slope failure is that of Marius of Aventicum, who was bishop in Lausanne toward the end of the 6th century. In his chronicle he describes a rockfall, which took place in the year 563 on Mt. Tauretunum. The rock mass fell into Lake Geneva, producing a large wave that devastated the shore and destroyed all settlements far inland. The rockfall that occurred in Italy, near Rovereto on the river Adige in 883 must have been of an extreme size. It is reported that the rock mass buried a town and blocked the river so that the town of Verona was deprived of water for a long time. Even if Dante's account of this catastrophe in his *Divine Comedy* is poetically exaggerated, the disaster was undoubtedly enormous, as evidenced by the debris field extending in the valley to a distance of several kilometres (Slavini di San Marco).

The Folkestone, England, landslide

An example of extensive sliding on sea coasts is the well-known landslide near Folkestone, in southern England. Upper Cretaceous rocks overlie the Gault Clays on a steep bank. During the last hundred years a number of large landslides have interrupted the Dover–Folkestone railway line several times. The motivating force is marine abrasion of clays at sea level, which results in unloading of the foot of the steep bank and, consequently, in slumping along the curved slide surfaces. Stability is decreased by hydrostatic water pressure in the fissures and joints traversing the Cretaceous rocks. Tests on samples taken in borings have revealed that the Gault Clays near the slide surface possess only a small part of the strength of the undisturbed clays. During every new landslide, clays at the toe are squeezed out and heaved into a ridge that rises as an island from the sea; in the course of time the ridge is removed by abrasion until it disappears completely. If the erosion of squeezed-out clays could be prevented, the danger of sliding would be diminished, because their weight contributes to the stability of the slope. Therefore, thick retaining walls with transverse buttresses have been built along the shore to protect it from abrasion and make possible the deposition of coastal sediments.

Disastrous slope failures were often provoked by ill-founded quarries. In 1618 the undermining of the slope of Monte Conto, north of Lake Como, by pits on talc schists promoted a rockfall that destroyed Plurs, a rich and well-built town, and buried more than two thousand inhabitants. Near Elm, in the Swiss Alps in 1881, a rockfall was caused by the undermining of the slope by a slate quarry. In a few minutes more than 10,000,000 cubic metres (13,000,000 cubic yards) of rock fell; 83 houses were demolished, and 115 lives were lost.

The Frank disaster

Mining operations set the stage for the rock slide in 1903 that destroyed part of the town of Frank, below Turtle Mountain, in Canada (Figure 5). The mountain ridge above the town consists of solid limestones that are thrust upon relatively soft sandstones and shales. Limestones dip 50° toward the slope and are strongly jointed; the sandstones and shales are intensely folded and steeply inclined. Part of the slope broke off across the bedding plane, and more than 30,000,000 cubic metres (39,000,000 cubic yards) of rock debris covered the valley plain. The failure was almost instantaneous, lasting less than two minutes. Movement was provoked by deformation following the exhaustion of a coal seam at the foot of the slope and by the wedging effect of freezing water in the fissures.

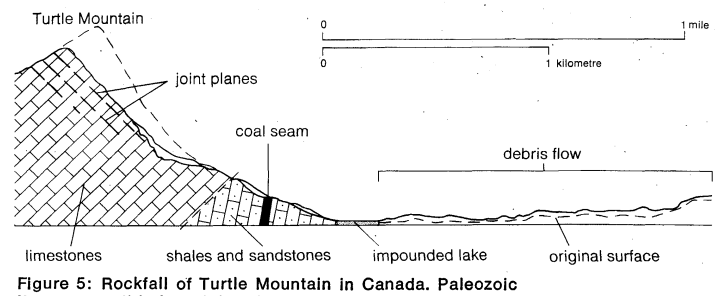

Figure 5: Rockfall of Turtle Mountain in Canada. Paleozoic limestones slid along joint planes.

Slope failures may likewise be induced by careless excavation works for transport routes and dam abutments, by sudden lowering of the level of lakes, and others. This type of human interference represents the trigger for many slope failures; the basic cause is a particular combination of topography, geology, and climate.

(Q.Z.)

Earthquakes

An earthquake commonly is described as a sudden individual tremor within the Earth that creates shaking at the surface. Many earthquakes disturb the surface only to a degree observable with sensitive instruments, however, and some authorities therefore refer to earthquakes as the generation of elastic waves (seismic waves) in the Earth rather than to physical shaking.

In addition to sudden events, there are gradual effects such as slow creeping of earth materials that are closely related to the production of earthquakes. Earthquakes often occur in succession, or in earthquake swarms, the effect of which is that of continuous disturbance. Other causes, largely meteorological, produce waves that are recorded on seismograms and often go on for hours or days; these are known as microseisms, but ordinarily they are not considered as earthquakes. Recently, certain extremely small individual events have been called microearthquakes. A final category includes artificial earthquakes, which are produced by man through disturbance of subsurface conditions by any of several means.

Earthquake damage and precautions

Earthquakes have been objects of concern and superstitious awe through most of recorded history. No other natural event is disastrous over so large an area in so short a time. Lives lost as a result of a single earthquake often range to the tens of thousands, sometimes to the hundreds of thousands. Nearly all this loss and most of the enormous accompanying damage are unnecessary and preventable; it generally is caused by the collapse of weak structures that would not be erected under any modern system of building regulation and inspection. Persons are crushed and buried under these falling structures, or are burned to death in fires that rage out of control following building failures. In addition, many casualties and much damage have resulted from tsunamis, the great sea waves that have swept coastal areas on the heels of large earthquakes.

The most generally important application of earthquake study is directed toward abatement of earthquake risks. Knowledge of the behaviour of structures during earthquakes has led to recommendations for safe construction of ordinary small buildings. Geographical study has revealed the areas of greatest earthquake risk, which therefore should be avoided unless special precautions are taken. It is generally known today, for example, that soft foundations—those in alluvium, sands, or artificial fill—are much more unstable than those in solid rock.

Specific earthquake warnings are at best only a hope for the distant future; but tsunami warnings are a present reality. Tsunami waves travel much less rapidly than the earthquake disturbance that creates them, and seismological stations often record an earthquake long before the sea waves can reach populated coasts. A Pacific warning service is in operation with headquarters near Honolulu.

Many other important applications result from earthquake or seismic study. Earthquake waves are used to investigate the interior of the Earth as a whole as well as the geology and subsurface structures of an area being investigated for oil or minerals. There exists a highly developed industry and profession of geophysical prospecting by seismic methods, using recordings of small artificial explosions. Similar procedure on a global scale, using the relatively high energies released in nuclear detonations, has advanced man's knowledge of the innermost parts of the Earth. Much effort also has been directed toward the detection and identification of nuclear tests; this involves distinguishing nuclear explosions from natural earthquakes.

This article treats of the causes and distribution of earthquakes and their magnitude, motion, and energy. For further information on the instrumentation involved, see SEISMOGRAPH; for the utilization of earthquake data in general Earth studies, see EARTH, STRUCTURE AND COMPOSITION OF; and ISLAND ARCS; and for additional details of the nature and transmission of seismic waves, see WAVE MOTION; ELASTICITY; and EARTH, MECHANICAL PROPERTIES OF.

CAUSES OF EARTHQUAKES

Natural causes: rock fracture and volcanism. Earthquakes can originate in various ways but one principal cause is responsible for all large earthquakes and for a majority of small ones. This is the fracturing of rocks in the outer part of the Earth as a result of the gradual accumulation of strain during geological processes. Sudden fracture occurs when strain exceeds the strength of the rocks; generally, rupture follows established lines and surfaces of weakness, which are active geologic faults. Fracture usually begins at depths of 17 to 34 kilometres (11 to 21 miles) or much more; but in large earthquakes, it often extends to the surface, and relative displacements of the two sides are observed along the line or zone of intersection between the fault and the surface. This fault displacement may be vertical, horizontal, or both (Figure 1).

Figure 1: The Garlock Fault, California, looking west.

The ultimate cause of distortion and faulting is the same as that responsible for the warping and breaking of the crust of the Earth during geological time, thereby producing mountain ranges and ocean basins. An earlier generation of workers confidently attributed all this to the wrinkling of the surface of a cooling and shrinking Earth. That idea gradually became untenable and is being replaced by variations of a hypothesis that the flow of heat within the Earth causes transfer of material by convection, and that these slow but inexorable motions provide the driving forces for geologic changes. The latest and most fruitful development, called the new global tectonics, has revived the temporarily neglected idea of continental drift and combined it with the new notions of sea-floor spreading and transform (offset) faulting, phenomena that are substantiated by the paleomagnetic history of oceanic rocks (see further SEA-FLOOR SPREADING).

The most important of the minor causes of earthquakes is volcanism. Earthquakes are caused not merely by explosions and other eruptive processes, but also by gradual displacements of subterranean volcanic material, or magma.

Artificial earthquakes. Artificial earthquakes include all quake events that are in some way induced by or related to man's activity. These range from the vibrations produced by machinery and common vehicular traffic to the shocks of underground nuclear explosions; the former yield a seismogram pattern that is akin to that associated with naturally occurring microseisms and the latter produce a pattern quite like that of natural major quakes. Two other means of inducing earthquakes involve dam and reservoir construction and the underground injection of liquids through wells. The earliest relevant observations of shocks associated with dams and reservoirs were made in the area of Lake Mead on the Colorado River. Special recording over a number of years showed that these events correlated with changes of water level in the reservoir, being most frequent when the level was changing most rapidly. This indicated that instability existed among the Earth's crustal blocks in the area but that the quakes were artificially triggered. Several other large reservoirs were monitored during the construction and filling periods, but no similar results were obtained. Local earthquakes, however, have been correlated with the filling of large reservoirs in Greece, Zambia, and India. The last culminated in a destructive earthquake at the town of Koynanagar in 1967, although the Koyna Dam and Reservoir were not seriously damaged.

Changes in overlying and subsurface pressures

A series of earthquakes began suddenly in 1962 in the vicinity of a deep well near Denver, into which liquid wastes were being pumped. The shocks clearly were associated with the pumping, allowing for a time lag. The largest shocks caused some damage in Denver, where perceptible earthquakes otherwise have been infrequent. After pumping terminated, these earthquakes continued, and one of the last events was the largest of the whole series. These later events also were farther from the well. It is inferred that the pumping disturbed the equilibrium of the subsurface layers of rock and thus triggered the earthquake process.

DISTRIBUTION OF EARTHQUAKES

Geographic and geologic occurrence. Detailed knowledge of the geography of earthquakes depends on sensitive seismographs, which record all earthquakes of consequence, even at the greatest distances. Data from one well-equipped station would suffice for complete global listing of major events. With hundreds of stations now in continuous operation, cataloging extends to events of lesser magnitudes.

An early, unexpected finding was that the majority of earthquake sources occur beneath the sea. The greatest submarine seismicity is usually near continental coasts or island chains, so that the larger events often have strong effects on land. Nevertheless, the large earthquakes that attract public attention constitute only a minor fraction of those identified by seismographic recordings.

Historical listing is likely to give a disproportionate impression of the seismicity of Mediterranean Europe, northern Africa, and the Near East, because centres of population there include many examples of weak and ancient types of construction. These tend to fail under comparatively moderate shaking, often resulting in appalling loss of life (for example: 12,000 killed at Agadir, Morocco, in 1960). Even seismographic catalogs may lead to an erroneous conclusion simply because there are a relatively large number of good recording stations in Europe and because there is exceptional interest in earthquakes occurring there. This causes many small events to be studied and included in published lists, whereas larger and more numerous earthquakes in remote parts of the world may not be sufficiently recorded because their locations are not precisely known. This unevenness in treatment is gradually disappearing as more and more stations are established.

Major earthquake activity is primarily confined to comparatively narrow belts; this is particularly true beneath the sea. On the continents there are some broad areas, as in eastern Asia, where earthquakes occur along a sheaf of roughly parallel fault zones. Small earthquakes are more generally distributed, and there are few large areas without them.

Seismicity in the Pacific and Alpine belts and in the oceanic ridges

Most earthquakes are shallow in the seismological sense; they originate within the rocks of the Earth's crust, above the Mohorovičić Discontinuity, which separates the crust and mantle. In certain regions, however, particularly around the Pacific, there are deep-focus earthquakes that occur at depths of more than 700 kilometres (450 miles) below the surface; their sources are chiefly within comparatively thin slablike zones that are inclined at angles of about 45°. Usually the inclination is toward the continents, but generally it is toward the concave side of island arcs. For this reason, the dip is toward the Pacific in the New Hebrides and some other areas.

Shallow seismicity is associated mainly with: (1) the circum-Pacific belt of active structures, particularly the island arcs; this includes various branches, one extending into Indonesia and another around the Caribbean; (2) the trans-Asiatic belt, extending from Mediterranean Europe to the Pacific, with the relatively narrow Alpine belt along its southern margin; (3) the midoceanic ridges, now considered to form a connected worldwide rift system.

Earthquakes are nearly absent from much of the ocean basins, notably between the midoceanic ridges and the zones off the continental coasts; the Hawaiian rift structure is a conspicuous exception. They are also relatively sparse in the central, stable areas of the continents—the oldlands or shields, such as the Canadian Shield, the Brazilian Shield, and the Baltic Shield. The absence of earthquakes on the Antarctic continent is well confirmed, except for small ones near active volcanoes and a few that appear to be icequakes rather than ordinary earthquakes. These result from the fracturing of large ice masses.

Major seismicity in the circum-Pacific and Alpine belts is regionally associated with the youngest mountains, whereas minor earthquakes, and occasional large ones, occur in the areas of older mountain building, such as the Appalachian region of the United States, the southernmost part of Africa, and southeastern Australia.

Occasional large earthquakes occur in unusual locations. In 1811 and 1812, large earthquakes originated in the Mississippi Valley, centring not far from New Madrid, Missouri; they were comparable to the largest earthquakes of record in the western United States.

Tectonic theories must account for the orderly association of earthquakes and other geophysical phenomena with active island arcs of the Pacific type. In such an arc, there is a succession of definite zones of which the outermost is an oceanic trough or deep. Major shallow earthquakes originate chiefly under the slope that descends from the continent or large islands into this deep. Along the same zone appear remarkable deficiencies of gravity; small, nonvolcanic islands also occur here. The next arcuate zone, between the outermost zone and the continent, typically consists of large islands, such as those of Japan or the East Indies, with a central alignment of active volcanoes. Earthquakes occur at depths of 100 to 150 kilometres (60 to 90 miles) beneath these islands. Another interior zone exists in some arcs, including older and largely extinct volcanoes, beneath which earthquakes occur at depths of 200 kilometres (120 miles) or more. Still farther within the concave side of the arcuate structure, earthquakes occur at even greater depth, ranging from 300 to 700 kilometres (190 to 440 miles). Plots of the epicentres (points on the earth's surface directly above the focuses of earthquakes) against depth for shallow and deep earthquakes reveal the inclination (45°) of the active surface previously mentioned.

Earthquakes at great depth were known only from the Pacific region (including Indonesia) until 1934, when a large one originated at a depth of 650 kilometres (400 miles) under Spain. Earthquakes at depths of as much as 400 kilometres (250 miles) occur under the Tyrrhenian Sea west of Italy, and earthquakes at depths of 150 kilometres (90 miles), some rather large, have occurred repeatedly under Romania. A most remarkable repeating source is located at a depth of about 220 kilometres (140

miles) under the Hindu Kush mountain range, on the border between Pakistan and Afghanistan; associated with it are other sources at slightly shallower depth. These are displaced somewhat in the geographical sense, and the entire group defines a remarkable deep zone.

Earthquakes associated with block faulting

Not all large-scale earthquake activity occurs in arcuate structures, even in the Pacific belt. The major exception is a large part of the Pacific coast of North America, from northern Mexico to southeastern Alaska. Here deep earthquakes are absent, and volcanism is minor or extinct. The local earthquakes are associated with block displacements involving faults of considerable length, the outstanding one being the San Andreas Fault in California. A similar but smaller zone of block faulting in New Zealand includes the main seismic areas of both large islands; in the North Island it impinges on a zone that includes active volcanoes and earthquakes at depths to 200 kilometres (120 miles), occasionally more, and still farther north is the typical arc of the Kermadec Islands. Much of the activity of the trans-Asiatic belt, especially north of the Alpine belt, appears to involve block faulting.

Deep-focus earthquakes. Deep-focus earthquakes are those originating in the Earth's mantle—below the Mohorovičić Discontinuity, which occurs at a depth of about 35 kilometres (22 miles) beneath the continents and about 10 kilometres (6 miles) beneath the ocean floors. Shallow earthquakes originate in the Earth's crust. Focal depths of earthquakes are not always precisely determined, and the distinction between shallow and deep shocks is sometimes uncertain. An additional distinction between intermediate earthquakes, at depths ranging to 300 kilometres (190 miles), and deep-focus earthquakes in the restricted sense, from 300 kilometres to more than 700 kilometres, also is made, however. No earthquakes have definitely been assigned to depths exceeding 750 kilometres. The intermediate and deep groups show a difference in geographical distribution, which is very clear if the level of separation is taken slightly above or below the 300-kilometre level in some areas.

Investigation of intermediate and deep earthquakes depends almost entirely on seismographic recording. Even large events at great depth ordinarily produce only moderate shaking at the surface. Certain large earthquakes that occurred in 1881 in the Aegean and eastern Mediterranean region were correctly recognized as originating at relatively great depth, although some of these may have been within the crust.

Existence of deep-focus earthquakes was first emphasized about 1922, however, when the time of arrival of the primary wave group (first arrivals) was recorded. The wave groups from all earthquakes start from an earthquake focus at the same instant and proceed to the recording site. Because waves travel faster in the mantle than in the crust, however, there is a greater difference between the arrival times of primary and secondary groups of waves when the focus is deep—within the mantle (Figure 2). This was the case in Japan in 1929 when

From *The Earth Sciences* (1963) by Arthur N. Strahler, Fig. 20.11, p. 376, Harper & Row Publishers, Inc. (after L. Don Leet, 1950, *Earth Waves*, Cambridge, Mass., Harvard University Press)

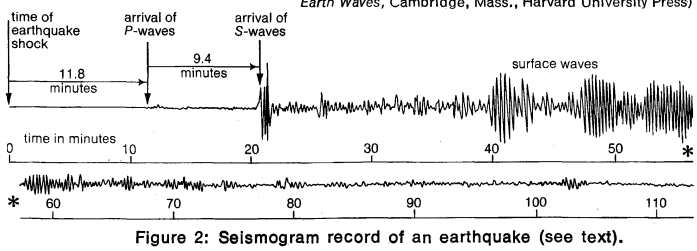

Figure 2: Seismogram record of an earthquake (see text).

the study of seismograms of earthquakes suggested that some quake events were originating at great depth.

Another distinguishing feature of seismograms of deep earthquakes is the small amplitude (wave height) of surface waves—those travelling near the Earth's surface—relative to other wave types. This is because the surface disturbance decreases rapidly as the depth of the source increases. Precise study has revealed the effect of increasing focal depth on the times of arrival of all the various waves at distant stations.

Particular significance attaches to the recording of waves of a special type. A wave can be reflected at the Earth's surface and then arrive at a given station in three ways; *i.e.*, there are three possible points of reflection. One point is roughly one-half the distance between epicentre and station; a second point is on the far side of the Earth, in which case the wave passes through the core twice; the third is a steep path from a deep source to the surface, with reflection relatively near the epicentre, toward the distant station along a route close to that of the direct path from the source (Figure 3).

From *The Earth Sciences* (1963) by Arthur N. Strahler, Fig. 20.15, p. 378, Harper & Row Publishers, Inc. (after B. Gutenberg, 1951, *Internal Constitution of the Earth*, New York, Dover Publications)

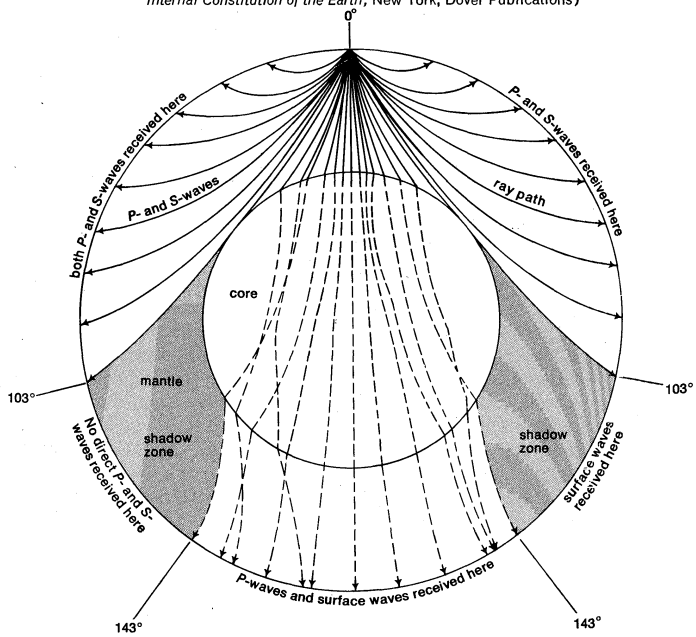

Figure 3: Possible ray paths from single earthquake source (see text).

Evidence for deep-focus earthquakes was received rather skeptically at first, because it conflicted with then-current ideas about the state of material at such depths, where strain might be expected to be relieved by plastic flow rather than by fracture. When the evidence became overwhelming, sudden changes of state were suggested. Because a large proportion of shearing fracture at the source is indicated, an appeal was made to the time element; some materials yield gradually under slowly changing load and yet fracture under sudden strain.

The "new global tectonics" attributes deep-focus earthquakes to fracture within slabs of crustal material that are being dragged down into the depths by convection in the mantle. These slabs form the active surfaces, dipping toward the concave side of Pacific-type arcs, on which the deep focuses are located. In most regions these zones of deep focuses are very thin. Fracturing, with resulting earthquakes, is considered to occur there much as for shallow earthquakes in the crust but with mechanical modifications appropriate to the greater pressure and temperature.

MAGNITUDE, MOTION, AND ENERGY OF EARTHQUAKES

Seismic intensity and magnitude scales. In 1935 an instrumentally founded magnitude scale for earthquakes was introduced. The objective was to eliminate gross errors in earthquake statistics caused by confusion of the terms intensity and magnitude. Essentially, there was confusion of the local effects of an earthquake with its dimensions and extent as a physical event. This was caused by three factors that are insufficiently understood: (1) a rapid decrease in the intensity of shaking with distance from the earthquake centre; (2) local enhancement of shaking on unstable ground, regardless of

distance from the source; (3) an exaggerated impression of violence derived from serious damage or total collapse of weak construction following only moderate shaking.

Mercalli intensity scale

In seismology, intensity is a relatively old, established term; it refers to the degree of shaking at a specified place. Usually it is expressed by means of an adopted arbitrary scale, which for many years was the Rossi–Forel scale of ten degrees. This has been gradually replaced by successive versions of the Mercalli scale of 12 degrees. The successive degrees do not derive from physical measurement of any kind; they merely represent ratings assigned by experienced workers from observations or reports of earthquake effects. Accordingly, intensity is usually stated in Roman numerals (I, II, . . ., XII), rather than in ordinary numbers, which might be interpreted to represent measurement.

The Mercalli scale levels are represented by rather long descriptions of effects. A few significant points are as follows: intensity I is ordinarily not perceptible to persons; II is felt by few; IV is sufficient to rattle windows and doors; VII may cause damage, even seriously, but only to inferior construction; VIII and IX are destructive; X is usually catastrophic in a centre of population; and XII is reserved for effects of extreme violence, which are only rarely seen.

There is a belief that the levels of the Mercalli scale can be correlated with the acceleration of the ground during earthquake shaking, thus indicating the internal forces acting within buildings. Any such correlation is extremely inaccurate and uncertain. A common rule of thumb associates intensity VII with acceleration of 0.1 gal (one gal equals one centimetre per second per second); this is often applied by engineers in designing structures for resistance to earthquakes.

An intensity scale, applied with judgment, affords a limited means to compare earthquakes with each other. If local intensities of two earthquakes, *A* and *B*, are entered on a pair of maps, it may be observed that event *A* developed higher intensity near its epicentre than did event *B*, and that the limits of successive lower intensities are wider for *A* than for *B*. The area affected, either in terms of damage or of perceptible shaking, is larger in the first instance. Earthquake *A* may then be said to be of greater magnitude than *B*, independently of instrumental recording or of any particular magnitude scale. Nevertheless, if both affect the same general region but have different epicentres, some localities may be shaken with greater intensity in event *B*, generally because they are closer to its epicentre than to that of *A*. Moreover, estimates of intensity may be distorted by exaggerated damage in large centres of population located on unstable ground.

Such comparisons and, consequently, estimates of magnitude in the general sense, are difficult to make for earthquakes originating offshore or in unpopulated areas. Accordingly, the term magnitude was introduced together with a formal scale (the Richter scale) based on instrumental recordings. The results cannot claim a high degree of precision, but experience has shown that they are generally more satisfactory than those based only on noninstrumental data.

Full understanding of the relation between intensity and magnitude requires a good foundation in fundamental physics, because the relationship involves a general property of radiated energy. It is possible, for example, to contrast the local intensity of illumination with the actual luminosity of a lamp, or the strength of a radio signal on a given receiver with the power rating of the station in kilowatts. In all such cases, local intensities are affected not only by distance, but also by conditions at the point of observation and along the path to that point from the source.

The Richter magnitude scale

The first magnitude scale was devised for use in southern California, where there was a group of recording stations with identical seismographs. These stations permitted the location of epicentres for earthquakes originating in this area, so that it was possible to study the decrease in recorded ground motion with increasing distance from the epicentre. By plotting the amplitude read from each seismogram against distance from the source, a sort of standard attenuation curve could be set up. The observed range of amplitudes was so large that the amplitude was plotted logarithmically. On the logarithmic plot, the curves representing different earthquakes were seen to be roughly parallel, which would imply that the amplitudes recorded for two given earthquakes are in constant ratio at corresponding distances. The logarithm of this ratio was defined as the difference in magnitude between two events, M_1 and M_2, which may be written: $M_1 - M_2 = \log A_1 - \log A_2$, in which M_1 and M_2 are the magnitudes involved, and A_1 and A_2 are the corresponding amplitudes. It remained to fix the zero level of magnitude. This was arbitrarily chosen to fit some of the smallest true earthquakes recorded by good seismographs. Magnitude 3 was fixed as a maximum trace amplitude of one millimetre on the recording sheet of a torsion seismometer, with a free pendulum period of 0.8 second, static magnification of 2,800, and damping of 0.8 critical (see SEISMOGRAPH).

Later developments have largely removed the restriction of magnitude to the data derived from a particular type of seismograph.

The magnitude scale is not itself an instrument but a procedure for using instruments. A common error is to suppose that it is "a scale of ten." Although the logarithmic base 10 is used, there is no fixed upper or lower limit. As a matter of observation, no earthquake has been confidently assigned a magnitude higher than 8.9. Special instruments have recorded very small earthquakes, smaller than those of zero magnitude, so that negative magnitudes apply to these "microearthquakes."

Extension of magnitudes to earthquakes recorded at great epicentral distances (teleseisms) was based not on the recorded body waves, which constitute the maximum of the seismogram at short distances, but on the large surface waves, with periods of oscillation near 20 seconds, which appear as the maximum on seismograms of shallow teleseisms as written by the seismographs most in use. Restriction to particular instruments was overcome by referring the scale to the actual amplitude of the ground oscillation, as calculated from the seismogram readings and from the known characteristics of the seismograph used. The scale was adjusted as far as possible to agree with the California local scale. The resulting tabulations could be mainly represented by a simple formula. A later modification of this formula, adopted at an international conference in 1967, equates the magnitude to the logarithm of the amplitude and the distance involved in the expression: $M = \log A + 1.66 \log \Delta + 2.0$, in which A is the maximum amplitude of the ground for surface waves with periods of about 20 seconds, and Δ (delta) is the distance from epicentre to station, expressed in degrees of arc of a great circle over the Earth's surface (one degree being about 111 kilometres or 69 miles). The formula fails when Δ exceeds about 150°. At each recording station, there should be a small local correction, expressing the normal deviation from the mean of all stations; at Pasadena, California, for example, this correction is −0.1 magnitude. Other special corrections can be applied where amplitudes are found to be regularly high or low along certain paths.

Use of body waves to determine magnitude

Tables have been developed for finding magnitude from deep-origin or body waves. This required beginning with shallow earthquakes whose magnitudes had been found from surface waves; it was then extended to deep-focus earthquakes. For body waves, it is necessary to use the amplitude divided by the corresponding measured period of oscillation, T.

For theoretical reasons, the magnitude determined from body waves has been preferred by some authorities to that determined from surface waves; but many questions have arisen in general practice, and the surface-wave magnitude provides a more satisfactory standard. There are three principal difficulties:

(1) The tables yield body-wave magnitudes, m, which agree with those from surface waves, M, in the range 6.7 to 6.9, but deviate from them for larger and smaller values; the relation between m and M can be expressed as $m = 2.5 + 0.63\,M$.

(2) For deep-focus earthquakes, the tabulations involving m did not allow for loss of energy in the low-velocity zone of the mantle; the effect is to overestimate earthquakes originating below that zone.

(3) Many workers fail to consider the largest waves, but take only the first few oscillations, which usually are smaller; the magnitude then reported applies to these earlier events, with a ludicrous underestimate of the main shock (magnitudes near 5 have often been given for earthquakes or magnitude obviously 7 or over).

Magnitude, energy, and nuclear explosions

Various equations intended to relate magnitude, M, to total radiated energy, E, have been published. The one most commonly employed equates the logarithm of energy to the magnitude in the form: $\log E = 11.4 + 1.5\,M$, in which E is energy in ergs and M is magnitude. This is at best only approximate; the relation between E and M appears to be variable. The number M is probably more closely related to the maximum rate of radiation of energy, which is power, measured in kilowatts or horsepower.

Many errors have resulted from applying the earthquake-magnitude scale to seismograms of nuclear explosions. The fundamental tables, constructed for relating ground motion to distance, do not properly apply to events originating near the Earth's surface. Moreover, the process by which nuclear energy is converted into seismic waves differs greatly from the mechanism of natural earthquakes. A separate magnitude scale can be developed for comparing the seismic effects of explosions, however. Magnitudes thus found are not necessarily directly related to the yield, which is the total energy released, commonly stated in kilotons. An appreciable fraction of the yield energy is temporarily stored, elastically surrounding the explosion centre, and does not contribute to the seismograms. Some of this energy is later released during collapse events, sending out seismic waves often recorded by stations some hundreds of miles distant.

Finally, it is important to note that the magnitude scale does not supersede intensity scales; their purposes are complementary. Unfortunately, no one has yet succeeded in constructing a satisfactory intensity scale based on physical measurements.

Seismograms and their interpretation. A typical seismogram is complex; it consists of a series of characteristically successive curves that represent the arrivals of seismic waves at the site of the recorder. The curves begin sharply or gradually, each continuing for a small part of the duration of the entire recorded disturbance. It was initially supposed that this complexity arose from a succession of events at the source; but later it became clear that most of the arriving signals are the result of a single event of comparatively brief duration and that the successive arrivals are caused by waves that started at the same time but that travelled over differing paths with various speeds.

P, *S*, and *L* waves

Analysis of seismograms began by empirically separating the recorded motions into two groups. Of these, one is a train of relatively large, slow oscillations, which formed the most conspicuous part of the records of normal large earthquakes as recorded by the instruments first in general use; this group came to be called the "principal earthquake." With improved recording, these oscillations were observed to be normally preceded by some minutes by smaller and more rapid vibrations, at first called the "preliminary tremor." The latter could often be subdivided into two succeeding groups, termed the first and second preliminary tremor. These two groups were designated by *P* (initial of *primae*) and *S* (*secundae*). Current writers sometimes call these "primary" and "secondary" waves, which is slightly misleading, because nothing more than the succession in time is implied.

The large waves of the "principal earthquake" were symbolized by *L* (for *longae*) because of their long periods of oscillation. They represent energy travelling around the earth, chiefly near its surface, whereas *P* and *S* are "body waves," propagated by the interior of the earth. Because the body waves have a shorter path and generally travel with higher velocity than surface waves, they often reach the recording station many minutes earlier. The velocity of *P* waves in several earth materials is shown in Figure 4.

P and *S* correspond to the two principal types of elastic waves that can exist in a solid body. In the *P* type, the oscillation of individual particles is along the ray, in the direction of propagation, and perpendicular to the wave front, just as for sound waves in air. The *P* waves are, in fact, essentially sound waves in the Earth, although their frequency of vibration is mostly well below the range for audible sound. Oscillation of *S* waves is along the wave front or perpendicular to the direction of propagation. Whereas *P* waves are longitudinal in vibration, *S* waves are transverse; this gives *S* waves some geometrical properties like those of light waves, so that they show such effects as polarization.

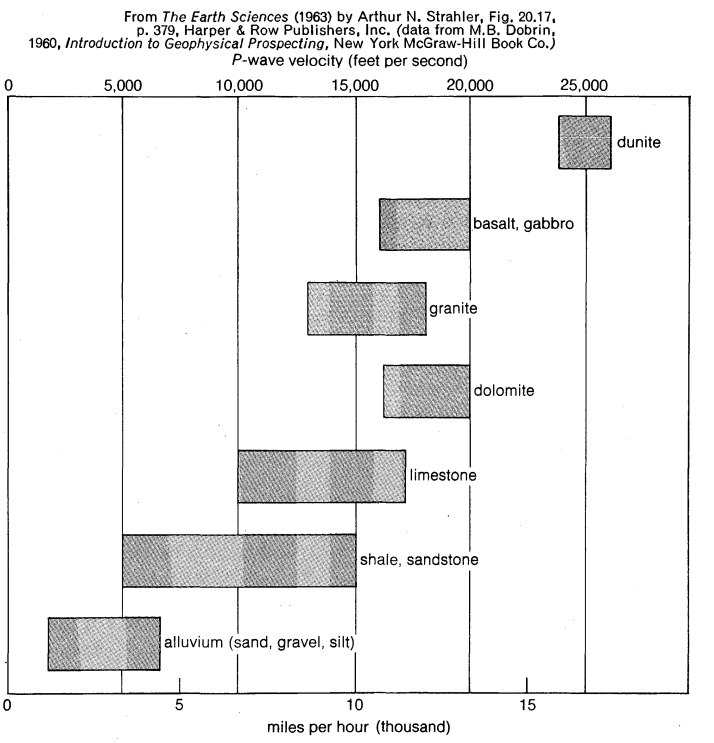

Figure 4: Velocity of propagation of *P* waves in various earth materials.

P waves are accompanied by compression and rarefaction, like ordinary sound waves; but *S* waves produce local shearing and deformation without change of volume. Because liquids are incapable of supporting shear, *S* waves can pass only through solids; in this manner, it can be concluded that the outer part of the earth's core is liquid, because *S* waves do not pass through it.

Wave motion in the core and mantle

The different recorded groups of body waves are designated by letter symbols that represent successive segments of the path traversed. For convenience, waves of longitudinal or *P* type within the core (or specifically in its outer portion) are assigned the letter *K*. Each such wave that has traversed both mantle and core is lettered *PKP*, showing that it begins and ends as *P* in the mantle. Longitudinal waves in the inner core are separated by the letter *I;* thus a wave passing through the whole earth along a diameter is called *PKIKP*.

Whereas seismic waves in the Earth are everywhere of the two main types, *P* (with *K* and *I*) and *S* (plus a hypothetical, *J*, for possible transverse waves in the inner core), analysis of seismograms confirms many possibilities because of reflection and refraction, mainly at the lower surface of the crust or at the interface between the core and mantle. Careful and difficult analysis also is being directed toward identifying reflections and refractions at the boundary that exists between the inner and outer cores.

The number of observable waves traversing the mantle alone is augmented by transformation from *P* to *S*, or the reverse, upon reflection. A single reflection at the surface

may result in *PP*, *PS*, *SP*, or *SS*, the letters being in the order in which the two parts of the path are traversed. Observable double reflections are *PPP*, *PPS*, *PSP*, *PSS*, *SPP*, *SPS*, *SSP*, *SSS*. Some of these (such as *PPS*, *PSP*, *SPP*) have identical travel times for a surface source but separate times for earthquakes originating at appreciable depth.

Reflections from the outside of the core are often observed; to distinguish these, an index, *c*, is inserted, so that the single reflections are *PcP*, *PcS*, *ScP*, and *ScS*.

Reflections from inside the core boundary are observed with sensitive recorders; the most common are *PKKP* and *SKKP*, in which repetition of *K* indicates the reflection. *PKP* may be reflected at the surface, so that it is possible to observe *PKPPKP*, and even *PKPPKPPKP*, as well as *SKPPKP*.

The most important refracted body wave is *PKP*. The drop in velocity at the surface of the core may greatly deflect this ray; there is a focussing effect (technically a caustic) at angular distances of about 142° from source to station. *SKP* begins as a transverse wave but becomes longitudinal in the core and thereafter; it has a similar focus or caustic at about 135°. *SKS*, which is transverse in the mantle and longitudinal in the core, is conspicuous on seismograms at distances from 85° to 100°, where it precedes *S* and confuses observation of that wave.

Surface waves are also of several kinds. These are not as clearly separable as the types of body waves; their generally greater wave lengths lead to complications not indicated by the simplified theories first applied. Ideally, there are two main types, associated with the personal names of two scientists who investigated these waves, Rayleigh and Love. These are related somewhat as *P* to *S* waves. Oscillation of the theoretically ideal Rayleigh wave should take place in a vertical plane through the source and the point of observation, with both vertical and horizontal displacements; those of the ideal Love wave should be horizontal, transverse to the direction of propagation.

Rayleigh waves and Love waves are instances of channel or boundary waves, associated with horizontal propagation in a limited range of levels, which may be near the surface of the Earth or along some deeper horizon, like low-velocity level in the mantle. Certain channel waves produced by earthquakes in the waters of the ocean, impinging on the continental coasts, produce recordings of a peculiar type called *T* waves.

A typical seismogram

The following is an abbreviated account of the main features of the seismogram of a typical shallow earthquake, preceding the arrival of surface waves:

At relatively short distances, up to about 1,000 kilometres (9°) from the epicentre, the record shows principally the *P* and *S* groups, separated by an interval ranging from a few seconds up to about 100 seconds. Within the *P* and *S* groups there is complexity because of the overlap of successive arrivals, caused by discontinuities at the base or structures within the Earth's crust. Beyond 1,000 kilometres, complexity originates chiefly from various internal reflections and refractions.

Distances are now given in degrees of arc from epicentre to stations over the Earth's surface, one degree being about 111 kilometres or 69 miles:

9°–85°. Principal wave groups are *P* and *S*, but at about 25°–35° there are often sharp arrivals of the core reflections *PcP*, *ScP*, *ScS*. Over continental paths *PP* may be large and conspicuous.

85°–105°. In this range *P* is clear, but identifying *S* often is difficult because of *SKS* immediately preceding and *PS* immediately following.

105°–142°. Here *P* is usually lost in the shadow of the core, which shuts off the rays as they dip deeper into the earth. In this shadow zone seismographs show *P* waves diffracted around the core boundary; also, there are occasional sharp recordings of *PKP* waves that have been widely deflected by the boundary of the inner core. *SKP*, and shortly after it, *PKS*, arrive with large amplitudes near 135°. *PKKP* is most evident near 120°. *PP* and *PS* are large and sometimes are mistaken for *P* and *S*, implying much too short a distance.

142°–180°. Near 142°, *PKP* arrives with strikingly large amplitude. It is followed, at an interval increasing with distance, by *PKP* that has travelled around through the core and covered a range of central angle of more than 180°. There are few conspicuous waves following *PKP*, though *SKKS* is sometimes large enough to be taken for *S*. Reflections such as *SS* and *SSS* may appear as large waves; finally, the surface waves begin, often more than an hour after the initial *PKP*, so that the recording looks like that of two separate disturbances.

BIBLIOGRAPHY. The nature of seismic waves and their measurement and interpretation are topics that are treated in all texts on seismology. Among such works the interested reader should consult KEITH E. BULLEN, *Seismology* (1954), and *An Introduction to the Theory of Seismology*, 3rd ed. (1963); MILTON B. DOBRIN, *Introduction to Geophysical Prospecting*, 2nd ed. (1960), which gives an elementary account of gravity, magnetics, and other geophysical methods, in addition to seismology; and CHARLES F. RICHTER, *Elementary Seismology* (1958). The relationship of earthquakes to the Earth's structure and composition is treated in the related articles cited in the introduction to this article. Worthy of note as references in this vein are JOHN H. HODGSON, *Earthquakes and Earth Structure* (1964); BENO GUTENBERG and CHARLES F. RICHTER, *Seismicity of the Earth and Associated Phenomena*, 2nd ed. (1965); and the collected geophysical papers in P.J. HART (ed.), *The Earth's Crust And Upper Mantle* (1969).

Earth Sciences

The systematized knowledge of the solid Earth and the fluids within and around it constitutes the Earth sciences. Three main families of sciences are involved; namely, the geological sciences, which deal with the rocky crust of the Earth and its interior; the hydrologic sciences, which are concerned with all the waters of the Earth; and the atmospheric sciences, which encompass the physical and chemical properties of the atmosphere as well as air and its motions.

This article is concerned with the characteristics and contributions of these families of Earth sciences and with their relationships to each other and to other disciplines as perceived from a historical viewpoint. Accordingly, the principal theme of this article is the development of ideas and concepts that are central to the Earth sciences. For further coverage of the scope and methods of the many disciplines involved, see GEOLOGICAL SCIENCES; HYDROLOGIC SCIENCES; and ATMOSPHERIC SCIENCES. The actual subject matter or content of any particular discipline is presented in the many articles on the Earth and its development—*e.g.*, MINERALS; OCEANS AND SEAS; WINDS AND STORMS.

This article is divided into the following sections:

I. Nature and origins of the Earth sciences
  Physical, historical, and applied aspects
  Foundations in myth and legend
  Central ideas and observations
II. From antiquity to the 16th century
  Geological sciences
  Hydrologic and atmospheric sciences
III. The 16th, 17th, and 18th centuries
  Geological sciences
  Hydrologic sciences
  Atmospheric sciences
IV. The 19th century
  Geological sciences
  Hydrologic sciences
  Atmospheric sciences
V. The 20th century
  Geological sciences
  Hydrologic sciences
  Atmospheric sciences
  Emerging trends

I. Nature and origins of the Earth sciences

PHYSICAL, HISTORICAL, AND APPLIED ASPECTS

Each of the three families of Earth sciences is conventionally divided into disciplines and subdisciplines according to its particular subject matter. More than 100 special fields of Earth science have already been named, and the definition and classification of all these specialties lie beyond the scope of this article. For convenience in

discussion the special subject fields may be grouped as physical sciences, historical sciences, and applied sciences. Those fields dedicated primarily to understanding the dynamical, physical, or chemical properties of natural phenomena under their purview will be called physical sciences. Those concerned with the sequential changes that have taken place on the Earth will be called historical. Fields dealing with the application of scientific information and historical inferences to the solution of practical problems will be called applied sciences; the latter can also be termed technologies.

Threefold groupings in hydrologic, atmospheric, and geological sciences

To illustrate this threefold grouping, meteorology is the science of the atmosphere; paleoclimatology, the reconstruction of ancient weather conditions over long average time periods, is its historical counterpart; and weather forecasting is one of the practical applications of this science. Hydrology is the science of the waters that occur on the Earth. Physical oceanography, limnology, potamology, and hydrogeology are subdivisions dealing, respectively, with oceans, lakes, rivers, and water contained in the voids in rocks. Glaciology is a special field concerned with the frozen water of glaciers. Paleohydrology is a historical branch, dealing generally with the origin, chemical evolution, and migration of the Earth's water through time; it includes special fields such as paleolimnology, the reconstruction of conditions that obtained in ancient lakes. Among the applications of hydrology, prospecting for and conservation of groundwater comprise two prominent subjects.

In geology, the scientific disciplines are often grouped under the heading of physical geology, which includes the sciences of minerals (mineralogy), rocks (petrography and petrology), structures in the solid Earth (structural geology), sedimentary strata and their fossil content (stratigraphy and paleontology, respectively), and landforms (geomorphology). The history of the development of these natural entities is broadly comprehended under the heading of historical geology. Applied geology, or economic geology as it is often called, includes mining geology, engineering geology, and petroleum geology.

Scope of geophysics and geochemistry

Geophysics and geochemistry are major branches of Earth science that overlap many of the special fields named above. Broadly speaking, geophysics is concerned with the physical properties and dynamics of the Earth in all its parts. Among the phenomena investigated by geophysicists are the Earth's fields of gravity and magnetism, the thermal properties of the Earth, the motions of fluids within and surrounding the solid Earth, and the release of mechanical and thermal energy in earthquakes and volcanoes. Geochemistry deals with the composition of the planet and with the chemical changes that occur in nature. Although both of these geosciences are concerned with changes affecting the Earth at present, they also have the aim of discovering the chains of events that led up to present conditions. Much effort is currently directed toward reconstructing the thermal history of the Earth, for example, which is envisioned as a heat machine with a finite store of energy ultimately to be dissipated. Paleomagnetics is a flourishing new field dealing with past changes in the Earth's magnetic field. Working in laboratories where the behaviour of Earth substances subjected to high temperatures and pressures simulates changes presumed to obtain at great depth, the geochemist seeks to understand how ancient rocks in the crust of the Earth were formed. The practical applications of these two major geosciences are also numerous. Geophysical prospecting, using instruments designed to measure differences in the magnetic or gravimetric fields over small areas or to measure variations in the rate of propagation of elastic waves through different kinds of rock layers, has successfully guided exploration for a variety of things, including the cannon of sunken Spanish galleons and vast subterranean supplies of petroleum and natural gas. Variations from place to place in the chemical composition of plants and of the soils in which they grow have also been used in prospecting for mineral deposits. In some instances, variations in the concentration of certain elements in the plants eaten or the water drunk by animals may be correlated with regional differences in the incidence of specific diseases and malfunctions. In the emerging subdiscipline of medical geology, geochemistry promises to play an important role.

FOUNDATIONS IN MYTH AND LEGEND

The countless special questions for which Earth scientists seek answers reduce to a few general queries, such as the following: Of what is the Earth made, and how are its parts connected? How old is it, and how did it come to its present condition? What causes the changes of landscape that go on all the time? What is man's place in the order of nature? What of the Earth is useful or otherwise valuable? These are among the perennial questions for which answers were attempted long before the Earth sciences existed, and the prescientific answers often took the form of creation stories and myths.

Stories of the creation

The creation story that undoubtedly has played the most conspicuous part in the debate about the Earth from which the historical sciences have grown is the one told in the first chapter of Genesis. Biblical scholars trace elements of the Mosaic account back to the Babylonian creation epic (*Enuma elish*), which was current in the 22nd century BC. As known from clay tablets found in the ruins of Ashurbanipal's library at Nineveh, the Babylonian epic interprets the creation of the world in terms of a conflict between deities. In the beginning, Tiamat, a monstrous goddess of darkness, ruled over a chaotic world. Marduk, supreme god of the Babylonians, led a host of other deities from their home in the midst of heaven to wage war against Tiamat. Marduk slew Tiamat and cut her body into two parts. One part he raised up to form the sky, a firm barrier that then separated the "upper waters" from the waters of the Earth. Then Marduk created the luminous bodies of the heavens, arranging the stars in patterns to resemble the images of the great gods. The Moon god he next created and appointed to watch over the night and keep track of the days. Like the Babylonian, the Hebraic account begins with a world in chaos and darkness. Light was created from the darkness. A firmament, or sky, was created to separate the upper from the lower waters, allowing rain to fall only when the windows of heaven were opened. The lower waters gathered into one place; dry land emerged, and vegetable life grew on it. The luminous bodies of heaven were created for the ordering of time as days and nights, seasons and years. In the last stage, animal life was placed on the Earth, and finally man was created.

The Mosaic account of creation has been identified as a work written during the Babylonian Exile in defense of monotheism against the Babylonian view that the world originated through a conflict of deities. Granting the motivation, the creation story is still cast in the form of Earth history, in which the successive events are attributed to supernatural causes. The ideas that chaos preceded order, that plants preceded animals, and that man appeared late on the scene can also be fitted into purely naturalistic versions of cosmogony and geology. Thus the creation story came to be accepted as an embodiment of scientific as well as theological truth and is still so interpreted in some quarters today.

Poseidon as the cause of earthquakes

Less pretentious in scope and intent than the creation stories are the myths that relate specific natural phenomena to the work of supernatural agencies. Spectacular events, such as earthquakes and volcanic eruptions, have evoked images of powerful and capricious gods and goddesses. Thus the early Greeks attributed earthquakes to the angry outbursts of the sea god Poseidon (the Roman Neptune). With his three-pronged spear he could control the waves of the sea, shatter rocks, and shake the shores. One Earth-shaking episode has Poseidon pursuing Polybotes, an upstart giant who defied the gods. When the chase led past Cos, the sea god tore off a piece of the island and hurled it at Polybotes, burying him beneath it. Poseidon, not content with his ocean domain, contested with other gods for possession of the land. He was also the ruler of springs and turned them on and off at will. Poseidon was worshipped along the shores and at inland temples in regions affected by earthquakes.

Pele, the volcano goddess

The old Hawaiians believed that the active volcano Kilauea, on the island of Hawaii, is the home of a family of fire deities headed by the goddess Pele. From her original home in the western Pacific, Pele was driven by her sister and implacable enemy, Na-maka-o-ka-hai, goddess of the sea, who persistently attacked Pele's home with floods and high tides. Pele fled first to the northwestern end of the Hawaiian Islands, where she attempted to build a new home on the lowlands of Kauai. With her magical digging tool, the *pa-oa*, she struck down into the Earth to make fire pits in which she could take refuge. But water quickly quenched the fires she kindled. So Pele went southeastward from island to island trying to dig other fire pits, but these too were so near the sea that water rushed in and put out the fire in great explosions of steam. Finally Pele found a place on Kilauea where she could make an enduring fire pit and live in safety with friendly members of her family. Na-maka-o-ka-hai, seeing the great fiery clouds rising from the pit of Halemaumau, gave up the chase. There Pele lives today. A petulant goddess, Pele sometimes creates new land with lava flows; at other times she sends down streams of lava to destroy the dwellings of her kinsmen. Whenever she stamps her feet in anger the Earth quakes.

The stories of Poseidon and Pele are examples of myths that relate natural occurrences in a rational way, up to the point at which they invoke supernatural forces as ultimate causes. Both myths relate the retreat of cliffy shores to attacks by waves. The Poseidon myth rightly connects earthquakes with local changes in the flow of streams and springs. The Pele myth properly associates earthquakes with volcanic outbursts and the construction of ash cones to the meeting of fire and water. Moreover, the Hawaiians seemed to have grasped that the deeply dissected Kauai, Pele's early home, is older than Hawaii, where Kilauea is still in the constructional phase of its development. The mythic element enters where the storyteller deifies the forces that move the waves, shake the land, and start the volcanic fires.

CENTRAL IDEAS AND OBSERVATIONS

Earth scientists contend with two difficulties inherent in their subject. Most of the Earth is inaccessible for direct observation. And the history of the Earth is not given but must be inferred from present configurations of matter, present transformations of energy, and from the changes observed to have taken place on Earth during the brief span of recorded history. Despite these difficulties, three major ideas have been shaped that profoundly modified ancient and traditional views of nature. The first is that the Earth is mobile, always changing in its configurations. The second is that the world is almost inconceivably ancient. The third is that prehistoric life, as known from fossils, has changed with time and that the usual outcome of these changes has been the extinction of species.

Cartographers and mariners: Earth configuration

The image of the accessible world first began to emerge from the efforts of cartographers and mariners. Scientific cartography of the ancient world reached its peak in the work of Ptolemy (Claudius Ptolemaeus; flourished *c.* AD 120–170). Using the astronomical and mathematical principles then available, Ptolemy produced a map covering about 180° of longitude and 80° of latitude centring near the Persian Gulf. Soon afterward, religious cosmography took over in the West, and until the 15th century the world was commonly drawn as a circular disk, oftentimes with Jerusalem at the centre and the Garden of Eden and Paradise also indicated. Interest in cartography revived with the great voyages of exploration beginning in the 15th century. Mercator's chart of the world, produced in 1569, shows fairly well the congruency of the opposing coasts of South America and Africa, a symmetry that later led to the theory of continental drift, the idea that the continents are separating as the ocean basins expand through time. Thereafter maps have steadily improved and have been used at bases for regional analysis of all kinds of geologic, hydrologic, and atmospheric data.

Forebears of modern oceanographers, the mariners added much from their personal experiences to knowledge of the waves, currents, tides, and variations in the temperature and saltiness of seawater. Their success at navigation depended largely on the reliability and capability of their instruments. When Magellan set out on his voyage in 1519 he had at hand a terrestrial globe, theodolite and quadrants, compasses and hourglasses. Then and long afterward one of the hazards to navigation lay in faulty determination of longitude, whose calculation requires knowledge of the precise time of observation. Following a series of ship disasters around 1690, the Board of Longitude was set up in England, and encouragement was given to the development of better timekeeping devices. With the improved chronometers developed by 1764, Captain James Cook set out exploring the South Pacific in 1768, voyages that mark the beginning of modern navigation. Cook's soundings to 200 fathoms (1,200 feet) and observations of winds, currents, and temperature of seawater have since been praised for their accuracy.

The obvious mobility of the atmosphere and hydrosphere only accentuates the seeming stability of the solid Earth. Ancient observers knew, of course, about the dislocations in the ground that sometimes attend earthquakes. But the first evidence for profound changes in the position of land and sea was provided by marine fossils contained in the rocks of high mountains. This evidence, however, was not generally accepted at face value until after the 17th century. The motive force for elevation of the continents itself remained mysterious until late in the 18th century, when the solid Earth was envisioned as a machine driven by internal thermal energy. The source of this energy was assumed to be solely residual from the Earth's original molten state until a century later, when it was discovered that heat is generated by radioactivity.

The antiquity of the Earth has long been a subject of debate argued both from scientific and theological grounds. Until well into the 18th century the short Christian chronicle held sway; but geologists of the 19th compiled such lengthy sequences of terrestrial events that to some of them geological time seemed virtually limitless. Geochemical dating of radioactive minerals has finally shown that the Earth must be at least 4,600,000,000 years old.

Before the middle of the 19th century the order of succession of different kinds of fossils in rock strata was fairly well-known. Moreover, it was recognized that nearly all species described by paleontologists are extinct. An explanation of the developmental trends observable in the fossil record was not forthcoming, however, until the appearance on the scene of the evolutionary biologists led by Charles Darwin.

Contributions from chemistry, physics, and technology

Knowledge of the composition and dynamical characteristics of the Earth has come mostly from applications of chemistry and physics after the latter part of the 17th century and from technology in the form of improved scientific instruments. Chemical oceanography began with investigations by Robert Boyle around 1670, and atmospheric chemistry developed about 100 years later in the work of Carl Scheele and Henry Cavendish. Chemical classifications of minerals were standard after 1850, and the later development of physical chemistry made possible modern experimental mineralogy and petrology. Sir Isaac Newton's application of the law of gravitation to the behaviour of the tides in 1684 was a landmark in the history of geophysics, and it led to Pierre-Simon Laplace's dynamical theory of tides in 1775. Knowledge of what is supposed to exist far below the Earth's surface rests on physical principles relating to gravity, magnetism, thermodynamics, and the propagation of energy in elastic media.

The organization of scientific societies has given impetus to the development of science generally. Perhaps not coincidentally, the 17th century, which marks the beginning of scientific societies in Italy, France, and England, was also the time when a host of new instruments were developed and improved for research. In addition to the telescopes and microscopes that extended the range of human vision, there were pendulum clocks, barome-

ters, and thermometers, which sharpened observations and experiments by yielding quantitative data. These were the forerunners of the myriad instruments subsequently developed to quantify information about the Earth and thus make data amenable to mathematical analysis and statistical study.

The progress of science is constrained by whatever society will tolerate or support, and the utilitarian aspects of science have ranked high in the popular view since the 17th century. Atmospheric science has always been overshadowed by its practical application in forecasting weather. At the beginning of the 19th century, when European travel was by sailing ship, horseback, or coach, a great interest in the weather led to establishment of meteorological departments. But interest lagged for a time with the coming of the steamer and railway. The greatest geological effort of the 20th century has been the exploration for fossil fuels, and no doubt the present acceleration of interest in oceanography is prompted by hopes of developing additional stores of food and minerals. This is not to deprecate applied science. Petroleum geology, for example, has paid handsome scientific dividends, among other matters having added the third dimension of depth to the geological map in many remote and relatively inaccessible parts of the world. Techniques of drilling developed in search of oil have been applied to coring the ocean's floor for purely scientific purposes, and exploration geophysics has added much to knowledge of the Earth's interior.

II. From antiquity to the 16th century

GEOLOGICAL SCIENCES

Classification of rocks and minerals by Theophrastus

Knowledge of Earth composition and structure. The oldest known treatise on rocks and minerals is the *De lapidibus* of Theophrastus (*c.* 372–287 BC). Written probably in the early years of the 3rd century, this work remained the best study of mineral substances for almost 2,000 years. Although reference is made to some 70 different materials, the work is more an effort at classification than systematic description. Theophrastus recognized two main categories: stones and earths. Stones are classified according to their colour, tenacity, texture, density, fusibility, inflammability, solubility in water, magnetic properties, utility, and value. He identified the essential characteristics of building stones and mentioned localities where different kinds of building stones are found. Both organic and inorganic substances were included with the stones. Coal and asphalt, which will burn, he contrasted with substances such as red garnet, which are seemingly unaffected by fire. The organic amber is mentioned in context with the inorganic magnetite (iron oxide), because both have the ability to attract foreign objects: straws and bits of wood by rubbed amber and iron by the lodestone. The treatise ends with a brief account of "earths," which include substances then in common use as pigments, cosmetics, and insecticides. Red ochre, yellow ochre, vertigris, lapis lazuli, realgar, orpiment, and cinnabar are listed among the pigments. White lead, produced by the action of acetic acid vapour on lead, was used both as a cosmetic and as a pigment. Boiled bituminous clay and sand is reported as effective against the predations of woodworms on vines. In discoursing on stones, Theophrastus casually included the artificial along with the natural. His category *gypsos*, for example, includes the manufactured plaster of paris and quicklime as well as ordinary gypsum.

Chinese writings on minerals and ore deposits

In early Chinese writings on mineralogy, stones and rocks were distinguished from metals and alloys, and further distinctions were made on the basis of colour and other physical properties. Systematic treatments of mineral substances are found in pharmacopoeias, in works on alchemy, and in treatises describing different kinds of rocks used as inkstones (for grinding blocks of carbon-black ink with water). In the pharmacopoeias the minerals were sometimes ranked according to their imputed therapeutic value, the number of mineral substances in works of this kind ranging from 46 in writings from near the beginning of the Christian Era to 215 in a list from the early 12th century. The speculations of Cheng Ssu-hsiao (died AD 1332) on the origin of ore deposits were more advanced than those of his contemporaries in Europe. In brief, his theory was that ore is deposited from groundwater circulating in subsurface fissures. He envisioned the rocks below the surface as traversed by a vast network of cracks filled with fluids. It was, he wrote, as though the Earth were "hanging and floating on a sea boundlessly vast." Ore was thought to be formed by evaporation or precipitation from the fluids underground.

Speculations on earthquakes and volcanic eruptions

Ancient accounts of earthquakes and volcanic eruptions are sometimes valuable as historical records but tell little about the causes of these events. Aristotle held that volcanic explosions and earthquakes alike are caused by spasmodic motions of hot winds that move underground and occasionally burst forth in volcanic activity attended by Earth tremors. Strabo (64 BC–*c.* AD 21) subscribed to the same idea and went on to suggest that volcanoes act as safety valves to vent the explosive force of winds pent up within the Earth. Classical and medieval ideas on earthquakes and volcanoes were brought together in William Caxton's *Mirrour of the World* (1480), an influential work and one of the earliest encyclopaedias in the English language. Earthquakes are here again related to movements of subterranean fluids. Streams of water in the Earth compress the air in hidden caverns. If the roofs of the caverns are weak, they rupture, causing cities and castles to fall into the chasms opened thereby; if strong, they merely tremble and shake from the heaving by the wind below. Volcanic action follows if the outburst of wind and water from the depths is accompanied by fire and brimstone from hell.

Chinese invention of the seismograph

The Chinese have the double distinction of keeping the most faithful records of their earthquakes and of inventing the first instrument capable of detecting them. Records of the dates on which major quakes rocked China go back to 780 BC. In order to detect quakes at a distance, the mathematician, astronomer, and geographer Chang Heng (AD 78–139) invented an instrument that has been called the first seismograph. This consisted of a large bronze vessel containing a heavy pendulum. Arms radiating in eight directions of the compass were levered in the walls of the vessel so that they could be moved by the first swing of the pendulum. When the pendulum was set in motion by earthquake waves, one or another of the arms would be moved, releasing a bronze ball that would fall into a cup attached to the bottom of the vessel. With this release the pendulum was immobilized. The position of the ball that had fallen permitted an estimation of the direction from which the quake had come.

Knowledge of Earth history. The occurrence of seashells embedded in the hard rocks of high mountains aroused the curiosity of early naturalists and eventually set off a controversy on the origin of fossils that continued through the 17th century. Xenophanes of Colophon (flourished *c.* 560 BC) was credited by later writers with observing that seashells occur "in the midst of earth and in mountains," that the prints of fish and of seals are to be found in rocks quarried at Syracuse, Sicily, and that there are all kinds of marine animals in the rocks of Malta. He is said to have believed that these relics originated during a catastrophic event that caused the Earth to be mixed with the sea and then to settle out, burying the organisms in the drying mud. For these views Xenophanes is sometimes called the father of paleontology. Theophrastus is the author of a work on "fishes remaining in a dry condition," a description of fossils found in rocks to the south of the Black Sea. Herodotus and Strabo both accepted the organic nature of fossils and used these in turn as evidence of past changes in sea level. Throughout the Middle Ages, however, fanciful ideas on the nature of fossils were more popular among European authors, or, if the organic hypothesis was entertained, the fossils were usually treated as victims of Noah's Flood.

Fossil evidence of changes in sea level and climate

Petrified wood was described by Chinese scholars as early as the 9th century AD, and around 1080 Shen Kua cited fossilized plants as evidence for change in climate. Stands of petrified bamboo had been uncovered in alluvium near Yen-chou. Shen Kua marveled at this, be-

cause bamboo does not now grow in this area. He suggested that "in very ancient times the climate was different so that the place was low, damp, gloomy, and suitable for bamboos." Other kinds of fossils that attracted the attention of early Chinese writers include spiriferoid brachiopods ("stone swallows"), cephalopods, crabs, and the bones and teeth of reptiles, birds, and mammals ("dragon's bones and dragon teeth"). Although these objects were commonly collected simply as curiosities or for medicinal purposes, Shen Kua (*c.* 1070) recognized marine invertebrate fossils for what they are and for what they imply historically. Observing seashells in strata of the T'ai-hang Shan-mo range, he concluded that this region, though now far from the sea, must once have been a shore. What is today a continent, he observed, must have been of mud and other sediment that was once below the water. The work of the Huang Ho (Yellow River) and the other great rivers of China in carrying sediment to the sea and depositing it there shows how the whole continent must have been laid down.

Knowledge of landforms and of land–sea relations. Changes in the landscape and in the position of land and sea related to erosion and deposition by streams were recognized by a number of the early writers. Herodotus (*c.* 484–426 BC) correctly concluded that the northward bulge of Egypt into the Mediterranean is caused by the deposition of mud carried by the Nile. He records that a sounding line let down in 11 fathoms (66 feet) of water from a ship still a day's sail from the delta brought up mud like that deposited by the Nile during its annual floods. The flatland of the delta and the narrowing floodplain to the south, he reasoned, are "the gift of the Nile," which has filled an ancient gulf with its sediment. He cites marine fossils in strata of northern Egypt as evidence for the former existence of the gulf. Herodotus also cites other areas where smaller rivers draining into the sea have built new land as alluvial plains and, in some instances, have tied former islands to the mainland. Strabo generalized the view of Herodotus on the work of streams in stating that

Formation of river deltas and alluvial plains

> all streams imitate the Nile in that they keep converting the channel just in front of them to land . . .; to a less extent those that do not bring down much mud but to a greater extent those that flow for a great distance through a country with a soft soil and have many torrents as tributaries.

Strabo was willing to believe that streams draining Asia Minor may in time build deltas connecting Cyprus with the mainland.

The early Chinese writers were not outdone by the Romans and Greeks in their appreciation of changes wrought by erosion. In the *Chin shu* ("History of the Chin Dynasty") it is said of Tu Yü (AD 222–284) that when he ordered monumental stelae (huge rock slabs) to be carved with the records of his successes, he had one buried at the foot of a mountain and the other erected on top. He predicted that in time they would likely change their relative positions, because the high hills will become valleys and the deep valleys will become hills.

The concept of cyclicity

Aristotle guessed that changes in the position of land and sea might be cyclical in character, thus reflecting some sort of natural order. If the rivers of a moist region should build deltas at their mouths, he reasoned, seawater would be displaced and the level of the sea would rise to cover some adjacent dry region. A reversal of climatic conditions might cause the sea to return to the area from which it had previously been displaced and retreat from the area previously inundated. The idea of a cyclical interchange between land and sea was elaborated in the *Discourses of the Brothers of Purity*, a classic Arabic work written between AD 941 and 982 by an anonymous group of scholars at Basra (Iraq). The rocks of the lands disintegrate and rivers carry their wastage to the sea, where waves and currents spread it over the sea floor. There the layers of sediment accumulate one above the other, harden, and, in the course of time, rise from the bottom of the sea to form new continents. Then the process of disintegration and levelling begins over again. Cycles of this kind are also mentioned in the Chinese literature. In the 12th century Chu Hsi envisioned that episodes of uplift of mountains and drowning of lowlands were sudden and catastrophic. According to Joseph Needham, the leading Western scholar on the history of Chinese science and technology, Chinese ideas of periodic cataclysms in which the world has been destroyed and created anew are of Indian origin, probably brought to China by the Buddhists.

HYDROLOGIC AND ATMOSPHERIC SCIENCES

The only substance known to the ancient philosophers in its solid, liquid, and gaseous states, water is prominently featured in early theories about the origin and operations of the Earth. Thales of Miletus (*c.* 624–*c.* 545 BC) is credited with a belief that water is the essential substance of the Earth. Anaximander of Miletus (*c.* 610–545 BC), although unwilling to concede that water or any other tangible substance could be considered the ultimate source of all things earthly, held that water was probably the source of life. Animals, he proposed, originated in water and later migrated to the land, where they shed their outer coverings (husks or shells) and otherwise adapted to meet the new conditions. In the system proposed by Empedocles of Agrigentum (*c.* 490–430 BC) water shared the primacy Thales had given it with three other elements: fire, air, and earth. The doctrine of the four earthly elements was later embodied in the universal system of Aristotle (384–322 BC) and thereby influenced Western scientific thought until late in the 17th century.

Knowledge of the hydrologic cycle. The idea that the waters of the Earth undergo cyclical motions, changing from seawater to vapour to precipitation and then flowing back to the ocean, is probably older than any of the surviving texts that hint at or frame it explicitly. Xenophanes held that the source of precipitation is to be sought in the sea, which is "the begetter of clouds and winds and rivers." Aristotle was more specific when he wrote in his *Meteorologica* that by the Sun's heat

> the finest and sweetest water is every day carried up and is dissolved into vapor and rises to the upper region, where it is condensed again by the cold and so returns to the earth. . . . So the sea will never dry up; for before that can happen the water that has gone up beforehand will return to it.

The idea of the hydrological cycle developed independently in China as early as the 4th century BC and was explicitly stated in the following passage from *Lü-shih Ch'un Ch'iu* ("The Spring and Autumn Annals of Mr. Lü"), written in the 3rd century BC:

> The waters flow eastward from their sources, resting neither by day nor by night. Down they come inexhaustibly, yet the deeps are never full. The small [streams] become large and the heavy [waters in the sea] become light [and mount to the clouds].

Origin of rivers, springs, and precipitation

A circulatory system of a different kind, involving movements of water on a large scale within the Earth, was envisioned by Plato (*c.* 428–348/347 BC). In one of his two explanations for the origin of rivers and springs, he described the Earth as perforated by passages connecting with Tartarus, a vast subterranean reservoir. Upsurges in Tartarus force water through the connecting cavities and out into seas, lakes, rivers, and springs. The waters of streams ultimately drain back into Tartarus, thus completing the cycle. In Caxton's *Mirrour* the circulation of water in the hidden passages of the Earth is compared with the circulation of blood.

> Just as the blood of a man runs through the veins of the body and issues forth at a particular place, so the water runs through the veins of the earth and comes to the surface in springs and fountains.

A coherent theory of precipitation is found in the writings of Aristotle. Moisture on the Earth is changed to airy vapour by heat from above. Because it is the nature of heat to rise, the heat in the vapour carries it aloft. When the heat begins to leave the vapour, the vapour turns to water. The formation of water from air produces clouds. Heat remaining in the clouds is further opposed by the cold inherent in the water and is driven away. The cold presses the particles of the cloud closer together, restoring in them the true nature of the element water.

Water naturally moves downward, and so it falls from the cloud as raindrops. Mist is what is left behind after rain has fallen. Snow falls from clouds that have frozen.

In Aristotle's system, the four earthly elements were not stable but could change into one another. If air can change to water in the sky, it should also be able to change into water underground. Streams head in mountains, which act like sponges soaking up air. This air, losing its heat and taking up cold, turns to water, which flows out as springs to nourish streams in their headwaters. Streams, of course, get a part of their water from rain, but since perennial streams flow on sunny as well as rainy days, they must have more reliable sources in the Earth.

The origin of the Nile. Of all the rivers known to the ancients, the Nile was most puzzling with regard to its sources of water. Not only does this river maintain its course up the length of Egypt through a virtually rainless desert, but it rises regularly in flood once each year. Along the southern boundary of Egypt the annual rise begins in June and reaches a maximum in early September. Speculations on the queer behaviour of the Nile were many, varied, and mostly wrong. Thales suggested that the strong winds that blow southward over the delta in summertime hold back the flow of the river and cause the waters to rise upstream in flood. A later variant on this theme was proposed by the Venerable Bede (AD 672/673–735), who thought that these same winds produced waves in the Mediterranean, which in turn build sandbars across the mouths of the distributaries, thus backing up the waters to cause floods. Oenopides of Chios (flourished *c.* 475 BC) thought that heat stored in the ground during the winter dries up the underground veins of water so that the river shrinks. In the summer the heat disappears, and water flows up into the river, causing floods. In the view of Diogenes of Apollonia (flourished *c.* 435 BC), the Sun controls the regimen of the stream. During the hot summers the Sun evaporates water from the surface, drawing up new sources of water from underground passages that connect ultimately with the sea. This action was compared with the movement to the wick of fluid in a lamp. The idea that the Nile waters connect with the sea is an old one, tracing back to the geographic concepts of Hecataeus of Miletus (*c.* 520 BC). Hecataeus conceived the lands of the world to be circular in plan and surrounded by a great swift stream, Oceanus. Of all the rivers, the Nile alone draws its headwaters from Oceanus, whose surgings are reflected in its annual rise and ebb. Ephorus, a Greek historian of the 4th century BC, favoured a solar theory, which envisioned the Sun's "sweating out" water from pores in the Earth during the summer. Other more reasonable explanations related the discharge of the Nile to precipitation in the headwater regions, as snow (Anaxagoras of Clazomenae, *c.* 500–428 BC), or from rain that filled lakes supposed to have fed the river (Democritus of Abdera, *c.* 460–*c.* 357 BC). Eratosthenes (*c.* 276–194 BC), who had prepared a map of the Nile Valley southward to the latitude of modern Khartoum, anticipated the correct answer when he reported that heavy rains had been observed to fall in the upper reaches of the river and that these were sufficient to account for the flooding.

Knowledge of the tides. The tides of the Mediterranean, being inconspicuous in most places, attracted little notice from the Greek and Roman naturalists. Herodotus noted the tides of the Red Sea, and from the voyage of Pytheas (born *c.* 300 BC) came the report of the high spring tides in Pentland Firth between Scotland and the Orkney Islands. Also in the early 4th century, sailors with the expedition of Alexander the Great experienced the tides at the mouth of the Indus. Poseidonius (135–50 BC) correlated variations in the tides with phases of the Moon. Throughout the medieval period in Europe tides were commonly attributed to lunar influence.

Observations of the tidal bore near Hangchow

By contrast, the tides along the eastern shores of Asia generally have a considerable range and were subjects of close observation and much speculation among the Chinese. In particular, the tidal bore on the Ch'ien-t'ang Chiang (Ch'ien-t'ang River) near Hangchow attracted early attention; with its front ranging up to 12 feet in height, this bore is one of the largest in the world. As early as the 2nd century BC, the Chinese had recognized a connection between tides and tidal bores and the lunar cycle. Wang Ch'ung, writing in the 1st century AD, declared that

> the natural processes of Heaven and Earth have remained the same from the most ancient of times. . . . When the rivers fall into the sea there is nothing but rapid motion, but when the sea enters the rivers the waters begin to roar and foam, doubtless because their channels are small, shallow, and narrow . . . the rise of the wave follows the waxing and waning moon.

Tables recording the height of the tides were systematically kept in China at least as far back as the 9th century AD, some four centuries in advance of the earliest European tables.

Prospecting for groundwater. Although the origin of the water in the Earth that seeps or springs from the ground was long the subject of much fanciful speculation, the arts of finding and managing groundwater were already highly developed in the 8th century BC. The construction of long, hand-dug underground aqueducts (*qanats*) in Armenia and Persia represents one of the great hydrological achievements of the ancient world. *Qanats* derive their water from permeable deposits of gravel and sand washed down by streams from mountain ranges into drier lowlands along their borders. Seepages in these alluvial fans (*q.v.*) or patterns of vegetation suggesting proximity to sources of underground water guided the well diggers in their prospecting. Whenever water was found in sufficient quantity, a tunnel was then begun at the downslope location at which delivery of water was desired. The tunnel was then extended toward the head well until the water-bearing beds were penetrated, whereupon the water would flow by gravity to a point of discharge for use in irrigation or for household purposes. These tunnels are quite commonly ten to 16 kilometres (six to ten miles) long and range in depth up to nearly 120 metres (400 feet) below the surface. After some 3,000 years *qanats* are still a major source of water in Iran, where there are more than 270 kilometres (170 miles) of these tunnels in operation.

Construction of *qanats*

In the 1st century BC, Vitruvius (Pollio Vitruvius), a Roman architect and engineer, described methods of prospecting for groundwater in his *De architectura libri decem*. To locate places where water wells should be dug, Vitruvius recommended looking for spots where mist rises from the Earth in early morning. Concentrations of plants of kinds known elsewhere to inhabit marshy situations are also guides to groundwater at shallow depths. More significantly, Vitruvius had learned to associate different quantities and qualities of groundwater with different kinds of rocks and topographic situations. Underground supplies of water are more likely to be found in compact gravel and sand than in loose gravel or clay. Foothills and lowland belts along the borders of mountains are favourable situations for prospecting, because rain falling in the uplands percolates through openings in the rocks and moves underground toward the piedmont belts. Compared with water drawn from clay and loose gravel, water from flinty rocks and from the foothill areas is colder and more wholesome.

III. The 16th, 17th, and 18th centuries

GEOLOGICAL SCIENCES

Ore deposits and mineralogy. A common belief among alchemists of the 16th and 17th centuries held that metalliferous deposits were generated by heat emanating from the centre of the Earth but activated by the heavenly bodies. The Sun influenced the production of gold, which therefore should be most abundant in the hot tropics. In the same mysterious way the Moon generated deposits of silver, Mercury quicksilver, Venus copper, Mars iron, Jupiter tin, and Saturn lead. The origin of the subterranean fire itself was a subject of disagreement. Johann Rudolf Glauber, writing in 1652, proposed that the fire was generated by energies originating in the stars. More than a century earlier Georgius Agricola had offered a

more mundane explanation, attributing the interior heat of the Earth to the burning of coal, bitumin, or sulphur.

Agricola's *De natura fossilium*

Georgius Agricola has with much justification been called the father of mineralogy. Trained first in philology and then in medicine, he became interested in minerals while practicing in the Bohemian mining centre of Joachimsthal. Of his seven geological books, *De natura fossilium* (1546) contains his major contributions to mineralogy and, in fact, has been called the first textbook on that subject. In Agricola's time and well into the 19th century, "fossil" was a term that could be applied to any object dug from the Earth. Thus Agricola's classification of fossils provided pigeon holes for organic remains, such as ammonites, and for rocks of various kinds in addition to minerals. The classification is based on observable physical properties of natural substances, without reference to magical properties then so commonly attributed to various minerals, rocks, and fossils. Individual kinds of minerals, their associations and manners of occurrence, are described in detail, many for the first time.

With the birth of analytical chemistry toward the latter part of the 18th century, the classification of minerals on the basis of their composition at last became possible. Abraham Gottlob Werner (1750–1817) was one of those who favoured a chemical classification in preference to a "natural history" classification based on external appearances. His last of several classifications, published shortly after his death, recognized 317 different substances ordered in four classes. This was still a mixed classification: two of his four classes reflected chemical composition, but his "earthy minerals" and "combustible minerals" reflected other properties reminiscent of the older natural histories.

Paleontology and stratigraphy. During the 17th century the guiding principles of paleontology and historical geology began to emerge in the work of a few individuals. Nicolaus Steno, a Danish scientist and theologian, presented carefully reasoned arguments favouring the organic origin of what are now called fossils. Also, he elucidated three principles that made possible the reconstruction of certain kinds of geological events in a chronological order. In his *Canis carcariae dissectum caput* (1667) he concluded that large tongue-shaped objects found in the strata of Malta were the teeth of great sharks, whose remains were buried beneath the sea floor and later raised out of the water to their present situations. This excursion into paleontology led Steno to confront a broader question. How can one solid body, such as a shark's tooth, become embedded in another solid body, such as a layer of rock? He published his answers in 1669 in a hastily written paper entitled (in translation) "A Preliminary Discourse Concerning a Solid Body Enclosed by Processes of Nature Within a Solid." Steno cited evidence to show that when the hard parts of an organism are covered with sediment it is they and not the aggregates of sediment that are firm. Consolidation of the sediment into rock may come later, and, if so, the original solid fossil will become encased in solid rock. He recognized that sediments settle from fluids layer by layer to form strata that are originally continuous and nearly horizontal. In abbreviated wording, his principle of superposition of strata states that in a sequence of strata, as originally laid down, any stratum is younger than the one on which it rests and older than the one that rests upon it. The principle of initial continuity of strata states that wherever the bared sides of strata are seen, one may infer that their original extensions have been removed (as by erosion) or dislocated (by faulting). The principle of initial horizontality of strata states that where strata are now tilted at high angles one may infer that they have been rotated from their original near-horizontal positions. Applying these principles to the geology of Tuscany, where Steno worked under the patronage of the Grand Duke Ferdinand II, Steno concluded that the sedimentary rocks, geological structures, and physiography of that region record six stages of development. He illustrated this history with geological cross sections, thought to be the first ever published.

Steno's principles of superposition, continuity, and horizontality of strata

In 1667 and 1668, Robert Hooke read papers before the Royal Society in which he expressed many of the ideas contained in Steno's works. Hooke forcefully argued for the organic nature of fossils, which he affirmed are as essential to the study of the Earth's history as coins and urns are to the study of ancient civilizations. Elevation of beds containing marine fossils to mountainous heights he attributed to the work of earthquakes. Streams attacking these elevated tracts wear down the hills, fill depressions with sediment, and thus level out irregularities of the landscape. Unfortunately Hooke's addresses were not published until 1705, by which time most of his ideas had been incorporated in the writings of others.

Earth history according to Genesis, Werner, and James Hutton. Theorists of the late 17th and 18th centuries invented elaborate geological histories, most of which have proved worthless. Thomas Burnet's popular *Sacred History of the Earth* (1681) fitted a state of earthly paradise and Noah's Flood into the geological chronicle and went on to predict a chaotic episode from which the Golden Age will emerge. Georges-Louis Leclerc, comte de Buffon, author of *Époques de la nature* and the encyclopedic *Histoire naturelle*, divided the history of the Earth into seven epochs corresponding to the seven days of Genesis. Assuming that the Earth was originally molten, Buffon calculated that 74,832 years were required for cooling to its present condition. His "epochs" therefore ranged up to 35,000 years in length—too long for the theologians of the Sorbonne, who once forced Buffon to retract his views on the antiquity of the Earth. The two major theories of the 18th century, however, were the Neptunian and the Plutonian.

Neptunists and the universal ocean

The Neptunists, led by Werner and his students, maintained that the Earth was originally covered by a turbid ocean. The first sediments deposited over the irregular floor of this universal ocean formed the granite and other crystalline rocks that Werner called Primitive. Then, as the ocean began to subside, the Transitional Rocks and Stratified Rocks were laid down in succession. Later the Alluvium was washed down to cover parts of the continents. The Volcanic Rocks were the youngest; Neptunists took small account of volcanism and thought that lava was formed by the burning of coal deposits underground.

James Hutton, leader of the Plutonists, viewed the Earth as a dynamic body that functions as a heat machine. Streams wear down the continents and deposit their waste in the sea. Subterranean heat causes the outer part of the Earth to expand in places, uplifting the compacted marine sediments to form new continents. The history of the Earth is a repetition of these cycles of denudation and rejuvenation of the lands. Hutton recognized that granite is an intrusive igneous rock and not a primitive sediment as the Neptunists claimed. Intrusive sills and dikes of igneous rock provide evidence for the driving force of subterranean heat. Great angular unconformities separating sedimentary sequences, such as the one exposed at Siccar Point near his farm in Scotland, Hutton viewed as evidence for past cycles of sedimentation, uplift, and erosion. These events must have required vast amounts of time, but "time is to nature endless and as nothing." In the historical record recorded in the rocks, he found "no vestige of a beginning, no prospect of an end." Hutton's *Theory of the Earth*, published as an essay in 1788, was expanded to a two-volume work in 1795. John Playfair, a professor of natural philosophy at the University of Edinburgh, defended Hutton against the counterattacks of the Neptunists, and his *Illustrations of the Huttonian Theory* (1802) is the clearest contemporary account of Plutonist theory.

HYDROLOGIC SCIENCES

The idea that there is a circulatory system within the Earth, by which seawater is conveyed to mountain tops and there discharged, persisted until early in the 18th century. Two questions left unresolved by this theory were acknowledged even by its advocates. How is seawater forced uphill; how is the salt lost in the process?

The rise of subterranean water. René Descartes supposed that the seawater diffused through subterranean

Ideas on the origin of springs

channels into large caverns below the tops of mountains. There, warmed by the internal heat of the Earth, the water was distilled, the distillate condensing on the roofs of the caverns and pouring out to the surface as springs. The Jesuit philosopher Athanasius Kircher in his *Mundus subterraneus* (1664) suggested that the tides pump seawater through hidden channels to points of outlet at springs. The water of hot springs he assumed to have been warmed in passing through conduits near caverns filled with fire. To explain the rise of subterranean water beneath mountains, Robert Plot, first professor of chemistry at Oxford, appealed to the pressure of air, which forces water up the insides of mountains just as it forces quicksilver up the tube of the barometer. The idea of a great subterranean sea, "a mighty collection of water inclosed in the bowels of the earth," connecting with the ocean and supplying it with water together with all springs and rivers, was resurrected in 1695 in John Woodward's *Essay towards a Natural History of the Earth and Terrestrial Bodies.* Against the proposition that water springs from mountain tops, so often stated in theories of internal circulation, John Keill, an Oxford mathematician, observed that such is not the experience of those who have climbed mountains. Keill cited as expert witness Edward Lhuyd, a Welsh paleontologist and keeper of the Ashmolean Museum, who asserted that "throughout all his travels over Wales, he could observe no such thing as a running spring on the top of a mountain."

Relation of precipitation and surface runoff

Coexisting with the idea of a hydrological cycle propelled from within the Earth was the concept of an external cycle by which the subsurface and surface waters of the Earth are derived from precipitation of moisture evaporated from the sea. Leonardo da Vinci held that both types of cycles operated simultaneously. The French Huguenot Bernard Palissy, famous for his invention of a technique for making enamelled pottery, stoutly maintained, to the contrary, that rainfall is the sole source of rivers and springs. In his *Discours admirables* (1580) he described how rainwater falling on mountains enters cracks in the ground and flows down along these until, diverted by some obstruction, it flows out upon the surface as springs. Perennial streams, he reasoned, must be fed by a host of little springs. Palissy scorned the idea that seawater courses in veins to the tops of mountains. For this to be true, sea level would have to be higher than mountain tops, mountain springs would all be salty and would fluctuate in volume with the rise and fall of tides, and the conduits leading from sea to mountains would have to be watertight—an obvious impossibility.

Explanation of artesian flow

In his *Discours* Palissy suggested that water would rise above the level at which it was first encountered in a well provided the source of the groundwater came from a place higher than the bottom of the well. This is an early reference to conditions essential to the occurrence of artesian water, a popular subject among Italian hydrologists of the 17th and 18th centuries. Bernardino Ramazzini was one of those who wrote about the famous artesian wells and springs around the city of Modena in the Po Valley. To account for the force that caused these waters to gush forth, he assumed that a great natural cistern lay nearby in the "bowels of the Apennines." Water flowed from this cistern down through an underground channel beneath the Po Valley, so that wells dug into this channel would allow the water to rise and spill out their tops. How the water got into the cistern in the first place posed a problem. Ramazzini thought it might be supplied by the sea. Antonio Vallisneri, president of the University of Padua, came close to the right answer when he concluded that meltwater from mountain snowfields sinks into the ground to form subterranean streams that pass below Modena. In wells drilled to intersect these streams the water must necessarily rise because it is under great pressure. Issues raised in the discussions about the hydrologic cycle and the origin of water in springs and streams were finally settled by measurements of precipitation, discharge from drainage basins, and evaporation of seawater.

In the latter part of the 17th century, Pierre Perrault and Edmé Mariotte conducted hydrological investigations in the basin of the Seine River that established that the local annual precipitation was more than ample to account for the annual runoff. Perrault's studies covered only a small drainage basin above Ayney le Duc, Mariotte's the entire basin above the confluence of the Marne. Perrault's calculations showed that only about one-sixth of the water that falls as rain and snow during the year is accounted for by stream discharge. Mariotte's figures showed that the annual volume of water flowing in the Seine past a point near Pont Royal is less than one-sixth the volume of water annually precipitated in the drainage basin upstream. Extrapolating from his findings, Perrault deemed it likely that "the waters of rains and snows are sufficient to cause the flow of all the rivers of the world."

Halley's explanation of ocean salinity

Evaporation from the sea. The question remained as to whether the amount of water evaporated from the sea is sufficient to account for the precipitation that feeds the streams. Edmund Halley and his associates at Gresham College measured the rate of evaporation from pans of water exposed to the air during hot summer days. Assuming that this same rate would obtain for the Mediterranean, Halley calculated that some 5,280,000,000 tons of water are evaporated from this sea during a summer day. Assuming further that each of the nine major rivers flowing into the Mediterranean has a daily discharge ten times that of the Thames, he calculated that a daily inflow of fresh water back into that sea would be 1,827,000,000 tons, only slightly more than a third of the amount lost by evaporation. Halley went on to explain what happens to the remainder. A part falls back into the sea as rain before it reaches land. Another part is taken up by plants, later to be "exhaled in vapour by the action of the sun" and then carried elsewhere by the winds. "Yet," he concluded, "after several vicissitudes of rising in vapour and falling in rain or dews, each particle of the water is at length returned to the sea from whence it came."

In the course of the hydrological cycle, Halley reasoned, the rivers constantly bring salt into the sea in solution, but the salt is left behind when seawater evaporates to replenish the streams with rainwater. Thus the sea must be growing steadily saltier. Knowing the salinity of the sea and the annual input of new salt from streams, it should be possible to estimate the age of the Earth, he suggested.

ATMOSPHERIC SCIENCES

Water vapour in the atmosphere. After 1760 the analytical chemists at last demonstrated that water and air are not the same substance in different guises. Long before this development, however, investigators had begun to draw a distinction between water vapour and air. Otto von Guericke, who invented the air pump around 1650, produced artificial clouds by releasing air from one flask into another one from which the air had been evacuated. A fog then formed in the unevacuated flask. Guericke concluded that air cannot be turned into water, though moisture can enter the air and later be condensed into water.

Guericke's experiments, however, did not answer the question as to how water enters the atmosphere as vapour. Descartes, in *Les Météores* (1637), envisioned water as composed of minute particles that were elongate, smooth, and separated by a highly rarified "subtle matter." When the Sun warms water, the heat agitates this subtle matter and the water particles fly into the air just as dust is raised by the kick of a boot. These clouds of water particles raised into the air constitute water vapour, which is thus made of the same particles as water but separated by much more of the subtle matter. Other investigators associated vapour with fire. The priest Urbano d'Aviso suggested in 1666 that water vapour consists of tiny bubbles that are filled with fire and ascend through the air like balloons. The idea that fire, conceived as a material substance, is mainly responsible for evaporation persisted until near the end of the 18th century. A third view of evaporation held that water is dis-

solved in the atmosphere to produce vapour just as salt is dissolved in water. Charles Le Roy, who defended this position in 1752, went on to affirm that temperature determines how much water air can dissolve, just as it determines how much salt water can hold in solution.

Cloud formation and motion

The same uncertainty as to how water gets into the air surrounded the question as to how it remains suspended as clouds. A popular view in the 18th century was that clouds are made of countless tiny bubbles that float in air just as highly vesicular bits of pumice float in water. Guericke had suggested that the fine particles in his artificial clouds were bubbles. Other observers professed to have seen, with the aid of microscopic devices, bubble-shaped particles of water vapour rising from warm water or hot coffee.

Pressure, temperature, and atmospheric circulation. If clouds are essentially multicompartmented balloons, their motions could be explained by the movements of winds blowing upon them. Descartes suggested that the winds might blow upward as well as laterally, causing the clouds to rise or at least preventing them from descending. In 1749, Benjamin Franklin explained updrafts of air as due to local heating of the atmosphere by the Sun. Sixteen years later, the mathematical physicist Johann Heinrich Lambert described the conditions necessary for the initiation of convection currents in the atmosphere. Lambert reasoned that the warm air rising by local heating flows laterally aloft into bordering areas of cooler air, increasing the downward pressure of these and causing their lower layers to flow into the area of ascending currents, thus producing circulation.

Importance of the barometer

The fact that Lambert could appeal to changes in air pressure to explain circulation reflects an important change from the view still current in the late 16th century that air is weightless. This misconception was corrected after 1643 with the invention of the mercury barometer. Almost immediately it was discovered that the height of the barometer varied with the weather, usually standing at its highest during spells of clear weather and falling to the lowest marks on rainy days. This was exactly the opposite of the results anticipated, for common sense would seem to require that clear air is lighter than murky air.

Toward the end of the 18th century it was beginning to be understood that variations in the barometer must somehow be related to the general motion and circulation of the atmosphere. That these variations could not be due solely to changes in humidity was the conclusion of Horace Bénédict de Saussure in his *Essais sur l'hygrométrie* (1783). From experiments with changes of water vapour and pressure in air enclosed in a glass globe, Saussure calculated that if the entire atmosphere should change from a state of full saturation to one of complete dryness, a change of only a half inch in the mercury would result. He concluded that changes in temperature must be immediately responsible for variations of the barometer and that these in turn must be related to the movement of air from one place to another.

The idea that clouds lose their rain by mechanical effects of colliding with hills was an imperfect explanation of a phenomenon so common that it must have been noted by observers of all times. Orographic precipitation is the name now given to the rain and snow precipitated from moist air blowing in from the sea and forced to rise above uplands with attendant cooling. In 1693 Halley described the characteristics of orographic precipitation and went on to draw a providential moral on the purpose of the hills.

> This, if we may allow final causes, seems to be the design of the hills, that their ridges being placed through the midst of the continents, might serve . . . to distil fresh water for the use of man and beast, and their heights to give a descent to those streams to run gently, like so many veins of the macrocosm, to be more beneficial to the creation. . . .

IV. The 19th century

GEOLOGICAL SCIENCES

Crystallography and the classification of minerals and rocks. René-Just Häuy, whose treatises on mineralogy and crystallography appeared in 1801 and 1822, respectively, has been credited with advancing mineralogy to the status of a science and with establishing the science of crystallography. From his studies of the geometrical relationships between planes of cleavage, he concluded that the ultimate particles forming a given species of mineral all have the same shape and that variations in crystal habit only reflect differences in the ways identical molecules are put together. Meanwhile, Jöns Jacob Berzelius was improving methods for chemical analysis of minerals, and in 1814 he published a system of mineralogy offering a comprehensive classification of minerals based on their chemistry. Berzelius recognized silica as an acid and introduced into mineralogy the important group of minerals known as silicates. At midcentury James Dwight Dana's *System of Mineralogy* appeared in a third edition reorganized around a chemical classification, which thereafter became standard for mineralogic handbooks.

Optical studies of rocks

The development of the polarizing microscope and the technique for grinding sections of rocks so thin as to be virtually transparent came in 1827 from studies of fossilized wood by William Nicol. In 1849 Clifton Sorby showed that minerals viewed in thin section could be identified by their optical properties, and soon afterward improved classifications of rocks were made on the basis of their mineralogic composition. Ferdinand Zirkel's *Mikroscopische Beschaffenheit der Mineralien und Gesteine* (1873) contains one of the first mineralogic classifications of rocks and marks the emergence of microscopical petrography as an established branch of science.

William Smith and faunal succession. In 1683 the zoologist Martin Lister proposed to the Royal Society that a new sort of map be drawn showing the areal distribution of the different kinds of British "soiles" (vegetable soils and underlying bedrock). The work proposed by Lister was not accomplished until 132 years later, when William Smith published his *Geologic Map of England and Wales with part of Scotland* (1815). A self-educated surveyor and engineer, Smith had the habit of collecting fossils and making careful note of the strata that contained them wherever his professional travels took him. He discovered that the different stratified formations in England contain distinctive assemblages of fossils. His map, reproduced on a scale of five miles to the inch, showed 20 different rock units, to which Smith applied local names in common use—*e.g.*, London Clay and Purbeck Beds. In 1816 Smith published a companion work, *Strata Identified by Organized Fossils*, in which the organic remains characteristic of each of his rock units were illustrated. His generalization that each formation is "possessed of properties peculiar to itself [and] has the same organized fossils throughout its course" is the first clear statement of the principle of faunal sequence, which is the basis for worldwide correlation of fossiliferous strata into a coherent system. Smith thus demonstrated two kinds of order in nature: order in the spatial arrangement of rock units and order in the succession of ancient forms of life. In his own words:

> Fossils have been studied as great curiosities, collected with great pains, treasured with great care and at great expense, and shown and admired with as much pleasure as a child's rattle or a hobby horse is shown and admired by himself and his play fellows, because it is pretty; and this has been done by thousands who have not paid the least regard to that wonderful order and regularity which Nature has disposed of these singular productions, and assigned to each class its peculiar stratum.

Other paleontologists, William Buckland, for example, were interested more in what fossils can tell about ancient life than in their usefulness for correlating strata. This difference in interest divides the stratigraphical paleontologists from the paleobiologists until the present. Before the end of the 19th century, systematic studies had been made on the main groups of fossil animals and plants. The results are summarized in Karl A. von Zittel's *Handbuch der Palaeontologie*, compiled over 17 years beginning in 1876.

Smith's principle of faunal sequence was another way of saying that there are discontinuities in the sequences of fossilized plants and animals. These discontinuities

Cuvier's catastrophic viewpoint

were interpreted in two ways: as indicators of episodic destruction of life or as evidence for the incompleteness of the fossil record. Baron Georges Cuvier was one of the more distinguished members of a large group of naturalists who believed that paleontological discontinuities bore witness to sudden and widespread catastrophes. Cuvier's skill at comparative anatomy enabled him to reconstruct from fragmentary remains the skeletons of large vertebrate animals found at different levels in the Cenozoic sequence of northern France. From these studies he discovered that the fossils in all but the youngest deposits belong to species now extinct. Moreover, these extinct species have definite ranges up and down in the stratigraphic column. Cuvier inferred that the successive extinctions were the result of convulsions that caused the strata of the continents to be dislocated and folded and the seas to sweep across the continents and just as suddenly subside.

Charles Lyell and uniformitarianism. In opposition to the catastrophist school of thought, Charles Lyell proposed a uniformitarian interpretation of geologic history, first expounded in his *Principles of Geology* (3 vols., 1830–33). His system was based on two propositions: the causes of geologic change now operating include all the causes that have acted from the earliest time to which we can look back; and these causes have always operated at the same average levels of energy as at present. These two propositions add up to a "steady-state" theory of the Earth, whose history is without definite directional trends either physically or organically. There has been no progressive cooling of the Earth through time. Changes in climate have fluctuated around a mean, reflecting changes in the position of land and sea. Progress through time in the organic world is likewise an illusion, the effect of an imperfect paleontological record. If mammalian fossils seem to be missing from the older strata, this is probably due to the fact that ancient mammals were terrestrial, whereas these strata are predominantly marine. Given the vast duration of geological time, a host of small changes can produce spectacular results: a long series of quakes with upward dislocations of only a few feet each could in time produce an Andean chain, and given enough time a small stream could cut a Grand Canyon. Appealing to convulsions of nature to explain past changes is a procedure "calculated to foster indolence, and blunt the keen edge of curiosity." The main part of the *Principles*, however, was devoted less to theory than to procedures for inferring events from rocks; and for Lyell's clear exposition of methodology his work was highly regarded throughout its many editions, long after the author himself had abandoned anti-progressivist views on the development of life.

The steady-state view of Earth history

Louis Agassiz and the Ice Age. Huge boulders of granite resting upon limestone of the Jura Mountains were subjects of controversy during the 18th and early 19th centuries. Saussure described these in 1779 and called them erratics. He concluded that they had been swept to their present positions by torrents of water, even though their nearest possible sources lay in croppings of granite 100 kilometres (60 miles) away. Saussure's interpretation was in accord with the tenets of diluvial geologists, who interpreted erratics and sheets of unstratified sediment (till or drift) spread over the northerly parts of Europe and North America as the work of the Deluge.

Argument for large-scale glaciation of Europe and Asia

In 1837, the Swiss zoologist and paleontologist Louis Agassiz delivered a startling presidential address before the Helvetian Society, proposing that, during a geologically recent stage of refrigeration, glacial ice had covered Eurasia from the North Pole to the shores of the Mediterranean and Caspian. The onset of glacial climate must have been sudden, because mammoths in Siberia were frozen in their tracks. Wherever erratics, till, and striated pavements of rock occur throughout the world, these provide sure evidence of this recent catastrophe. The reception accorded this address was glacial, too, and Alexander von Humboldt advised Agassiz to return to his fossil fishes. Instead, he began intensive field studies and in 1840 published his *Études sur les glaciers*, a monumental and superbly illustrated work, clearly demonstrating that Alpine glaciers had been far more extensive in the past than now. That same year he visited the British Isles in the company of Buckland and extended the glacial doctrine to Scotland, northern England, and Ireland. In 1846 he carried his campaign to North America and there found much additional evidence for an Ice Age.

Geological time and the age of the Earth. By the middle of the century the fossiliferous strata of Europe had been grouped into systems arrayed in chronologic order. The stratigraphic column, a mental composite of these systems, was pieced together from exposures in different regions by application of the principles of superposition and faunal sequence. Time elapsed during the formation of a system became known as a period, and the periods in turn were grouped into eras: the Paleozoic (Cambrian through Permian periods), Mesozoic (Triassic, Jurassic, and Cretaceous periods), and Cenozoic (Tertiary and Quaternary periods).

Charles Darwin's *Origin of Species* (1859) offered a theoretical explanation for the empirical principle of faunal sequence. The fossils of the successive systems are different not only because parts of the stratigraphic record are missing but also because most species have lost in their struggles for survival and also because those that do survive evolve into new forms with the passage of time. On the tree of life there are many dead branches and branches fallen to the ground surround its trunk, but all life is interrelated, grown from the same stock. Darwin borrowed two ideas from Lyell and the uniformitarians: the idea that geologic time is virtually without limit and the idea that a sequence of minute changes integrated over long periods of time produce remarkable changes in natural entities.

Limitations based on the Earth's heat production

Both the evolutionists and the historical geologists were embarrassed when, beginning in 1864, William Thomson (later Lord Kelvin) attacked the steady-state theory of the Earth and placed numerical strictures on the length of geological time. The Earth might function as a heat machine, but it could not also be a perpetual motion machine. Assuming that the Earth was originally molten, Thomson calculated that not less than 20,000,000 and not more than 400,000,000 years could have passed since the Earth first became a solid body. Other physicists of note put even narrower limits on the Earth's age ranging down to 15,000,000 or 20,000,000 years. All these calculations, however, were based on the common assumption, not always explicitly stated, that the Earth's substance is inert and hence incapable of generating new heat through time. Shortly before the end of the century this assumption was negated by the discovery of radioactive elements that disintegrate spontaneously and release heat to the Earth in the process.

Concepts of landform evolution. The scientific exploration of the American West following the end of the Civil War yielded much new information on the sculpture of the landscape by streams. John Wesley Powell in his reports on the Colorado River and Uinta Mountains (1875, 1876) explained among other matters how streams may come to flow across mountain ranges rather than detour around them. The Green River does not follow some structural crack in its gorge across the Uinta Mountains; instead it has cut its canyon as the mountain range was slowly bowed up, somewhat as a rotary saw cuts a slot in the log pressed against it. "The mountains," Powell wrote, "are carved by the clouds—patient artists who take what time may be necessary for their work." Or, streams cutting down through surfaces of unconformity could become superimposed across the structural grain of the strata beneath and cut across the belts of harder rock later brought into relief by erosion. Given enough time, streams will erode their drainage basins to plains approaching sea level as a base. Grove Karl Gilbert's *Report on the Geology of the Henry Mountains* (1877) offered a detailed analysis of fluvial processes. According to Gilbert (1843–1918) all streams work toward a graded condition, a state of dynamic equilibrium that is attained when the net effect of the flowing water is neither erosion of the bed nor deposition of sediment, when the landscape reflects a balance between the resistance of the

Gilbert's statement of dynamic equilibrium

rocks to erosion and the processes that are operative upon them. After 1884 William Morris Davis developed the concept of the geographical cycle, during which elevated regions were supposed to pass through successive stages of dissection and denudation characterized as youthful, mature, and old. Youthful landscapes are said to have broad divides and narrow valleys. With further denudation the original surface on which the streams began their work is reduced to ridgetops. Finally in the stage of old age, the region is reduced to a nearly featureless plain near sea level or its inland projection. Uplift of the region in any stage of this evolution will activate a new cycle. Davis' views dominated geomorphic thought until well into the 20th century, when quantitative approaches resulted in the rediscovery of Gilbert's ideas.

Gravity, isostasy, and the Earth's figure. Discoveries of regional anomalies in the Earth's gravity led to the realization that high mountain ranges have underlying deficiencies in mass about equal to the apparent surface loads represented by the mountains themselves. In the 18th century Pierre Bouguer had observed that the deflections of the pendulum in Peru are much less than they should be if the Andes represent a load perched on top of the Earth's crust. Similar anomalies were later found to obtain along the Himalayan front. To explain these anomalies it was necessary to assume that beneath some depth within the Earth pressures are hydrostatic (equal on all sides). If excess loads are placed upon the crust, as by addition of a continental ice cap, the crust will sink to compensate for the additional mass and will rise again when the load is removed. The tendency toward general equilibrium maintained through vertical movements of the Earth's outer layers was called isostasy in 1899 by Clarence Edward Dutton.

Concept of the geosyncline and mountain building

Evidence for substantial vertical movements of the crust was supplied by studies of regional stratigraphy. In an address published in 1883, James Hall demonstrated that Paleozoic rocks of the folded Appalachians were several times as thick as sequences of the same age in the plateaus and plains to the west. He concluded that the folded strata in the mountains must have accumulated in a linear submarine trough that filled with sediment as it subsided. Downward crustal flexures of this magnitude came to be called geosynclines.

HYDROLOGIC SCIENCES

Darcy's law and groundwater flow. Quantitative studies of the movement of water in streams and aquifers led to the formulation of mathematical statements relating discharge to other factors. Henri Darcy was the first to state clearly a law describing the flow of groundwater. Darcy's experiments, reported in 1856, were based on the ideas that an aquifer is analogous to a main line connecting two reservoirs at different levels and that an artesian well is like a pipe drawing water from a main line under pressure. His investigations of flow through stratified beds of sand led him to conclude that the rate of flow is directly proportional to the energy loss and inversely proportional to the length of the path of flow. A coefficient whose value depends on the characteristics of the sand was also entered as a factor in Darcy's law. Jules-Juvénal Dupuit extended Darcy's work and developed equations for underground flow toward a well, for the recharge of aquifers, and for the discharge of artesian wells. Philip Forchheimer, an Austrian hydrologist, introduced the theory of functions of a complex variable to analyze the flow by gravity of underground water toward wells and developed equations for determining the critical distance between a river and a well beyond which water from the river will not move into the well. In the United States, Charles Sumner Slichter, unaware of Forchheimer's work, duplicated much of it. He developed an elaborate expression for the movement of water through a vertical column of soil and developed techniques for measuring the rate of flow of groundwater by injecting electrolytes into the ground at one point and detecting their arrival at another by use of an ammeter.

Surface water discharge. A complicated empirical formula for the discharge of streams resulted from the studies of Andrew Atkinson Humphreys and Henry Larcom Abbot in the course of the Mississippi Delta Survey of 1851–60. Their formula contained no term for roughness of channel and on this and other grounds was later found to be inapplicable to the rapidly flowing streams of mountainous regions. In 1869 Emile-Oscar Ganguillet and Rudolph Kutter developed a more generally applicable discharge equation following their studies of flow in Swiss mountain streams. Toward the end of the century, systematic studies of the discharge of streams had become common. In the United States the Geological Survey, following its establishment in 1879, became the principal agency for collecting and publishing data on discharge, and by 1906 stream gauging had become nationwide.

Foundations of oceanography. In 1807 Thomas Jefferson ordered the establishment of the U.S. Coast Survey (later Coast and Geodetic Survey and now the National Ocean Survey). Modelled after British and French agencies that had grown up in the 1700s, the National Oceanographic Survey was charged with the responsibilities of hydrographic and geodetic surveying, studies of tides, and preparation of charts. Beginning in 1842 the U.S. Navy began expansive oceanographic operations through its office of charts and instruments. Lieut. Matthew Fontaine Maury, officer in charge of operations, began to correlate observations of winds and currents made by ships of the Navy and promoted international cooperation in gathering meteorologic and hydrologic data at sea. In 1847 Maury compiled the first wind and current charts for the North Atlantic and in 1854 issued the first depth map to 4,000 fathoms (7,300 metres [24,000 feet]). His *Physical Geography of the Sea* (1855) is generally considered the first oceanographic textbook. Aside from Maury's scientific contributions, his charts greatly reduced the cost and time of travel across the Atlantic.

Maury's compilation of oceanographic data

The voyage of the "Beagle" (1831–36) is well remembered for the biological and geological contributions of its young naturalist, Charles Darwin. From his observations in the South Pacific, Darwin formulated a theory for the origin of coral reefs, which with minor modifications has stood the test of time. Darwin viewed the fringing reefs, barrier reefs, and atolls as successive stages in a developmental sequence. The volcanic islands around which the reef-building organisms are attached slowly sink, but at the same time the shallow-water organisms that form the reefs build their colonies upward so as to remain in the sunlit layers of water. With submergence of the island, what began as a fringing reef girdling a landmass at last becomes an atoll enclosing a lagoon. The development of these reefs thus records a contest between organisms and the blind forces of nature—an idea Darwin would use later in his theory of organic evolution.

Laying telegraphic cables across the Atlantic called for investigations of the configuration of the ocean floor, of the currents that sweep the bottom, and of the benthonic animals that might damage the cables. The explorations of the British ships "Lightning" and "Porcupine" in 1868 and 1869 turned up surprising oceanographic information. In waters west of the British Isles masses of bottom water adjacent to each other were found to have distinctly different temperatures. Living crinoids, a group of echinoderms thought to have been long extinct, were brought to the surface. Following closely upon these voyages, the "Challenger" was authorized to determine "the conditions of the Deep Sea throughout the Great Ocean Basins."

The "Challenger" expedition (1872–76)

The "Challenger" left port in December of 1872 and returned in May 1876, after logging 68,890 nautical miles. Under the direction of Wyville Thomson, Scottish professor of natural history, she occupied 350 stations scattered over all oceans except the Arctic. The work involved in analyzing the information gathered during the expedition was completed by Thomson's shipmate Sir John Murray, and the results filled 50 large volumes. Hundreds of new species of marine organisms were described, including new forms of life from deep waters.

The temperature of water at the bottom of the oceans was found to be nearly constant below the 2,000-fathom (12,000-foot) level, averaging about 2.5° C (36.5° F) in the North Atlantic and 2° C (35° F) in the North Pacific. Soundings showed wide variations in depths of water, and from the dredgings of the bottom came new types of sediment—red clay, and oozes made predominantly of the minute skeletons of foraminifera, radiolarians, or diatoms. Improved charts of the principal surface currents were produced, and the precise location of many oceanic islands was determined for the first time. Seventy-seven samples of seawater were taken at different stations from depths ranging downward to nearly a mile. Wilhelm Dittmar conducted quantitative determinations of the seven major constituents (other than the hydrogen and oxygen of the water itself); namely, sodium, calcium, magnesium, potassium, chloride, bromide, and sulfate. Surprisingly, the percentages of these components turned out to be nearly the same in all samples.

Tidal analysis and prediction

Efforts to analyze the rise and fall of the tides in mathematical terms reflecting the relative and constantly changing positions of Earth, Moon, and Sun, and thus to predict the tides at particular localities, has never been entirely successful, because of local variations in configuration of shore and sea floor. Nevertheless, harmonic tidal analysis gives essential first approximations that are essential to tidal prediction. In 1884 a mechanical analogue tidal prediction device was invented by William Ferrel of the U.S. Coast and Geodetic Survey, and improved models were used until 1965, when the work of the analogue machines was taken over by electronic computers.

ATMOSPHERIC SCIENCES

Composition of the atmosphere. Studies of barometric pressure by John Dalton led him to conclude that evaporation and condensation of vapour do not involve chemical transformations. Water vapour, he stated, "always exists as a fluid *sui generis*, diffused among the rest of the aerial fluids." If so, the introduction of vapour into the air by evaporation must change the average specific gravity of the air column and, without altering the height of that column, will change the reading of the barometer. Rudolf Clausius in 1857 clarified the mechanics of evaporation in his kinetic theory of gases. Evaporation occurs when more molecules of a liquid are leaving its surface than returning to it, and the higher the temperature the more of these escaped molecules will be in space at any one time.

Sampling the atmosphere by balloon

Following the invention of the hot-air balloon by the Montgolfier brothers in 1783, balloonists produced some useful information on the composition and movements of the atmosphere. In 1804 the celebrated French chemist Louis-Joseph Gay-Lussac ascended to 6,636 metres (21,766 feet), took samples of air, and later determined that the rarefied air at that altitude contained the same percentage of oxygen (21.49 percent) as the air on the ground. Austrian meteorologist Julius von Hann, working with data from balloon ascents and climbing in the Alps and Himalayas, concluded in 1874 that about 90 percent of all the water vapour in the atmosphere is concentrated below 6,000 metres (20,000 feet)—from which it follows that high mountains can be barriers against the transport of water vapour. In 1843 balloonist John Wise inadvertently demonstrated the violent motions of convectional updrafts in thunderstorms when he floated into such a storm near Harrisburg, Pennsylvania. He was lifted up and thrust down eight or ten times, and when he finally landed his beard bristled with hoarfrost and his equipment was covered with ice and snow.

Understanding of clouds, fog, and dew. Most of the names given to clouds (cirrus, cumulus, stratus, nimbus, and their combinations) were coined in 1803 by Luke Howard. Howard's effort was not simply taxonomic: he recognized that clouds reflect in their shapes and changing forms "the general causes which effect all the variations of the atmosphere, just as the countenance of a person reflects the state of his mind or body."

After Guericke's experiments, it was widely believed that water vapour condenses into cloud as soon as the air containing it cools to the dew point. That this is not necessarily so was proved by Paul-Jean Coulier from experiments reported in 1875. Coulier found that the sudden expansion of air in glass flasks failed to produce an artificial cloud if the air in the system was filtered through cotton wool. He concluded that dust in the air was essential to the formation of cloud in the flask. John Aitken carried the Coulier experiments further to show that the fewer the dust particles in the system the coarser grained the fog. These and subsequent investigations have shown that the dust particles, or nuclei of condensation, are mostly invisible sea salts and products of combustion. Even in unsaturated air water may form on these nuclei to produce haze.

Discovery of condensation nuclei

Beginning around the second quarter of the century, efforts were made to classify precipitation in terms of the causes behind the lowering of temperature. In 1841 Elias Loomis recognized the following causes: warm air coming into contact with cold earth or water, responsible for fog; mixing of warm and cold currents, which commonly results in light rains; and sudden transport of air into high regions, as by flow up a mountain slope or by warm currents riding over an opposing current of cold air, which may produce heavy rains. The formation of dew Loomis attributed to radiation, but in this he had been anticipated by demonstrations conducted after 1812 by William Charles Wells. Among other matters Wells had disposed of the idea that dew on plants is transpired solely by the plants themselves, pointing out that dew forms on dead vegetation as well as on live.

Observation and study of storms. Storms, particularly tropical revolving storms, were subjects of much interest.

Recognition of the revolving nature of storms

As early as 1697 some of the more spectacular features of revolving storms were recorded in William Dampier's *New Voyage Round the World.* On July 4, 1687, Dampier's ship survived the passage of what he called a "tuffoon" off the coast of China. The captain's vivid account of this experience clearly describes the calm central eye of the storm and the passage of winds from opposite directions as the storm moved past. Heinrich Wilhelm Dove in 1828 recognized that tropical revolving storms are travelling systems with strong winds moving counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. The whirlwind character of these storms was independently established by William C. Redfield in the case of the September hurricane that struck New England in 1821. He noted that in central Connecticut the trees had been toppled toward the northwest, whereas some 80 kilometres (50 miles) westward they had fallen in the opposite direction. Redfield identified the belt between the equator and the tropics as the region in which hurricanes are generated, and he recognized how the tracks of these storms tend to veer eastward when they enter the belt of westerly winds at about latitude 30° N. In 1849, Sir William Reid studied the revolving storms that occur south of the Equator in the Indian Ocean and confirmed that they have reversed rotations and curvatures of path compared with those of the Northern Hemisphere. Captain Henry Piddington subsequently investigated revolving storms affecting the Bay of Bengal and Arabian Sea, and in 1855 he named these cyclones (from the Greek word for the coil of a snake) in his *Sailor's Horn-book for the Laws of Storms in all Parts of the World.*

Consideration of energy sources

Beginning in 1835 James Pollard Espy began extensive studies of storms from which he developed a theory to explain their sources of energy. Radially convergent winds, he believed, cause the air to rise in their area of collision. Upward movement of moist air is attended by condensation and precipitation. Latent heat released through the change of vapour to cloud or water causes further expansion and rising of the air. The higher the moist air rises the more the equilibrium of the system is disturbed, and this equilibrium cannot be restored until moist air at the surface ceases to flow toward the ascending column. Though Espy greatly overestimated the energies inherent in rising air, he called attention to one of the forces that drives storms.

That radially convergent winds are not necessary to the rising of large air masses was demonstrated by Loomis in the case of a great storm that passed across the northeastern United States in December of 1836. From his studies of wind patterns, changes of temperature, and changes in barometric pressure, he concluded that a cold northwest wind had displaced a wind blowing from the southeast by flowing under it. The southeast wind made its escape by ascending from the surface of the Earth. Loomis had clearly recognized what today would be called a frontal surface.

Weather and climate. Modern meteorology began when the daily weather map was developed as a device for analysis and forecasting, and the instrument that made this kind of map possible was the electromagnetic telegraph. In the United States the first telegraph line was strung in 1844 between Washington, D.C., and Baltimore. Concurrently with the expansion of telegraphic networks, physicist Joseph Henry arranged for telegraph companies to have meteorological instruments in exchange for current data on weather telegraphed to the Smithsonian Institution. Some 500 stations had joined this cooperative effort by 1860. The Civil War temporarily prevented further expansion, but, meanwhile, a disaster of a different order had accelerated development of synoptic meteorology in Europe. On November 14, 1854, an unexpected storm wrecked British and French warships off Balaklava, now Ukrainian S.S.R. Had word of the approaching storm been telegraphed to this port in the Black Sea, the ships might have been saved. This mischance led in 1856 to the establishment of a national storm-warning service in France. In 1863 the Paris Observatory began publishing the first weather maps in modern format.

The first national weather service in the United States began operations in 1871 as an agency of the Department of War, with responsibility assigned to the Signal Service. The initial objective was to provide storm warnings for the Gulf and Atlantic coasts and the Great Lakes. In 1877 forecasts of temperature changes and precipitation averaged 74 percent in accuracy, as compared with 79 percent for cold-wave warnings. After 1878 daily weather maps were published.

Synoptic meteorology made possible the tracking of storm systems over wide areas. In 1868 Alexander Buchan published a map showing the travels of a cyclonic depression across North America, the Atlantic, and on into northern Europe. In the judgment of Sir Napier Shaw, Buchan's study marks the entry of modern meteorology, with "the weather map as its main feature and forecasting its avowed object."

Mapping regional variations

In addition to weather maps, a variety of other kinds of maps showing regional variations in the components of weather and climate were produced. In 1817, Alexander von Humboldt published a map showing the distribution of mean annual temperatures over the greater part of the Northern Hemisphere. Humboldt was the first to use isothermal lines in mapping temperature. Dove produced maps in 1848 showing mean monthly temperatures and in 1852 introduced further refinements showing thermal anomalies (local departures from mean temperatures). Buchan drew the first maps of mean monthly and annual pressure for the entire world. Published in 1869, these maps added much to knowledge of the general circulation of the atmosphere. Maury's charts of winds and currents (1848–60) were the first to use observations of winds made at sea. In 1886 Léon Teisserenc de Bort published maps showing mean annual cloudiness over the Earth for each month and the year. The first world map of precipitation showing mean annual precipitation by isohyets was the work of Loomis in 1882. This work was further refined in 1899 by Andrew John Herbertson's maps showing precipitation for each month of the year.

Thus although the 19th century was still in the age of meteorologic and climatologic exploration, broad syntheses of old information fairly well kept pace with acquisition of the new. For example, Julius Hann's massive *Handbuch der Klimatologie*, first issued in 1883, is mainly a compendium of works published in the *Meteorologische Zeitschrift*, of which Hann was long the editor. The *Handbuch* was kept current in revised editions until 1911, and this work is still sometimes called the most skillfully written account of world climate.

V. The 20th century

GEOLOGICAL SCIENCES

Radiometric dating. In 1905, shortly after the discovery of radioactivity, Bertram Boltwood suggested that lead is one of the disintegration products of uranium, in which case the older a uranium-bearing mineral the greater should be its proportional part of lead. Analyzing specimens whose relative geological ages were known, Boltwood found that the ratio of lead to uranium did indeed increase with age. After estimating the rate of this radioactive change he calculated that the absolute ages of his specimens ranged from 410,000,000 to 2,200,000,000 years. Though his figures were too high by about 20 percent, their order of magnitude was enough to dispose of the short scale of geological time proposed by Kelvin. Later studies have shown that radioactivity is a more complex process than Boltwood realized. At present the decay series generally used for dating minerals and rocks include isotopes in the following couplets of parent and daughter elements: thorium–lead, rubidium–strontium, potassium–argon, and carbon–nitrogen.

Advent of geochronology

Radiometric dating has confirmed the chronological order of the geological systems as first established solely on stratigraphic and structural principles and has set a lower limit on the age of the Earth. The oldest sedimentary rocks thus far discovered occur in the Swaziland sequence of South Africa, from which samples dated at 3,375,000,000 (± 10,000,000) years have been taken. Igneous rocks with ages in the range of 3,000,000,000 to 3,500,000,000 years have been found in South Africa, northwestern U.S.S.R., and Minnesota. By extrapolating backward in time to a situation when there was no lead that had been produced by radiogenic processes, a figure of about 4,600,000,000 years is obtained for the minimum age of the Earth. This figure is of the same order as ages obtained for certain meteorites and lunar rocks.

Experimental study of rocks. Experimental petrology began with the work of Jacobus Henricus van't Hoff, one of the founders of physical chemistry. Between 1896 and 1908 he elucidated the complex sequence of chemical reactions attending the precipitation of salts (evaporites) from the evaporation of seawater. Van't Hoff's aim was to explain the succession of mineral salts present in Permian rocks of Germany. His success at producing from aqueous solutions artificial minerals and rocks like those found in natural salt deposits stimulated studies of minerals crystallizing from silicate melts simulating the magmas from which igneous rocks have formed. Working at the Geophysical Laboratory of the Carnegie Institution of Washington, D.C., Norman L. Bowen conducted extensive phase-equilibrium studies of silicate systems, brought together in his *Evolution of the Igneous Rocks* (1928). Experimental petrology, both at the low-temperature range explored by van't Hoff and in the high ranges of temperature investigated by Bowen, continues to provide laboratory evidence for interpreting the chemical history of rocks.

A second branch of experimental science began in 1906 when Percy W. Bridgman developed a technique for subjecting rock samples to high pressures similar to those obtaining deep in the Earth. Studies of the behaviour of rocks in the laboratory have shown that their strength increases with confining pressure but decreases with rise in temperature. Down to depths of a few kilometres the strength of rocks would be expected to increase. At greater depths the temperature effect should become dominant, and response to stress should result in flow rather than fracture of rocks. In 1959 M.K. Hubbert and William W. Rubey demonstrated that fluids in the pores of rock may reduce internal friction and permit gliding over nearly horizontal planes of the large overthrust blocks associated with folded mountains.

Seismology and the structure of the Earth. Earthquake study was institutionalized in 1880 with the formation of

Discovery of the Earth's core and of the Moho

the Seismological Society of Japan under the leadership of John Milne. Milne and his associates invented the first accurate seismographs, including the instrument later widely known as the Milne seismograph. Seismology has revealed much about the structure of the Earth's core, mantle, and crust. R.D. Oldham's studies of earthquake records in 1906 led to the discovery of the Earth's core, which lies about 2,900 kilometres (1,800 miles) below the surface. From studies of the Croatian quake of October 8, 1909, Andrija Mohorovičić discovered the discontinuity (now called the Moho) that separates the crust from the underlying mantle. Since 1950 additional information on the crust has been obtained from analysis of artificial tremors produced by explosions, including underground nuclear blasts. These studies have shown that the Moho is apparently present under all the continents at a variable depth averaging around 35 kilometres (22 miles) and that the crust above it locally thickens beneath mountain ranges with folded structure. The pattern of elastic-wave velocities suggests that the upper part of the continental crust is granitic in composition and that the upper part of the oceanic crust is made of basalt-like substance.

Lunar studies. Analysis of materials and information gathered during the Apollo missions to the Moon is still under way, but results to date indicate that the surface materials are mostly of lunar origin with relatively small amounts of meteoritic material. The rocks are mainly igneous, similar to terrestrial basalt and dolerite but higher in iron and titanium and lower in alkaline content. Organic materials appear to be missing. Some rocks appear to have been fractured and otherwise modified by impact of meteorites, which were probably responsible for finely divided materials forming the regolith or "lunar soil." Radiometric dating shows that the rocks are different ages but all very old, ranging back about 4,000,000,000 years or more. Many of the craters appear to be definitely the result of impact of extralunar objects, whereas others represent former volcanism. The sinuous steep-sided valleys called rills may represent collapsed lava tubes. The origin of the flattened depressions called maria remains unresolved, but there is no evidence that their flat floors contain the sediments of former seas; rather they seem to have been formed by floods of lava.

Precambrian life. New forms of ancient life continue to be discovered, and their description and classification continues to swell the volume of a literature already so vast as to require a remarkable specialization among paleontologists. Paleoecology, the study of relationships between the plants and animals of the past and their presumed contemporary environments, has flourished since the late 1950s. New techniques for recovering and preparing fossils have given paleontologists better materials to work with, and the scanning electron microscope has revealed structures in fossils that were never before seen. The history of life before the Cambrian Period remains sketchy, but rodlike bacteria and both unicellular and multicellular forms suggesting blue-green and green algae have been found in the Fig Tree Series of South Africa in rocks dated at 3,100,000,000 years. The Gunflint Chert of Ontario has also yielded a varied assemblage of plant microfossils believed to be near 2,000,000,000 years in age.

Study of fossil algae by electron microscopy

Continental drift, rock magnetism, and sea-floor spreading. In 1915 the German meteorologist Alfred Wegener proposed that throughout most of geological time there was only one continental mass, which he named Pangea. At some time during the Mesozoic, Pangea fragmented and the parts began to drift apart. Westward drift of the Americas opened the Atlantic Ocean, and the Indian block drifted across the Equator to join with Asia. In 1937 Alexander L. Du Toit modified Wegener's hypothesis by suggesting two primordial continents: Laurasia in the north and Gondwana in the south. Aside from the congruency of continental shelf margins across the Atlantic, proponents of continental drift have amassed impressive geological evidence to support their views. Similarities in fossil terrestrial organisms in pre-Cretaceous (older than 136,000,000 years ago) strata of Africa and South America and in pre-Jurassic rocks (older than 190,000,000 years ago) of Australia, India, Madagascar, and Africa are explained if these continents were formerly connected but difficult to account for otherwise. Fitting the Americas with the continents across the Atlantic brings together similar kinds of rocks and structures. Evidence of widespread glaciation during the Late Paleozoic is found in Antarctica, southern South America, southern Africa, India, and Australia. If these continents were formerly united around the south polar region, this glaciation becomes explicable as a unified sequence of events in time and space.

Interest in continental drift heightened during the 1950s as knowledge of the Earth's magnetic field during the geological past developed from the studies of Stanley Keith Runcorn, P.M.S. Blackett, and others. Ferromagnetic minerals such as magnetite acquire a permanent magnetization when they crystallize as components of igneous rock. The direction of their magnetization is the same as the direction of the Earth's magnetic field at the place and time of crystallization. Particles of magnetized minerals released from their parent igneous rocks by weathering may later realign themselves with the existing magnetic field at the time these particles are incorporated into sedimentary deposits. Studies of the remanent magnetism in suitable rocks of different ages from over the world indicate that the magnetic poles were in different places at different times. The polar wandering curves are different for the several continents, but in important instances these differences are reconciled on the assumption that continents now separated were formerly joined. The curves for Europe and North America, for example, are reconciled by the assumption that America has drifted about 30° westward relative to Europe since the Triassic Period (190,000,000 to 225,000,000 years ago).

Remanent magnetism and polar wandering

Increased knowledge of the configuration and composition of the ocean's floor has provided additional evidence for drift. A major result of the new bathymetry has been the delineation of the Mid-Ocean Ridge, a broad swell with a relief up to 2.4 kilometres (1.5 miles), which follows a sinuous course of nearly 60,000 kilometres (40,000 miles) along the bottoms of the major ocean basins. In the early 1960s Harry H. Hess and Robert S. Dietz proposed that new oceanic crust is being generated by igneous activity along the crest of the Mid-Ocean Ridge. Molten material rises from beneath the crests, cools, and is later pushed aside by new intrusions. Thus the ocean floor is pushed at right angles and in opposite directions away from the crests, and these moving plates carry not only the oceanic crust but the continents as well. The hypothesis of sea-floor spreading has gained strong independent support from studies of oceanic magnetic anomalies and deep-sea sediments. Seismic profiles and cores from boreholes in the sea floor reveal that the sediments covering the oceanic crust are in most places no more than a few hundred feet thick. No sedimentary rocks older than the Jurassic have yet been found on the ocean floor. These findings are incompatible with the venerable doctrine of the permanency of the continents and ocean basins. Putting all of the evidence together, it seems likely that the Americas were joined with Europe and Africa until about 200,000,000 years ago, when a rift split them apart along what is now the crest of the Mid-Atlantic Ridge. A movement of one to two centimetres a year would suffice to bring the continents to their present position.

Nature of marine sediments

HYDROLOGIC SCIENCES

Water resources and seawater chemistry. Quantitative studies of the distribution of water have revealed that an astonishingly small part of the Earth's water is contained in lakes and rivers. Ninety-seven percent of all the water is in the oceans; and, of the freshwater constituting the remainder, three-fourths is locked up in glacial ice and most of the rest is in the ground. Approximate figures are also now available for the amounts of water involved in the different stages of the hydrologic cycle. Of the 859 millimetres (33.8 inches) of annual global precipitation, 23 percent falls on the lands; but only about a third of the precipitation on the lands runs directly back to the

sea, the remainder being recycled through the atmosphere by evaporation and transpiration.

With refinements in analytical techniques, the chemistry of seawater has been shown to be more complex than previously realized. Of the naturally occurring elements, some 77 have already been detected in seawater or in the organisms that inhabit it, and it is thought to be only a matter of time until traces of the others are detected. Contrary to the idea widely circulated in the older literature of oceanography, that the relative proportions of the ocean's dissolved constituents are constant, investigations since 1962 have revealed statistically significant variations in the ratios of calcium and strontium to chlorinity. The role of organisms as influences on the composition of seawater has become better understood with advances in marine biology. It is now known that plants and animals may collect certain elements to concentrations as much as 100,000 times their normal amounts in seawater. Abnormally high concentrations of beryllium, scandium, chromium, and iodine have been found in algae; of copper and arsenic in both the soft and skeletal parts of invertebrate animals; and of zirconium and cerium in plankton.

Desalinization, tidal power, and minerals from the sea. For ages a source of food and common salt, the sea is increasingly becoming a source of water, chemicals, and energy. In 1967 Key West, Florida, became the first American city to be supplied solely by water from the sea, drawing its supplies from a plant that produces more than 2,000,000 gallons of refined water daily. Magnesia was extracted from the Mediterranean in the late 19th century; at present nearly all the magnesium metal used in the United States is mined from the sea at Freeport, Texas. Harnessing the energy of the tides was accomplished on a small scale in the tidal mills of England and Wales as early as the 12th century. Since that time many ambitious schemes for using tidal power have been devised, but the first major hydrographic project of this kind was not completed until 1967, when a dam and electrical generating equipment were installed across the Rance River in Brittany. The annual power output is about 500,000,000 kilowatt-hours. The sea floor and the strata below the continental shelves are also sources of mineral wealth, actual and potential. Concretions of manganese oxide, evidently formed in the process of subaqueous weathering of volcanic rocks, have been found in concentrations as high as 100,000 tons per square mile of sea floor. In addition to the manganese, these concretions contain copper, nickel, cobalt, zinc, and molybdenum. To date, oil and gas have been the most valuable products to be produced from beneath the sea. Already about 20 percent of the world's oil and gas comes from offshore drilling, and it is predicted that by the end of the century this figure will rise to more than 50 percent.

Economic potential of the sea floor

Ocean bathymetry. Modern bathymetric charts show that about 20 percent of the surfaces of the continents are submerged to form continental shelves. Altogether the shelves form an area about the size of Africa. Continental slopes, which slant down from the outer edges of the shelves to the abyssal plains of the sea floor, are nearly everywhere furrowed by submarine canyons. The depths to which these canyons have been cut below sea level seem to rule out the possibility that they are drowned valleys cut by ordinary streams. More likely the canyons were eroded by turbidity currents, dense mixtures of mud and water that originate as mud slides in the heads of the canyons and pour down their bottoms.

Profiling of the Pacific Basin prior to and during World War II resulted in the discovery of hundreds of isolated eminences rising 1,000 or more metres (about 3,000 feet) above the floor. Of particular interest were seamounts in the shape of truncated cones, whose flat tops rise to between a mile and a few hundred feet below the surface. Hess has interpreted the flat-topped seamounts (guyots) as volcanic mountains planed off by action of the waves before they subsided to their present depths. Subsequent drilling in guyots west of Hawaii confirmed this view; samples of rocks from the tops contained fossils of Cretaceous age representing reef-building organisms of the kind that inhabit shallow water.

Ocean circulation, currents, and waves. Early in the century, Vilhelm Bjerknes and Vagn Walfrid Ekman investigated the dynamics of ocean circulation and developed theoretical principles that have influenced subsequent studies of currents in the sea. Bjerknes showed that very small forces resulting from pressure differences caused by nonuniform density of seawater can initiate and maintain fluid motion. Ekman analyzed the influence of winds and the Earth's rotation on currents. He theorized that in a homogeneous medium the frictional effects of winds blowing across the surface would cause movement of successively lower layers of water, the deeper the currents so produced the less their velocity and the greater their deflection by the Coriolis effect (an apparent force due to the Earth's rotation that causes deflection of a moving body to the right in the Northern Hemisphere and to the left in the Southern Hemisphere), until at some critical depth an induced current would move in a direction opposite to that of the wind.

Results of many investigations suggest that the forces that drive the ocean currents originate at the interface between water and air. The direct transfer of momentum from the atmosphere to the sea is doubtless the most important driving force for currents in the upper parts of the ocean. Next in importance are differential heating, evaporation, and precipitation across the air–sea boundary, altering the density of seawater and thus initiating movement of water masses with different densities. Studies of the properties and motion of water at depth have shown that strong currents also exist in the deep sea and that distinct types of water travel far from their geographic sources. For example, the highly saline water of the Mediterranean that flows through the Strait of Gibraltar has been traced over a large part of the Atlantic, where it forms a deep-water stratum that is circulated far beyond that ocean in currents around Antarctica.

Improvements in devices for determining the motion of seawater in three dimensions have led in recent years to the discovery of new currents and to the disclosure of unexpected complexities in the circulation of the oceans generally. As recently as 1951 an immense countercurrent moving eastward across the Pacific was found below depths as shallow as 20 metres (65 feet), and in the following year an analogous equatorial undercurrent was discovered in the Atlantic. In 1957 a deep countercurrent was detected beneath the Gulf Stream with the aid of subsurface floats emitting acoustic signals. The Gulf Stream and other currents sometimes called "ocean rivers" have proved to consist of numerous disconnected filaments moving in complex patterns.

Countercurrents and the Gulf Stream

Surface waves of the ocean are also exceedingly complex, at most places and times reflecting the coexistence and interferences of several independent wave systems. During World War II, interest in forecasting wave characteristics was stimulated by the need for this critical information in the planning of amphibious operations. Harold Ulrick Sverdrup and Walter Heinrich Munk combined theory and empirical relationships in developing a method of forecasting "significant wave height"—the average height of the highest third of the waves in a wave train. Subsequently, this method was improved to permit wave forecasters to predict optimal routes for mariners. Forecasting of the most destructive of all waves, the tsunami, or "tidal waves," caused by submarine quakes and volcanic eruptions, is another recent development. Soon after 159 persons were killed in Hawaii by the tsunami of 1946, the U.S. Coast and Geodetic Survey established a seismic sea-wave warning system. Using a seismic network to locate epicentres of submarine quakes, the installation predicts the arrival of tsunami at points around the Pacific Basin often hours before the arrival of the waves.

Glacier motion and the high-latitude ice sheets. Beginning around 1948, principles and techniques developed in metallurgy and solid-state physics were brought to bear on the mechanics of glacial movements. Laboratory studies showed that glacial ice deforms like other crystal-

line solids (such as metals) at temperatures near the melting point. Continued stress produces permanent deformation. In addition to plastic deformation within a moving glacier, the glacier itself may slide over its bed by mechanisms involving pressure melting and refreezing and accelerated plastic flow around obstacles. The causes underlying changes in rate of glacial movement, in particular those spectacular accelerations called surges, will require further study. Surges involve massive transfer of ice from the upper to the lower parts of glaciers at rates as much as 20 metres a day, in comparison with normal advances of a few metres a year.

Analysis of cores from the Greenland and Antarctic ice sheets

As a result of numerous scientific expeditions into Greenland and Antarctica, the dimensions of the remaining great ice sheets are fairly well-known from gravimetric and seismic surveys. In parts of both continents it has been determined that the base of the ice is below sea level, probably due at least in part to subsidence of the crust under the weight of the caps. In 1966 a borehole was drilled 1,390 metres (4,560 feet) to bedrock on the North Greenland ice sheet, and two years later a similar boring of 2,162 metres (7,091 feet) was cut through the Antarctic ice at Byrd Station. From the study of annual incremental layers and analyses of oxygen isotopes, the bottom layers of ice cored in Greenland were estimated to be more than 150,000 years old, compared with 100,000 years for the Antarctic core. With the advent of geochemical dating of rocks it has become evident that the Ice Age, which in the earlier part of the century was considered to have transpired during the Quaternary Period, actually began much earlier. In Antarctica, for example, potassium–argon age determinations of lava overlying glaciated surfaces and sedimentary deposits of glacial origin show that glaciers existed on this continent at least 10,000,000 years ago. The causes of continental glaciation, whether in recent or ancient times, are still not understood.

ATMOSPHERIC SCIENCES

Probes, satellites, and data transmission. Kites equipped with meteorgraphs were used as atmospheric probes in the late 1890s, and in 1907 the U.S. Weather Bureau recorded the ascent of a kite to 7,044 metres (23,111 feet) above Mt. Weather, Virginia. Kites were later replaced by balloons, to which recording instruments with parachutes were attached. Experimentation with balloons up to altitudes of about 31 kilometres (19 miles) showed that columns of warm air may rise more than a mile above the surface of the Earth and that the lower atmosphere is often stratified, with winds in the different layers blowing in different directions. In the 1930s airplanes began to be used for observations of the weather, and the years since 1945 have seen the development of rockets and weather satellites. TIROS (Television Infra-Red Observation Satellite), the world's first all-weather satellite, was launched in 1960, and in 1964 the Nimbus Satellite of the United States National Aeronautics and Space Administration (NASA) was rocketed into near-polar orbit with cameras continuously trained on the Earth.

In the 1920s the radio replaced the telegraph and telephone as the principal instrument for transmitting weather data. By 1936 the radio meteorgraph (radiosonde) was developed, with capabilities of sending signals on relative humidity, temperature, and barometric pressure from unmanned balloons. Radar and television are later developments that give visual images of cloud formations. The television equipment on Nimbus sends down more than 1,000 pictures a day in a spectacular round-the-clock surveillance of changing cloud patterns over the world.

Bjerknes' polar front theory of cyclones

Weather forecasting. Efforts at incorporating numerical data on weather into mathematical formulas that could then be used for forecasting were initiated early in the century at the Norwegian Geophysical Institute. Vilhelm Bjerknes and his associates at Bergen succeeded in devising equations relating the measurable components of weather, but their complexity precluded the rapid solutions needed for forecasting. Out of their efforts, however, came the polar front theory for the origin of cyclones and the now-familiar names of cold front, warm front, and stationary front for the leading edges of air masses. The polar front theory envisioned cyclones as spinning off the undulatory boundary separating predominantly west-moving cold polar air from prevailingly east-moving masses of warmer moist air in middle latitudes. In 1935 the U.S. Weather Bureau organized a section for air-mass analysis, and the following year the familiar lines for fronts began to appear on its weather maps.

In 1922 the British mathematician Lewis Fry Richardson demonstrated that the complex equations of the Norwegian school could be reduced to long series of simple arithmetic operations. With no more than the desk calculators and slide rules then available to the arithmeticians, however, the solution of a problem in procedure only raised a new one in manpower. In 1946 John von Neumann and his fellow workers at The Institute for Advanced Study, Princeton, New Jersey, began work on an electronic device to do the computation faster than the weather developed. Four years later the von Neumann group could claim that, given adequate data, their computer could actually forecast the weather as well as a weatherman. To say this was not to claim perfection. In his *Book of Weather Signs*, written around 300 BC, Theophrastus noted some 200 portents of the weather, and a few of these, such as red sunrises as portents of rain, are accurate about 70 percent of the time. In 1887 official forecasts in the United States were about 74 percent accurate. Later this figure rose to about 80 percent for forecasts 12 to 18 hours in advance, and the application of computer technology has added about 5 percent to this figure.

Cloud physics. Studies of cloud physics have shown that the nuclei around which water condenses vary widely in their degree of concentration and areal distribution, ranging from a hundred or so per cubic inch over the oceans to more than 65,000,000 in the polluted air of some cities. The droplets that condense on these foreign particles may be as small as 0.001 centimetre (0.0004 inch) in diameter. Raindrops apparently may form directly from the coalescence of these droplets, as in the case of tropical rains, or in the temperate zones through the intermediary of ice crystals. According to the theory of Tor Bergson and Walter Findeisen, vapour freezing on ice crystals in the clouds enlarges the crystals until they fall. What finally hits the ground depends on the temperature of air below the cloud—if below freezing, snow; if above, rain.

The Van Allen radiation belts

Properties and structure of the atmosphere. Less than a year after the Space Age began with the launching of the U.S.S.R. Sputnik I in 1957, the U.S. satellite Explorer I was sent into orbit with a Geiger counter for measuring the intensity of cosmic radiation at different levels above the ground. At altitudes around 1,000 kilometres (600 miles) this instrument ceased to function due to saturation by charged particles. This and subsequent investigations showed that a zone of radiation encircles the world between about latitude 75° N and 75° S, with maximum intensities at 5,000 and 16,000 kilometres (3,000 and 10,000 miles). Named after the American physicist James Van Allen, a leading investigator of this portion of the Earth's magnetosphere, these zones are responsive to events taking place on the Sun. The solar wind, a stream of atomic particles emanating from the Sun in all directions, seems to be responsible for the electrons entrapped in the Van Allen region as well as for the teardrop shape of the magnetosphere as a whole, with its tail pointing always away from the Sun. Following solar flares, the Van Allen region may become overloaded with electrons, which then cascade downward into the atmosphere, producing auroras.

In 1898 Teisserenc de Bort, studying variations of temperature at high altitudes with the aid of balloons, discovered that at elevations around seven miles the figure for average decrease of temperature with height (about 5.5° C per 1,000 metres [3° F per 1,000 feet] of ascent) dropped and the value remained nearly constant at

around −55° C (−67° F). De Bort named the atmospheric zones below and above this temperature boundary the troposphere and stratosphere. Subsequent explorations by sounding rockets and satellites have added much information about the physical and chemical characteristics of the atmosphere. Although the chemical composition of the troposphere has been found to be nearly constant, a layer of ozone (triatomic oxygen, O_3) has been found concentrated in the stratosphere at an altitude of about 26 kilometres (16 miles). This layer shields the Earth from much of the ultraviolet radiation from space that otherwise would be harmful to life. The ionosphere, which is the region above the stratosphere between about 55 and 600 kilometres (35 and 400 miles), contains the electrically conducting layers capable of reflecting radio waves. Like the two spheres of air below it, the ionosphere consists mainly of molecular nitrogen, but it also contains significant percentages of atomic nitrogen, oxygen, and hydrogen. The exosphere, uppermost envelope of the atmosphere, extending outward from about 600 kilometres (400 miles), consists mainly of hydrogen above 2,400 kilometres (1,500 miles); its boundary with the interplanetary medium is indefinite.

Discovery of the jet streams

Toward the end of World War II the B-29 Superfortress came into use as the first large aircraft to cruise regularly at 10,000 metres (30,000 feet). Heading westward from bases in the Pacific, these planes sometimes encountered unexpected head winds that slowed their flight by as much as 300 kilometres (200 miles) per hour. The jet streams, as these high-altitude winds were named, have been found to encircle the Earth following wavy courses and moving from west to east at velocities ranging upward to 500 kilometres (300 miles) per hour. Aircraft have also proved useful in studies of the structure and dynamics of tropical hurricanes. Following the destruction wrought to the Atlantic Coast of the United States in 1955 by hurricanes Connie and Diane, a national centre was established in Florida with the missions of locating and tracking and hopefully of learning how to predict the paths of hurricanes and to dissipate their energy.

Weather modification. The modification of weather has long been a dream of those who suffer from droughts or endure the ravages of storms. Many of the early schemes for making rain had no more basis in science than the rainmaking ceremonies of aboriginal peoples. As late as the 1890s experiments were conducted in the United States to the end of producing rain by setting off charges of dynamite lofted by balloons or kites. Aside from the total destruction of the balloons and kites no positive results were reported. More promising were the cloud-seeding experiments of the 1940s, in which silver iodide was released into clouds as smoke or solid carbon dioxide broadcast into clouds from airplanes. The results are still ambiguous, though it seems that clouds about to give up their moisture from natural causes may do so more readily after seeding. The inadvertent weather modification that has followed industrialization and the building of large cities has, however, already produced measurable changes in local climate and may someday produce effects more widespread. The introduction of some 12,000,000,000 tons of carbon dioxide into the atmosphere each year from the burning of fuels may in time raise the Earth's average temperature. Cities affect the flow of wind, warm the atmosphere over them, and send pollutants into the sky. Updrafts and an abundance of condensation nuclei may increase rainfall and winter fog and reduce sunshine and daylight.

Classification of climate. Renewed interest in the classification of world climates was manifest first in the work of Albrecht Penck (1858–1945), who in 1910 proposed a system of classification based on the rate of precipitation. His humid climates were those in which precipitation exceeds evaporation, the opposite of arid climates. Nival climates are characterized by more snowfall than can be lost through ablation—*i.e.*, the combined processes by which wastage of ice or snow occurs. In 1918 Wladimir Köppen (1846–1940) incorporated some of Penck's ideas in a revision of his own earlier classification. Four of his five major classes were based on seasonal variations in temperature (winterless climates, summerless climates, climates with only mild winters, and climates with severe winters but distinct summers); the fifth, dry climates, was based on precipitation. Classifications developed by Charles W. Thornthwaite, beginning in 1931, re-emphasize the importance of precipitation and relegate temperatures to secondary rank. In differentiating climatic types, he used ratios between precipitation and temperature and between precipitation and evaporation as measures of the "efficiency of temperature" and the "effectiveness of precipitation." The difficulty inherent in classification of climates is essentially the same as that impeding the progress toward a satisfactory classification of soils: too many independent climatic variables in addition to the dependent variables of plant physiology, rock weathering, and economic activity.

Climate systems of Köppen and Thornthwaite

EMERGING TRENDS

As the Earth sciences have grown in manpower and other resources, they have exhibited trends toward increasing specialization on the part of their practitioners, more team research, more general employment of quantitative approaches to problems, and increasing involvement in social issues.

With growth in numbers of research workers, the sheer bulk of their writings has itself become an obstacle to the communication of findings. A recent survey of the literature of the geological sciences alone indicates that upwards of 30,000 titles are published annually, not counting any in Oriental languages. Bibliographic and indexing services are no longer able to keep pace with the presses.

Increasing specialization. The high degree of specialization in the fields of modern science has often been diagnosed as a cause of intellectual tunnel vision. Generalists are few in a population characterized by such experts as the boundary-layer meteorologist, the biochemical oceanographer, and the paleomagneticist. But this diversity of specialists only reflects the complexity of their subjects. For example, the history of ancient man has recently been found to span more than 2,000,000 years, and, to help elucidate the story of human development, the archaeologist must enlist the aid of various specialists in the Earth sciences. At important archaeological sites assistance is often required of the stratigrapher, sedimentologist, vertebrate paleontologist, invertebrate paleontologist, paleobotanist, and soil scientist. If materials suitable for geochemical dating are present, the geochronologist will also make his contribution. The overall aims in such an investigation are to reconstruct as completely as possible the physical and biological environment in which ancient humans lived and to place their occupation of the site in a framework of time approximated in years.

Interdisciplinary problems

Team research. Team research has become commonplace in projects crossing the major disciplinary boundaries. It is now accepted that understanding of the motions of the oceans and atmosphere will require integrated studies by hydrologic and atmospheric scientists; and the tropical belts have been selected as the logical places for such joint investigations to begin. The warm oceans are major sources of the energy that powers the global circulation of water and air, but much remains to be learned about the mechanisms by which solar energy absorbed in the ocean is released to do its work. The Barbados Oceanographic and Meteorological Experiment (BOMEX), conducted in the summer of 1969 by scientists from Canada and the United States, marked the first large-scale study of energy transfer in the tropics. The region studied was square in cross section, 500 kilometres (300 miles) to the side, extending downward into the ocean for 500 metres (1,600 feet) and upward into the atmosphere for five kilometres. Preliminary analyses of the vast amount of numerical data collected show that the rate of evaporation (over six millimetres per day) was higher than expected. Moreover, the time of greatest evaporation was not around noon, when the input of heat into the ocean was greatest, but near sunset. The rate of water vapour transport, accomplished through large ed-

dies elongated downwind, differed significantly from the rate of heat transport, which was controlled by smaller eddies. An even more ambitious study to be sponsored by nine countries under the Global Atmospheric Research Program is scheduled for 1974. The belt to be investigated extends on either side of the Equator from Central America to the eastern edge of Africa. The objective is a better understanding of atmospheric processes as a basis for constructing more accurate numerical models of the atmosphere.

Use of electronic computers

Quantitative approach to problems. The conduct of experiments with numerical models of natural phenomena has been made possible by electronic computers and is but one example of the trend toward quantification in the Earth sciences generally. Numerical modelling of the weather has always been intimately associated with computers. Current operational models compute wind velocities and temperatures at six levels within a horizontal area of 300 kilometres (200 miles), but all the factors needed to forecast local weather situations cannot yet be included directly. Research models even more elaborate tax the capabilities of the largest and fastest computers. A better understanding of meteorological processes, more detailed observational information on weather, and still faster computers will be needed before accurate five-day forecasts become possible.

BOMEX is on the small end of the "big science" that requires not only teams of specialists but large investments in equipment and services. To conduct the field study off Barbados, it was necessary to employ some 28 aircraft, 12 ships, satellites and buoys, hundreds of radiosonde balloons, and floating-laboratory instrument platforms (which in this age of acronyms are known as "flips"). At the other end of the spectrum in big science is the ongoing program of lunar and planetary exploration. All mammoth projects in Earth and planetary science require public funding, often from more than one nation.

Involvement in social goals. The atomic bombing of Hiroshima in 1945 first made the global public aware of science. Since that event there has been increasing support of scientific research and development, but a growing sentiment requires that this support should be directed toward constructive ends. Ecology, environment, relevance, and pollution are watchwords symbolizing the new drift in the Earth sciences toward humanitarian goals. Some observers fear that political insistence on instant application of new findings to betterment of the human condition will dry up support for basic research.

Underground waste disposal and earthquake attenuation

This need not be the case. Denver, Colorado, was shaken by unaccustomed earthquakes in 1966. These coincided in time with efforts of the U.S. Army to dispose of nerve gas products by pumping them in fluid form and under high pressure into deep wells nearby. Seismologists suspected a causal connection. Experiments later conducted in fluid injection of oil wells in California confirmed that the frequency of quakes there seemed to vary with the hydrostatic pressure at depth. If so, the possibility is opened for postponing quakes by pumping fluids from the fault zones along which they occur and of inducing more frequent but less destructive quakes by pumping fluids into these same zones. Earthquake prediction and control would surely promote the general welfare; and the research needed to provide the techniques and put them to practice would just as surely strengthen the theoretical bases of seismology and structural geology.

East Africa, History of

In the following historical account, East Africa may be taken to comprise the geographical area covered by the modern states of Kenya, the Somali Democratic Republic, Tanzania, and Uganda.

This article is divided into the following sections:

I. The coast until 1856
  Azania
  The Shirazi migration
  The Portuguese invasion
  The Omani ascendancy
II. The interior before the colonial era
  The Stone Age

The spread of ironworking and the Bantu migrations
Migrations of Nilotic and Cushitic peoples
Developments in the 19th century
Political activities
Arabs and East African trade
III. The colonial era
The arrival of the Europeans
Colonial rule
The new order
"White man's country"
The colonial economies
Opening a breach: Somalia
The crises of the 1950s
The approach of independence
IV. Independence and after
The beginnings
The Somali Republic
Economic cooperation
The Zanzibar revolution and the Tanganyika mutiny
Ujamaa in Tanzania
Political unrest in Uganda
Kenyatta's Kenya

I. The coast until 1856

Evidence of the existence of microlithic industries—very small tools typical of the Late Stone Age (*c.* 500 BC)—have been found at various points along the East African coast. Such industries appear to have been established by small hunting communities similar to those that survive to this day in other parts of eastern and southern Africa. No coastal settlement that predates the Islāmic period (from *c.* 700) has as yet been found, and, if it were not for some historical evidence to the contrary, it would be tempting to link the advent of iron with that of the Muslims.

The earliest written accounts of the East African coast occur in the *Periplus Maris Erythraei*—apparently written by a Greek merchant living in Egypt in the second half of the 1st century AD—and in Ptolemy's *Guide to Geography*, the East African section of which, in its extant form, probably represents a compilation of geographical knowledge available at Byzantium *c.* 400. The *Periplus* describes in some detail the shore of what was to become Somaliland. It records the existence of six or so places where some kind of commerce was being organized and notes that regular customs dues were collected from both sides of what was later to be called Cape Guardafui. Ships, it goes on, sailed from the coast to western India to bring back cotton cloth, grain, oil, sugar, and ghee, while others moved down the Red Sea to the East African coast bringing cloaks, tunics, copper, and tin. Aromatic gums, tortoiseshell, ivory, and slaves were traded in return.

AZANIA

But, because of its offshore islands, better landing places, and wetter climate, it was the part of the East African coast farther to the south that Arab traders seem to have preferred. They sailed there with the northeast monsoon, returning home in the summer with the southwest. They dubbed the part of the coast to which they sailed Azania, or the Land of Zanj—by which they meant the land of the blacks and by which they knew it till the 10th century. South of Sarapion, Nikon, the Pyralaae Islands, and the island of Diorux (about whose precise locations only speculation seems possible), the chief town was Rhapta, which may lie buried in the Rufiji Delta. Here the situation differed somewhat from that in the north, and, though tortoiseshell and rhinoceros horn were exported from there—as were quantities of ivory and coconut oil—no mention is made of slaves. Rhapta's main imports were metal weapons and iron tools—suggesting that iron smelting was not yet known. Mafia island, which lies out to sea here, could perhaps be Menouthias, the only island named in both the *Periplus* and by Ptolemy, although this could also be either Pemba or Zanzibar (perhaps there has been a conflation of all three in the one name).

Azania, it was said, was always ultimately subject to the most important power in Arabia—Charibael (or Qaribil) of Ḥimyar, in southwestern Arabia, is specifically mentioned—but was more usually directly subordinate to the people of Mocha in the Yemen. There was some mutual linguistic understanding and some intermarriage, but there was nothing to suggest that the local inhabitants were as yet Bantu.

There is little firm information concerning the period till the 8th century. Greek and Roman coins have been found, and there are some accounts of overseas migrations to the coast. No settlements from this period have been found.

Arab geographical designations in the 9th century

A new period opened, it seems, in the 9th century. The first identifiable building sites are dated from this time, and, according to Arab geographers, the East African coast was then generally thought of as being divided into four: 1) Berber, which ran down to the Webi Shebeli; 2) Zanj proper; 3) the land of Sofala, whence gold was beginning to be shipped by about the 10th century; and 4) a vaguely described land of Waq waq, beyond. The only island that is mentioned is Qanbalu, which appears to have been what is now called Pemba. Speakers of Bantu language now seem to have reached the coast. They had rulers, priests, warrior bands, and cattle, which they harnessed like horses. Muslims, too, are reported at Merka and Manda, on Qanbalu, and later at Zanzibar. Though there is some suggestion that in the 10th century the Muslims had not yet begun to move farther south and that thus they were not to be found at Brava, Malindi, or Mombasa, on Qanbalu they soon became rulers of a pagan population, whose language they adopted. Moreover, at Zanzibar an extant Kūfic inscription (the only one) recording the construction of a mosque by Shaykh as-Sayyid Abū'Imrān Mūsā ibn al-Ḥasan ibn Muḥammad in 1107 confirms that by this time substantial Muslim settlements had been established.

The main coastal settlements were sited on islands, largely, no doubt, because of the greater security these provided against attacks from the mainland; and their populations seem mostly to have been made up from migrants from the Persian Gulf—some from the great port of Sīrāf, others from near Bahrain—though conceivably some too came from Daybul, at the mouth of the Indus River, in northwestern India. They exported ivory (some of it went as far as China) and also tortoiseshell, ambergris, and leopard skins. Such trade goods as they obtained from the interior were apparently bought by barter at the coast.

Some of the ruins at Kilwa, on the southern Tanzanian coast, probably date from the 9th or perhaps from the 8th century. They have revealed an extensive pre-Muslim settlement standing on the edge of what was the finest harbour on the coast. Though there is little evidence to suggest that its inhabitants had any buildings to begin with, wattle-and-daub dwellings appeared in due course, and by the 10th century short lengths of coral masonry wall were being built. The inhabitants, whose main local currency was cowrie shells, traded with the peoples of the Persian Gulf and, by the early 11th century, had first come under Muslim influence. By 1300, like the inhabitants of neighbouring Mafia, they were living in Muslim towns, the rulers of which were Shī'ites. Although no houses were being built of coral, stone mosques were being constructed.

External trade was increasing: glass beads were being imported from India and porcelains, transshipped either in India or in the Persian Gulf, were arriving from China. There appears also to have been a rather extensive trade with the island of Madagascar.

The most important site of this period yet to have been found is at Manda, near Lamu, on the Kenyan coast. Apparently established in the 9th century, it is distinguished for its seawalls of coral blocks, each of which weighs up to a ton. Though the majority of its houses were of wattle and daub, there were also some of stone. Trade, which seems to have been by barter, was considerable, with the main export probably of ivory. Manda had close trading connections with the Persian Gulf—with Sīrāf in particular. It imported large quantities of Islāmic pottery and, in the 9th and 10th centuries, Chinese porcelain. There is evidence of a considerable

iron-smelting industry at Manda and of a lesser one at Kilwa.

THE SHIRAZI MIGRATION

For much of the 13th century the most important coastal town was Mogadishu (modern Mogadiscio), a mercantile city to which new migrants came from the Persian Gulf and southern Arabia. Of these, the most important were called Shirazi, who, in the second half of the 12th century, had migrated southward to the Lamu islands, to Pemba, to Mafia, to the Comoro Islands, and to Kilwa, where by the end of the 12th century they had established a dynasty. Whether they were actually Persian in origin is somewhat doubtful. Though much troubled by wars, by the latter part of the 13th century they had made Kilwa second in importance only to Mogadishu. When the Kilwa throne was seized by Abū al-Mawāhib, major new developments ensued: Kilwa captured Mogadishu's erstwhile monopoly of the gold trade with Sofala and exchanged cloth—much of it made at Kilwa—and glass beads for gold; and with the great wealth that resulted new pottery styles were developed, a marked increase in the import of Chinese porcelain occurred, and stone houses, which had hitherto been rare, became common. (The great palace of Husuni Kubwa, with well over 100 rooms, was built at this time and had the distinction of being the largest single building in all sub-Saharan Africa. Husuni Ndogo, with its massive enclosure walls, was probably built at this time, too, as were the extensions to the great mosque at Kilwa. The architectural inspiration of these buildings was Arab; their craftsmanship was of a high standard; and the grammar of their inscriptions was impeccable.) Kilwa declined in the late 14th century and revived in the first half of the 15th but then—partly because of internal dynastic conflict but also partly because of diminishing profits from the gold trade—declined again thereafter.

The Shirazi dynasty

Elsewhere, especially on the Kenyan coastline, the first half of the 15th century seems to have been a period of much prosperity. Whether at Gedi (south of Malindi) or at Songo Mnara (south of Kilwa), architectural styles were relatively uniform. Single-story stone houses, mostly of coral, were common. Each coastal settlement had a stone mosque, which, typically, centred upon a roofed rectangular hall divided by masonry pillars. Chinese imports arrived in ever larger quantities, and there are signs that eating bowls were beginning to come into more common use.

When Ibn Baṭṭūṭah, the Arab traveller, visited the coast in the early 14th century, he described Mogadishu as a large town with many rich merchants and a highly developed court life revolving around a ruler. By the 15th century, Mombasa was a very substantial town, as was Pate. The ruling classes of these towns were Muslims of mixed Arab and African descent who were mostly involved in trade; beneath them were African labourers who were often slaves and a transient Arab population.

The impetus in this society was Islāmic rather than African. It was bound by sea to the distant Islāmic world, whence immigrants still arrived to settle on the East African coast, to intermarry with local people, and to adopt the Swahili language. The impact of these settlements was limited, while their influence upon the East African interior was nonexistent.

During the 15th century, Shirazi families continued to rule in Malindi, Mombasa, and Kilwa and at many lesser places along the coast. They also dominated Zanzibar and Pemba. The Nabahani, who were of Omani origin, ruled at Pate and were well represented in Pemba as well. Coastal society derived a certain unity by its participation in a single trading network, by a common adherence to Islām, and by the ties of blood and marriage among its leading families. Politically, however, its city-states were largely independent, acknowledging no foreign control, and their limited resources confined their political activities to East Africa and to a variety of local rivalries—Zanzibar and Pemba, for example, appear frequently to have been divided between several local rulers. Mombasa occupied the premier position on this part of the coast, although its control over the area immediately to the north was disputed by its main rival, Malindi. Close connections seem to have existed between Mombasa and a number of places to the south. Its Shirazi rulers were able to mobilize military support from some of the inland peoples, and as a result of the place it had won in the trade of the northwestern Indian Ocean they had turned Mombasa into a prosperous town. Its population of about 10,000 compared with only 4,000 at Kilwa.

The rise of Mombasa

THE PORTUGUESE INVASION

This was the situation on the East African coast when Portuguese ships under Vasco da Gama arrived in 1498. The manifestly superior military and naval technology of the Portuguese and the greater unity of their command enabled them, in the years that lay ahead, to mount assaults upon the ill-defended East African city-states. Though the Portuguese became skilled at playing one small state against another, their global enterprise was such that they did not immediately impose direct rule.

The coastal cities were quite unprepared for the Portuguese. As early as 1502 the *shaykh* at Kilwa was obliged to agree to a tribute to the Portuguese, as the ruler of Zanzibar was later. A large Portuguese fleet established a Portuguese factory (trading post) at Sofala in 1505, and shortly afterward the Portuguese sacked both Kilwa and Mombasa. They sacked Brava in 1506 and forced Lamu and Pate to submit, and only Mogadishu escaped unscathed. Within eight years of their arrival they had managed to dominate the coast and the trade routes that led from there to India.

Their effect on Kilwa was serious from the first. A Portuguese fort was built, and for a time a garrison was maintained. More serious, however, was the Portuguese assumption of Kilwa's previous control over the Sofala gold trade. A more terrible fate struck the city in 1587 when the Simba, a marauding warrior people who had migrated from the Zambezi Valley, massacred its population.

Malindi, to the north, moved perhaps by its rivalry with Mombasa, proved to be the most reliable of Portugal's allies.

In retaliation against a revolt, the Portuguese sacked Mombasa for a second time in 1528, and from the mid-16th century Jesuit and Dominican missionaries arrived from Portugal and Augustinian canons set up houses at Faza, Pate, Mombasa, and Zanzibar. Converts were not, however, numerous.

Toward the end of the 16th century, first in 1585 and again in 1588, Turkish expeditions descending the northern coast with promises of assistance against the Portuguese encouraged the coast north of Pemba to revolt. A Portuguese fleet from Goa, which had been summoned by Malindi, secured a temporary submission in 1587, but a second fleet had then to be dispatched—more particularly against Mombasa. In 1589, in association with a force of marauding Simba, who had now moved northward, the Portuguese sacked Mombasa for a third time. Soon after, when a major expedition sent from Mombasa against Malindi was surprised and overwhelmed by the Segeju tribe, which had been moving down the coast, Mombasa passed much more firmly under Portuguese control. This was helped by the death of Mombasa's last Shirazi ruler, Shah ibn Mishhan, who, in leaving no clear successor, gave the Portuguese the opportunity to install Shaykh Aḥmad of Malindi in his place. In 1593, with an architect from Italy in charge and with masons from India to assist them, the Portuguese set about building their great Ft. Jesus at Mombasa. In the following year it was occupied by a garrison of 100 men.

Turkish attacks

With Mombasa's downfall, the major hindrance to Portuguese power on the East African coast was overthrown. Henceforth, throughout the 17th century Mombasa became the main Portuguese base in East Africa under its own Portuguese "captain." (Ft. Jesus rarely seems to have had a garrison of more than a few hundred men, and there seems never to have been more than 1,000 Portuguese at any one time upon the whole

coastline.) Hitherto, although the Portuguese had periodically ravaged the coastal cities and had inflicted considerable damage upon them, they had never exercised any continuing authority. Concerned, however, at the possibility of further Turkish incursions, they turned their established system of alliances involving the intermittent collection of tribute into a firmer and more ongoing dominion. They installed garrisons elsewhere than at Mombasa and brought about the downfall of a number of Shirazi dynasties, and, although they did not exercise day-to-day control over local rulers, they did make them dependent on them for their position. (Local rulers were in particular required to pay regular tribute to the Portuguese king on pain of dethronement and even of death.)

Portugal's chief interests were not imperial but economic. With Mombasa in their grip, they controlled the commercial system of the western Indian Ocean. Customs houses were opened at Mombasa and Pate, and ironware, weapons, beads, jewelry, cotton, and silks were imported. The main exports were ivory, gold, ambergris, and coral. There was a flourishing local trade in timber, pitch, rice, and cereals but few signs of any considerable traffic in slaves. Individual Portuguese traders often developed excellent relations with Swahilis in the coastal cities.

The new *shaykh* of Mombasa became much disturbed at both the arrogance and the importunities of the Portuguese, about which, in 1614, he complained to the Portuguese viceroy at Goa, in India. Given little satisfaction, he returned to Mombasa, but then fled to the *nyika* ("wilderness"), where, at the instance of the Portuguese, he was murdered. Though his son Yūsuf, who was taken to Goa to have a Portuguese education, returned to Mombasa in 1630—a baptized Christian and married to a Portuguese wife—he too ran afoul of the Portuguese. On August 15, 1631, he murdered the Portuguese commandant at Mombasa, renounced Christianity, adopted Islām, and ordered the massacre of most of the Portuguese in the town. Although there were risings sympathetic to him at Tanga and Mangata, his call to revolt secured little support elsewhere along the coast. Zanzibar especially held to its Portuguese alliance. Nevertheless, with Ft. Jesus under his control, Yūsuf successfully resisted the first of the two Portuguese fleets sent against him from Goa; and it was only as a result of disaffection in his own ranks that he had to flee the city before the second Portuguese fleet arrived. In the next few years he was actively engaged in stirring up a succession of revolts against the Portuguese—including a rebellion at Pate in 1637—until in 1638 he died at Jidda while seeking Turkish support.

Yūsuf's rebellion

Though the Portuguese managed to ride out these local upheavals, their authority over a much wider area was already being undermined by the intensity of Dutch and English commercial competition elsewhere in the Indian Ocean and by the rise of new powers on the Persian Gulf. They lost Hormuz to the Persians in 1622 and Muscat to the Imām of Oman in 1650. Two years later the Omanis launched their first major intervention into East Africa's affairs when in response to a Mombasan appeal the Imām sent ships to Pate and Zanzibar and killed their Portuguese inhabitants. As a consequence, Pate became the centre of East Africa's resistance to Portuguese rule. At Pate's invitation the Imām returned in 1660 to attack both Faza and Mombasa. In 1669 he thrust southward and narrowly failed to capture Mozambique. In 1678, following further intrigues, the Portuguese attacked Pate and executed the rulers of Pate, Lamu, Siu, and Manda, but in January 1679, on the appearance of a fleet from Muscat, they hurriedly retreated far to the south. Pate rebelled once again, in 1686, but its then ruler was captured by the Portuguese and executed at Goa in December 1688. Eventually, however, in 1696, in alliance with Pate—as upon most previous occasions—the Imām of Oman sailed to East Africa with a fleet of over 3,000 men, to lay siege to Mombasa, and, although Ft. Jesus was reinforced, the great Portuguese stronghold finally fell to Sayf ibn Sulṭān in December 1698. A few years later Zanzibar, the last of Portugal's allies in East Africa, also fell to the Imām.

Defeat of the Portuguese

THE OMANI ASCENDANCY

There ensued, after the Omani victory, a century during which, despite a succession of Omani incursions, the East African coast remained very largely free from the dominance of any outside power. Oman itself suffered an invasion by the Persians and was long distracted by civil conflict. Its originally successful Yarubi dynasty lost prestige as a consequence, fell from power, and was then superseded by the Albusaidis, who very soon found themselves preoccupied by conflicts at home. Moves against them also originated along the East African coast.

In 1727 Pate joined with the Portuguese to expel the Omanis, especially from Mombasa, where in 1728–29 Portuguese authority was momentarily restored. But the Mombasans wanted as little to be controlled by Portugal as by Muscat and soon evicted the Portuguese once again. Thereafter, Kilwa, Zanzibar, Lamu, and Pate largely kept themselves free from both Omani and Portuguese control. Distracted though it was by protracted internecine quarrels, Pate was pre-eminent in the Lamu archipelago and like all the other coastal towns was ambitious to preserve its independence.

Even so, Mombasa, in quite new circumstances, in the 18th century reached the apogee of its power as an independent city-state. The architects of this achievement were the Mazrui, an Omani clan who had provided some of the Imām's governors to Mombasa but who, because they were opposed to the Albusaidis, did not long persist in their allegiance to Muscat. They owed their authority in Mombasa itself to an ability to hold the balance between the rival factions in the Swahili population and also to their ability peacefully to overcome all but one of their dynastic successions. In 1746 a Mazrui notable, Liwali ʿAlī ibn Athman al-Mazrui, overthrew an Omani force that had murdered his brother. Soon after he seized Pemba and, but for a family quarrel, might have won Zanzibar; his successor, Masʿūd ibn Nāṣir, initiated a pattern of cooperation with Pate, which survived even Pate's successive civil upheavals, maintained close links with inland Nyika, and established Mazrui predominance from Pangani to Malindi.

Both Mombasa and Pate were disastrously defeated by Lamu in the battle of Shela, *c.* 1810. Pate's pre-eminence in the Lamu islands was destroyed, Mombasa's authority on the coast was diminished, and the way was open to Muscat's great intrusion into East African affairs. Lamu appealed to Oman for a garrison to assist it, to which Sayyid Saʿīd of Muscat very soon responded.

The Albusaidis, who had captured Kilwa in 1785, had their main footing upon the coast in Zanzibar, which had long held to its association with them. Thanks to the city's growing success, from the end of the 18th century onward, in turning itself into the main entrepôt for the trade in the area south of Mombasa, Zanzibar soon rivalled Mombasa as the focal point for the whole coastline and as such was both developed and used by Sayyid Saʿīd as the base for his growing ambitions. Having won the succession to Muscat after an internecine struggle following his father's death in 1804, Sayyid Saʿīd spent much of the next two decades establishing his authority there. (In this he was assisted by the British, who were much concerned to safeguard their route to India, which ran close to Muscat on its way past the Persian Gulf.) He wrested Pemba from Mazrui control in 1822 and by 1824 had installed a Muscat garrison in Pate as well, thus bringing to an end the previous influence that the Mazrui had exercised.

The rise of Zanzibar

Sensing the increasing threat from Muscat, the Mazrui appealed to the British for assistance. Though their application was formally denied, a British naval officer, Capt. W.F. Owen, on his own initiative raised a British flag of protection over Mombasa in 1824. Since the British had no desire formally to extend their authority to East Africa at this time, let alone to break with

their ally Sayyid Sa'īd, it was hauled down in 1826. This gave Sayyid Sa'īd his opportunity, and two years later he mounted his first assault upon Mombasa. His first attack failed to establish his authority, as did two further assaults in 1829 and 1833, and it was only when he successfully intervened in a dynastic dispute among the Mazrui, which followed on the death of a *liwali* in 1835, that he was able in 1837 to fasten his control over Mombasa and to topple the Mazrui from their position. His dominion along the whole coastline thus became assured, and after over a century's interval the East African littoral once more found itself dominated by a single outside power. Though this outcome owed much to the inability of the coastal towns to unite against an invader, it owed much as well to the striking personality of Sa'īd himself, to his investment in a navy, to his force of Baluchi soldiers (with which he supplemented his Omani levies), and to the support he received from the British.

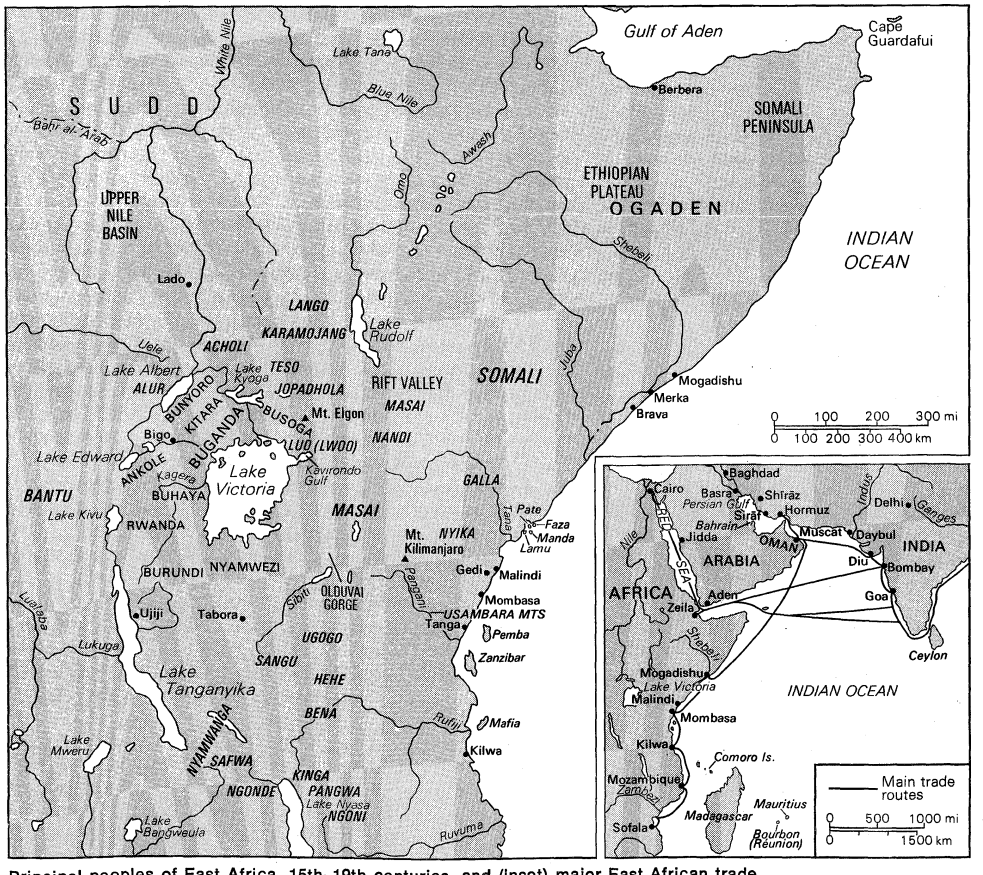
It also stemmed from his intimate association with the major economic developments then taking place along the East African coast. These began with a marked growth in the hitherto-marginal slave trade, particularly at first in the Kilwa region, more especially from 1780 to 1810 as a result of French demand for slaves in Mauritius and Bourbon. This was succeeded by the discovery that cloves could be successfully grown on Zanzibar and by the development of flourishing plantations. British pressure on Sa'īd to end the export of slaves to "Christian" markets came to fruition in 1822, when he reluctantly signed what became known as the Moresby Treaty. In the event, however, it made very little difference, both on the coast and in the interior, since slaves were being increasingly required for the plantations on both Zanzibar and on Pemba and for export to the Persian Gulf and beyond.

Increasing commercial activity brought Sayyid Sa'īd sufficient wealth to buy ships and pay troops. It also attracted to the East African coast migrant Indians, who became heavily involved in the country's economic expansion; and, together with the Arabs who were beginning to make profits from their clove plantations, Indians helped to finance the new upcountry trading caravans.

The increased economic activity that centred upon the islands of Zanzibar and Pemba served to enhance the importance of the smaller towns that stood on the mainland opposite. It also attracted an influx of European traders, of which the most important were the Americans. They were the first Westerners to conclude a trade agreement with Sayyid Sa'īd (1833) and the first also to establish a consul at Zanzibar (1836). (Their prime achievement was to capture the cloth trade to East Africa —so that cheap cotton cloth henceforth came to be known there as Americani.) The British followed with a trade agreement in 1839 and a consul in 1841. The French made similar provisions in 1844, and some Germans from the Hanseatic towns moved in at about the same time. British trade, however, never flourished, and in fact died away; but by 1856 America and France were both making purchases in East Africa of over $500,000 a year, while exports to India, particularly British India, were higher still. Some of the main items of trade, such as ivory, were traditional, but copal, sesame, cloves, cowries, hides, and coconut oil were also important. Because of this increased activity, Sa'īd's economy in due course became less dependent upon the export of slaves, and he therefore showed himself more ready than he might otherwise have been to accept the so-called Hamerton Treaty of 1845, by which the export of slaves to his Arabian dominions was forbidden.

Diminution of the slave economy

Since by this time the revenues from Sa'īd's East African territories had overtaken those he received from Oman, it is understandable that in 1840 he should have transferred his own capital from Muscat to Zanzibar. At his death in 1856, Zanzibar was firmly established as the East African coast's main centre, from which major new incursions into the interior had begun to radiate extensively.



Principal peoples of East Africa, 15th–19th centuries, and (inset) major East African trade routes in the Indian Ocean.

II. The interior before the colonial era

THE STONE AGE

The coast was never more than East Africa's fringe. Beyond the harsh *nyika*, which lay immediately inland and was nowhere pierced by a long, navigable river, thornbush country extended to the south, sometimes interspersed with pleasanter plains toward the centre, while to the north cooler forested highlands ran into harsher country. Westward lay the Rift Valley and, beyond, the regions of the great lakes whence the Nile ran northward through its usually impassable as-Sudd (marshes).

Sources of information

Since there are no written records antedating the last century or so for this region, its history has to be deduced from often uncertain linguistic, cultural, and anthropological evidence; from oral traditions—where they are available, which at best is only for recent centuries—and from archaeological findings. Since investigations and analyses are still at a very early stage and since the first hypotheses have proved vulnerable to criticism, the statements that follow must be only tentative. Moreover, bolder categories such as the Bantu are strictly only linguistic and must be treated with caution. Furthermore, all accounts of tribal migration must allow for innumerable short-run moves and may refer only to small—if important—minorities. They must also take account of probable interactions with other peoples en route and often, indeed, of extensive absorption. Above all, care must be exercised over anachronistic concepts of "tribe."

Two features of the pre-19th-century period may be stressed: first, although it seems to have been in this part of Africa that man first developed, in the three or four most recent millennia the key innovations in man's evolution seem to have occurred elsewhere; second, the extensive agricultural revolution in East Africa, which took place during this time, had the vital consequence that sizable populations grew up in areas of adequate rainfall, which could not be easily brushed aside by subsequent alien invaders.

During the earlier stages of the Stone Age down to *c.* 50,000 BC, hand ax industries were established in the Rift Valley areas of Kenya and of Tanzania (especially at Olduvai Gorge) and along the Kagera River in Uganda. During the Middle Stone Age (thence to *c.* 10,000 BC), new stone-making techniques evolved, and the use of fire was mastered. Spreading to other parts of East Africa, in the Late Stone Age man clustered into specialized hunting and gathering communities from which may have developed some still-existing ways of life. The largest number of relevant sites is close to the homeland of the Hadzapi—the last contemporary hunters and gatherers—and to that of the Sandawe, who are physically and linguistically akin to the Bushmen of southern Africa. Remnants of other hunting and gathering communities—such as the Pygmies of western Uganda—or at least the memory of them, are found in many places. Latterly, they often lived in precisely those highland regions where agriculture and animal domestication in East Africa first occurred.

Food production and the keeping of cattle seem to have begun in the highland and Rift Valley regions of Kenya and of northern Tanzania in the 1st millennium BC and to have derived from Caucasoid peoples who were probably southern Cushites from Ethiopia. Some traces of these interlopers remain among, for example, the Iraqw of Tanzania; and it may be that the age-old systems of irrigation found throughout this region owe their origins to this period as well. Agriculture preceded the smelting of iron in these areas, and hunting and gathering continued to be important for the domestic economy. It looks as if in due course southern Cushites spread deep into what is now southern Tanzania, but, so far as has been ascertained, food production did not develop in the period BC elsewhere in Tanzania, nor in what is now Uganda.

THE SPREAD OF IRONWORKING AND THE BANTU MIGRATIONS

It is still far from clear when and whence iron smelting spread to the East African interior. Certainly there was no swift or complete transfer from stone to iron. At Engaruka, for example, in that same region of the Rift Valley in northern Tanzania, a major Iron Age site, which was both an important and concentrated agricultural settlement using irrigation, seems to have been occupied for over a thousand years. Significantly, its styles of pottery do not seem to have been related to those that became widespread in the 1st millennium AD. It is a reasonable assumption that its inhabitants were Cushitic speakers, but it would seem that its major period belongs to the middle of the 2nd millennium AD.

The spread of cultivation techniques

The major occurrences of the 1st millennium AD involved the spread of agriculture—more particularly, the cultivation of the banana—to the remaining areas of East Africa. Simultaneously or perhaps previously went the spread of ironworking, with which "dimple based" and related pottery was often associated, and fairly certainly too the diffusion of Bantu languages—except in the core of the Cushitic wedge and to the north of an east–west line through Lake Kyoga. If, as seems probable, proto-Bantu languages had their origins in the eastern interior of West Africa, it does not seem inconceivable that over a lengthy period of time some of its speakers, probably carrying with them a knowledge of grain agriculture and conceivably a knowledge of ironworking, should have diffused along the tributaries of the Congo River to the savanna country south of the Congo forest into what is now the region of Shaba (Katanga). Nor does it seem inconceivable that the banana, originally an Indonesian plant particularly suitable in tropical conditions, should have spread to that same region up the Zambezi Valley (certainly the Malayo-Polynesian influences in Madagascar in the 1st millennium AD are well attested in other respects). At all events, the linguistic and archaeological arguments for a fairly rapid eastward and northward expansion during the 1st millennium AD from the Katangan area now have wide acceptance. Bantu languages came to dominate most of this region (many Cushitic speakers in what is now Tanzania seem to have switched over to them or to have been eliminated). More varieties of banana developed in East Africa than anywhere else in the world. Ironworking was soon prevalent. Remarkably similar pottery styles were being used; and, where rainfall, soil nutrients, and the absence of the tsetse fly allowed, population growth increased decisively.

Sometime before the middle of the 2nd millennium AD, some of the most interesting developments were occurring in the interlacustrine area—*i.e.*, the region bounded by Lakes Victoria, Kyoga, Albert, Edward, and Tanganyika. Vague accounts of rulerships in various parts of this area date from the first half of the 2nd millennium AD, and it is at least possible that they existed—though they may well have been judicial arbitrators or ritual leaders rather than more strictly political figures. Whether they had their origins in roving Cushitic or Nilotic cattle keepers from the north or northeast—as has been variously suggested—is impossible to say, though some such explanation would not be difficult to believe. What seems certain is that around the middle of the present millennium a sudden cultural and political climax was marked by a short-lived, though widely acknowledged, dynasty of Chwezi rulers.

The Bigo enclosure

Many are ready to assume that these Chwezi people are to be associated with the great earthwork sites at Bigo, Mubende, Munsa, Kibengo, and Bugoma, in western Uganda. That at Mubende seems to have been a religious centre. The largest is at Bigo, where a ditch system, over six and a half miles long, some of it cut out of rock, encloses a large grazing area on a riverbank. It looks as if it comprised both a royal capital and a well-defended cattle enclosure. Its construction must certainly have required a considerable mobilization of labour—which, apart from indicating that it must have been the work of a substantial political power, would support the view that the distinction between cultivators and a pastoral aristocracy, which later became typical of this area, is of very long standing. Radioactive carbon dating suggests Bigo was occupied from the mid-14th to the early 16th century. This correlates with the evidence of oral tradition

that around the turn of the 15th century the Chwezi were supplanted in the north by Luo (Lwoo) rulers of the Bito clan (who provided the dynasties that ruled in Bunyoro, Koki, Buganda, and parts of Busoga) and that they were superseded to the south by various Hima rulers of the Hinda clan (in Ankole, Buhaya, Busubi, and around to the southeast of Lake Victoria). Under these (and the corresponding Nyiginya dynasty in Rwanda) powerful traditional rulerships among the interlacustrine Bantu persisted after the middle of the 20th century.

Their relatively common experience was reinforced in the aftermath of the Chwezi dynasty by the prevalence among them of a variety of (often commemorative) Chwezi religious movements. In some areas these took the form of spirit-possession cults; in others, pantheons of deities were developed. In various guises—sometimes in support of the existing political order, sometimes against it—they spread into Bunyoro, Buganda, Busoga, Ankole, Buha, Rwanda, Burundi, and even to Nyamwezi country, in what is now Tanzania. So extensive a diffusion of a basically common religious tradition in any other part of the East African interior before the much later arrival of Islām and Christianity was rare indeed.

The *ntemi* kingdoms

In northwestern Tanzania, dynasties of a pre-Chwezi kind apparently spread from the interlacustrine area during the middle centuries of the present millennium. *Ntemi* (as the office was called) became prevalent among both the Sukuma and the Nyamwezi. They (the *ntemi*) were probably as much ritual leaders as political rulers. Certainly they do not seem to have exercised before the 19th century that "state" authority that was characteristic of the later interlacustrine rulers. By about the 16th century there may have been an extension of this style of chieftainship southward into southwestern Tanzania. At all events, the chiefly groups among the Nyamwanga, the Nyika, the Safwa, the Ngonde, the Kinga, the Bena, the Pangwa, the Hehe, and the Sangu have common traditions of origin, and it seems clear that they are to be distinguished from their significantly different, matrilineal neighbours in southern Tanzania, Zambia, and Zaire. There also seem to have been secondary movements of *ntemi*-like institutions in the 18th century to Ugogo, Safwa, Kaguru, Kilimanjaro, and Usambara. At the same time, the development of chieftainship in these other areas of Tanzania may originally have occurred independently of influences from elsewhere.

Although it is believed that some of the northeastern Bantu were once ruled by chiefs, these did not survive. The spread of some Bantu to the northern coast of East Africa during the 1st millennium AD is supported by the memory of a settlement area named Shungwaya situated to the north of the Tana River. (Its name appears on European maps from 1596 onward.) The traditions and origins of several Bantu peoples who then moved southward are traced to this area. It would seem as if it had its heyday as a Bantu settlement area between perhaps the 12th and the 15th centuries and was subjected to a full-scale invasion of Cushitic-speaking Galla in the 16th century. Bantu are no longer found so far north. There is controversy as to whether the ancestors of the present Kamba and Kikuyu of Kenya were from Shungwaya, but it would seem that they probably broke away from there some time before the Galla onslaught. It has been suggested, indeed, that the Kikuyu spread through their present territories from 1400 to 1800.

The old Cushitic wedge checked them from spreading farther westward. This extended, as it would seem to have done for two or more millennia past, over both sides of the Kenyan and northern Tanzanian Rift Valley. In the middle of the present millennium it was subjected to one of the multiple waves of invading Nilotic peoples —who were partly agriculturists and partly pastoralists—that moved into much of the northern and northwestern parts of East Africa during the three or four centuries that ensued.

MIGRATIONS OF NILOTIC AND CUSHITIC PEOPLES

The supersession of the Chwezi by Luo dynasties in the northern interlacustrine region at about the end of the 15th century resulted from the migrations of Nilotic peoples southward—in this instance, it has seemed, from a cradleland in what is now the Sudan. For some 18 generations or so Bito rulers of Luo origin held sway over the kingdom of Bunyoro-Kitara, to the east of Lake Albert. Though at first their dominion seems to have been widely extended, they began to be rivalled in the 16th and 17th centuries by the rise of Buganda, under its ruler, or *kabaka*. Working on interior lines and based upon a particularly fertile region, Buganda developed a strength and cohesion that from the 18th century onward was to make it—with Rwanda—one of the two most formidable kingdoms of the region.

The Luo dynasties

Their Luo rulers and such followers as had accompanied them were soon fully absorbed into the Bantu population of these kingdoms. Immediately to the north (where the Bantu did not extend) there occurred the greatest independent expansion of the Luo peoples, who formed the Acholi; provided ruling groups for peoples to the west who came to be called Alur; and bred the Jopaluo and Jopadhola to the east and also the sizable Luo populations who, between the mid-16th and the mid-18th centuries, came to settle on the northern side of the Kavirondo Gulf to the northeast of Lake Victoria and spread thereafter to its southern shore as well.

Over to the east, into the former Cushitic domain that centred upon the Rift Valley, there appears to have been, in about the middle of the present millennium, a great expansion of Kalenjin peoples, whom it has been usual to call Nilo-Hamites but whom it would now seem proper to call Nilotes (Highland Nilotes to distinguish them from, among others, River–Lake Nilotes such as the Luo). They seem to have absorbed most of the previous southern Cushites who remained there and also to have successfully held the core of this ancient wedge, if not its earlier dimensions, against further Bantu incursions. By 1700, however, a second expansion into this old protrusion was beginning. During the 18th century the Masai (Plains Nilotes, as they are now being called) spread over most of the area, until they came to be found as far south as Gogo country in central Tanzania. Already divided into pure-pastoralist and mixed-agriculturist subtribes, they were soon to be found to the east near Mt. Kilimanjaro. The earlier Kalenjin thus found themselves confined to the hillier country between the Rift Valley and Lake Victoria, where—constituting the Keyu (Elgeyo), the Suk (Pokot), the Nandi, the Kipsigis, and the Tatoga of more recent times—they entered into a variety of interactions with their various Luo and Bantu neighbours. Farther to the north in the areas beyond Mt. Elgon a shorter run series of migrations by other Plains Nilotes was simultaneously taking place. First, in the 17th century, the Lango began moving southwestward (and became much affected by their River–Lake Nilotic neighbours, the Acholi). Then, in the 18th century, the Teso, Karamojong, and others began also to move in various southward directions.

It has been suggested that all these Highland and Plains Nilotic migrations were set off, both before and after the middle of the present millennium, by successive pressures from the eastern Cushitic Galla to the north, who were themselves being pressed upon by their own Cushitic neighbours, the Somalis.

If the basic Somali populations first spread into the horn of Africa from farther south, the first important Somali leaders were those who crossed over from Arabia in the 10th and 12th centuries. From that time onward the Dir, Darod, and Issa Somalis began to press steadily upon the Galla to the south. By the middle of the 16th century they had taken over much of northern Somaliland and the Ogaden region of Ethiopia. Since they were Muslims, the Somalis became involved in the Muslim conflict at this time with Christian Ethiopia. Already, moreover, the Galla in the 15th century had begun their own most wide-ranging expansion, which by the end of the 16th century was affecting much of the Ethiopian highlands. What was more, their southern thrusts were pushing on past Shungwaya and the Tana River and by the 17th century were even penetrating areas inland from

Mombasa. Behind them, however, the Somalis were also once more on the move and by the end of the 17th century were occupying all the territory on which the Galla had previously settled north of the Juba (Giuba) River.

The Somali "sultans"

The Somali "sultans" were scarcely more than figureheads and lacked any firmly institutionalized political power. They were often indeed less important than the elders of their clans. This, with variations, was the case with most of the leaders of the Nilotes as well. Indeed, Nilotes established "states" only where, as in the interlacustrine area over to the west, they came to rule other peoples who may very well have had traditions of rulership before they arrived. Such distinctions were to be of immense importance for the future. Among the Galla, the Masai, the Kalenjin, and—by adoption—some of their immediate Bantu neighbours, there were age systems of one kind or another. Farther south there were Bantu who had *ntemi* and other vague versions of chieftainship; there were somewhat similar figures among the River–Lake Nilotes. Only in the interlacustrine area were there powerful rulers and well-established kingdoms.

DEVELOPMENTS IN THE 19TH CENTURY

Political activities. In the 19th century there were a number of new movements and new political developments among the enlarged populations of East Africa before the advent of Western imperialist forces. In the south some parties of Ngoni—themselves originally refugees from the Zulu wars in southeastern Africa—moved northward following the breakup of their main body after 1845, at the north end of Lake Nyasa. Some Ngoni groups made their way to Songea; another struck north to Lake Victoria. They carried, to the area west of Lake Tanganyika, a new style of raiding and appear to have precipitated among such peoples as the Holoholo and the Ndendehule, the Sangu, and the Bena—in part, at least, as a safeguard against Ngoni raids—the creation of new political institutions, including more powerful rulerships. The most notable of such developments were, in the first place, among the Hehe, where, under Munyigumba and then on his death, in 1879, under his son Mkwawa, a powerful state was built up; then among the Nyamwezi, where between 1870 and 1884 the warrior chief Mirambo established a powerful personal rulership; and also among the Kimbu, where, between 1870 and 1884, Nyungu and his *ruga-ruga*s (or bands of warriors) created a dominion that survived his death.

Nothing quite so striking occurred to the northeast. Conflict persisted between the smaller Chagga rulers on Mt. Kilimanjaro. Around 1800, Orombo and, after 1860, Sina of Kibosho and Rindi of Moshi built up powerful combinations; but no one established a single political authority. In the middle decades of the 19th century, Kimweri enjoyed a considerable dominion in the region of the Usambara Mountains, but on his death, sometime in the 1860s, his rulership disintegrated. Further such disintegrations occurred in the 19th century among the rulerships of Buha and Buzinza, at the south end of Lake Victoria, and among the Buhaya kingdoms on its eastern shore. The kingdom of Mpororo, to the westward of Buhaya, had already broken up. By the 1890s its neighbour Nkore seems to have been in danger of disintegrating as well. Earlier in the century, Toro, to its north, had broken away from Bunyoro, previously the most extensive of the kingdoms in this area—while fragmentation was almost endemic among the Busoga kingdoms to the east.

The kingdom of Rwanda

But there were also political growing points in the interlacustrine area, where one of the largest kingdoms, Rwanda, first consolidated its rear by annexing Lake Kivu, then, in the aftermath of a succession war, swallowed the small kingdom of Gissaka, to its east. It failed to defeat Burundi, to the south, but under its *mwami*, or ruler, Kigeri IV (who reorganized its military forces) it extended its control by raiding to the north.

Its power was equalled in this region only by the kingdom of Buganda. Having annexed the large area of Buddu, to its southwest, in the late 18th century, Buganda thereafter generally refrained from any further territorial extensions. Its rulers steadily increased their authority at home by enhancing the power of appointed chiefs at the expense of the clan leaders, while abroad they preferred to make satellites rather than subjects of their neighbours. They had a good deal of success eastward in Busoga and southward along the western shore of Lake Victoria and around its southern rim. In the 1870s and 1880s Buganda's protégés were on several occasions installed in petty rulerships in Busoga. In 1869 Bunyoro successfully survived Buganda interference in one of its succession conflicts (as Nkore did in 1878) and indeed in the 1870s and 1880s was renewing its strength. As in Rwanda and farther south, military reorganization was of vital importance. Bunyoro's improved position turned much on its new military formations, the *abarasura*, while Buganda's successful predation owed a good deal to its new military efforts under the *mujasi*, or military commander, as well as to the building of a formidable fleet of canoes.

To the north and northeast the previous migrations of the Luo from west to east were followed in the 19th century by a new wave of migrations from east to west. The Lango, for example, further expanded in two southward and westward waves toward Lake Kyoga and toward the Victoria Nile, where they ran up against the Acholi. To their south the Teso and the Kumam were also moving west and south. A flourishing trading network developed around Lake Kyoga, and during the course of the 19th century the Teso in particular were converted from pastoralism to agriculture.

Activity was rife also among the pastoral peoples to the east. In about 1850 the Turkana began to migrate from a base west of Lake Rudolf. South of them the Suk were the terror of their neighbours, but by the 1880s they in their turn were being threatened by the Turkana. To the east the Somalis were once more on the move. After 1850 one of the Darod Somali groups, the Marehan, crossed the Juba in force. In 1865 they went on to break the Tana Galla and by 1880 had turned on the Boran. Pagan peoples in this region were now being dominated by Muslims, and peasants by nomads from the north. Moreover, after 1880 especially, the Ethiopians, fired by their new imperial ambitions, were advancing too.

Southward stood the Masai, the warrior people of the plains and open plateaus north and south of the string of Rift Valley lakes west of Mt. Kenya. From 1830 onward their various subtribes were engaged, under the auspices of their rival *laibon*s, or ritual leaders—among whom Mbatian, who succeeded his father, Subet, in 1866, was the most famous—in a succession of internecine conflicts largely over cattle and grazing grounds. Their wars denuded the Laikipia and Uasin Gishu plateaus of their former Masai occupants and increased the diaspora of Masai, the so-called Wakwavi, who, being deprived of their cattle, switched to agriculture. They also helped the Nandi, who, with the Uasin Gishu Masai now troubling them no more, took to raiding on their own account from a base between the Rift Valley and Lake Victoria. Under the leadership of their *laibon*-like *orkoiyot*s the Nandi and their kinsfolk, the Kipsigis, were soon the new powers in the land. Some of their neighbours who lived in open country put up defense works against them—the Baluyia, to the west, for example, built mud walls around their villages—while others, such as the Teita (Taita), the Kamba, and the Kikuyu, who lived on higher ground and in forest country, were rather better placed and from their carefully guarded fastnesses could defy the Masai. On the edges of their country they even entered into some permanent trade and marriage relations with the Masai. Where the soil was fertile, moreover, such people considerably increased their populations. By the 1880s, for example, Kikuyu country was very populous. Though they had no chiefs, "prominent men" were accorded a recognized status among them, and by the close of the century some of these were fighting each other for local supremacy.

Arabs and East African trade. On the coast, following the death, in 1856, of Sayyid Sa'īd, his erstwhile domin-

ions in East Africa were split off from the imamate of Muscat. With the death of the last Myenyi Mkuu in 1873, the authority of the Albusaidi sultans on Zanzibar itself became complete, although there were still revolts against them on the coast—particularly at Pate and Mombasa (where the Mazrui retained their pre-eminence despite successive defeats)—and at Kilwa, to the south.

Closing of the slave markets

This arose chiefly from the Sultan's acceptance of the further measures against the East African slave trade pressed upon him by the British consul at his court. By the 1860s some 7,000 or so slaves were being sold annually in the Zanzibar slave market. In 1873 a treaty with the British closed the market at Zanzibar, and Sultan Seyyid Barghash, by two proclamations in 1876, reduced the export from the mainland to a trickle. As it happened, however, there was then a final period of unprecedented slaving on the mainland, where the trade in slaves had generally been closely connected with the trade in ivory and the demand for porters was still considerable.

Trade in the East African interior began in African hands. In the southern regions Bisa, Yao, Fipa, and Nyamwezi traders were long active over a wide area. By the early 19th century Kamba traders had begun regularly to move northwestward between the Rift Valley and the sea. Indeed, it was Africans who usually arrived first to trade at the coast, rather than the Zanzibaris, who first moved inland. Zanzibari caravans had, however, begun to thrust inland before the end of the 18th century. Their main route thereafter struck immediately to the west and soon made Tabora their chief upcountry base. From there some traders went due west to Ujiji and across Lake Tanganyika to found, in the latter part of the 19th century, slave-based Arab states upon the Luapula and the upper reaches of the Congo. In these areas some of those who crossed the Nyasa–Tanganyika watershed (which was often approached from farther down the East African coast) were involved as well, while others went northwestward and captured the trade on the south and west sides of Lake Victoria. Here they were mostly kept out of Rwanda, but they were welcomed in both Buganda and Bunyoro and largely forestalled other traders who, after 1841, were thrusting up the Nile from Khartoum. They forestalled, too, the coastal traders moving inland from Mombasa, who seemed unable to establish themselves beyond Mt. Kilimanjaro on the south side of Lake Victoria. These Mombasa-Pangani traders only captured the Kamba trade by first moving out beyond it to the west. By the 1880s, however, they were operating both in the Mt. Kenya region and around the Kavirondo Gulf (where some of them became particularly associated with Mumia of the Wanga, or Hanga) and were even reaching north toward Lake Rudolf.

Suggestions that the Sultan of Zanzibar might at this time establish his dominion over the East African interior prompted Sultan Barghash to send a Baluchi force to Tabora. But the idea was never pursued. A comparable notion, however, led Khedive Ismāʿīl Pasha of Egypt to appoint in 1869 the Englishman Samuel White Baker as governor of the Equatorial Province of the Sudan in order that he might carry the Egyptian flag to the East African lakes. Though Baker reached as far south as Bunyoro in 1872, he was soon obliged to leave. His successor, Charles George Gordon, proposed to circumvent both Bunyoro and Buganda by going straight up the Nile's banks. Gordon also encouraged the ultimately frustrated expedition of McKillop Pasha, which the Khedive sent around the horn of Africa and down the East African coast to the mouth of the Juba River. Mutesa I, *kabaka* of Buganda, frustrated Gordon's efforts on the Nile; and by the early 1880s, with bankruptcy in Egypt and the Mahdist revolt in the Sudan, only remnants of the Egyptian enterprise remained.

III. The colonial era

THE ARRIVAL OF THE EUROPEANS

The Egyptian incursion had been the climax to the search by many European explorers for the headwaters of the Nile. This quest had obsessed the later years of the Scots missionary David Livingstone and had prompted the discovery in 1858 of Lake Tanganyika by the English expedition of Richard Burton and John Hanning Speke. Speke returned first to discover Lake Victoria in 1858 and then with James Grant in 1862 became the first white man to set eyes on the source of the Nile, which Speke named Ripon Falls. By circumnavigating Lake Victoria 12 years later, H.M. Stanley stilled the controversy that had ensued in Europe over Speke's claim.

The origins of missionary incursions

The revelations of these explorers, the example of David Livingstone, concern in western Europe over the East African slave trade, and the Catholic and evangelical fervour that existed there inspired the invasion of the East African interior by a motley collection of Christian missionary enterprises. Johann Ludwig Krapf and Johannes Rebmann of the Church Missionary Society, who had worked inland from Mombasa and had, in the 1840s and 1850s, journeyed to the foothills of Mounts Kenya and Kilimanjaro, were followed by a British Methodist mission. Catholic missionaries reached Zanzibar in 1860 and settled at Bagamoyo in 1868. An Anglo-Catholic mission first tried to establish itself in the Shire highlands, then in 1864 transferred to Zanzibar. Anglican missionaries arriving in Buganda in the mid-1870s at the request of Kabaka Mutesa were soon followed by Catholic White Fathers—there and elsewhere on Zanzibar's Tabora route—while the London Missionary Society sent men both to Unyamwezi and to Lake Tanganyika.

There were, of course, a number of localized religious movements among the peoples of East Africa during the 19th century. These included the Mbari cult among the Nyakyusa, the Nyabingi in Rwanda, and the Yakany movement north of Mt. Ruwenzori. None of them, however, spread in quite the way that the Chwezi movement had earlier. Islām, on the other hand—spread widely at the instance of the Zanzibari traders and long established on the coast—had secured a scattering of converts in the interior as in the key kingdom of Buganda.

This was the scene onto which Christian missionaries first entered. Although by 1885 there were nearly 300 of them in East Africa, they did not, initially, win many converts, and those they at first obtained came only from among freed slaves and refugees from local wars. After 1880, however, they made important conversions in Buganda, and by the end of the century Christianity was spreading in the Lake Victoria area over most of the region in which the Chwezi movement had previously percolated—and before very long over a much larger area as well. There were a good many African peoples who, secure in their own beliefs and rituals, were impervious to such alien religion, others who were actively hostile, to them, but others, too, who found that one or other of them met some of their deepest needs. In Buganda in 1876 there were even Muslim martyrs, when their ruler, the *kabaka*, turned against them, and, a decade later in similar circumstances, Christian ones too.

Philanthropic, commercial, and eventually imperialist ventures followed these evangelical endeavours. Nothing, however, of great moment occurred until in 1885, when a German, Karl Peters, riding a tide of diplomatic hostility between Germany and Britain in Europe, secured the grant of an imperial charter for his German East Africa Company. With this, the European scramble for east central Africa began. The genesis of this movement is subject to much controversy. Certainly all the major—and several minor—European states wanted new imperial possessions from which they could draw raw materials to feed their industrial revolutions and in which they could establish new markets. They also had some large-scale strategic interests and some strong feelings about what they saw as a call to civilize Africa.

There had already been rivalry over the Somali areas among the Egyptians, the Italians, the Ethiopians, the British, the French, and the Sultan of Zanzibar. When the Egyptians in 1884 were forced to withdraw from Harer, Zeila, and Berbera to consolidate their strength against the Mahdists in the Sudan, the Italians, somewhat encouraged by the British, who were fearful of French designs, proclaimed a protectorate in 1885 over the Eritrean coast. In the same period the French estab-

Italy's imperial pretensions

lished a protectorate in the Jibuti area, while the British declared a protectorate over the Somalis (who were becoming fearful of Ethiopian ambitions) in the area about Berbera. The Treaty of Uccialli (Wuchale), by which in 1889 the Italians believed that they had made Ethiopia into their protectorate, was disputed by the emperor Menelik II, who in 1896 inflicted a resounding defeat upon them at the Battle of Adowa. In the meantime, various Italian enterprises had managed to establish their claims to the area that was soon to become Italian Somaliland, and first in 1891 and later in 1894 various Anglo-Italian protocols settled the boundaries between the Italian and British spheres of influence. Moreover, at Harer in 1896, the British and the Ethiopians agreed to a treaty to define their boundaries.

The Anglo-German agreement of 1886

In east central Africa the key occurrence was the Anglo-German Agreement of 1886, by which the two parties agreed that their spheres of influence in East Africa should be divided by a line running from south of Mombasa, then north of Kilimanjaro to a point on the eastern shore of Lake Victoria. This ended any further question of Zanzibari dominion in the East African interior and began the extraordinary process by which the territories and subsequently the nations of East Africa were blocked out first upon the maps far away in Europe and only later upon the ground in East Africa itself, invariably, moreover, without regard for any social or cultural boundaries in the areas concerned. A British East Africa Association was created in 1887 to compete with the German company and it was transformed in 1888 into the Imperial British East Africa Company. The ensuing rivalry between the two European companies provoked such rivalry along the coastline and in the interior that the British and German governments were eventually obliged to conclude a further Anglo-German Agreement (1890), whereby German activity was confined to the area south of the 1886 line; Zanzibar was left to become a British protectorate; the boundary on Lake Victoria was bent due west to the border of the Congo; and the Germans acknowledged British claims to the headwaters of the Nile—while maintaining a crucial stretch of the "Cape to Cairo" route upon which much British romanticism had been lavished. Further international agreements—such as the Anglo-Congolese Agreement of 1894—and a good many detailed adjustments followed.

COLONIAL RULE

Both the British and the German companies soon surrendered such territorial controls as they had to direct imperial administrations—as did the various Italian enterprises. The German government took over from the German East African Company in 1890, while the British company handed over its claims upcountry to a British protectorate administration in 1893. In 1895 it also surrendered its territory nearer to the coast. Only gradually, however, was even a limited colonial administration extended upon the ground—in the western British territories by 1914, in parts of the northern territories as late as the 1920s.

The extension of administrative control was marked by violent conflict, in which the Europeans used mercenaries, sometimes from elsewhere in Africa, sometimes even from India. Innumerable military clashes in the German sphere included a major conflict on Mt. Kilimanjaro in 1892, a protracted war with the Hehe between 1888 and 1898, and stern resistance until 1899 from the Yao ruler of the Makonde plateau. The British, except for one occasion, successfully avoided clashes with the Masai, but they launched five distinct campaigns against the Nandi between 1895 and 1908. There was war in Buganda between 1891 and 1893 and again between 1897 and 1899, protracted conflicts in Bunyoro, a number of encounters in Busoga and Ankole, and, in the next two decades, countless clashes with the peoples throughout the northern British spheres.

Nothing in this region equalled the resistance of the Somalis under Sayyid Muḥammad Abdille Hassan, a leading member of the militant Ṣalīḥiyah branch of the Aḥmadīyah order. Deeply perturbed by the threat to his people's Muslim faith by Christian colonial activity, he raised a great revolt against the British in 1900 and withstood them four times before (at Illig in 1905) agreeing with the Italians to settle in their sphere. He also fought the Ethiopians. He took up arms again between 1908 and 1920 until his stronghold at Taleh fell, and he died shortly after.

Somali resistance

Resistance was also sharp elsewhere. In 1888–90 a major assault under Bushiri was mounted by the coastal peoples against the Germans. Elsewhere the resistance of the Nandi and the Banyoro against the British, and of the Hehe against the Germans, was both skillful and courageous. As in Somaliland, some of the most forceful resistance was mounted in association with religious movements. Of these, some, such as the Yakany cult, which originally developed against the Nile traders, inspired a considerable upheaval against the British in the West Nile district of Uganda in 1919. To the south the Nyabingi cult, which had first developed in resistance to Rwanda depredations, became a scourge to the British in Kigezi District through much of the 1910s and again in 1928. Other movements, such as the Mumbo cult among the Gusii or the Kamba exorcism cults, seem to have been precipitated by the European pressures. Of these, the most notable was the fiercely repressed Maji Maji rising of 1905–07. Originally a protest against an ill-advised cotton scheme, it rapidly developed—in association with the Kolelo cult—into a widespread revolt against the Germans throughout the southern parts of their territory.

Some African peoples had welcomed the imperial rulers from the outset, seeing in them likely allies who could defend or enlarge their own local interests. Alliances thus developed—between, for example, Sangu sultans, Masai *laibons*, Buganda chiefs, and the European rulers—which often became the basis for a stabilized colonial order.

European colonies in East Africa to 1914.

From their capital in Dar es Salaam, the Germans divided their colony into 14 "stations," and, over and above their links with certain local chiefs, they widely extended their Zanzibari inheritance of appointed *liwalis*, *akidas*, and *jumbes*.

The British sphere, as seen above, became divided between two British administrations. From the very beginning it had two focuses deep in the interior: the remnants of the Egyptian Equatoria Province and the promising Christian missions in Buganda. The Imperial British East Africa Company sought, originally, to take over the first —and thus early on directed its attention to the far interior. But during 1890–92 its caravan leaders were diverted to Buganda, because of a favourable opportunity that presented itself to them there as a result of an oligarchal revolt against its *kabaka*, Mwanga, in 1888. Capt. Frederick (later Lord) Lugard and his successors, by interposing themselves between the Muslim and Christian parties in the internecine conflict that ensued, were able by 1894 to establish British control over the most powerful African regime in the interior. And when, as a result of its impending bankruptcy, the company announced its withdrawal from Buganda, a British imperial protectorate was eventually established over "Uganda" in 1894. Since it was obvious that its commissioner would have difficulty in exercising authority nearer the coast, in 1895 a separate British East Africa Protectorate was established over the areas nearer the coast. The boundary between the two originally ran on the east side of the Rift Valley, but in 1902 it was shifted westward to the vicinity of Mt. Elgon. It became in due course the international boundary between Kenya and Uganda.

Buganda and the Uganda Protectorate

Thereafter, the two British protectorates developed very differently. Despite the Sudanese mutiny and the Kabaka's revolt in 1897–99, the new regime in Buganda—secured as it came to be by the so-called Uganda Agreement of 1900—was locked with a victorious oligarchy of Christian chiefs, and Buganda's inherited political institutions were readjusted so that under a new and less powerful *kabaka*, Daudi Chwa (1897–1939), three senior chiefs formed a three-man Buganda government, while the others came to be stratified into a three-tiered hierarchy of county, subcounty, and parish chiefs with both administrative and judicial powers. In the years that followed, this Buganda model was exported in one way or another to the rest of the Uganda Protectorate. In some areas former war-band leaders or petty rulers found themselves uncomfortably pressed into being administrative chiefs. Especially in the "stateless societies" in the north, where specialized political offices had not previously existed, the system was largely novel. Between 1895 and 1905 a Buganda general named Kakunguru had established his own Buganda-like "empire" there, but it was taken over by the British, who then used "Buganda Agents" in extending their rule there and elsewhere. After 1910 these were steadily replaced by local men, but everywhere a hierarchical structure, as first elaborated in Buganda, became established, and British officials in Uganda took pleasure in declaring, "The best method of developing the country is through the native governments."

From an imperial point of view, the advantage of working through "native governments" led British officials next door to proclaim paramount chiefs among the Kikuyu, Masai, and Baluyia. The belief that such appointments secured a better position for Africans led many of them there (and later in Tanganyika) to press for them. But in the East Africa Protectorate there were major problems. Scarcely anywhere within its boundaries was there any previous, distinctly political office on which to build. There was some possibility that, as in the south, *liwalis* and *jumbes* would be employed, but, when the hub of the country was shifted upcountry from Mombasa to Nairobi in 1902, the hope that local chiefs could be enlisted into British service was soon frustrated. Though an attempt was made to enlist local courts of elders after 1908, they were no use for ordinary administrative purposes. The result was that the Kenya administration came to base itself thereafter not upon any pre-existing indigenous authorities but upon its own imposed structure of directly appointed chiefs and headmen. There can be little doubt that they were more appropriate to many local societies than were those ritual leaders or petty rulers who were pressed into administrative service. But the appointed chiefs in Kenya (as the proponents of paramount chieftaincies very well understood) could neither withstand the colonial administration nor provide the more sympathetic administrators with a "native" instrument of development. Further attempts to enlist the cooperation of local leaders in the creation of local native councils in the 1920s never matched the success of the development of councils in Uganda, and local administration in Kenya not only remained very largely under European direction but was mainly controlled from the centre as well.

In several respects World War I (1914–18) was very important for East Africa. There was protracted conflict between the British (and the South Africans) and the Germans in Tanganyika—both sides used large numbers of Africans—and it was only in 1918 that the latter finally surrendered. Britain was then granted a League of Nations mandate over Tanganyika. Important new developments in the administration of the country then occurred when Sir Donald Cameron (governor 1925–31) and his able secretary for native affairs, Philip Mitchell, introduced "indirect rule," the system whereby local authority was formally vested in traditional African authorities. By contrast with Kenya there had in fact been a variety of African chiefs in this region, as seen above, in the past (though none of them with the power of the Uganda rulers), so that the policy of indirect rule could be pursued there with some success.

The new order. Important patterns common to the three territories now began to emerge. A money economy was beginning to be adopted, and Christian missions were becoming widespread in all three. Western education was primarily in the hands of Christian missionaries, and much that was dramatically new in East Africa derived from this connection. Out of the mission-school system came the beginnings of a Western-educated African elite. With no local university education and little opportunity to travel abroad, they combined pride in their heritage with the belief that since they were powerless to overthrow the colonial system their best course was to seize the opportunities it provided. Some of them among the Kikuyu of Kenya, with Johnstone (later Jomo) Kenyatta in their midst, vehemently defended during the late 1920s their people's practice of cliterodectomy (female circumcision) against the denunciations of the missionaries. Samwil Chiponde of Tanganyika, on the other hand, was heard to declare in 1925, "People can say what they want, but to the African mind, to imitate Europeans is civilisation." Probably, however, Kabaka Daudi Chwa spoke for the majority when in his pamphlet "Education, Civilisation and Foreignisation" (1935) he declared himself broadly in favour of the first two but opposed to the last.

The effects of missionary education

It was usually these men, who as chiefs, clergymen, schoolmasters, prosperous farmers, and entrepreneurs, led the way in the immensely important processes of aggregation—and particularly of political aggregation—that in a variety of ways took place at a local level. Previously, many of the bonds uniting those who spoke the same language and possessed closely similar cultural practices had been tenuous. But as, in the 20th century, they found themselves caught in a larger framework and a fast-changing environment, their sense of a common tribalism was heightened. This development was often encouraged by the colonial authorities, whose colonial administrative structures often provided the chief institutions within which it advanced. Local administrative boundaries were often adjusted to meet the resulting strains.

"White man's country." It was precisely these processes of aggregation that became caught up in the major uncertainty that hung over East Africa in the first half of the 20th century: whether it was or was not to become a "white man's country." The doubts here stemmed from a basic dispute over whether the economic development of East Africa should be based on African peasant farming or on European estates. Though there were always champions of African production, most European governing circles at the beginning of the 20th century

believed that the right way to proceed, wherever conditions allowed, was to build up the production of European estates. As the railway, which had been built through the British East Africa Protectorate between 1895 and 1901, showed little sign of paying its way, strenuous efforts were made to attract white settlers to the Kenya highlands in order to make both the railway and the protectorate pay—the assumption being that all necessary labour could be procured from the neighbouring well-populated African areas. German settlers had meanwhile been encouraged to settle in the German sphere.

Opposition to the settler doctrine

The settler doctrine did not go unchallenged even among British officials in the Kenyan highlands. In Uganda, more particularly under its then governor, Sir Hesketh Bell (1905–10), the production by African peasants of cotton was actively fostered—especially in the south central and eastern parts of the country; while moved in part by developments in Uganda, the German governor Albrecht von Rechenberg (1906–12) made a notable effort to encourage African peasant production in his territory and even secured German government finance to build Tanganyika's central railway so as substantially to forward its prospects. His plans were, however, resisted by the German settlers, who, after his departure, gained a political pre-eminence that exceeded that achieved at this time by the British settlers to the north. There, those British administrators who were concerned to withstand settler pressures upon Africans were by 1910 in full retreat (especially after the dubiously manipulated transfer of the Kenyan Masai into a compact southern reserve), while even in Uganda a handful of European planters were now assuming an influence that threatened the predominance of the African peasant sector.

The effects of World War I

World War I had a paradoxical effect upon this ambiguity. On the one hand, it destroyed the position of the German settlers—who were only slowly replaced by a new influx of British and other settlers into Tanganyika. On the other hand, the British settlers to the north used the leverage that their government's need of them during the war provided to establish their claims to elected representation on the legislative council and to seats on the governor's executive. Their advance to power was symbolized by the change in name of the territory in 1920 from the East Africa Protectorate to Kenya Colony.

Two subsequent occurrences were of major importance. First, in 1921 the collapse of the world primary produce market ruined the Uganda planters. (African peasant production, however, survived and with the addition of coffee to the existing cotton crop thenceforth provided the unrivalled base for the Uganda economy.) Secondly, an attempt by the Kenya settlers in the early 1920s to secure complete control of their country's internal affairs was sharply rebuffed. Essentially because they became embroiled in a dispute about the political rights of the Asian population in Kenya—the result of a larger migration paralleling theirs—they faced the opposition both of the British government of India and of various philanthropic bodies in Great Britain. Thanks to missionary intervention, the Devonshire White Paper of 1923, which sought to resolve the dispute, declared that African interests would thenceforth be paramount in Kenya. Although this turned out to be little more than a verbal smoke screen, the White Paper also stated, "His Majesty's Government cannot but regard the grant of responsible self-government [for the British settlers, that is] as out of the question within any period of time which need now be taken into consideration," and it said as well, "It will be necessary to see how matters develop, especially in regard to African representation." These statements were in fact adhered to for 40 years. But they did not stop the settlers from having a preponderant influence over the government of Kenya, an influence they regularly employed to secure for themselves important economic advantages, for example, in the construction of railway sidelines. Even in Uganda, moreover, European and Asian monopolies managed to control the processing and marketing, if not the actual production, of the country's cash crops (very largely thanks to the Uganda government's passion for tidiness), while in Tanganyika the small body of British settlers enjoyed a position after 1921 that those in Uganda had previously possessed.

Through a series of commissions—Ormsby-Gore (1924), Hilton Young (1927), Wilson (1929), and finally a Joint Select Committee of both houses of the British Parliament in 1930–31—the prevailing uncertainty was aggravated by a concerted attempt of the British government to create an East African federation. Although the Kenya settlers were doubtful of its effects, Africans and Europeans in both Tanganyika and Uganda alike were certain that it would lead to settler rule from Nairobi and steadily opposed it—none more so than the Kabaka of Buganda and the governor of Tanganyika, Donald Cameron. Thanks to the help of a liberal lobby in Great Britain, the proposal to federate was eventually shelved. But in 1935 the ambiguity in eastern Africa was then sharpened once again when the Fascist armies of Italy attacked the African kingdom of Ethiopia, and Italian activity in Somaliland was simultaneously increased.

THE COLONIAL ECONOMIES

20th-century economic needs

At the beginning of the 20th century the economies of East Africa were at once simple and poor, needing as a first step to improvement the creation of a cash economy. The next necessary step was to link the cash economy with the world market, since only in this way could any economic return provoke economic production beyond the existing subsistence, handicraft, and hunting stage. Real disadvantages were inherent in dependence on an outside market. In 1929, for example, sisal dropped from £40 a ton to £12, while in 1930 coffee dropped from £120 a ton to £70. Enormous advantages, nevertheless, flowed from the higher prices that were paid during the 1920s and during the great boom of the 1940s and early 1950s. The aliens, into whose hands the levers of economic power had fallen, brought to East Africa, moreover, new and essential economic skills. The Asians, particularly, took risks in expanding retail trade into the remotest parts of East Africa and were often vital to its growing economic networks.

Viable exports were the key to any kind of development. Moreover, their growth was central to the expansion of government revenues, without which improved provision for health, education, and transport would have been impossible. In Zanzibar cloves were the single most important source of weath and revenue; in Uganda cotton made up from 55 to 85 percent of the country's exports between the 1910s and the 1950s, by which time coffee was beginning to play a large part. Total export earnings in Uganda rose from £1,500,000 in 1921 to £47,400,000 in 1951, while government revenues over the same period climbed from £800,000 to £22,300,000. Though Tanganyika did not share in the prosperity of the 1920s and was badly hit by the 1930s slump, its total exports rose from £1,100,000 in 1921 to £40,500,000 by 1951. During that time, however, government revenues increased from £900,000 to only £11,900,000. Kenya's position, meanwhile, was different yet again. Though exports of £1,800,000 in 1921 grew to only £24,100,000 in 1951, government revenue climbed from £1,300,000 to £23,400,000 over the same period. Kenya's sizable deficits on external trade were partly offset by invisible earnings accruing from Nairobi's position as East Africa's main commercial and industrial centre and by Kenya's surplus on interterritorial trade. In Italian Somaliland the budget rose from a mere 2,500,000 lire in 1908 until it averaged 74,000,000 lire in the early 1930s. Local revenue, however, never approached expenditure and, indeed, produced considerably less than half the colony's budget. Exports, mainly of cotton, bananas, hides, and skins, gradually increased, but the adverse balance of trade was always marked; it reached a peak of 131,000,000 lire in 1929 and was still 29,000,000 lire in 1934. The position was just as bad in British Somaliland, to the north. There in the late 1930s imports were twice the value of exports, while as late as 1937 the colony's budget was still only £213,139.

The mineral finds in East Africa were in no way comparable to those of West, Central, and South Africa. There was a short-lived gold rush to Kakamega, in Kenya, in the 1930s and a spectacular find of diamonds near Shinyanga in the early 1940s, which in due course contributed significantly to the Tanganyikan budget; and in the 1950s copper began to be mined at Kilembe, in western Uganda.

Improvements in transportation

Railways were extended between the wars. The Uganda railway, hitherto running only through Kenya, reached Kampala, the main commercial centre of Uganda, in 1931 (it was not taken on into western Uganda until the 1950s). The central Tanganyikan line was meanwhile extended to Mwanza, at the south end of Lake Victoria, following a controversial British government decision of 1924. The advent of motor trucks, more especially after 1920, was no less revolutionary in its effect in the rural areas, though the building of a network of macadam roads in Kenya, Uganda, and Tanganyika had really to wait until the 1950s. Few novelties were more important than the bicycle. This was usually the first item an African would buy with any surplus cash he had.

Subsistence was, of course, the major concern of most Africans throughout this period, as it was of their colonial administrators. Concerned, as they were, by the threat of famine, they often insisted that particular "famine" crops should be grown. Large government food stores were built; and, later, soil erosion caused much concern. Throughout, the departments of agriculture of the colonial administrations were of prime importance in guiding the production of existing crops and developing new ones. Their research stations wrestled with crop diseases and produced new crop strains; and, especially after 1930, the scientific capability (if not yet the economic knowledge) of the colonial agricultural services reached a very high standard.

In Kenya's Nyanza Province cotton production was tried, but without success. Nor did it ever make quite the headway in Tanganyika's West Lake Province that it did in Uganda, to the north. African coffee cooperatives flourished on Mounts Kilimanjaro and Elgon; but African coffee production in the Mt. Kenya region was held back by settler opposition. Sugar production began in Uganda in 1924 and under Indian management successfully supplied the local market. The discovery in 1935 that the pyrethrum daisy yielded the most potent insecticide yet known stimulated its growth in the Kenyan highlands. Rubber was tried but never brought much return, nor did flax. A groundnut (peanut) scheme in Tanganyika that the British government sponsored in the years after World War II was a spectacular failure.

Because coffee played such a large part in European production, the settlers in East Africa had the particular distinction of being at one and the same time substantial capitalist employers of labour and resident farmers. Yet because Africans almost always possessed their own means of production, they never quite became a proletariat similar to the working classes of Europe. But in the decades immediately preceding World War II, most African societies, once they had made the initial adaptation to a money economy—to which they were impelled by the imposition of taxation and simultaneously attracted by a variety of new needs—were making very little progress. Although there were some signs—for example, in Kikuyu country—of an increase in economic activity, it was not until the 1940s and 1950s that a new economic momentum gathered force.

OPENING A BREACH: SOMALIA

World War II served to mark the beginning of the end of European rule and European predominance in East Africa in two respects. First, relations between the colonial rulers and a new African elitist generation worsened. In Kenya, for example, leaders of several local proto-nationalist political associations were imprisoned in 1940, while in Uganda the government's stringent handling of the wartime economy alienated many educated Africans. Second, the defeat by the British and their allies of the Italians in the horn of Africa and the restoration of Emperor Haile Selassie to Ethiopia in 1941 raised the question of the future of Somaliland. In the event, Somalia became an Italian trust territory in 1950—on the important condition that it should become independent in ten years.

Preparations for independence

This unusual requirement was faithfully carried out. Under its pressure the Italian administration set about preplanning the transfer of power. It opened a School of Politics and Administration at Mogadishu in 1950; in 1952 it instituted an imaginative five-year educational development plan; and by 1956 all districts and provinces were under the direct charge of Somali administrative officers. Municipal elections had already been held, and district councils were set up. A Somali Youth Club, formed in 1943, had by 1947 become the 25,000-strong Somali Youth League. Standing for election to the Legislative Assembly of (Italian) Somalia in 1956, at which time the assembly was granted full powers over the internal affairs of its country, it won 43 of the 60 open seats, and its candidate, Abdillahi Ise, became Somalia's first prime minister. Despite much political dispute in the years that followed, Abdillahi's government survived to take Somalia into independence on July 1, 1960.

These developments exercised very little influence over events in British Somaliland in the north, where British control had been restored after the short-lived Italian conquest in 1940. But eventually elections to the territory's legislative council were held in February 1960, and, as the victorious Somali National League declared its intention of joining hands with Somalia forthwith, the British granted independence to their territory three days before the Italians did to theirs.

THE CRISES OF THE 1950S

So shortsighted a policy was, however, only part of a general British reluctance to prepare for independence in East Africa. After World War II, in lieu of an East African federation, the British created the East African High Commission to oversee various intraterritorial services as well as the common market that had grown up between the three main territories. The still-persisting uncertainty in the evolving political order was then embodied in the doctrine of "partnership" between Africans, Europeans, and Asians in East Africa, which at the instance of the British government found numerical formulas for their representation in the legislative and executive bodies of its territories. Objections to these formulas from the European minorities were soon overtaken by the objections of Africans, who saw in the contradictory relationship of representation to population ratios a device whereby the preponderant influence of the European community over government could be continued.

By the late 1940s many Africans in Kenya, and more particularly the Kikuyu, had become profoundly alarmed about their future political prospects. Long aggrieved by the loss of some of their lands to settlers in the first decades of the century, they remembered the armed repression of a political gathering in Nairobi and the exile in 1922 of its leader, Harry Thuku, and recalled the subsequent suppression of various other such associations. When in 1944 the Kenya African Union (of which Jomo Kenyatta became president in 1946) was formed, it was soon made clear too that the possibility of their having any share in the government of their country was for the time being almost endlessly remote.

The Kikuyu revolt

By 1950 the Kikuyu were heading for revolt, and oaths were being pledged to the movement known as Mau Mau. Outbreaks of violence in 1952 caused the new governor, Evelyn Baring, to declare an emergency and to request that British troops be flown in. In some respects the violence that occurred took the form of a civil war between the "haves" and the "have nots" among the Kikuyu themselves. Most of the fighting took place in Kenya's forests, and it was not until 1959 that the emergency was lifted. Although some Africans had by then been allowed to vote for their own legislative representatives, the old regime held on against increasing strains. Some Europeans were beginning to think of compromising with the Afri-

can politicians, while others merely hardened in their attitudes amid them. New conflicts were at the same time racking the African elitist groups, and the older chiefs no longer seemed to be effective political intermediaries. From 1954 onward the Swynnerton Plan committed Kenya's Department of Agriculture to a more determined development of African agriculture and began to give new shape to the Kenyan economy.

In neighbouring Uganda the 1950s opened with government declarations in support of the dubiously formulated partnership doctrine, and in 1953 a sudden fear that an East African federation was once again being contemplated touched off a major crisis in the central kingdom of Buganda that led to the deportation by the British of its *kabaka*, Mutesa II. In an effort to settle the ensuing furore, the British reverted to their earlier declarations that Uganda was "primarily an African country"—and in a crucial step for the whole of East Africa broke through, in the Namirembe Agreement of 1955, the existing formula for a "balanced" racial representation in its legislative and executive councils and gave to Africans a handsome majority.

The focus then shifted to Tanganyika, which had become the chief testing ground for the partnership doctrine. There, under the leadership of Julius Nyerere, the Tanganyika African Association (originally set up in 1929) was transformed in 1954 into the Tanganyika African National Union (TANU). Carried along on a wave of discontent at increased European control of agricultural development (much of which may have been well intentioned) and helped by the absence of sharp tribal rivalries, it contested and won the multiracial elections of 1958, thus opening the way to African majority rule.

THE APPROACH OF INDEPENDENCE

Although Tanganyika was the least well endowed economically and educationally of the four British East African territories, its nationalist movement was organizationally united to a degree that was unique in East Africa, and it was the first to win independence, in 1961.

Economically, Uganda had prospered during the mid-1950s largely because of a coffee boom. As a result, educational and economic progress was marked—the Owen Falls hydroelectric dam was opened, for example, in 1954. But Uganda's nationalist movement was never united, largely because, as early as 1954, it had become clear that independence was approaching before too long, so that the main issue was not how to attain independence but how power should be distributed upon its attainment. Accordingly, during the 1950s neither the Uganda National Congress (founded in 1952) nor the (largely Protestant) Progressive Party (1955) nor the (Roman Catholic) Democratic Party (1956) nor the (breakaway) United Congress party made much headway. The main split was between the Baganda and the other peoples of Uganda (who in combination formed a majority). By 1960 the Baganda were represented by Kabaka Yekka (KY; The King Only) party, while the latter was represented by the Uganda People's Congress (UPC), led by Milton Obote. A surprising victory by the Democratic Party on a minority vote in 1961, and its formation of the first African government of Uganda, only precipitated a political deal between KY and the UPC, which, following another election in April 1962, led to their coalition in a new government under Milton Obote. Uganda achieved independence under this government on October 9, 1962.

Proliferation of parties in Uganda

Zanzibar meanwhile was somewhat similarly confused, first by rivalry between the (essentially African) Afro-Shirazi Party and the (largely Arab-led) Zanzibar National Party (ZNP) and then by the emergence of the Zanzibar and Pemba People's Party (ZPPP) and of the Ummah Party. Elections took place in July 1957 and in January and again in June 1961. After these last elections a ZPPP–ZNP coalition government was formed. Though the two parties had won only a minority of the votes, they remained in office despite another equally unsatisfactory election in July 1963 and took the country to independence on December 10, 1963.

Kenya, meanwhile, though benefitting from the highly successful handling of the economy during Baring's governorship, was first stopped by its colonial government in the aftermath of Mau Mau from having country-wide political parties and then saw two established in 1960 —the Kenya African National Union (KANU) and the Kenya African Democratic Union (KADU). The former represented mainly the Kikuyu and the Luo, the latter most of the smaller tribes. KADU formed a government with non-African support following the general elections of 1961, then formed a KADU–KANU coalition in 1962. KADU was decisively defeated by KANU (with Kenyatta at its head) in the elections of May 1963. Independence for Kenya followed on December 12, 1963.

IV. Independence and after

THE BEGINNINGS

Demography and language

As independence approached, there were just over 25,000,000 people in the four former British territories of East Africa and 2,500,000 in the newly constituted Somali Republic. Tanganyika, with almost 364,000 square miles (942,000 square kilometres), had 8,700,000 inhabitants (most of them clustered in the south and southwest); Uganda, with 91,000 square miles (236,000 square kilometres), had 7,000,000; Kenya, with 225,000 square miles (583,000 square kilometres), had 9,000,000 (clustered in the south and southwest); and the islands of Zanzibar and Pemba combined had a mere 300,000. Only 2 percent of the total population was non-African; there were about 100,000 Europeans and about 330,000 Asians. English was the official language in East Africa, Italian of the Somali Republic. Tanganyika, however, steadily pressing for Swahili to be given pride of place, had 70 percent of its newspaper circulation in that language (as compared to about 40 percent in Kenya). Half of Uganda's daily newspaper circulation continued to be in English, though at the core of the country there was a large newspaper circulation in Luganda as well. The gross domestic product for the four territories was estimated to be £557,000,000 in 1961, of which £302,000,000—£155,000,000 of it of a non-monetary kind—came from a variety of primary industries. This provided a very low per capita income, which varied from £20 a year in Tanganyika to £31 in Kenya (1961 figures). Only just over 4 percent of the African population was in salaried employment, and, although 50 percent were under 16, of these only 2,000,000 were having any kind of education. Makerere College in Uganda, founded in 1921, had become a university college by 1949 and by 1963 had produced 20 of the 49 cabinet ministers in the three larger East African countries, but Nairobi's Royal Technical College did not become a university college until 1958, and the University College of Dar es Salaam was not founded until 1962. At independence, therefore, though the East African elite was markedly smaller than that of West Africa at a comparable time, it was significantly larger than that of either the Congo or the Central African countries.

THE SOMALI REPUBLIC

At independence in 1960, though the politics of the Somali Republic was still conditioned by tribal allegiances, its first major problems arose from the last-minute marriage between the former Italian trust territory and the former British protectorate. Urgent improvements in communications between the two areas were necessary, as were a number of readjustments in their legal and judicial systems. Administrative and bureaucratic structures had to be realigned and delicate political arrangements made. The first independent government was formed by a coalition of the Somali Youth League (SYL) and the northern-based Somali National League (SNL). Abdi Rashid Shermarke (from the south) became the prime minister; Mohammed Ibrahim Egal, who had briefly been prime minister of British Somaliland, became minister of education; while in July 1961 Aden Abdullah Osman (a long-standing SYL figure) was confirmed as first president of the republic. Even so, discontent fermented in the north, expressing itself in December 1961 in an abortive coup d'etat by British-trained

officers. Potentially more serious was the resignation in September 1962 of Egal. But he then participated in forming the Somali National Congress, and thereafter in all the more prominent alignments, effective cross-linkages between the politicians of the two former territories were formed, and it soon became clear that the merger had been successfully accomplished.

In the first postindependence elections, on March 30, 1964, the SYL captured 69 of the national assembly's 123 seats and increased its strength to 90 thereafter. When, at the instance of Osman, Shermarke was replaced as prime minister by his former close associate Abdirizak Haji Hussein, a six months' political crisis ensued, which was concluded only with the enlargement of the Cabinet that Abdirizak had originally put together.

Somali realignment

For the Somali Republic the crisis came at a peculiarly inopportune moment. Late in July 1964 at a meeting in Cairo the member states of the Organization of African Unity (OAU) passed a resolution, in the face of open Somali opposition, whereby they pledged to respect the frontiers existing on the achievement of independence. Ever since the two Somali territories had been linked together at independence, the new republic's prime concern had been to secure the accession to it of French Somaliland and of the adjacent areas of Ethiopia and Kenya in which compact Somali populations lived. In 1962, moreover, the British government had undertaken to decide the future of the Somali areas of Kenya before internal self-government was established there, and in October 1962 it had even appointed a commission to ascertain public opinion in the area. Though an overwhelming Somali majority favoured union with the Somali Republic, the British, anxious to retain the goodwill of the African government of Kenya, which was opposed to the transfer, refused to authorize the decision. Accordingly, the Somali Republic broke off relations with the British in March 1963, and by the end of the year it had turned to the People's Republic of China for £7,000,000 of aid and to the Soviet Union for £11,000,000 of military assistance. Guerrilla operations in Kenya's northern frontier district soon followed.

The conflict with Ethiopia, meanwhile, was even more serious. The mobile Somali population in northeastern Ethiopia had long been at odds with the Ethiopian government, and at the end of 1963 the Somali Ogaden tribe came out in open revolt against it. Fighting also broke out between Somali and Ethiopian regular soldiers and was ended only when OAU intervention and Sudanese mediation secured the Khartoum Agreement of March 30, 1964. Local conflict was nevertheless endemic, periodically giving rise to such episodes as that at Webi Shebeli in which three Frenchmen were killed in February 1968. The situation was aggravated by the support that the Russians gave the Somalis and the U.S. to the Ethiopians. Despite animosity over French Somaliland (now the French Territory of Afars and Issas) half of whose population was Somali, 60 percent voted for the maintenance of French rule on March 19, 1967.

In June 1967 Shermarke defeated Osman for the presidency and in July nominated Egal as prime minister. This change of government soon led to a change in the "Greater Somali" policy, which had so far proved to be ineffectual. Violence was now eschewed, and the right of Somalis everywhere to self-determination was stressed. At an OAU meeting in the former Belgian Congo (now Zaire) in September 1967 Egal laid the basis for a friendly meeting in Addis Ababa with the Ethiopians later in the month. On October 28, 1967, following some mediation by the president of Zambia, Kenneth Kaunda, Egal and President Kenyatta of Kenya signed the Arusha Understanding. Ambassadors were exchanged (and a British ambassador returned to Mogadishu). In July 1968 Shirmarke and Egal were received in state in Nairobi, and the state of emergency in northeastern Kenya was ended. In September 1968 Egal was welcomed in Paris by the French president Charles de Gaulle, and further meetings in 1967 and 1968 took place between Egal and Haile Selassie, the emperor of Ethiopia. Clashes on the ground continued, however, and despite Egal's success in the national assembly there were always those who openly questioned his policies.

But under his leadership, the SYL won 73 of the 121 seats at the general elections of March 26, 1969, and in the aftermath Egal secured almost unanimous support for his government. There were now, however, strong feelings that malpractices during the election had been excessive, and the triumvirate that ruled the country—Shermarke, Egal, and the minister of the interior, Yasin Nur—was obviously becoming very unpopular. Shermarke was assassinated in October 1969 (apparently as a result of a family quarrel), and the denouement came one week later, on October 21, when the army led by Maj. Gen. Mohammed Siyad staged a coup d'etat. A 25-strong Revolutionary Council of officers and Cabinet of young civilians, which were in consequence set up, reorganized district administration, expelled the U.S. Peace Corps, and increasingly sought Soviet support. Egal's initiatives toward a Greater Somalia were shelved.

Economic difficulties

One major reason for the military takeover was a strong feeling that there was all too little to show for the $200,000,000 of foreign aid that had been received since independence. There had been a five-year development plan in 1963–68 and a short-term plan for 1968–70. Though a deep-sea port had been constructed at Berbera with Russian money and deep-sea berths at Kismayu with American money, there had been failures in wheat, cotton, and oilseeds developments. Foreign disbursements in aid of revenue were still required, and the only considerable exports were sheep, goats, and bananas. Nor did the export of these commodities proceed according to plan. Though a Livestock Development Agency had been established in 1966 and a meat-processing plant had been built at Kismayu, the sheep and goat trade, which was largely in private hands and most of whose produce went through Berbera to Arabia and the Persian Gulf, was threatened by the consequences of overgrazing and erosion in the herding areas. Moreover, the Banana Marketing Board was experiencing increased difficulty with its sales of bananas to Italy, for, after the closure of the Suez Canal in 1967, stocks had to be conveyed via the Cape and tended to spoil. From an early stage the republic had been an associate member of the European Economic Community (EEC) and there were protracted negotiations over the possibility that it might join the East African Community, but by 1972 no such link had been effected.

ECONOMIC COOPERATION

Close links, especially economic ones, among the former British territories in East Africa were maintained after independence. In 1961 a commission, led by Sir Jeremy Raisman, had produced an acceptable formula for a more equitable fiscal redistribution among the three mainland territories: the East African High Commission was re-formed to become the East African Common Services Organisation (EACSO), and the pre-existing common currency, common market, and customs union that they shared (with some participation by Zanzibar) was maintained. It seemed for a time, indeed, as if the links among the three territories would be considerably reinforced by the growing association among their African leaders. This had been inaugurated in the Pan-African Freedom Movement for East and Central Africa, which first met at Mwanza in Tanganyika in 1958, and had before very long provoked Julius Nyerere (of Tanzania) and Tom Mboya (of Kenya) to talk of that formerly forbidden possibility—an East African federation. The climax came when, following a euphoric OAU meeting in Addis Ababa in 1963, Kenyatta, Obote, and Nyerere issued, on June 5, 1963, a declaration of intent to create an East African federation before the end of the year. Since no proper investigation of its implications had, however, been made, the project soon collapsed. Links among the countries were further strained as Tanzania (as it became in 1964) worried increasingly about their economic advantage to Kenya, and had it not been for the signing of the Kampala Agreement of 1964, which was modified at Mbale in 1965 and which complemented Raisman's fis-

cal equalization by an arrangement to equalize the distribution of industry, the common market could very well have collapsed.

The agreement, however, was never put into operation, since Kenya refused to ratify it. In 1965 each country decided to establish its own central bank and its own currency; and when, in 1966, Kenya's share of interterritorial exports climbed to an unprecedented two-thirds, Tanzania announced that it would place severe restrictions upon its imports from there. The three governments agreed, however, to establish a ministerial commission, under an independent Danish economist, Kjeld Philip, and after considerable negotiation signed in Kampala on June 6, 1967, a new Treaty of East African Cooperation, by which, on December 1, 1967, they replaced EACSO with the East African Community. Unlike its predecessors, its headquarters were to be in Arusha, Tanzania, rather than in Nairobi, while the headquarters of the various common services were to be decentralized. An East African Development Bank was set up, and, in an effort to check imbalances in interterritorial trade, arrangements for a transfer tax were instituted. The customs union and the common market accordingly survived. Considerable strains were nevertheless imposed upon it in 1971 both by the refusal of Nyerere to recognize the military regime that came to power in Uganda and by the differential responses to the world monetary crisis that followed upon the collapse of the Bretton Woods system in the West.

Though there was much talk of Somalia, Rwanda, and Burundi joining the community and of Zambia becoming an associate member, the community was still, despite protracted negotiations, confined to its original three partners. There had been an important event in 1963, when the Kenya, Uganda, and northern Tanganyikan railway system had eventually been linked to the central Tanganyikan line. Following Rhodesia's unilateral declaration of independence in 1965, a pipeline, moreover, was built between Tanzania and Zambia, and after lengthy negotiations major assistance was procured from the Chinese government for a "Tanzam" railway. Much could be said for establishing closer connections between the East African Community and its like-minded neighbours. The difficulty was to see how newcomers could be associated with a system that, uniquely for Africa, had been in operation for over half a century.

Tentative economic moves toward the West

During these years the East African governments had also to decide their relationship with the EEC. Originally in 1962 they had decided that they would not apply for associate membership of the kind possessed by the West African countries. Since association with the EEC did nevertheless promise obvious advantages, negotiations were set in motion; but they broke down, both in March 1965 and more particularly in November 1966, over the EEC's insistence upon reciprocal rights. Following East African concessions, however, an agreement of association was eventually signed at Arusha on July 26, 1968, whereby East African goods were to be admitted duty free into Europe in exchange for 59 types of European goods being admitted duty free into East Africa.

THE ZANZIBAR REVOLUTION AND THE TANGANYIKA MUTINY

Upon these and related matters the political leaders of East Africa regularly conferred. Interests such as these were always, however, secondary to their main preoccupations, which were primarily concerned with their countries' internal affairs.

Within two months of Tanganyika's independence, Nyerere had dramatically resigned its prime ministership (to which Rashidi Kawawa, the vice president of TANU, temporarily succeeded) so that he might weld his party more firmly to his support. In November 1962, following the declaration of a republic, he was elected to the presidency by 97 percent of the votes cast. But these were only the first steps of a program designed to consolidate the fragile authority of government at the national level. Subsequently, the first legislative acts of the new republican government turned leading TANU officials into area and regional commissioners. (As such, they succeeded to the positions formerly held by colonial district and provincial commissioners.) In 1963 the chiefs were abolished, with the most acceptable among them becoming executive officers to local councils. In view of Tanganyika's shortage of manpower, its considerable size, and the fluctuations that had previously beset its political structures, these were viewed as shrewd measures.

Despite such precautions, Tanganyika was rocked, before long, by two important occurrences. First, on January 12, 1964, the racial and political crisis in Zanzibar erupted into violent revolution, precipitated, it seems, by the attempt of the ZNP government to purge the Zanzibar police of those whom it believed untrustworthy. The outbreak led to countless killings—particularly of Arabs. Those of any prominence who survived were swiftly imprisoned for indefinite periods. Though the Sultan, who had only just succeeded his father—himself only very recently the successor to Sultan Khalifa—escaped to England, his palace on the waterfront at Zanzibar now became the Peoples' Palace. A Revolutionary Council was set up, and in a highly symbolic gesture the entrée into the previously highly exclusive Arab club was thrown open, and the land—so much of it formerly owned by the Arab ruling class—was nationalized. In this way the African and local Afro-Shirazi majority vigorously overthrew the supremacy of the long-established Arab regime.

Zanzibar revolutionaries

At the outset, the exotic figure of so-called Field Marshal John Okello (a wanderer from Uganda) dominated the scene, but it was not long before he was brushed aside by two more permanent figures. One was the dockworker leader of the Afro-Shirazi Party, Abeid Karume; the other was the colourful figure of Mohammed Babu, leader of the Ummah Party, an Arab by birth and a Communist and revolutionary by conviction. Between them they quickly made Westerners unwelcome in Zanzibar and secured support both from the East Germans and from the Chinese for the development of the islands. A people's republic was inaugurated, and Zanzibar appeared to have become a Communist outpost.

The initial eruption was portentous for Nyerere. He had, as it happened, long-standing connections with Karume, whom he had encouraged and supported since the mid-1950s; and very soon after the outbreak Tanganyikan police were welcomed by the revolutionary regime in the island. Their return a few days later coincided, however, with a second event that unhinged the government of Tanganyika in January 1964.

On January 19, 1964, aroused no doubt by the Zanzibari example, a mutiny occurred at the Colito barracks, outside Dar es Salaam. Led by Hingo Ilogi, the mutineers locked their British and African officers in the guardroom, seized a number of government buildings, and rampaged through the town. Sympathetic outbreaks occurred at two other military stations upcountry. Nyerere went into hiding, and the Tanganyikan government came to a halt. The minister of defense, Oscar Kambona, managed, however, to make contact with the mutineers, and two days later the President emerged from hiding but was then put to the humiliating experience of seeking British help. On January 25 a Royal Marine Commando force was landed, and the mutineers were speedily rounded up. The position of the existing government was therefore fairly readily restored.

Nyerere next turned his attention to the new regime in Zanzibar, boldly effecting an agreement with its Revolutionary Council in April 1964 whereby the new United Republic of Tanganyika and Zanzibar (later renamed Tanzania) was set up. He remained president of the new republic, Karume first vice president, and Kawawa second vice president. Several Zanzibari leaders were appointed to the union Cabinet, and their Revolutionary Council was empowered to appoint 36 out of a total of 189 members of the national assembly upon the mainland. Although control over Zanzibar itself remained in the Revolutionary Council's hands, Tanganyika felt that it nevertheless possessed some check upon the potential dangers that its offshore revolutionary island presented.

Internally, Zanzibar went very much its own way. By 1970 it had received $12,000,000 of Chinese aid, had

welcomed a 400-strong Chinese mission, and had had its 3,000-man army trained by them. But, though Karume called the Chinese his best friends, he did not allow them to dominate him. He permitted 120 East Germans on the island and accepted a United States donation of over $1,000,000 for a technical school. Despite staff shortages, 80 percent of the children were receiving free primary education. Karume himself took an interest in a housing program. There were important developments in the improvement of water supplies, and as a consequence of the land distribution each cultivator was entitled to a three-acre plot. Since the hiring of labour was prohibited, there were problems at the picking seasons; but in 1969 the value of clove production rose to TShs. 80,000,000 (from TShs. 40,000,000 in 1968).

The problems on Pemba

Even so, there was much discontent on Pemba, the northern of the two islands. People's courts were set up, and in 1967 an alleged plot against the regime led to some key Zanzibaris being handed over to the Revolutionary Council by the mainland authorities and to the summary execution of four of them. In 1970 there were also stories of the forced marriages of young Arab and Persian girls to the Zanzibari leaders. Such occurrences were an embarrassment to Nyerere. They gave grounds to his detractors' attacks and, for all its unusual completeness, placed the Zanzibari revolution low on the list of models to which the world's revolutionaries now looked.

Then in April 1972 Karume was assassinated. Abeid Jumbe, however, succeeded him, and there were fewer changes in the revolutionary regime than might have been expected.

Both the original revolution and the mutiny were rather more than embarrassing upheavals in Nyerere's orbit: they underlined the tenuousness of political authority in East Africa and the latent vehemence of those who were excluded from the privileges enjoyed by its ruling elites. Nyerere himself had long been an idealist—for example, in his support for interracial harmony at a time when this was far from popular; but he had long been a pragmatist too—as his association with the last British governor, his resignation as prime minister, and his union with Zanzibar had shown. In the heat of the events of 1964 his idealism and his pragmatism fused. Elitism now not only seemed inappropriate to Zanzibar but, on the impoverished mainland, unwarranted and dangerous as well.

UJAMAA IN TANZANIA

In the latter part of 1964, therefore, he arranged that TANU members in groups of ten houses should form cells and that their leaders should be required to act as agents for the superior units of state and party. (There was some conflict with the village development committees that were instituted in 1963, until it was decided that these should be composed of cell leaders.) The presidential commission that was set up in January 1964 recommended that no similar fusion of party and state should take place. Tanzania, however, became a one-party state and at the general elections in September 1965 instituted an ingenious arrangement by which two candidates were chosen by TANU for each of the contested parliamentary seats. Nyerere was once more elected president, but a number of sitting members lost their seats to other TANU candidates, who, it was hoped, would be more careful of their constituents' interests. In 1966 a civil form of compulsory public service was introduced. Protests by university students at being required to serve with others of their generation were firmly rebuffed, and checks upon the pretensions of the Tanzanian elite were initiated.

The Arusha Declaration

The Arusha Declaration of February 1967, which Nyerere drew up, declared that TANU would henceforth establish a democratic Socialist government of the people and would see that the government exercised effective control over the principal means of production and would pursue policies that would facilitate collective ownership of the country's resources. More specifically, it laid down that no civil servant was to own more than the house in which he lived or own shares of stock or have an income from more than one job. The banks were nationalized immediately after, and majority control over a number of foreign concerns was instituted. There were negotiations over compensation—some of them protracted—but banking operations were taken over by the national bank of commerce. Nyerere issued a further pronouncement in July 1967 in which he called for a new attitude within the educational system that would be more appropriate to the self-help and egalitarianism that were the order of the day. He confirmed his interest in Ujamaa (Familyhood) Socialism, as he called it, by increasing the development of *ujamaa* villages and by encouraging the national development corporation that had been set up in 1965 to initiate large-scale Socialist production. Perhaps the key statement of Nyerere's policy appeared in a pamphlet on Socialism and Rural Development in which he proposed that the people of Tanzania should move from being a nation of individual peasant producers to a nation of *ujamaa* villagers where the people would cooperate directly in small groups that would cooperate together for joint enterprises. By 1969 it was reckoned that 10 percent of the population were to be found in *ujamaa* villages. In a presidential circular of March 20, 1969, government officials were instructed to encourage the "growth of cooperative production, cooperative marketing and distribution and communal rather than private expenditure patterns," to emphasize the "advantage of living together and working for the good of all," and to discourage "the continuance of private individual farming"; and in presenting the second five-year development plan (which was to run on from 1969) Nyerere announced that not only was there to be still more emphasis upon rural development but also that *ujamaa* villages were to be established throughout the country.

The first five-year plan

The first five-year plan (1964–69) had shown some success. In 1964, 15 percent of the wealth produced in the country was being reinvested; by 1967 the figure was 23 percent. Of the total investment, moreover, 70 percent had been from within the country—and teacher enrollments had nearly quadrupled. But industry still accounted for only 7 percent of the gross domestic product —less than had been hoped. Sisal prices, on which a great deal had depended, dropped catastrophically after 1965; and the census showed that the population was growing at a much faster rate than had hitherto been thought. Nyerere himself estimated that there were proportionately fewer children going to primary school than in the past—fewer, indeed, than 50 percent. In these circumstances he called for hardheaded decisions to be made and, while facing the fact that primary education for all could not be attained before 1989, insisted that for the good of the nation it would be best during the period of the second plan to give one child seven years' education rather than two of them four.

Though Nyerere carried most of his countrymen with him, he lost the support of Oscar Kambona (the former minister of defense and secretary general of TANU), who fled the country in 1967. In 1968 he clashed with the national assembly, from which he expelled six members. A year later a conspiracy against him was uncovered, and in February 1970 those concerned were sentenced to long prison terms. Nevertheless, at the ensuing general elections on October 30, 1970, Nyerere was re-elected with 95 percent of the votes in a 72.3 percent pool, while more members of parliament held their seats under the new electoral arrangements than in 1965. In 1971 the new assembly provided for the compulsory acquisition of all rented buildings worth over TShs. 100,000.

Between 1965 and 1970 Nyerere had been his own foreign minister. He had retained Tanzania's membership in the Commonwealth but after 1964 had sought to adopt a middle, nonaligned position in international affairs and in particular had exchanged visits with leaders of the Chinese People's Republic. Though between December 1965 and July 1968 he broke off diplomatic relations with Britain because of his hostility toward Britain's Rhodesian policy, with equal impartiality he vehemently denounced the Russian invasion of Czechoslovakia in 1968. Within the OAU, Tanzania played a leading part in the campaign against the white-dominated countries to the south. Dar es Salaam became a base for various exiled

leaders of the South African National Congress, the Zimbabwe African National Union, the South West Africa People's Organisation, and the National Liberation Front for Mozambique (FRELIMO). At the same time, Tanzania provided a refuge for exiles from Malawi, and, despite some official meetings in 1969, differences with Hastings Banda, president of Malawi, remained considerable. There were differences, too, with Nigeria when, on April 13, 1968, Tanzania accorded recognition to the breakaway state of Biafra. There were also differences with Uganda when, in 1971, after a military revolution against Milton Obote, Nyerere at first refused to recognize the succession of Gen. Idi Amin.

POLITICAL UNREST IN UGANDA

Amin's coup brought to an end the nine-year primacy in Uganda of Milton Obote. The political problems Obote had faced were far more serious than any that had confronted Nyerere, and they precluded the effective elaboration of the Socialist doctrine he professed.

Although Uganda was still much underdeveloped, its economic position was better than Tanzania's; in 1966, for example, Uganda's population was estimated at 7,740,000 and Tanzania's at 10,717,000; but Uganda's growth rate was reckoned at 5.6 percent per annum, while Tanzania's was 4.2 percent. The consequences can be seen in the statistics on education: in 1966 Uganda had 633,000 children in primary and junior secondary schools; Tanzania had only 100,000 more.

In 1968, 77 percent of Uganda's exports came from its two long-standing primary products—coffee and cotton. Production of coffee was limited by the world quota system, which in 1967 allocated to Uganda 167,000 tons. Even so, it was now the country's highest foreign-exchange earner. Cotton production was also doing well. In 1966 a new record of 445,000 bales was produced. Tea production was increasing, too. In 1967, 24,000,000 pounds were produced; 30,000,000 pounds in 1968; and 39,000,000 in 1969. Uganda, in fact, now had a higher tea yield per acre than any other country except Japan. Tobacco and sugar production were also going up, and tourism was on the way to being the country's third-largest foreign-exchange earner. Industry was expanding —at twice the rate of the economy as a whole. In 1968 a contract was signed by which Japan undertook to take all Uganda's copper for the next five years.

Economic changes

The economic organization of the coffee and cotton crops had by now set a pattern for the Uganda economy as a whole. Production was in the hands of its peasant producers—some large, some small, many employing labour and, if not owning their own land, having relatively easy access to it. Processing was increasingly in the hands of farmers' cooperatives, while marketing was the responsibility of coffee and lint marketing boards. Sugar production was largely privately owned; while the government controlled the production of tea through the Uganda Tea Growers Corporation; the Produce Marketing Board controlled the sale of such crops as tobacco, maize, beans, groundnuts, sesame (simsim), and chillies; the National Trading Corporation had a monopoly of the distribution of shirts, cement, steel windows, and hoes; and the Import Licensing Board promoted the "Ugandization" of commerce and industry. Perhaps the most efficient institution was the Uganda Electricity Board, responsible for the Owen Falls Dam and for planning a second dam on the Nile.

Politically, it was Buganda and all that Buganda stood for that haunted Obote's era. In 1963 a number of his Kabaka Yekka (KY) associates had published a pamphlet arguing for closer association with his Uganda People's Congress (UPC). In June 1963 nine KY members joined the UPC, and in October Obote confirmed his alliance with the leaders of Buganda by securing the election of Kabaka Mutesa II as first president of Uganda. He was troubled, however, by the possibility that the Buganda members might switch their support to his Democratic Party (DP) opponents. In February 1964 the DP won four out of six seats on the Kampala municipality and all six seats in Jinja. Obote therefore did everything he could to encourage further shifts to his own party and already in January 1964 had begun to talk about a one-party state. Changes of allegiance, both from the KY and the DP, did in fact ensue, until with 60 UPC members as against 15 KY members and 16 DP members in the national assembly Obote took the fateful step on August 24, 1964, of ending his coalition. When on the last day of 1964 the DP leader changed sides, only nine of the original 24 DP members were left. By this time the UPC was in control of all the district councils outside Buganda; and in July 1965 six out of the remaining 14 KY members finally joined the UPC as well.

All this was of first importance because by 1964 conflict with Buganda was acute. There was a long-standing clash over the administration of Buganda's finances and over the size of Uganda's subventions to Buganda. The Kabaka, moreover, was actively sponsoring an attempt to frustrate a referendum in the western counties of Buganda as to whether they should now revert to Bunyoro. Obote held the referendum on November 4; the "lost counties" were returned to Bunyoro; a Buganda government fell from power; and Obote emerged triumphant.

Even so, there were during 1965 several motions of no confidence in the UPC in the district councils. At the end of April 1964 the UPC's secretary general had been replaced, and by 1965 party rivalries ran deep. During 1965 there was also much anxiety over Obote's support to the rebellious groups in the northeastern Congo.

The Kabaka versus Obote

The ensuing climax was reached on February 4, 1966, when, during Obote's absence from Kampala, Daudi Ocheng won Cabinet support for a motion accusing Colonel (later General) Amin—and by extension Obote himself—of peculation in the course of their Congo contacts. Obote ordered a rigorous enquiry, but, following the capture on February 15 of Buganda's UPC by a moderate faction, now emerging as opposed to him personally, at a Cabinet meeting on February 22 he arrested five of his leading colleagues. Immediately after (angered by Kabaka Mutesa's appeal at this time to the British high commissioner for assistance), he declared himself executive president, and on April 15 he extracted the support of the national assembly for a new constitution, which they had not even seen; by this the federal provisions of the constitution agreed at independence were abrogated. The Buganda *lukiko* ("council") thereupon demanded the expulsion of the central government's offices from Buganda by May 30, and Obote in turn arrested the three chiefs who had moved the motion. As soon as this news became public, violence broke out in Buganda, and in response, on May 24, 1966, Obote despatched Amin's forces against the Kabaka's palace. Mutesa escaped to Britain.

Three major consequences ensued. Obote was now heavily dependent for the maintenance of his regime upon the support of the army. He had handled it cautiously when it had joined in the series of mutinies set off in Tanzania in January 1964. From 1963 onward it had had to contend with a violent revolt by the Konjo (Bakonjo) and Amba (Bwamba) peoples of Mt. Ruwenzori against their continued incorporation in Toro. It had been concerned as well with events on the southern frontier, where, following the Rwanda revolution of 1961, more than 100,000 Tutsi refugees had crossed into Uganda. It was also preoccupied with the protracted revolt in the southern Sudan. By the end of 1968 over 150,000 refugees had crossed into Uganda from The Sudan, and various consequential episodes gravely impaired the relations between the two countries. After 1966 Obote had to be particularly solicitous of the army's desires. Before long, over 10 percent of Uganda's budget was devoted to its upkeep—nearly the total of the Kenyan and Tanzanian military budgets together. But he sought also to divert power from the commander in chief and to build up his own "praetorian" guard.

Following the attack on the Kabaka's palace, he not only abolished the centuries-old rulership and its government in Buganda but in 1967 abolished the rulerships in the neighbouring kingdoms also, thus bringing all the local governments that had hitherto fashioned themselves

upon the Buganda model much more directly under his own government's control. Because of the relative autonomy that each of these had during the colonial period, they had been able to act in considerable independence of the central government. In a series of amendments to Uganda's local-administration legislation, Obote's government had already sought to curb their freedom. Now with the destruction of the prototype in Buganda it was able altogether to reduce them to submission.

Having proceeded violently against the Buganda kingdom and then having reduced its replicas in the rest of the country as well, President Obote, as he had now become, had in effect destroyed the major political resource that Uganda had inherited upon its independence. Since he was then essentially a dictator dependent upon the army, he became greatly exercised by the need to recreate his political authority and his political resources. During 1967 he had a third constitution (since independence) extensively discussed, and he then embarked upon a series of "meet the people" tours, during which he repeatedly stated that there was now in Uganda one state, one government, one parliament, and one people. He also declared that he and his ministers had come to meet their masters. This, however, availed him very little—particularly in Buganda. Altering course, he refurbished his populist and Socialist creed, announced a move to the left and a new political culture for Uganda, and published his "Common Man's Charter." At a conference in December 1969 this was endorsed by the UPC, whom Obote urged to uproot ruthlessly such elements of feudalism that might still remain. In May 1970 he proclaimed that the government would assume majority control of a number of commercial enterprises, and in July 1970 he published his *Proposals for New Methods of Election of Representatives of the People to Parliament*, in which he proposed to adopt the Tanzanian scheme of multiple candidates from the governing party but also to add a complex provision that required candidates to obtain votes from four different parts of the country simultaneously. Its purpose, so Obote declared, was to break the hold of Uganda's tribal masters and to insist that the national assembly and its members were national.

During these years Obote was much assisted by the decision of the majority of senior civil servants, many of them Baganda, to stay at their posts. He was further assisted by the death in London on November 21, 1969, of Kabaka Mutesa. Not only, however, was his attempt to secure popular support ineffectual but he also lost three of his closest associates when A.A. Nekyon and Godfrey Binaisa left the Cabinet in May 1967 and Cuthbert Obwangor was dismissed in July. He further alienated support in 1968 when he proceeded against Mayanja and Neogy, a Muganda politician and a journalist. At the UPC conference in December 1969 he was himself the object of an assassination attempt. By the end of the 1960s Uganda was to all appearances a dictatorship; an elaborate spy network existed, and a great many people were afraid to speak freely. Most leading politicians were fearful, moreover, lest in the forthcoming elections they should lose their seats.

The denouement came in January 1971, when, during Obote's absence at a Commonwealth conference in Singapore, a forceful attempt to establish control over the army before the elections were held misfired, and Amin retaliated with a coup d'etat.

Despite a change in leadership, the old problems remained. Though Amin had Mutesa II's body returned to Buganda and there buried in state, he was careful to declare that the kingdoms could not be restored. Though he, too, went on meet-the-people tours and assiduously proclaimed concern for the opinions of the elders, he had the elections postponed; and the local governments found their position further attenuated. In August 1972 Amin ordered expulsion of most of Uganda's Asians, who were the dominant force in the nation's economy.

KENYATTA'S KENYA

Kenya was dominated throughout these years by Jomo Kenyatta. A month after independence, Kenya suffered a military mutiny similar to that of its two neighbours, but, as nothing untoward resulted, the authority of the government was considerably strengthened thereafter. In the first year of independence KADU still stood in opposition to the KANU government but following several changes of allegiance went into voluntary liquidation in November 1964. On August 14, 1964, Kenyatta announced that the regional authorities were to be abolished, and under the terms of a constitutional amendment in November he became president of the new republic rather than prime minister.

To a greater degree than in either Uganda or in Tanzania, parliament in Kenya throughout the ensuing decade provided an open forum for lively national debate, but successive amendments to the constitution continued to increase the authority of the president. Built very deliberately upon the existing edifice of colonial administration, this was chiefly exercised—again in contrast to Uganda and Tanzania—through the bureaucratic hierarchy of provincial and district commissioners (all of them African by 1965). In December 1964 control over the provincial administration was transferred from the Ministry of Home Affairs to the president's office, and as the 1960s wore on the provincial administration became very close not only to the president himself but also to his party.

Though by 1965 Kenya had become in effect a one-party state, considerable intraparty differences were apparent. There were differences in foreign policy over the degree of Kenya's associations with the "East" and with the "West": differences too between Luo and Kikuyu; between the major Luo politicians Oginga Odinga and Tom Mboya; and more particularly between those who argued for the interests of the majority and those who affirmed that they were not going to rob people of property and then claim that they were carrying out the tenets and the requirements of African Socialism. In May 1965 Kenyatta's government, in effect associating itself with the latter, published its Sessional Paper No. 10 on *African Socialism and Its Application to Planning in Kenya*, which explicitly rejected the expropriation of property and the full nationalization of the means of production and argued for a mixed economy tempered by state control so as to procure both a fairer distribution of wealth and increased equality of opportunity. Thereafter, the breach between the two factions became substantial. At a party conference in March 1966 Odinga was ousted as KANU's sole vice president, and in April he resigned from the government. He then assumed the leadership of the newly formed Kenya People's Union (KPU) with 30 other dissenting members. The government responded by introducing a constitutional amendment that required members who changed their party allegiance to resign their seats. There followed the "little general election" of June 1966, in which, though Odinga himself was returned and the KPU won a majority of the votes, only nine KPU members were elected to face the large KANU majority.

Kenyatta's conservative Socialism

The KANU government harassed the KPU remorselessly. It denied the latter permission to hold meeting, had Bildad Kaggia arrested early in 1968, prevented Odinga from going abroad in March 1968, and in August disqualified KPU candidates from the local government elections. Finally, in January 1969, when the Minister of Education banned Odinga from speaking at the University College in Nairobi, the government sent troops against the students who protested.

By this time, however, owing to Kenyatta's advancing years, there were new strains within the government itself, essentially over who should be his successor. Tom Mboya had shown himself to be the government's ablest parliamentarian, and as secretary general of KANU and minister of economic planning and development he was holding key positions. But he was a Luo, and many Kikuyu, flushed by the now-extensive Kikuyu dominance of government, bureaucracy, and African commerce in Kenya, were determined that power should continue to remain in Kikuyu hands. By 1969 there was a new wave of Kikuyu oath taking, and on July 5 Mboya was murdered. Kikuyu confronted Luo at his funeral, and when

Kenyatta visited Luo country in October 1969 open violence erupted. Thereupon he had Odinga and his fellow KPU parliamentarians detained and their party altogether banned.

He next proceeded to hold a general election on January 3, 1970. With only one party allowed to contest it, its conclusion was foregone. Many real contests in the primaries, however, preceded it; almost half the sitting KANU members—including five Cabinet ministers and 14 junior ministers—lost their seats.

He and his regime lived on into the early 1970s. There was a treason trial in 1971 involving some prominent Luo. But in March 1971 Odinga was released from detention, and a few months later he rejoined KANU.

During these latter years there had been a strong move toward the Africanization of commerce in Kenya; and both there and in the neighbouring countries this meant that large numbers of Asians were deprived of their livelihoods. By 1966 Kenya had a population estimated at nearly 10,000,000. Its gross domestic product was now £385,000,000, while in 1968 its gross farm revenue attained a new record of £70,000,000. By that time, 1,209,680 of Kenya's children were in primary school. All of these were levels of achievement well above Tanzania's. Kenya's industries were, moreover, dominant in East Africa. Its primary production included tea, maize, rice, coffee, cotton, sugar, wheat, sisal, pyrethrum, beef, mutton, and dairy produce. Although between 1964 and 1968 sisal production dropped, pyrethrum production went up from 4,300,000 tons to 12,000,000; tea from 20,000,000 tons to 30,000,000; wheat from 128,000,000 to 225,400,000; sugarcane from 591,400,000 to 919,300,000; and maize from 87,000,000 to 351,000,000 tons. Kenya's economic policy was at one, moreover, with its sociopolitical policy. Kenyatta, by contrast with Nyerere and later with Obote, preached the doctrine of personal endeavour, which was embodied in his slogan "*Harambee*" ("Self-help"). Private ownership and private industry were actively encouraged, and it was strongly argued that in view of the gross poverty that existed it was irresponsible not to go out for every possible kind of economic contribution. Such income disparities as resulted, it was argued, could be checked by policies of progressive taxation.

Kenya's "*Harambee*" policy

In East Africa there was as a result a keen debate between the merits of this Kenyan method of development and that of Socialist Tanzania. The outcome of the debate was still unresolved in the early 1970s.

East African Cultures

The cultures described in this article are those of the region of Africa stretching from the upper Nile Basin, through Uganda, Kenya, Tanzania, and parts of central Zambia to southern Mozambique, Rhodesia, Botswana, and South Africa. The cultures of Ethiopia and Somalia are excluded, as are those of the predominantly matrilineal peoples of northern Mozambique and Zambia (see ETHIOPIAN AND SOMALIAN CULTURES).

Peoples and their cultures are nowhere susceptible to precise classification, and this is especially so in this region. A good deal of the information necessary for a full account of the peoples of the area is still unavailable or uncertain. Reliable ethnographic and historical studies are limited, both in geographical and cultural respects, and only a handful of cultures have been adequately described in detail. The conventional classification, which is not entirely agreed on by all anthropologists, is somewhat arbitrarily based on a combination of linguistic and ethnohistorical characteristics; but many of these cut across similarities and differences of an economic, political, or religious kind. In the following brief and simplified account only the more important peoples are mentioned. The contemporary population figures are only approximate indications, since demographic data tend to be unreliable in most of the countries concerned and since in many countries enumeration by ethnic or cultural group is avoided.

THE PEOPLES OF THE AREA

In the north of this region, in the upper Nile Basin, the western Nilotes are separated geographically and linguistically into northerners (Nuer, 300,000; Dinka, 500,000) in The Sudan, and southerners (Luo, 900,000, in western Kenya; Lango, 350,000, Acholi, 275,000, and the Alur, 120,000, in northern Uganda). The eastern Nilotes, often referred to by the hybrid misnomer "Nilo-Hamites," are separable into three clusters: the Beir and Lotuko in the southernmost Sudan (data unavailable); the Teso (375,000), Karamojong (130,000), and Turkana (120,000) in northwestern Kenya and northeastern Uganda; and the Kalenjin (500,000) and Masai (230,000) in west central Kenya and northern Tanzania. The Nilotic languages have been ascribed to the Eastern Sudanic family of African languages.

Languages and population

The languages spoken in the rest of East Africa belong to the Bantu, or the southern branch, of the Niger-Congo family. The northeastern Bantu live in the highlands (Kikuyu, 1,500,000; Meru, 450,000; Chagga, 300,000) and in the lowlands eastward to the Indian Ocean (Kamba, 1,000,000; Mijekenda, 400,000); and people of similar cultures are found in western Kenya (Luhya, 750,000; Gusii, 300,000). Farther west, the interlacustrine (living between lakes) Bantu comprise the peoples of the large kingdoms, whose language, history, and state systems are all closely related (Ganda, 1,000,000; Nyoro, 110,000; Nkole, 425,000; Rwanda, 2,600,000; Rundi, 4,000,000). In northwestern Tanzania are a number of peoples, culturally related in some ways, divided among smaller chiefdoms (Haya, 300,000; Ha, 300,000; Sukuma, 1,000,000; Nyamwezi, 400,000). The other peoples of mainland Tanzania can be roughly categorized as follows: Rift Cluster (Gogo, 300,000; Turu, 200,000; Iramba, 140,000); Matrilineal Eastern Cluster (Luguru,

Approximate distribution of the major cultural groups of East Africa.

200,000; Kaguru, 90,000); Rufiji Cluster (Hehe, 200,000; Bena, 200,000); and Nyasa Cluster (Nyakyusa, 250,000; and the Kinga, 60,000). In Zambia the people of the centre of the country (Tonga, 250,000; and the Ila, 60,000) are identified by their emphasized association with cattle. In Rhodesia, all but the southwestern area was occupied by the Shona peoples, though now they are interspersed with extensive European settlements. The Shona (about 1,000,000) divide into distinctive cultural subgroups: Korekore in the north, Zezuru in the centre, Manyika and Ndau in the east, and Karanga in the south. The Thonga peoples to the east, in southern Mozambique, are linguistically and probably ethnohistorically linked with the Shona. To the south are the numerous Sotho peoples: the Northern Sotho of the Transvaal, the Western or Tswana Sotho of Botswana and northwestern Transvaal (900,000), and the Southern Sotho (Basuto) mainly of Lesotho (1,000,000). The Nguni peoples are divided among the Swazi of Swaziland (410,000), the Zulu of Natal (2,000,000), and the South Nguni (Xosa [Xhosa] and Pondo, 2,400,000), with a 19th-century offshoot, the Ndebele (400,000), in the southern part of Rhodesia.

Cultural significance of cattle

The majority of East African peoples were subsistence farmers. Some combined animal husbandry with agriculture, and a few were primarily pastoralists economically dependent on their herds. This region has, however, been characterized as the East African Cattle Area because of the common and widespread interests—political, legal, mystical, emotional, and aesthetic—culturally associated with cattle. There is some validity in this view. Even those farmers who were dependent on cultivation for their livelihood gave great attention and high value to their cattle, in contrast to African cattle keepers in other parts of the continent. From the Nguni in the south to the Nilotes in the north, cattle had a special cultural emphasis and importance in the people's lives. But the particular kinds of significance and the ideas and values varied a good deal. Possession and use of cattle thus could be political prizes and the means of domination or they could express cooperative egalitarianism; cattle could embody deep mystical qualities or be treated as entirely profane; they could be vehicles of aesthetic expression but not always so. Much depended on the culture and other interests of the cattle keepers. There was also inevitable difference of emphasis between societies in which there were many cattle and those in which cattle were less numerous than human beings. In most cases, too, goats and sheep, though less valuable individually, could be used for almost all of the same purposes as cattle. Finally, cattle were not kept by peoples living in forest areas or in the extensive central areas infested with insect-borne disease.

As regards other cultural features, this area contained a wide variety of institutions, values, means of organization, and beliefs, and this was consistent with the very considerable historical movements and diverse origins of the peoples, as well as with the wide range of environmental conditions from rain forest to desert and coastal plain to high mountain. External influences from the Indian Ocean shores (Arab, Persian, Indian, Indonesian, and latterly European) spread slowly and irregularly and generally indirectly so that for the most part East Africa

remained isolated from the outside world until well into the 19th century. Technology was quite limited, and, despite a few notable exceptions in the major kingdoms, political and economic organization was comparatively simple and embraced small groups of people. The only world religion to affect the area before the mid-19th century was Islām, and it seldom spread beyond the coastal areas, despite many centuries of existence there.

FAMILY AND KINSHIP

Extended families. The isolated nuclear family of a married couple and their unmarried children (typical of Western industrialized cultures) was rare in traditional East African cultures. It occurred fairly regularly only in a few societies with highly individualized ownership of property and among some of the shifting cultivators of the central part of the region. Some kind of compound family homestead or hamlet was more typical. A patriarchal extended family, sometimes within a single fenced enclosure (as among the Swazi) was one form: this comprised an elderly man, with his wife or wives, his married sons and their wives and children, and sometimes younger brothers of the family head. Other forms occurred when brothers, and sometimes paternal cousins, lived together with their wives and children or when an influential man attracted close kinsmen and their wives. Even when something like the nuclear family was more emphasized, the practical and moral requirements of kinship obligations produced households containing a variety of dependents: aged kin, widows and divorcées and their children, and younger siblings and cousins.

Invariably, however, the unit of a woman and her children was the nucleus of family composition and domestic activity. Usually, each wife had her own house, sometimes partly or wholly fenced off, as among the Karamojong, or in some cases, as among the Gogo and Nyakyusa, her own room in a large house. A wife had her own kitchen hearth, where she cooked for her children, and often her own food store or granary. Older children sometimes had separate sleeping houses in the larger domestic groups. Even when a man had but one wife he often had his own separate house or separate room, where he kept his possessions and entertained visitors.

Polygyny

Virtually everywhere polygyny was the accepted ideal, even though only realized by a minority of men in most societies. Apart from male prestige and the benefits of more labour and more children, polygyny was encouraged by the widespread numerical preponderance of women and by the common custom whereby young women were first married to older men and then were inherited or remarried at the death of the husband. Pre-colonial statistics are not available but in Basutoland (Lesotho), for example, almost one man in five had two wives and one in 27 had more than two (1912). Among the nomadic Turkana of northern Kenya, largely untouched by modernization in 1949, 80 percent of men about 40 years of age or over had more than one wife. These were probably among the higher polygyny rates in this region, and it is likely that no more than 5 percent of men could afford second marriages in most of these societies. Such men would have been the more wealthy, and the higher officeholders in the chiefdoms.

With or without polygyny, in some cultures the basic unit of mother and children was especially emphasized as being a permanent "house," using the same word as for the physical dwelling. Among Nguni and Sotho peoples of the south and some of the eastern Nilotes in the north—to some extent in all cultures in which herds were large—each wife was allocated animals and sometimes land, for which she assumed managerial responsibility and from which she obtained her food supply. A wife's allocation became in due course the heritable portion of her adult sons. This group of brothers, also referred to as the "house," jointly inherited, and for a time or, even permanently, controlled and used the property.

Descent systems. In kinship relations beyond the domestic domain of the compound family, the predominant organizing principle was that prime rights and obligations, mutual assistance and coresponsibility, were intimately connected with common descent in the male line (*i.e.*, patrilineally). Wider kin groups were founded on this principle. There were only two areas in which matrilineal descent was the dominant mode: in east central Tanzania among such peoples as the Luguru and Kaguru, and in south central Zambia among the Tonga and Ila. In the narrow coastal strip from southern Somalia to northern Mozambique, the Swahili and Shirazi peoples, despite centuries of Arab-Muslim influence, gave more or less equal recognition to kin traced through both parents. In some areas (Mafia Island, for example) people could choose to associate with one or more groups in which descent was traced through both males and females from a known or hypothetical ancestor. Even wider, multilateral recognition of kinship, with little or no acknowledgment of descent lines, occurred among some peoples of southern Tanzania.

Lineage and clan organization

In those cultures in which descent and the lineal principle were followed, there was commonly an important lineage based on a founding ancestor of three to five generations preceding that of the older living men. Often, though not invariably, this lineage had a territorial basis, even though some members might live outside lineage land. The genealogically senior member was generally recognized as head and through him the lineage exercised overriding control over land and other property that members severally held. Even when lineage members were scattered among people of other lineages (as among the Tonga) and especially when there was considerable residential unity (as among the Tswana), there was a great deal of continuous cooperation and interdependence. Among the Nguni and the western Nilotes especially, this lineage formed one segment of a more extensive hierarchy of lineages, each more inclusive lineage being focussed on a more remote ancestor. Each level of lineage tended to be associated with a territorial area in which it held or at least was the focus of political influence or control. Beyond the lineage of largest span was the clan, a pseudodescent group in which genealogical connections were often unknown but which was focussed on a semimythical ancestor, a culture hero, who was one of the claimed founders of the culture group. Sometimes such clan founders were not known, but invariably clan membership was determined by descent and was associated with ritual prescriptions. Certain clans, or certain lineages within them, held special privilege over political office or in ritual leadership such as rainmaking or divination.

Marriage and bridewealth. Marriage was not permitted within some designated group—the lineage, one particular level of lineage in a hierarchy, or the clan. Usually, a man could not marry a girl known to be genealogically related within some degree. Among Sotho peoples, on the other hand, marriage was positively encouraged with close kin, including certain first cousins. Among the Lovedu of the Transvaal there was a strong injunction for a man to marry his mother's brother's daughter. Among the Southern Sotho a man's marriage to his father's brother's daughter was said to assist in keeping extended family property together. More generally among the Sotho, marriage was preferred with kin rather than with strangers. This was in marked contrast with many of the northern peoples, among whom there were sayings such as, "We marry those whom we fight": that is, men took their wives from other groups, not related by descent, with whom there was for that reason potential or active hostility.

Bridewealth composition

In most East African cultures, marriage was legitimated by the transfer of livestock (cattle preferentially) from the groom and his kin to the bride's father and his kin. Bridewealth amounts ranged from an average of 50 cattle and 100 or more goats among the nomadic Turkana, to two or three cattle among the Sotho. The size of bridewealth seems to have been directly correlated with (but not necessarily determined by) the number of kin on either side who participated in the transfer and with the general stability of marriage in a society. When livestock were few or absent, bridewealth was composed of other kinds of goods: barkcloth (among the Ganda),

foodstuffs, and ironware such as hoes, axes, knives, and spears. A legitimate marriage also required special ritual performance and the exchange of formal gifts. In most cases the transfer established legal paternity of all children born to the wife. In those societies in which bridewealth was high and divorce rare, a woman remained married to her husband even after his death, so that she could produce and rear his legitimate offspring by regularized consort with a pro-husband, preferably the dead husband's near kinsman. This was the case among both Nguni and the Nilotes; and among some of the Nilotes (for example, the Nuer) a woman could be married to a man already dead in order to raise children to his name (ghost marriage); and a wealthy woman could marry another woman, in both cases by the proper transfer of bridewealth.

An alternative to bridewealth was sometimes possible for a poor man (as among the Shona) and was the cultural norm in some societies of southern Tanzania. This was suitor-service, whereby the groom lived with his father-in-law and worked for him for an indefinite period. Where bridewealth was used, divorce required the repayment of the livestock to the husband, less a certain proportion if he wished to retain paternity and rights over any children of the marriage.

SOCIALIZATION AND EDUCATION

Early child training was the prime responsibility of the mother, but it took place within the milieu of the compound family domestic group in which a child found a range of partially substitute mothers among the other women and also among older sisters and female cousins. Universally, men showed much open affection for small children but were little concerned with their early education. If livestock were important, boys began herding work at least by the age of about eight years and often earlier among pure pastoralists such as the Turkana or Masai. They thus came under the tutelage of their fathers and other male kinsmen. Girls remained closely attached to their mothers, from whom they learned domestic and other skills and mores. Most typically, boys learned sexual knowledge and mores from their peers and those just slightly older, rather than from their parents. Throughout this region it was considered that parents and children, especially sons, should keep their sexual activities and interests quite separate. This was particularly characteristic of those societies in which adult males formed into age groups, as among the eastern Nilotes. There, informal, pre-initiation peer groups provided learning opportunities among equals; sometimes this was also the case for girls, as among the Rwanda. The recurrent dramatic ritual performances associated with marriage, birth, naming, puberty, and death provided some of the most important learning occasions as children and adolescents watched from the sidelines.

More formal education for males took place in connection with initiation and the formation of institutionalized age groups and their subsequent activities. Puberty or initiation "schools" were formally arranged among the Sotho and Nguni peoples and among some of the eastern Nilotes, although these were not universal in the region. Among the Masai, a young man's age group came under the authority and tutelage of a specified older age group in order to learn adult mores, the details of ritual performance, and the nature of political behaviour. In general, there was emphasis on learning among one's peers and from one's peers. Technical skills, however, were learned in the family context.

ECONOMIC SYSTEMS

Among the agricultural peoples, the typical residential pattern almost everywhere was one of scattered homesteads or of small hamlets, each surrounded by its arable land and perhaps some reserved pastureland. Compact villages existed in only a few societies. Round houses with wooden frames, mudded walls, and grass-thatched conical roofs were common throughout the region, but banana-fibre thatch was prevalent in areas in which bananas were staples. In central Tanzania, a number of peoples built low, mudded, thatchless houses, arranged in a hollow square to give an internal courtyard and cattle pen; and in a few areas somewhat similar houses were built in pits so that their earth roofs were only slightly above ground level. Conical houses without walls and thatched to the ground were built in northern Tanzania.

Among the mobile pastoral peoples—and in the semi-mobile cattle camps of more sedentary peoples, such as the Karamojong and Nuer—quickly constructed wind breaks and shade shelters took the place of houses. None of these people had developed a form of tentage.

Subsistence economies

Economies were all essentially subsistence, the household raising its own food supply and making its own clothes and houses. Specialization, other than ironworking, was not usual, although some individuals developed skills as part-time artisans in addition to their normal work: women potters, male woodcarvers, barkcloth makers, herbalists, and diviners provide examples. Even governmental officials (other than the higher officeholders in the larger states) were also farmers or herders. It was a moral as well as an economic responsibility for a man to ensure the production of sufficient food for his household. There was exceedingly little if any production for market exchange, although all households had to barter a little of their produce for minimal outside necessities, such as salt, iron goods, pottery, and medicines. East African farmers were mostly cereal producers: millets with some corn in the south, rather more corn in the central area, and sorghum with finger millet in the drier parts of the north. Quantitatively less important but invaluable as relishes and for variety were beans, sweet potatoes, groundnuts, squashes, and oil-bearing plants. In the wetter interlacustrine region of Uganda and the well-favoured mountain areas of Kenya and Tanzania and in other high-rainfall areas, bananas and plantains were prime staples. Beer was brewed from the staple cereal or from bananas.

Tools were limited to the soft-iron hoe, bushknife, and ax. A few peoples retained wooden digging sticks until the colonial era. In the prevalent semi-arid bush and woodland areas, as on much of the open savanna and veldt, shifting cultivation was normal. Field areas were cleared, cut vegetation then being fired on the site to provide ash fertilizer. Fields were fallowed or virtually abandoned as fertility fell after two to four successive harvests. Where soils were infertile, acid, and deficient in humus, available land was exhausted before natural regeneration restored fertility in old fields, and periodically households or even whole communities shifted to new areas of woodland. With the generally low populations fresh land was readily available, and there was little incentive to develop techniques for the maintenance or improvement of soil quality. In the areas more favoured in soils and rainfall and where populations were denser (typically the mountain areas), permanent farms were normal, with usually a more efficient technology, including crop rotation, soil retention measures on slopes, irrigation, digging in of green weeds, and, occasionally, the use of animal manure. Yields even in these areas were much below those of modern farmers. In many of the more arid areas with lengthy dry seasons, during which agriculture was impossible and soils were damaged, the people recognized more or less regular "hungry months" in the late dry season and early wet season, for harvests were barely sufficient to last out the year. Poor years of inadequate rainfall were common everywhere except in the mountain areas, as was a notable famine perhaps once every two decades. High production years, on the other hand, were uncommon, since the peoples lacked the techniques, labour, and seed to take advantage of better wet seasons. Food was therefore seldom more than minimally sufficient; diets were notably deficient in protein and, on the peoples' own admission, generally monotonous. Few East African farmers had enough livestock to provide more than very occasional meat, and that was provided mainly as a by-product of the ritual slaughter of animals. Hunting, except for the few remnant hunting groups such as the Dorobo and Hadza (Kindiga), was more a leisure pursuit than a food-provid-

Dietary deficiencies

ing activity; but women and girls everywhere collected wild produce, mainly for relishes but of much dietetic value.

Mixed farming, mainly in the north (southern Sudan, northern Uganda, and Kenya) and in the south (South Africa), allowed some augmentation of the prevalent cereal diet with dairy produce (milk, butter, and, still only infrequently, meat). Milk yields from cattle were low, though with a high fat content. Eastern Nilotic peoples, such as the Turkana, Karamojong, and Masai, also fairly commonly bled their animals to obtain a valuable food supplement. The Karamojong, as well as other peoples who might be classified as pastoralists, such as the Nuer of The Sudan, the Kipsigi, Gogo, and Sotho, supplemented arable produce from their herds; but households seldom had sufficient animals to give a regular supply of milk and meat.

Livestock for East Africans was a store of wealth and an investment. Domestic animals were the most valuable and valued assets to East Africans who possessed them, and even in outright famine years pastoralists were unwilling to exchange livestock, or even to slaughter them, for food. A man's animals were essential to his entire way of life. He and his male dependents could not marry without them, nor have legitimate children; he could not properly perform rituals nor acknowledge and entreat supernatural power except through sacrifice and by the sharing of meat with human participants; quite generally he could not make restitution for wrongs committed, nor give reward for favours and friendship, nor engage in gift-giving to reinforce useful social relationships without livestock. Political officeholders and men of rank and aspiration in the East African states sought to attract followers and to control supporters by strategic gifts or loans of cattle.

Land was seldom considered valuable property, if only because, with certain exceptions, it was plentiful, and because under shifting cultivation any particular piece of land tended to have only temporary usefulness. The common rubric in states and stateless cultures alike was that the household should have access to enough land to meet its residential and economic needs. There was little reason to have more than that since it could not be put to advantage. Only particularly favourable pieces of land, such as well-watered areas near streams or good arable land in the more densely populated areas had economic value through scarcity. A local group, such as an extended family, lineage, or village, however, often laid claim to an area, to the exclusion of others, in order to ensure future sufficiency at hand for its members. Group identity could also be expressed in this territorial fashion.

GOVERNMENT

Indigenous governmental systems in East Africa ranged from highly autocratic kingdoms to the "ordered anarchy" of completely decentralized tribes in which an egalitarian ethic and practice was culturally emphasized. The great interlacustrine kingdoms—Ganda in the east, and Nyoro, Toro, Nkole, Rwanda, and Rundi in the west —were efficiently organized predatory states in which everything centred on the hereditary king. In the western kingdoms he had certain superhuman qualities and abilities to reinforce his position, though he was not really a divine king, and these were particularly expressed in his intimate association with the national, magical drums. Only a few subordinate political offices were hereditary, so that appointment and dismissal of administrators and military leaders was tightly controlled by the king on the basis of loyalty and efficiency. In the western kingdoms there was a superior caste, Tutsi or Hima, comprising 10–15 percent of the population. This caste was pastoral and not agricultural, enjoyed certain privileges, and all the more important political and military appointments were made from it. In the Ganda kingdom, however, there was no more than an incipient aristocratic class. Each kingdom was integrated by a pervasive clientship hierarchy. The king held all property, much of which he allocated for use to major clients, such as senior officeholders, military leaders, and favourites. These, in turn, were patrons of their own similar clients by the suballocation of property and protection; and these, too, had their clients, down to the mass of the peasant-serfs. These peasants in the western kingdoms were an agricultural caste comprising about 85 percent of the population and were the autochthonous (indigenous) people of this area. There was a good deal of competition to amass clients at other patrons' expense in the struggle for power and prestige, for clients were effectively economic and political supporters. These kingdoms were conquest states that had gradually overpowered and incorporated their weaker neighbours.

Hereditary kingships

The southern kingdoms of the Sotho and Nguni peoples were rather smaller and less centralized, except for the Zulu empire created in the early 19th century. They were typically composed of homogeneous smaller chiefdoms. Subordinate chiefships and other offices were hereditary and tended to be supported by locally strong patrilineal groups, thereby retaining a degree of autonomy from the king. Officeholders and hereditary councillors met periodically in a national council at which public opinion could be represented to the king; chiefly lineages formed something of a permanent aristocracy.

A variety of smaller chiefdoms existed among the Xosa, Tswana, Venda, and others in the south akin to those larger kingdoms and among the Nyamwezi, Sukuma, Ha, Haya, and Soga in the northwest in the lacustrine area. Chiefs were autocrats, but the chiefdoms were rather unstable because of local competition with each other and the secessionary ambitions of junior branches of the chiefly lineages. Lesser chiefdoms, often rather loosely organized under comparatively weak chiefs, existed among the Shona and elsewhere.

Decentralized systems

In the central, eastern, and northern parts of the region noncentralized polities were general. Some were based on semi-autonomous local communities in which law and order were maintained and disputes and policy matters were settled on the basis of the kinship connections of the people, as among the Tonga. Farther north among eastern Nilotes and to a lesser extent among northeastern Bantu peoples, men were arranged into age groups cross-cutting kinship linkages. Each age group dealt with affairs between comembers and acted as supporting and coercive units in affairs between members of different groups. Where this system was most emphasized, as among the Masai and Kalenjin, each age group collectively passed through a regular sequence of grades as members grew older, with each grade involving public responsibilities for defense, police, political, judicial, and ritual activities for the community. Fraternal egalitarianism among members of the same age group was particularly stressed throughout their lives.

Among the western Nilotes and certain northern Bantu (the Gusii, for example), lineages acted collectively in defense of members' interests. Among some western Nilotes (Acholi, Alur, Lango) this pattern was associated with weak chiefships.

BELIEF AND AESTHETIC SYSTEMS

Ancestor and other spirit cults. Among the Bantu-speaking peoples, a belief in ancestral spirits was the characteristic focus around which religious ideas developed. These spirits of the dead required regular acknowledgment, propitiation, and supplication by congregations of their living descendants, whose welfare they affected or even controlled. Ancestral spirits of chiefs in all the southern kingdoms and chiefdoms were regarded as especially powerful and important because they gave legitimation and authority to their living successors and affected the welfare of the state and the fertility and well-being of the country and its people. In some cases, as among the Shona, the spirits of former chiefs could possess a living person, not necessarily a descendant, and issue information and instructions through their mouths under trance conditions. Nonchiefly ancestors were concerned only with the group of their own living descendants and with the sanctioning of proper behaviour and cooperation among them. Misconduct threatened major

canons of kinship morality and the perpetuation of group unity and was liable to punishment by the ancestors with misfortune, illness, and even death. Ritual performance in expiation and petition were the principal expressions of lineage unity, the interdependence of kinsfolk, and their common origins from and subjection to these ancestors. These spirits were not, however, concerned with the wider morality of proper behaviour to other people of different descent.

Ancestor cults were more developed among the southern peoples and were much less elaborated among interlacustrine and northern Bantu. There, and among the northern peoples without beliefs in the spirits of the dead, there was a concept of immanent supernatural power of impersonal character, sometimes residing in natural objects or invoked in cattle, to which ritual performance was directed. In these areas, too, and occasionally elsewhere, there was a belief in a remote, omnipotent, high god who was susceptible to human supplication and manipulation through sacrifice, prayer, and ritual. In the more arid parts of the region, rainmaking was important, and this was closely associated with the fertility of women, livestock, and fields. Rainmakers were ritual experts but seldom had much worldly power.

Medicine, magic, and sorcery

Ordained priests were rare, but specialist practitioners of supernatural power were widespread. These ranged from herbalists, whose main stock was natural substances magically treated (and often of some pharmaceutical value) to doctors who cured mainly by magical means and who could foretell the future and divine the causes of misfortunes. Among the southern peoples, particularly, doctors underwent lengthy apprenticeship; this was usually precipitated by spirit possession or other psychic experience. The most powerful doctors could detect and combat witches and sorcerers, though usually these specialists themselves could work magical substances so as to harm others on behalf of clients. Some belief in witchcraft was virtually universal in all these cultures but was more elaborated from Tanzania southward and less emphasized by the Nilotes. Witches were seldom claimed to be seen at work; essentially the belief was that certain individuals inherited or sometimes learned the power by which they could harm and kill their victims. Witches were associated with the night and with hyenas, snakes, and other disliked creatures; witches were the epitome of evil and represented the inversion of normality and morality.

Artistic expression. Compared with the rest of sub-Saharan Africa, the traditional cultures of this region were poor in aesthetic expression. Basketry and beadwork decoration of clothing and utensils were quite rich, but the plastic arts were almost totally neglected. In music, unaccompanied group singing was well developed for both social and ritual performance. Drums were principally associated with high rank and political office, reaching a peak significance in the sacred national drums of some of the interlacustrine kingdoms such as Rwanda and Nkole. Xylophones were prominent, especially among the Chopi of Mozambique and the interlacustrine Bantu. Ensembles of drums, xylophones, dancers, and singers were maintained at the courts of interlacustrine kings and involved large numbers of performers on state occasions. Except in the coastal areas long influenced by Arab culture, there was little sophistication in poetry; the words of songs were very simple, in marked contrast to the accompanying musical forms.

THE IMPACT OF THE MODERN WORLD

Cultural evolution and social change were at work in East Africa before the modern era, as climatic, demographic, economic, and political conditions changed and as innovation developed. A new empire, for example, was founded among the Zulu at the beginning of the 19th century, and older kingdoms expanded by conquest and dealt with problems of more extended administration. Tribes came into being as new areas were settled, as among the Chagga on the slopes of Kilimanjaro, while older cultural groups were augmented and often quite radically affected by migrants. The Bantu peoples were penetrating farther south, and the Masai and other pastoral groups were expanding their territories in the north during the 19th century. New or improved types of domestic plants percolated into the area from the outside world—plantains, rice, and corn, for example—creating new diets and calling for new agricultural techniques.

Political organization under colonial rule. Nevertheless, the potential for change increased tremendously with the advent of massive Western intervention. The whole area came under some form of white colonial rule, ranging from dominant interference to laissez-faire paternalism. The principal factors at work were the loss of political autonomy and the introduction of a cash economy. By the third quarter of the 20th century, however, there were areas and peoples, usually geographically remote and environmentally poor, that had still been only slightly affected: the semidesert areas and their nomadic peoples (such as the Turkana and Masai) and the arid bushlands of much of Tanzania and Mozambique, peopled by near-subsistence-level, shifting cultivators. And despite certain major changes, sometimes coercively imposed, nowhere had evolution gone so far as to obliterate the earlier major cultural identities and differentiation. Indeed, it was usually the case that colonial powers froze the ethnic-cultural pattern they found on their arrival, assuming it to be a static one. Under direct and indirect rule alike, the ethnic groups were taken as the units of new administration. In effect, though not always in intent, this gave a new emphasis to cultural identity and its symbols. Some ethnic groups gained unity for the first time under colonial rule, as among the Kikuyu or the Sukuma, and sometimes smaller autonomous but culturally related groups were enforcedly amalgamated, as among the Teso or Nyakyusa. With relatively few exceptions, the end of the colonial age showed a greater emphasis on ethnic (tribal) distinction than had previously existed. This was further emphasized as ethnic groups, especially the larger ones, became involved in modern politics as the power bases of the new African politicians and the units of competition for power and preference. Although quite radical changes had occurred in certain cultural features of most of these ethnic groups, traditional elements not only persisted but also were given prominence as symbols, as part of the ideology, of modern political conflict. On the whole, as a reaction to Western intervention and power, conservatism has been dominant, partly as a defensive mechanism, partly out of continued inability to utilize modern opportunities, and partly because traditional vested interests remained strong.

Employment of traditional rulers by colonial powers

If the indigenous political system was centralized, with recognized officials, the latter were used as local authorities with varying degrees of autonomy ranging from effective subservience in the south to comparative independence in the interlacustrine area. Yet chiefs, headmen, and others became in some degree dependent, for they were paid and could be dismissed by the colonial power. Commonly their position was ambivalent, as their subjects and their masters held different expectations of their roles. They were expected to undertake new tasks, such as the collection of taxes or the enforcement of agricultural regulations; and they had to accept new kinds of assistants and subordinates (responsible for new local government services) and new forms of popular representation, such as appointed or elected councils. They had to compete with a new class of Western-educated men who sought wealth and influence. Nevertheless, the chief, though in large part turned into an administrative official, remained important as a symbol and representative of his people until his office was abolished by independent African governments.

Formerly noncentralized societies had for the first time an organized, centralized administration imposed on them, and the indigenous leaders and notables lost their influence, since they were unable to assume radically novel roles. Political changes in such situations were sometimes considerable, as among the Kikuyu, although the new, wholly unfamiliar kind of government

was often chronically unable to cope with modern needs and responsibilities.

Economic and demographic changes. East Africans were typically first brought into direct contact with the outside economic system through labour migration to farms, plantations, railroads, and growing urban centres. In the south this had begun before the end of the 19th century and almost everywhere, except the southern Sudan, labour migration flourished in the period between 1910 and 1960. As a result, men learned to work for wages and to appreciate the significance of money and Western goods. The poorer areas continued to supply the distant, white-dominated labour markets; for even the rural subsistence economies now had at least minimal needs for cash to pay taxes, to buy some clothing and other store goods, and even to substitute money for traditional wealth in order to pay bridewealth, obtain cattle, and pay fines. Where white influence dominated, as in the south and in Kenya, Africans were positively discouraged from developing their rural economies. In Uganda and to a lesser extent in Tanzania, the development of cash-crop agriculture was fostered—cotton, coffee, tobacco, corn, cashew nuts, coconuts—linking local enterprise directly to the international market. In the kingdom of Buganda, in eastern Uganda, and among the Chagga and Nyakyusa of Tanzania, for example, considerable wealth was generated, leading to higher standards of living, a degree of individualism, and a spread of Western-influenced education, skills, and ambitions. Everywhere there was a tendency for older patterns of interdependence and cooperation to fade, whether among kinsmen or neighbours. Land tenure and economic production generally tended to become more individualized as group controls and communal enterprise slackened. In the environmentally favoured areas, as well as in those in which the Africans' lands were forcibly limited, population pressures became critical, thus inhibiting peasant, subsistence agriculture. Economic development —rapid or not—was threatened by this, and great strains were imposed on kinship and inheritance systems.

The introduction of a cash economy

Although the plow and the ox-wagon have been taken up by some African peoples, more particularly in the south, and even the tractor and truck in scattered instances latterly, the East African farmer still largely depends on hoe cultivation. In the poorer bush areas the traditional slash-and-burn, shifting cultivation persists. Under government pressure such techniques as contour ridging and crop rotation have been introduced; but traditional techniques continue to be only slightly modified by Western innovations.

20th-century urbanization

Apart from a few Arab-inspired coastal towns, there was no urban element in East African cultures until the 20th century. Modern cities, from Cape Town to Nairobi and many lesser towns, grew to serve primarily European and governmental interests; but they became the principal centres of multi-ethnic interaction for African workers and centres of cultural and political innovation. Until fairly recently the majority of African town dwellers were but temporary migrants who, after a period of employment, returned to their rural homes and preferred way of life. Even as the proportion of more or less permanent town dwellers has increased, men continue to visit their home areas and to take them as their cultural reference groups. So far, ethnic differentiation has been only slightly reduced and in some ways exacerbated by the urban experience. Particularly at the level of domestic life, kinship, and marriage, the influence of rural cultures continues. Outside of South Africa the people remained overwhelmingly rural in residence and orientation: in the early 1960s over 90 percent of Tanzanians lived in rural areas and about 85 percent of Kenyans; and even in South Africa the rural population amounted to about 53 percent. This tended to reinforce conservative cultural tendencies and the preoccupation with farming and small-scale social intercourse with kin and neighbours.

Christianity and witchcraft. In general, indigenous religious beliefs and activities have not persisted in the face of Western Christian and secular ideologies, the developing cash economy, and the shock of colonial domination. Intensive Christian mission activity and its close link with educational opportunity diverted converts from former beliefs in ancestral spirits or immanent psychic power. South African peoples in particular, especially Nguni, and others elsewhere in the area have developed many nativistic Christian churches in which Africans seek to become independent of European domination of worship and organization. Renewal of traditional religion and ritual, however, has been rare. Conversely, belief in witchcraft and sorcery has tended to strengthen, perhaps as an emotional and social reaction to insecurity and uncertainty in a period of change and the reduction of traditional sanctions. Short-lived but recurrent witch-finding movements and the widespread fame of certain doctor-diviners have been common throughout the area during the 20th century. This is especially noteworthy, since colonial governments and their modern successors sought to outlaw witchcraft accusations.

BIBLIOGRAPHY. There is no single general work devoted to the cultures of this area, but good summaries of ethnographic data are given in the various volumes of the east central and southern Africa sections of the *Ethnographic Survey of Africa*, ed. by DARYLL FORDE (1956–). Among symposia focussed on some parts of East Africa are JOHN MIDDLETON and EDWARD H. WINTER (eds.), *Witchcraft and Sorcery in East Africa* (1963); ROBERT F. GRAY and P.H. GULLIVER (eds.), *The Family Estate in Africa* (1964); and PAUL BOHANNAN (ed.), *African Homicide and Suicide* (1960). There are many studies of aspects of particular cultures. For the western Nilotes, E.E. EVANS-PRITCHARD's trilogy *The Nuer* (1940), *Kinship and Marriage Among the Nuer* (1951), and *Nuer Religion* (1956), are outstanding. G. LIENHARDT, *Divinity and Experience* (1961), is valuable on the Dinka. For the eastern Nilotes the most useful are P.H. GULLIVER, *The Family Herds* (1955), on the Jie and Turkana; PAUL SPENCER, *The Samburu* (1965); and P.H. GULLIVER, *Social Control in an African Society* (1963), on the Arusha. The northeastern Bantu are poorly described, but H.E. LAMBERT, *Kikuyu Social and Political Institutions* (1956), is reliable. The best studies of interlacustrine Bantu are L.A. FALLERS, *Bantu Bureaucracy* (1956), on the Soga, and *The King's Men* (1964), on the kingdom of Buganda; JOHN BEATTIE, *The Nyoro State* (1971); and J.J. MAQUET, *The Premise of Inequality* (1961), on the Rwanda kingdom, are also useful. Among the few good studies of Tanzanian cultures are PETER RIGBY, *Cattle and Kinship Among the Gogo* (1969); R.G. ABRAHAMS, *The Political Organization of Unyamwezi* (1967); P.H. GULLIVER, *Neighbours and Networks* (1971), on the Ndendehule; and MONICA WILSON's trilogy on the Nyakyusa: *Good Company* (1951), *The Rituals of Kinship Among the Nyakyusa* (1957), and *Communal Rituals of the Nyakyusa* (1959). ELIZABETH COLSON'S writings on the Tonga of Zambia are very valuable: *Marriage and the Family Among the Plateau Tonga of Northern Rhodesia* (1958), *The Plateau Tonga of Northern Rhodesia* (1962), and *Social Organization of the Gwembe Tonga* (1960). The best work on the Rhodesian Shona is J.F. HOLLEMAN, *Shona Customary Law, with Reference to Kinship, Marriage, the Family and the Estate* (1952). The southern cultures are more comprehensively described. A general and analytical account of traditional political systems is given in I. SCHAPERA, *Government and Politics in Tribal Societies* (1956). The most useful particular accounts are to be found in H.A. JUNOD, *The Life of a South African Tribe* (1912–13), on the Thonga; HILDA KUPER, *An African Aristocracy* (1947), on the Swazi; E. HUGH ASHTON, *The Basuto* (1952); the numerous works on the Tswana by I. SCHAPERA, of which the most general is *A Handbook of Tswana Law and Custom*, 2nd ed. (1955); A.T. BRYANT, *Olden Times in Zululand and Natal, Containing Earlier Political History of the Eastern-Ngumi Clans* (1929); and MONICA HUNTER, *Reaction to Conquest*, 2nd ed. (1961), on the Pondo.

Studies of cultural change in the 20th century are still meagre and often in scattered articles. The most useful are: P.H. GULLIVER (ed.), *Tradition and Transition in East Africa* (1969); A.I. RICHARDS (ed.), *Economic Development and Tribal Change* (1954), on the Ganda, and *East African Chiefs* (1959); P.H. GULLIVER, *Land Tenure and Social Change Among the Nyakyusa* (1958); I. SCHAPERA (ed.), *Western Civilization and the Natives of South Africa* (1934); HILDA KUPER, *The Uniform of Colour* (1947), on the Swazi; and B.G.M. SUNDKLER, *Bantu Prophets in South Africa*, 2nd ed. (1961). Two volumes in the Keiskammahoek Survey give a valuable picture of a South African reserve: M.E. ELTON MILLS and MONICA H. WILSON, *Land Tenure* (1953); and D.H. HOUGHTON and E.M. WALTON, *Economy of a Native Reserve*

(1953). There is an increasing number of studies of Africans in the new urban areas, such as AIDAN W. SOUTHALL and PETER C.W. GUTKIND, *Townsmen in the Making* (1957), on Kampala; J.A.K. LESLIE, *A Survey of Dar es Salaam* (1963); and PHILIP MAYER, *Townsmen or Tribesmen* (1961), on East London.

(P.H.Gul.)

East African Lakes

The majority of East African lakes lie within the great rift-valley system that forms a part of a series of gigantic fissures in the Earth's crust extending northward from the Zambezi Valley through eastern and northeastern Africa and the Red Sea to the Jordan Valley. In East Africa itself, southern, eastern, and western branches of the rift can be discerned. Occupying the Southern Rift is Lake Nyasa (Lake Malawi), which drains into the Zambezi River. Marking the course of the Western Rift are Lakes Tanganyika, Kivu, Edward, and Albert—the first two of which are within the drainage basin of the Congo River, while the other two constitute part of the Nile River drainage system. With the exception of Lake Rudolf, the lakes of the Eastern Rift are smaller than those of the Western Rift and comprise several independent inland drainage basins.

Located in a shallow downwarping between the Eastern and Western Rift highlands is Lake Victoria, which among the freshwater lakes of the world has a surface area second only to that of Lake Superior in North America. On a smaller scale, East Africa also includes some fine examples of crater lakes and, on Mt. Kenya and in the Ruwenzori Range, of glacial tarns, small lakes each of which occupies a basin, or cirque, scraped out by a mountain glacier. (For associated physical features, see CONGO RIVER; EAST AFRICAN MOUNTAINS; NILE RIVER; VIRUNGA MOUNTAINS; and ZAMBEZI RIVER.)

The eight largest lakes

Of the eight largest lakes—Victoria, 26,418 square miles (68,423 square kilometres) in area; Tanganyika, 12,700; Nyasa, 11,430; Rudolf, 2,473; Albert, 2,059; Rukwa, 1,100; Kivu, 1,042; and Edward, 850—only one, Rukwa, in Tanzania, lies wholly within a single political entity. The northern shore of Kenya's Lake Rudolf is in Ethiopia; Lake Victoria is divided among Uganda, Tanzania, and Kenya. In the west, the international boundary between Uganda and Zaire (former Democratic Republic of the Congo) runs through the centre of Lake Albert; the same boundary places two-thirds of Lake Edward in Zaire and the remainder in Uganda. Lake Kivu lies between Rwanda and Zaire; the waters of Lake Tanganyika are shared among Tanzania, Zaire, Burundi, and Zambia. Malawi and Mozambique have territorial waters on Lake Nyasa, and, since its independence, Tanzania has also advanced claims to its territorial waters because it also occupies a part of the lakeshore.

Although not all the shores of Lake Victoria are well settled, the lands marginal to the lake are among the most densely populated in Africa. The best known groups inhabiting these marginal lands are the Ganda, Soga, Luyia, Luo, Sukuma, and Haya, all these groups except for the Luo being Bantu-speaking. The lowlands at the northern and southern ends of Lake Nyasa are also well populated, but, in general, the shores of the Eastern and Western Rift lakes are sparsely settled.

On Lake Victoria the Luo and the Sese Islanders have shown a marked interest in the fisheries. Peasant fishermen operate in the northern part of Lake Tanganyika; the majority of the fishermen on Lake Nyasa also practice subsistence agriculture, except on Likoma Island, where there is little available agricultural support.

General description. *Eastern Rift lakes.* The surface levels of the lakes on the irregular floor of the Eastern Rift are of varying heights, rising from Lake Rudolf (1,230 feet) through Lake Baringo (3,200 feet) to Lake Naivasha (6,180 feet), after which there is a decrease in height to Lake Magadi (1,900 feet). The Omo River from the Ethiopian Highlands is the only perennial affluent of Lake Rudolf, which is the lowest of the major East African lakes. Although it has the typical elongated form of a rift lake, Rudolf is relatively shallow (240 feet), as are the other lakes of the Eastern Rift. Its eastern and southern shores are bounded by rocky margins of volcanic origin; the lower western and northern shores are mostly sandy sediments. South of Lake Rudolf the splaying continuation of the Eastern Rift into northern Tanzania is indicated by Lakes Natron, Manyara, and Eyasi.

Western Rift lakes. In the Western Rift, the northwestern and southwestern shores of Lake Albert are flanked by steep escarpments; wild ravines and fine cascades comprise a feature of these young tectonic (fault-formed) landscapes, the scale being greater on the Zaire than on the Uganda side. There is a considerable lowland area at the northern end of the lake, where, about 20 miles below Murchison Falls, the Victoria Nile enters Lake Albert, to leave almost immediately as the northward-flowing Albert Nile. The southern end of Lake Albert contains an alluvial flat and a papyrus-choked delta formed by the Semliki River, which carries the outflow from Lake Edward and drainage from the rain-soaked Ruwenzori Massif.

Lake Albert

Lake Edward, of which the deepest part (384 feet) is in the west under the Congo Escarpment, receives the Rutshuru River as its principal affluent. On the northeast it is connected with Lake George by the 3,000-foot-wide Kazinga Channel. At an altitude of approximately 3,000 feet above sea level, the surface of both lakes is nearly 1,000 feet higher than that of Lake Albert.

Separating the basins of Lake Edward and Lake Kivu are the Virunga Mountains, which thus divide the drainage system of the Nile River from that of the Congo River. With clear water, a broken shoreline, and a mountainous setting, including the relatively recent volcanoes of Nyamulagira and Nyiragongo, Lake Kivu possesses outstanding scenic attractions. Its outflow is southward by the turbulent Ruzizi River, which drops more than 2,000 feet on its way to Lake Tanganyika. This latter lake, long and narrow, is second only to the Soviet Union's Lake Baikal in depth, penetrating at its maximum to 4,710 feet, which is more than 2,000 feet below sea level. Typical, too, are the flanking escarpments, which often rise sheer from the lake; the only sizable lowland is the lower Ruzizi Valley. The drainage of the Malagarasi River system enters Lake Tanganyika about 25 miles south of Kigoma; at its southern end, on the frontier with Zambia, the 704-foot Kalambo Falls occur where the Kalambo River tumbles over the escarpment. The overflow to the Lualaba River, a tributary of the Congo, is via the shallow and sometimes obstructed Lukuga River outlet on the western side.

Lake Victoria. With its quadrilateral shape, relative shallowness (270 feet), and an area that is more than twice as great, Lake Victoria is quite different from Lake Tanganyika. Set in a region of erosion surfaces instead of tectonic escarpments, it is bounded by a shoreline of considerable variety: on the west a straight, cliffed coast gives way to papyrus swamp; headlands and deep indentations mark the intricate northern shores; a major inlet, the Kavirondo Gulf, is located on the east; and on the southern shores the Speke, Mwanza, and Emin Pasha gulfs lie amid rocky, granitic hills. Ukerewe, situated in the southeast, is the largest island in the lake; in the northwest the Sese Islands comprise a major archipelago. The Kagera River, largest of the affluents, may be considered as being the most remote headstream of the Nile. The outlet of the lake and the conventional source of the Nile is at Jinja, where after flowing over the now-submerged Ripon Falls, the Victoria Nile begins its journey toward the Mediterranean Sea through the sluices of the dam at Owen Falls.

Lakes Rukwa and Nyasa. Lake Rukwa is situated in a northwest- to southeast-trending side rift, parallel with the southern part of the Lake Tanganyika Rift and continuing the structural alignment of the northern end of Lake Nyasa. Lying on flat alluvium (soil, gravel, sand, and stone deposited by running water), Rukwa is extremely shallow (20 feet at the greatest depth), and any change of surface level causes great fluctuations in its area. Southeast of Lake Rukwa, beyond the volcanic mass of Rungwe Mountain, Lake Nyasa, third in size

among the East African lakes, has the same characteristics as Lake Tanganyika but in less extreme form. It is deepest in the north (2,310 feet), where, on the Tanzanian side, the Livingstone Mountains rise precipitously from the lake surface. In the northwest, however, there is a well-defined alluvial plain. From the east come the waters of the Ruhuhu River, and numerous streams flow across the Malawi plateaus to the western shore. In the shallower, southern part there are several lake plains and sandy beaches. The Shire River outlet at the southernmost end has an extremely small gradient in its upper section, but in its middle course the river is interrupted by cataracts.

Geological history. The East African rifts attained their present form mainly as a result of Pleistocene earth movements from 1,000,000 to 2,500,000 years ago, and the lakes must have been formed after the landscapes in which they are set. The shallowness of such lakes as Albert (maximum recorded depth 168 feet) and Edward (384 feet) is the result of the thick layers of sediment upon which they rest. In some lakes, too, volcanic activity has played a part in blocking drainage and shaping shorelines. Raised beaches indicate that the lake levels were higher and their surfaces were more extensive during rainy phases of the Pleistocene Epoch. In the Eastern Rift, for instance, Lakes Rudolf and Baringo were formerly part of one lake, from which there was a link via the Sobat River with the White Nile. Subsequent drier conditions caused the eastern lakes gradually to dwindle in size, with many fluctuations, to their present independent status.

Changes since the Pleistocene

The lakes of the Western Rift have experienced their own geological changes. Before the geologically recent blocking of the rift by the eruption of the Virunga Mountains, the drainage of Lake Kivu was probably northward into the Nile; the fossil record suggests that Lakes Edward and George were completely sterilized during a period of intense volcanic activity around their shores. In the middle Pleistocene (about 1,750,000 years ago), when the rise in the shoulders of the Western Rift resulted in the reversal of the westward-flowing drainage of such rivers as the Kagera, Katonga, and Kyoga-Kafu, Lakes Victoria and Kyoga were formed by water diverted from the northern section of the rift. Eventually, however, the drainage of most of Uganda returned to the Western Rift and to the Nile. The subsequent reductions in the level of Lake Victoria are indicated by a series of strandlines around its shores.

Climate. Those East African lakes that lie in inland troughs at, say, 2,000 feet or less above sea level, have a hot, dry climatic environment with a high potential evaporation. In the higher parts of the rift floors, however, climatic conditions approach those of the flanking highlands. In the Western Rift, moist Congo air is a source of the more humid conditions prevailing over Lakes Tanganyika and Kivu. The glacial tarns of Mt. Kenya and the Ruwenzori Range are in the frigid zone.

Influence of the lakes on climate

Lakes also tend to create or influence their own climates. This effect is most marked on the western and northern margins of the immense mass of Lake Victoria, where, in a zone 30 to 50 miles wide, temperatures rarely rise above 80° F (27° C) or fall below 60° F (16° C) and rainfall is well distributed throughout the year. Moreover, annual rainfall is high, being heaviest over the lake and decreasing inland from an average of 50 to 60 inches at the lake shores. At the northern end of Lake Nyasa, an annual rainfall total of about 120 inches results from similar influences reinforced by air convergence due to the funnel-shaped relief at the head of the lake. Sudden and dangerous storms are likely to arise over the waters of all the major lakes.

Hydrography. The levels of the East African lakes are perceptibly sensitive to climatic fluctuations. Seasonal ranges of level are small: no more than a foot on Lake Victoria, 1.3 feet on Lake Albert, and three to four feet on Lake Nyasa. Longer term fluctuations, with consequential effects on the shorelines, are greater: during the 20th century the extreme range recorded on Lake Victoria has been 10.3 feet, compared with 17.3 feet on Lake Albert and 18.8 feet on Lake Nyasa. In each case the recorded maximum occurred in the early 1960s. The effects of drought are enhanced in small, shallow lakes: Lake Nakuru, in Kenya, dried up completely in 1939–40; at the end of 1949 Lake Rukwa was estimated to be one-fifth its normal size; and Lake Chilwa, in Malawi, suffered a drastic reduction of area in 1968.

Lake levels

There is a significant correlation between rainfall and variations in the level of Lake Victoria, and Lakes Kyoga and Albert follow—with an appropriate time lag—the conditions of Lake Victoria. In addition to rainfall, other factors affect the longer term fluctuations of Lakes Tanganyika and Nyasa. The Lukuga River outlet of Lake Tanganyika tends to become blocked intermittently by silting, consolidated by swampy growth. Similarly, in the flat valley of the upper Shire River, periods of erosion alternate with the building of bars of silt and sand reinforced by reeds. As a result, between 1915 and 1935 there was virtually no outflow from Lake Nyasa.

Many of the lakes, especially those in the Eastern Rift, are brackish, but Baringo and Naivasha are exceptions in that they are freshwater lakes. At the other extreme of salinity, Magadi is a soda lake, in which the continuing source of sodium carbonate appears to be alkaline waters of deep-seated origin. Lakes Edward and George have the highest salinities among the lakes of the Western Rift, but the alkalinity is not excessive. The problem of the deeper lakes, such as Tanganyika, Nyasa, and Kivu, is that their deeper waters are permanently deoxygenated and thus comprise a biological desert: 75 percent of the volume of Lake Tanganyika and 99 percent of that of Kivu are within this category. Moreover, all three lakes contain lethal amounts of hydrogen sulfide in their deeper waters, and Lake Kivu also contains vast quantities of methane.

Geochemistry of the lakes

Animal life. *Fish.* Among the main genera of fish in the East African lakes are the mouthbreeders *Tilapia*, much the most important in number of species and in total quantity; *Haplochromis*, which, like the *Tilapia*, belong to the Cichlidae family, a group of small perch-like fish; *Clarias* (barbel) and *Bagrus* among the catfish; *Hydrocynus* (tiger fish); various carps, including *Labeo*, *Barilius*, and *Barbus; Protopterus*, a lungfish; *Mormyrus*, a member of the elephant-snout fish family; and *Stolothrissa tanganicae* (*dagaa*), a small sardine-like fish.

Fish population patterns

The more strongly saline lakes, such as Nakuru, Elmenteita, Manyara, and, above all, Magadi and Natron, have a severely limited fish life. Lake Kivu also has a fish population that is neither varied nor abundant. Although fish are present in enormous quantities in Lake Rukwa, the number of species is not large, and the stock is dominated by *Tilapia rukwaensis*, an endemic species of *Tilapia*. Successive droughts such as that of 1949 explain why there are so few species in Lake Rukwa; the years immediately following 1949, on the other hand, provide an excellent example of the amazing recovery powers of tropical fish populations.

The majority of the lakes, though, have a rich and varied fish life, of which a high proportion of species are endemic to the individual lake. The Cichlidae, for example, are especially prone to form new species, and there are about 90 species of the family in Lakes Victoria and Kyoga.

Lake Albert has a fish life that is related to that of the Nile; it includes Nile perch, tiger fish, and *Polypterus* (bichir). The physical barrier of Murchison Falls, situated near the northern end of Lake Albert, marks the frontier of a separate animal province formed by Lakes Victoria and Kyoga. Several of the Lake Albert genera are not found in these two lakes, which contain many unique species. Similarly, the rapids on the Semliki River have prevented the recolonization of Lakes Edward and George—otherwise particularly rich in fish—by fish from Lake Albert. On the other hand, the presence of Nile perch, tiger fish, and bichir in Lake Rudolf serves to indicate its former connection with the Nile. The transplantation of fish by man, however, has caused a man-made zoogeographical revolution, the full effects of which cannot yet be discerned.

Game animals. The hippopotamus is ubiquitous around the lake shores, except those of Lake Kivu; the crocodile is also widespread, although absent from Lakes Edward, George, and Kivu, each of which is sheltered from the spread of this reptile by falls in the outflow river, with cool mountain torrents and sunless forest as additional deterrents. There is an inverse relationship between the density of game and that of human settlement, but in recent times the establishment of national parks and game reserves has encouraged the increase of game population. Among the variety of game to be seen in the neighbourhood of the lakes are elephant, buffalo, and various antelopes.

Birds. Among the resident and migrant birds in evidence, waterfowl are especially noticeable. Several of the Eastern Rift lakes—such as Nakuru, Elmenteita, and Manyara—are famous for their vast congregations of flamingos. Forming the basis of a national park in which the emphasis is on aquatic birds, Lake Nakuru is an ornithologist's paradise; Lake Edward and the Kazinga Channel are also notably rich in bird life. The fish-eating birds—cormorants, darters, and kingfishers—are also part of the ecology of the lakes.

Plant life. The vegetation setting of the lakes varies from the semidesert, in which Lake Rudolf is situated, to the patches of closed evergreen forest on the western and northern shores of Lake Victoria. Between the two extremes and in accordance with the position of the individual lakes, bushland and thicket, grassland, savanna, or open woodland occur. The oil palm, which is characteristic of West Africa and the Congo region, is found on the shores of Lake Tanganyika. Heavily populated and intensively cultivated areas marginal to Lakes Victoria and Nyasa present vegetation types much modified by man.

The lake shores may comprise open landscapes of headland or beach or may contain plants associated with swamps, such as the giant sedge, *Cyperus papyrus*, which is the most prevalent.

Resources and development. Fishing is one of the major resources of the East African lakes, but the degree of exploitation varies considerably. During the early 1960s, for example, less than 1,000 tons of fish, mostly for local consumption, was taken annually from the well-stocked waters of Lake Rudolf, and even in the early 1970s this lake remained virtually unexploited. To the south, however, the much smaller Lake Baringo yields about 600 tons of fish annually. The introduction of black bass and several species of *Tilapia* forms the basis of a commercial fishery at Lake Naivasha, which is also a popular weekend resort for Nairobi residents and which, like Lake Rudolf, attracts many sport fishermen. At Lake Magadi, on the other hand, soda ash, the leading mineral export of Kenya, is extracted and refined.

The fisheries of Lake Victoria are important principally as a source of protein for the rural and urban population living in the vicinity of the lakes; the fisheries of Lake Kyoga are strongly developed. Although Lake Victoria is considered to be essentially a *Tilapia* fishery, there are also important catches of other species. The industry is controlled by independent fishermen, typically using planked canoes with outboard motors.

Hydroelectric power

Another important resource at Lake Victoria is the 150,000-kilowatt Owen Falls power station at Jinja. In addition to providing electricity for use in Uganda and Kenya, a dam at the falls enhances the potential of Lake Victoria as a storage reservoir for the Nile River.

The varied fish life of Lake Albert includes Nile perch and two genera of tiger fish, of which one, *Alestes*, provides two-thirds of the total weight landed on the Uganda shores. Calculations indicate, however, that the catch is below the maximum sustained yield of the lake. With the collapse of the Congo market in the early 1960s, a greater proportion of the output was absorbed by a developing home demand. A tourist attraction adjacent to Lake Albert is the Ruwenzori National Park, which extends down to the narrowing outlet at the northern end of the lake.

Lakes Edward and George support remarkably fertile fisheries. The Zaire shores of Lake Edward are enclosed within the Virunga National Park (Parc National du Virunga), while the Ugandan portion of the lake lies within the Kabarega National Park. Close to the north-eastern shore of Lake Edward, Lake Katwe, which lies in one of the numerous shallow craters within the Edward–George branch of the Western Rift, is a source of salt.

The fisheries potential of Lake Kivu is more limited than that of the other lakes of the Western Rift. Tourist attractions are being developed, and, at the outlet of the lake below Bukavu, a hydroelectric station on the Ruzizi River provides power to as far away as Bujumbura (Usumbura) on the northern shores of Lake Tanganyika.

As a whole, the borderlands of Lake Tanganyika are characterized by underdevelopment. Fisheries are dominated by the exploitation of *dagaa*. There is, however, a secondary commercial fishery based on other species; in the absence of shallow, marginal waters, however, *Tilapia* do not form a significant proportion of the catch. Despite the changes in water level to which it is liable and its remoteness from markets, Lake Rukwa is third to Lakes Victoria and Tanganyika among the freshwater fisheries of Tanzania.

In the southern part of Lake Nyasa, shallow, sheltered waters provide a good habitat for *Tilapia* and for *Labeo mesops* (a species of carp). Non-African commercial fishing, however, has intensified the demand upon the inshore species, resulting in a reduction of the fish population. In the northern waters the fish caught include the catfish and some species of carp. The total annual catch in Lake Nyasa and the upper Shire River area is about 20,000 tons.

European reconnaissance of the lakes

Exploration. Following in the track of earlier Arab trading expeditions, the British explorers Sir Richard Burton and John Hanning Speke reached the eastern shore of Lake Tanganyika in 1858. It was there, at Ujiji, that David Livingstone, the Scots explorer-missionary who had pioneered the Shire River route to Lake Nyasa in 1859, was met by the Welsh explorer Henry Morton Stanley in 1871, after which the two subsequently made a reconnaissance of the northern part of the lake. Then, in 1874, in the course of his east–west traverse of the continent, the English traveller Verney Lovett Cameron explored the Lukuga River outlet on the western shore of Tanganyika.

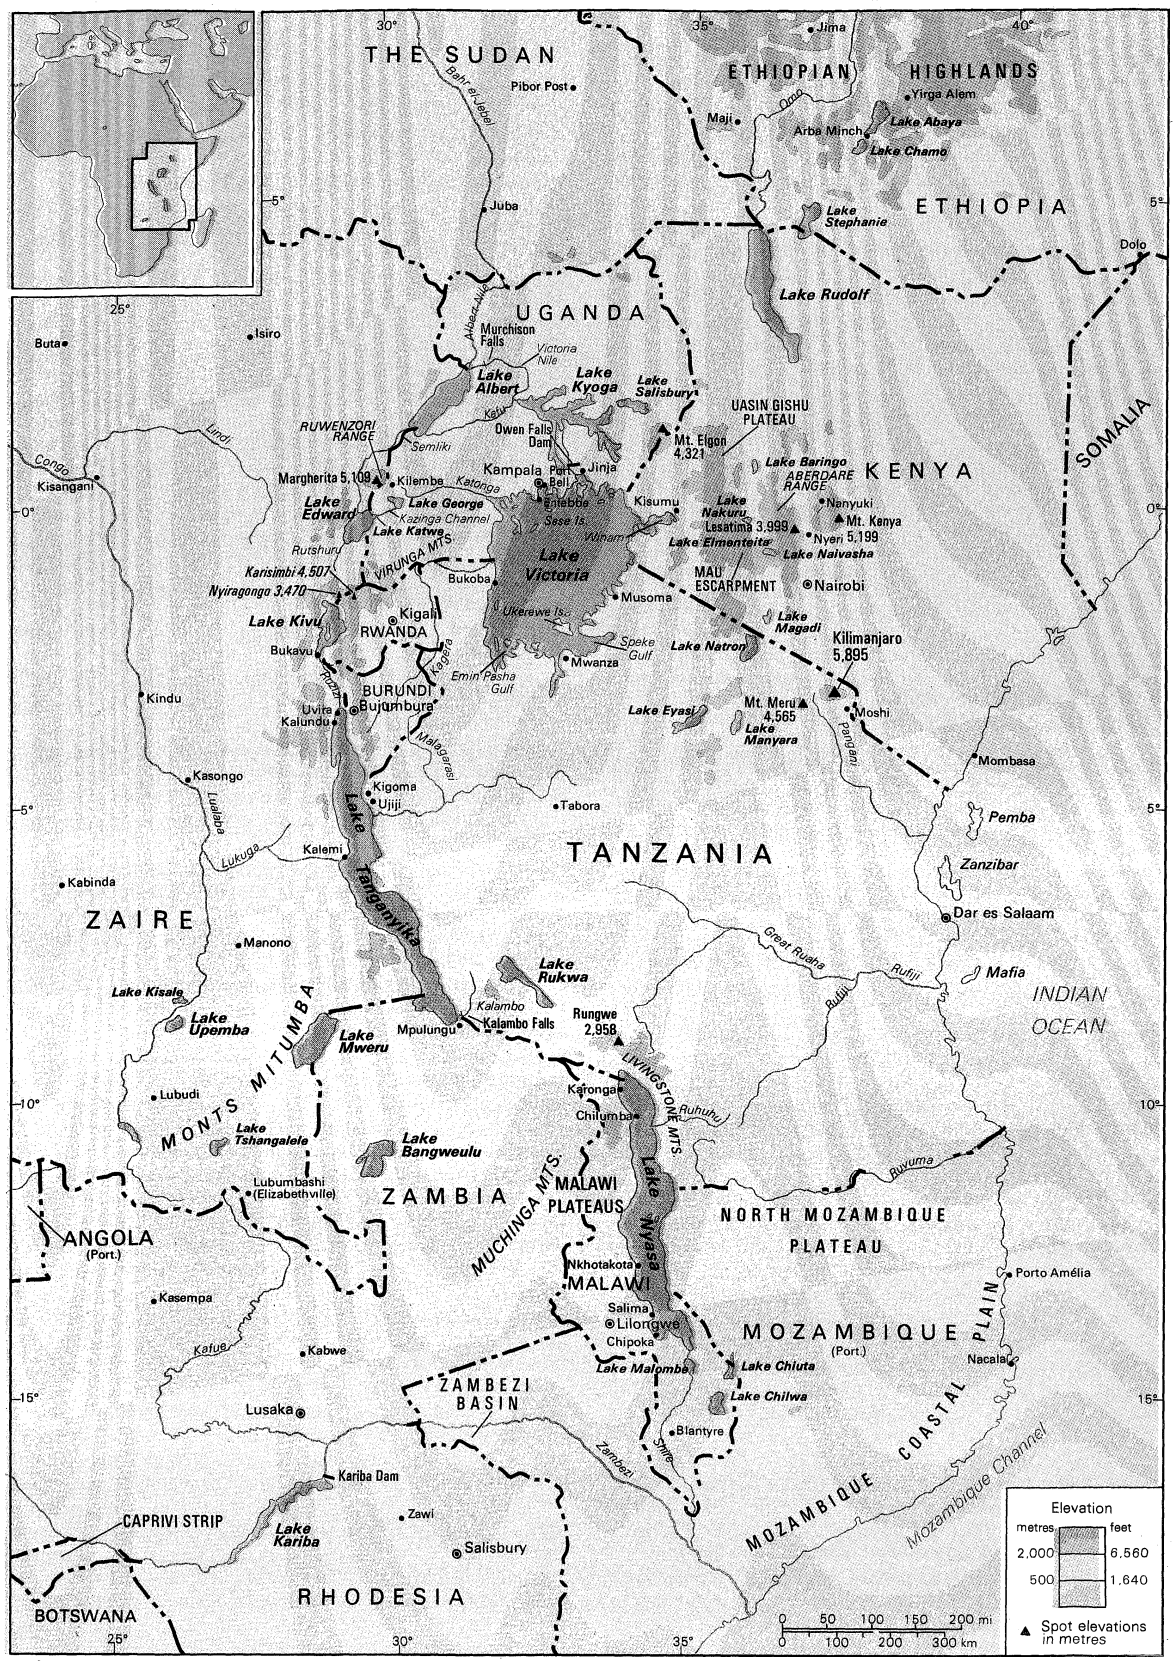
While Burton remained at Tabora in 1858, Speke journeyed northward and became the first European to view the waters of Lake Victoria. In 1862, after he returned to East Africa with a fellow countryman, James Augustus Grant, Speke stood above the Ripon Falls, which he proclaimed as the source of the Nile. The details of the Lake Victoria shoreline were filled in by Stanley when he circumnavigated the lake in 1875.

Meanwhile another Englishman, Samuel White Baker, together with his intrepid wife, had approached the East African lakes from the north, reaching Lake Albert in 1864. In 1888 to 1889 Stanley, in company with Emin Paşa, the German traveller, traced the Semliki River to its source in Lake Edward. Finally, in 1894, a German explorer, Adolf von Götzen, became the first European to visit Lake Kivu.

During the 1880s, Europeans explored the lakes of the Eastern Rift. Lakes Magadi and Naivasha were visited by a German traveller, Gustav Fischer, in 1883, and in the same year the Scots explorer Joseph Thomson reached the shores of Lake Baringo. Five years later two Hungarians, Count Samuel Teleki and Ludwig von Höhnel, reached Lake Rudolf.

Transport routes

Communications. Most of the East African lakes are reasonably accessible by road or air or both. Among the major lakes, however, Rudolf remains the least accessible by road. With the exception of Lake Albert, the main lakes of Uganda are well served by surface communications. There are good road communications to Lake Kivu, but access to Lake Tanganyika is more difficult, as is that to the eastern shores of Lake Nyasa. Scheduled inland-waterway services have been developed on Lakes Victoria, Tanganyika, and Nyasa; elsewhere,



Lakes and mountains of East Africa.

as on Lake Kivu, there are launch services. Otherwise, canoes and, to a smaller extent, dhows transport people and goods.

Fluctuations of the lake level and changing economic conditions have brought about the closure of a number of ports on Lake Victoria; the main ports in use are Kisumu, Musoma, Mwanza, Bukoba, Port Bell (serving the Kampala metropolitan area), and Jinja. Entebbe (in Uganda), which is no longer a lake port, is an international and regional airport. The East African Railways Corporation operates lake services on Victoria, including rail-ferry terminals at Jinja, Kisumu, Mwanza, and Musoma. Rail connections with the maritime ports are provided at the first three of these terminals. In the late

1960s the total lake trade—mostly in coffee, cotton, and cereals—remained well under 300,000 metric tons.

On Lake Tanganyika, the railways provide a service connecting Kigoma, terminus of the rail line from the Tanzanian capital of Dar es Salaam, with the Zambian port of Mpulungu. A Zaire company based at the railway port of Kalemi (Albertville) maintains links with Kigoma, Bujumbura (capital and lake port of Burundi), and Kalundu (for the Zairian town of Uvira). Malawi Railways, which provides services on Lake Nyasa, including the Tanzanian and Mozambique shores, has rail connections with Beira and Nacala on the coast of Mozambique. The lake rail terminal is at Chipoka, and the ports at which calls are most frequently made are Nkhotakota, Bhilumba (formerly Deep Bay), and Karonga, all on the western side of the lake.

East African Mountains

The East African mountains of Kenya, Tanzania, Uganda, Zaire, Rwanda, and Burundi are intimately related to a rift system, the fractures of which extend discontinuously between the Zambezi Valley and the Red Sea, and are flanked in many areas by highlands. Of the major mountains, all but one are of volcanic origin. Rising magnificently from the surrounding plateaus to altitudes of over 16,000 feet (5,000 metres), the highest peaks, despite their proximity to the Equator, are ice-capped.

Mt. Kenya, the Aberdare Range, and the Mau Escarpment are located wholly within Kenya to the north of Nairobi; Mt. Elgon lies astride the Uganda–Kenya border; Kilimanjaro extends along Kenya's southern boundary with Tanzania; and Mt. Meru is in northern Tanzania. The Ruwenzori Range stretches between Lakes Edward and Albert on the Uganda–Zaire border and, farther south, the Virunga Mountains extend along the contiguous borders of Uganda, Rwanda, and Zaire. (For a detailed discussion, see VIRUNGA MOUNTAINS. For associated physical features see EAST AFRICAN LAKES.)

The natural environment. *Topography.* The Aberdare Range, of which the highest peak is Ol Doiny Lesatima (Satima) at 13,120 feet (3,999 metres), and the Mau Escarpment rise steeply from the Eastern Rift. To the west, beyond the Uasin Gishu Plateau, Mt. Elgon emerges gently from a level of about 6,200 feet; but the spectacular cliffs of its western face dominate the lower plains of eastern Uganda, which lie at about 3,600 feet. The rim of Elgon's caldera (a vast explosion crater) is about five miles in diameter and contains several peaks of which Wagagai, at 14,178 feet (4,321 metres), is the highest.

Principal mountain features

A wide col, or saddle-shaped pass, separates the Aberdare Range from Mt. Kenya and forms the Nyeri–Nanyuki corridor. The second highest mountain in Africa, Mt. Kenya has a girth of about 95 miles at 8,000 feet, from which it rises boldly to its restricted summit zone. The craggy twin peaks of Batian (17,058 feet [5,199 metres]) and Nelion (17,022 feet [5,188 metres]) are closely followed in height by Point Lenana (16,355 feet [4,985 metres]).

Set amid low plateaus, Kilimanjaro is the highest mountain in Africa, rising to 19,340 feet (5,895 metres) at Uhuru peak on the Kibo cone. The generally smooth outlines of the cratered dome of Kibo are in marked contrast with the jagged form of Mawensi, or Mawenzi (16,890 feet [5,148 metres]); the two summits are connected by a seven-mile-long saddle, which lies at about 14,500 feet. Mt. Meru, about 40 miles southwest of Kilimanjaro, attains an altitude of 14,979 feet (4,566 metres).

The Ruwenzori Range runs parallel to the Western Rift, to which it drops steeply. The fall to the uplands of western Uganda, however, is more gradual. At its base the range is 75 miles long, and its greatest width is about 30 miles. The summit zone contains six distinct mountain massifs, which are separated by well-defined passes and deep river valleys. Mts. Baker and Gessi lie entirely within Uganda, while Mts. Stanley, Speke, Emin, and Luigi di Savoia form part of the Uganda–Zaire frontier. Of the ten peaks topping 16,000 feet, all but one are on Mt. Stanley, which includes the highest peak, Margherita, at 16,763 feet (5,109 metres).

The Virunga Mountains and their associated lava flows extend across the Western Rift. In the west, Nyamulagira, Nyiragongo, and Mikeno are in Zaire; Karisimbi—at 14,783 feet (4,507 metres) the highest of the Virunga volcanoes—and Visoke are centrally placed on the Zaire–Rwanda frontier; and farther east Sabinio (Sabinyo), Mgahinga (Gahinga), and Muhavura, also known as the Mufumbiro Mountains, are on the Rwanda–Uganda frontier. Not all of the cones culminate in craters, but several have crater lakes.

Glaciers

The relict glaciers that occur in the summit zones of Kilimanjaro, Mt. Kenya, and the Ruwenzori have little erosive force. Their more powerful predecessors, however, extended down to altitudes of between 12,000 and 10,000 feet and even lower and produced arêtes (sharp-edged ridges), cirques (glacial amphitheatres), rock tarns (rock basin lakes), U-shaped valleys, and moraines (boulders and other debris deposited by glacial action). Early glaciation also affected Mt. Elgon and the Aberdare Range. More than 30 small glaciers on the Ruwenzori together cover a surface of about two square miles, most of which is on Mts. Stanley and Speke; the lowest valley glacier descends slightly below 14,000 feet. Of the ten glaciers remaining on Mt. Kenya and covering less than 0.5 square miles, the largest are Lewis and Tyndall; the lowest tongue of ice reaches down below 15,000 feet. On Kilimanjaro, Kibo crater is strewn with giant blocks of ice, and the outer rims are covered with ice reaching down to 15,000 feet at the snout of the Penck Glacier on the wet southwestern moorlands. The 20th century has been marked in East Africa by a process of glacial retreat that has been rapid but neither constant nor conspicuous.

Geology. The peneplain of eastern Africa, dating from the Miocene Epoch (between 26,000,000 and 7,000,000 years ago), has been subject to a general elevational movement. The shoulders of the rift valleys have risen intermittently to produce highlands on which lavas ejected from fissures in the earth's surface have in some instances added considerable height. The most astonishing uplift is that of the Ruwenzori, the only East African mountains that are not volcanic. The ancient plateau surface of gneisses (coarse-grained, foliated crystalline rocks) and schists (foliated metamorphic rocks that can be split into thin flakes) was upfaulted on the west and upwarped on the east. Movements along the faults continue, and the Ruwenzori comprise an important earthquake epicentre.

Kilimanjaro is a volcano of complex structure and alkaline lavas situated at an intersection of fault lines. Shira was the first volcano of the group to become inactive, followed in turn by Mawensi and Kibo. Kibo retains its caldera—one and a half miles in diameter and 600

feet deep—within which there are successive inner cones and craters as well as fumaroles (holes or vents that emit gases).

The long-extinct volcano of Mt. Kenya has been much denuded, and the highest peaks consist of the crystalline nepheline–syenite (a granular rock of alkalic feldspar, nepheline, and other minerals), which plugged the former vent. Around this core are gently dipping lavas, agglomerates, and tuffs (rocks formed of compacted volcanic fragments).

Mt. Elgon belongs to the Eastern Volcanics of Uganda, which comprise soda-rich lavas and associated fragmental tuffs and agglomerates. The Western Volcanics are represented by the Virunga Mountains, of which Nyamulagira and Nyiragongo have been active during the 20th century. Major eruptions occurred in 1938 and 1948, and on several occasions a lava stream has reached the shores of Lake Kivu 12 miles south.

Drainage and soils. The Virunga Mountains separate the basins of the Nile and the Congo rivers and are the only East African mountains to form a drainage divide of continental stature. The entire drainage system of the Ruwenzori Range finds its way into the Semliki River, a tributary of the Nile. Because they are young, the mountain systems present good examples of consequent drainage (drainage that is determined by the initial slope of the land) such as the radial system of Mt. Elgon, in which streams radiate from a central area, and the parallel streams of the Aberdare dip slopes. The porous nature of volcanic materials often results in areas devoid of surface drainage.

The succession of soils is from the raw mineral type of the summit area, through the dark peaty loams of the Alpine zone and the strong brown loams of high organic content in the forest belt, to the ferruginous (iron-bearing) soils of the lower slopes. Volcanic material presents a range from the unaltered rock of the most recent eruptions to the well-developed fertile soils on longer exposed surfaces.

Climate. In a region of predominantly dry climate, the mountains are conspicuous as high-rainfall areas. Affected by the convergence of Indian Ocean and Atlantic airstreams, the Ruwenzori as a whole comprise the wettest and the cloudiest of the mountains, where moist conditions penetrate up to the peaks and about 80 inches (2,000 millimetres) of rain annually fall at 15,000 feet (5,000 metres). Kilimanjaro, Mt. Kenya, and Mt. Elgon are affected by their position in relation to southeasterly and northeasterly airstreams. Below 10,000 feet they are wettest on their southeastern and southern sides, with annual totals rising to 100 inches on Mt. Kenya; they are driest on their northern flanks, with less than 40 inches yearly. Rainfall decreases above a cloud ceiling at about 10,000 feet, especially on Kilimanjaro, where the Alpine zone is a veritable desert. On the western and southwestern slopes the diverted southeast trade winds are sucked up each of the mountains as westerlies, creating an increase of cloud and precipitation. At the summit of Mt. Kenya, temperatures seldom rise above the freezing point, and above 14,500 feet precipitation mainly occurs as snow.

The plant life of Mt. Kenya

Vegetation. The altitudinal succession of vegetation is well developed on Mt. Kenya. The succession emerges from the surrounding savanna (grassland with scattered bushes or trees) and begins on the lower slopes with a crescent of cultivated land. The montane forest extends upward from a lower limit of 5,000 to 7,000 feet to about 10,500 feet and includes giant trees, such as camphor and various figs, cedar, yellowwood, and the East African olive. From about 8,000 feet, the forest comprises montane bamboo, and at its upper limit parkland and low thicket fringe the succeeding zone of giant heather. At 11,000 to 12,000 feet, the heather zone gives way to the Alpine zone in which tree groundsel and the giant lobelia rise out of a ground vegetation of tussocky grassland and everlastings (composite plants, the flowers of which can be dried without loss of colour or form). Mosses and lichens survive up to about 15,000 feet, but bare rock and ice are exposed above that height.

The montane forest of Kilimanjaro is drier than that of Mt. Kenya. Bamboo is virtually absent, although it is abundant on neighbouring Mt. Meru, and there is no parkland zone. The heather zone is strongly represented, whereas the Alpine semidesert is poor in flowering plants. Mt. Elgon reaches into the Alpine zone, as do the summits of the Aberdare Range. On the northwest of the Ruwenzori, the lower slopes touch upon the equatorial forest, and the vegetation is moister and more luxuriant than that of the eastern mountains. Above the bamboo forest and the wooded parkland, the Virunga Mountains extend into the heather zone and, in the three highest volcanoes, into the Alpine zone.

The Afro-Alpine vegetation of the eastern mountains is unique. With the increase of temperatures in post-Pleistocene times (about 10,000 years ago) the cold-loving plants retreated to the mountains where they have been preserved and somewhat transformed. Despite the enormous distances that separate the mountains, plants in the respective Alpine zones are closely comparable. There are lobelia and *Alchemilla* (lady's-mantle) species common to all the mountains, although the tree groundsel species are limited within neighbouring mountains. The phenomenon of giantism is common, while dwarfism occurs at the highest altitudes.

Animal life. Elephants, rhinoceroses, buffalo, antelope, hyrax (one of several small, hooved mammals), bush pigs, and monkeys, including the black-and-white colobus, are among the main inhabitants of the montane forest. The bongo (forest antelope) and the giant forest hog have not been recorded from Kilimanjaro perhaps because of its lack of bamboo forest and its isolation from the mountains to the north. The golden monkey occurs in the Virunga Range and the chimpanzee in the Ruwenzori. Trout have been introduced into the streams of the more accessible mountains.

Mammals of the upper forests, including the leopard and antelope such as the duiker and the eland, penetrate into the moorland and Alpine zones, where the hyrax and the groove-toothed rat are the most obvious inhabitants. Birds include the lammergeier (one of the largest birds of prey, resembling the eagle and vulture), the mountain chat (a songbird), and the scarlet-tufted malachite sunbird (a small, brilliantly coloured songbird). Animal life, like the vegetation, shows resemblances that suggest a retreat of its distribution from the surrounding plateaus to the montane islands of refuge.

The human imprint. *Population.* Population is confined to the lower slopes, with the upper limit of settlement at about 7,000 feet. Bananas and millet are common subsistence crops, and coffee is an important cash crop. On the southern and eastern slopes of Kilimanjaro the Chagga have long used an effective system of irrigation based on the ridge and valley relief of the mountain.

Population densities

High population densities among the Chagga are matched by those among the Kikuyu and related groups on the slopes of the Aberdare Range and around the southern and eastern margins of Mt. Kenya. The Gisu have densely settled the western slopes of Mt. Elgon below the forest zone.

Population density is high on either side of the northern nose of the Ruwenzori; the Konjo hillmen live mainly on the eastern flank of the range. The pygmy Twa occupy the forests of the Virunga Mountains, the lower slopes of which are cultivated by the far more numerous Hutu.

Exploration. In 1848 the snow-covered summit of Kilimanjaro was observed by the German explorer Johannes Rebmann and in the following year Johann L. Krapf obtained a view of the snows of Mt. Kenya. In 1888 the Welsh explorer Henry M. Stanley glimpsed the Ruwenzori through a break in their cloud cover and equated them with the Mountains of the Moon of Ptolemy.

A number of expeditions on Kilimanjaro preceded that of 1889 in which the German geographer Hans Meyer conquered the summit of Kibo. Partial ascents of Mt. Kenya were made before H.J. Mackinder reached the summit of Batian in 1899. The Ruwenzori awaited the large-scale expedition of the Duke of Abruzzi in 1906

for the conquest of their major peaks, and in 1907–08 the Duke of Mecklenburg made a comparably comprehensive survey of the Virunga Mountains. The Elgon caldera had been visited in 1890, and in 1911 Wagagai was climbed. In 1932 a Belgian scientific mission explored the western slopes of the Ruwenzori and climbed several peaks.

Since 1931, air photography has assisted in the production of excellent maps of the major mountains. Under the stimulus of the International Geophysical Year of 1957–58, glaciological expeditions were mounted on the Ruwenzori, Mt. Kenya, and Kilimanjaro.

Kilimanjaro, Kenya, and Ruwenzori are names of African origin; the first two are of somewhat uncertain meaning, and Ruwenzori may come from Lunyoro words meaning "place of rain." Elgonyi was the Masai name for Elgon, but the Gisu name Masaba remains current in the Bantu languages. The names Kibo and Mawensi are of African derivation; and the highest peaks of Mt. Kenya were named after Masai chiefs. With one exception, Ensonga, the major mountains and peaks of the Ruwenzori have European names, while Virunga nomenclature is African.

Transport. The Ruwenzori form a barrier to east–west transport, and road connections between Uganda and Zaire pass south of the range. The Mau Escarpment and the Aberdare Range deflect the main roads to their northern and southern flanks, but each is crossed by a secondary road. The Nyeri col between the Aberdares and Mt. Kenya is used as a gateway to the north. There are circular routes around Mts. Kenya and Elgon, and the bases of all the mountains are reasonably accessible.

Resources. Copper ore is mined at Kilembe, Uganda, on the southeast flank of the Ruwenzori, where the narrow margin of ore reserves is a precarious factor in relation to future output. A hydroelectric installation in the nearby Mubuku Valley provides power for the mines.

Forestry and agriculture

The closed forests are mainly under forest reserve and are classed as presently productive of timber. The most important output of sawn wood has come from the more accessible mountains of Kenya and Tanzania, where cedar, podo (or yellowwood), and camphorwood are among the principal timbers. Land cleared for cultivation in the lower part of the forests forms rich agricultural zones in which a considerable variety of crops, including coffee, tea, wheat, pyrethrum (a chrysanthemum used in the production of insecticides), bananas, millet, root crops, and vegetables may be grown. Cattle are reared on the northern slopes of Mts. Kenya and Elgon and on Kilimanjaro. The narrow agricultural belt could be widened, and there is a tendency for the extension of cultivation into lower altitudes by the use of irrigation.

The mountains are an important tourist attraction. The whole of Mt. Meru is within Meru National Park, and other parks include Mt. Kenya above 10,500 feet, the moorland zone of the Aberdares, and a sector of the Kenya portion of Mt. Elgon. In the Uganda section of the Virunga Mountains, the Gorilla Game Reserve is situated on the northern slopes of Mts. Muhavura and Mgahinga (Gahinga). In the Rwanda and Zaire portions of the Virunga Mountains, gorillas are protected, respectively, in the Volcanoes National Park and the Virunga National Park (Parc National du Virunga).

BIBLIOGRAPHY. RENE JEANNEL, *Hautes Montagnes d'Afrique* (1950), extends its coverage to Ethiopia, but is chiefly important for the mountains of Tanzania, Kenya, Uganda, and Zaire. I.C. REID (ed.), *Guide Book to Mount Kenya and Kilimanjaro*, 2nd ed. (1963), is primarily intended as a rock-climbing guide to the central peaks; also contains information on the plant and animal life; PETER ROBSON, *Mountains of Kenya* (1969), is a guidebook designed primarily for the hill climber. *Tanganyika Notes and Records*, no. 64 (March 1965), is a special issue devoted to Kilimanjaro that contains an extensive bibliography. The *Traveller's Guide to the Belgian Congo and Ruanda-Urundi*, 2nd ed. (1956), provides a useful topographical description of the mountains within Rwanda and Zaire. X. DE GRUNNE *et al.*, *Le Ruwenzori: vers les glaciers de l'Equateur* (1937), contains contributions on the geology, physiography, plants, and animals on the East African mountains as a group.

(S.J.K.B.)

East Asian Cultures

East Asia as a cultural entity is defined in this article as comprising the Chinese and groups that have been derived from the Chinese ethnically or culturally and, secondly, those cultures that were greatly influenced by China at the time they became states. Among the first category, of course, are the Chinese themselves, the Taiwanese, and, with some equivocation, the Miao and Yao. The second category comprises such peoples as the Japanese, Koreans, Manchus, and Minchia. Other peoples have also been influenced by the Chinese, but, because they have not formed states of their own, this influence is difficult to determine and is often not emphasized. This is the case among, for example, the Nakhi of southwest China and the Ainu of Hokkaido.

Recognition of ties with China is the most characteristic feature of East Asian cultures. It unites peoples as disparate in many aspects of life as the Hui-hui of China's northwest, the Japanese, and the Manchus. The area thus has a special significance for many of the peoples themselves and is not simply a construct of social scientists.

It is to the south that it is most difficult to determine the boundary of East Asia. Here groups escaping the domination of Chinese power fled through China and finally into what are now designated as the states of Southeast Asia. Some of these peoples are closely related to others still within China. In addition, some peoples such as the Tai and Tibetans have been greatly influenced by the Chinese; but then again they have both been greatly influenced by the Indians. The Vietnamese are not only the most Sinified of the Southeast Asians but probably give the Chinese undue credit for the beginnings of civilization in the Red River Delta of North Vietnam. Vietnam is generally discussed in Western accounts in the context of a Southeast Asian culture area and is not discussed in this article (see SOUTHEAST ASIAN CULTURES).

To the north, the border of the East Asian cultural area is marked by the Great Wall of China, which passes within 35 miles (55 kilometres) of Peking. On the other side of the wall live those who, from about the 7th century BC on, have rejected the East Asian way of life.

GENERAL CONSIDERATIONS

People and languages. Some peoples in Asia more or less form a buffer zone around East as well as South Asia. These ethnic groups are of diverse origins and cultures. The Ainu, situated on the island of Hokkaido, appear to represent in ethnic terms a conservative autochthonous refugee group that cannot easily be connected with any other group. They are linguistically distinct from other groups but culturally akin to the peoples of the Soviet Maritime Province and Eastern Siberia. The Manchus, Xojen, Daghur, and Mongours are small ethnic groups situated along China's northern and northwestern frontier. The first two speak a language of the Tungusic branch of the Altaic linguistic family, while the Daghur and Mongours speak Mongolian languages, also of the Altaic family.

The Islāmic Hui-hui

The Hui-hui (also called Tungan in Chinese Turkistan and Panthay in southwest China), or Chinese Muslims, take their ethnic identity from their religion. Those aspects of life in which they differ from Chinese are related to their practice of Islām, although they also exhibit a greater esprit de corps and competitiveness. There is a natural tendency for members of an ethnic unit who can communicate readily with members of the dominant group to merge with that group, and many Hui-hui have seen themselves as predominantly Chinese. But it is also true that Chinese Muslims have regarded themselves as an alien and superior people to the Chinese.

Extending eastward from the Tibetan ranges and plateau, the Tsinling Mountains form a dividing line between border groups of Ural-Altaic linguistic affiliation to the north and Sino-Tibetan, Tai-Kadai, Austronesian (Malayo-Polynesian), Austro-Asiatic, and perhaps independent linguistic affiliations to the south. Most of the non-Chinese ethnic groups found along the borders of Tibet and China speak a language affiliated to the Tibeto-Burman branch of the Sino-Tibetan linguistic family.

The Lolo and Minchia have occupied the highland area of southwest China for over 1,000 years. A number of Lolo traits—among them a language that indicates an affinity to Tibeto-Burman, a tall stature with a high-bridged nose, the use of felt, a mixed pastoral and agricultural society, and the use of poisoned arrows—appear to indicate a culture with diverse and distant origins. The Lolo seem to be most alike in culture, language, and physical type to the peoples of southeastern Tibet. They appear to have originated in the same borderland that they now occupy, although perhaps more to the west.

The Minchia have been a part of a centralized political system since the 7th century, when their principal city, Tali, was the capital of the Nan Chao state. The Yüan dynasty emperor Kublai Khan conquered Nan Chao in 1253, but the area around Tali is to this day primarily inhabited by the approximately 500,000 Minchia. The Minchia have been rice cultivators for over 1,000 years and now are highly acculturated to Chinese ways of living. Many speak Chinese as well as Minchia.

The linguistic affiliation of the Miao and Yao to major linguistic groups is still in dispute, but there is no doubt but that the two are linguistically related to each other and have borrowed heavily from Chinese. Miao names for themselves are Hmong, Hmung, or Hmu, followed by a further word indicating subethnic affiliation. The Yao refer to themselves as Kim Mien, Kim Mun, and Yu Mien. The Miao number about 2,500,000 in China and 200,000 in Southeast Asia. The Yao number more than 600,000 in China and more than 100,000 to the south. Both derive from the Yangtze Valley region and, in the case of the Yao, probably from the mountains along the east coast of China. They appear to have been recognized by the Chinese as ethnic units for over 2,000 years. Both are distributed for the most part in small enclaves sometimes no larger than a village, although there are also larger settlements. The People's Republic of China has recognized a number of Yao autonomous counties (*hsien*), and an autonomous special administrative district (*chou*) has been set aside for the Miao in Hunan Province, as well as two autonomous regions in Kweichow Province. The sociopolitical fragmentation of the Miao and the Yao has apparently been caused by their countless attempts to escape domination and assimilation by the Chinese. The last independent Miao group disappeared at the end of the last Miao rebellion in 1870. Both Miao and Yao have drifted southward, and now both groups are found as far south as Thailand.

Ethnic and language groups in Taiwan

The original inhabitants of Taiwan (Formosa) were Austronesian (Malayo-Polynesian) speakers, but, within the last 300 years, after the establishment of trading posts on the island by the Dutch, the Austronesian speakers have been gradually pushed back into the mountains, in part by Hakka Chinese from Kwangtung Province but mostly by Minnan (Amoy) Chinese from Fukien Province, directly across the Formosa Strait. There are now about 12,000,000 Taiwanese. The majority speak one of several dialects of the Fukienese languages, a Sinitic tongue. A minority speak Hakka, another Sinitic language. Many mainlanders in Taiwan speak Mandarin Chinese. Within the last 25 years many Chinese have come to identify with the family, associational, and professional ties that they have established on Taiwan. As a result they and especially their children have come to associate more with Taiwan than with China.

Japanese is a composite speech in which Austronesian was the earliest ingredient. A later Altaic influence came to overlay Austronesian forms, and many Chinese words have subsequently been borrowed.

Korean linguistic affiliations seem to parallel those of Japan but with different emphasis. Altaic, specifically Tungusic, linguistic influences are very strong, and cultural influences from the north and east have been more prominent. The Chinese, for example, conquered Korea and established military colonies in the 1st century BC, one such outpost lasting until the 4th century AD.

The dominance of China. By definition the peoples of East Asia turn toward Chinese culture but with varying degrees of ambivalence. Perhaps the Koreans, Manchus, and Minchia have been the more assiduous students. One can contrast the attitudes of these nationalities with the open defiance and antagonistic acculturation maintained by the independent Lolo of the Ta-liang Shan and the belief of the Japanese from the 10th century on that they should be treated as equals rather than clients by the Chinese. On the other hand, such groups as the Miao, Yao, and some Lolo speakers lost their ability to control their affairs to any large extent beyond the village level, thus tending to accept the Chinese great tradition. In early China may be seen an approximation of the feudal system of Europe. Men who held political power and an authoritative position were overlords and not simply bureaucrats. The political structure was that of a lineage state; that is, it was considered that everyone, or at least everyone of importance, within the state was related. Ideally, therefore, a vassal was not only a subordinate—a client—but a relative as well. The lord should be a more direct descendant, a member of a senior generation, or in some way more closely related to the founder of the line than the vassal. If the kinship relationship between two men who wished to establish a vassal and lord relationship was not close enough, it appears that genealogical charters could be altered to fit social and political needs. The regularized system of interstate relationship, called tribute in the literature, between China and other countries was modelled upon a system of exchange between patron and client that existed in feudal China. According to the world view by which the tribute system operated, there was only one true universal culture—that of the Chinese. The tribute system was the means of emphasizing this fact. It consisted of a number of ceremonial acts, the most famous of which was the full kowtow, in which the ambassador from the foreign court prostrated himself full length in front of the emperor or the latter's representative. He thus expressed not only submission and subservience in military and civil affairs but also obsequious deference in cultural, ceremonial, and ethical matters. The tribute system was a means of carrying on diplomacy between the dominant power—that is, the "Middle Kingdom"—and other less equal powers and civilizations. Tribute was mostly an exchange of gifts, the Chinese often giving more in value than they received. The important element was the bringing of the various peoples together under the common umbrella of customary law and ritual, or attitudes toward virtue. The adoption of the Chinese ideographic system, calendar, Classical literature and art, court ceremonies, methods of government and law, and even dress and music were further aspects of the Chinese cultural hegemony.

The tribute system

The crucial period for the development of China and also East Asia was after the fall of the Han dynasty, about AD 220. Han society was comparable to Rome in its general complexity of organization and in its decline into equally fragmented pieces. Yet a central power was to reappear in the 7th century. The reasons for this revival were several, but the most important was that although the barbarian areas, especially those that threatened China, could fight well and at times conquer China, they never emulated it to the same extent that the Western barbarians emulated Rome.

There is some agreement that the pre-modernization periods in East Asia can be called "traditional" ("classical" has a different connotation and should refer to a period preceding the traditional). The traditional period has lasted a long time, not without change but with essentially the same types of social structures. In China the traditional period began during the T'ang dynasty; that is, during the 7th century AD. In Korea it began with the Yi dynasty in 1392 and in Japan with the Tokugawa shogunate in 1603.

TRADITIONAL SOCIAL STRUCTURES

It would seem that the peoples of East Asia originally had much the same type of social organization but that each group has developed a somewhat different world view.

Kinship patterns. The common bases upon which the luxuriant growths of East Asian social structure grew

are few in number and relatively simple. One is the tendency to maintain extended patrilocal families; that is, for sons to bring their wives to live within the same household or, if not, at least close enough for all descendants to form a single social, economic, and ceremonial unit during the lifetime of the father and very often the mother. Due to family or sometimes circumstances of wider importance, it may not be practical or even considered desirable for sons to live and work together, but almost always one of the children will be on hand to care for the aged parents. Sometimes, if there are no sons, a man will marry into the family, the husband of a daughter living with his wife's family.

Whether it is a woman or man who marries in, the effect seems to be the same. The spouse, or his or her children, tends to establish an identity for inheritance and descent through residence in the house into which they marry or into which they are born.

Main characteristics of the kinship system

Another basic element of East Asian social organization is the ego-centred kinship system. In such a system an individual does not place himself within a kinship group by reference to a group in which he has membership but rather calculates the distance of each relative from himself. He is thus the centre of the kin group, and those too far on the periphery cease to be relatives.

This ego-centred system has two forms. One is the kindred form, the type of kinship system found in the West, in which relatives on both the mother's and father's side are equally considered as kin. The second form may be regarded as an asymmetrical extension of the kindred form. This is the patrilineal segmentary lineage, which emphasizes the relationship between the parent and child on the father's side of the family. The line of descent from grandson to great-grandfather is thus given prominence.

Characteristic of the segmentary lineage is a tendency for residence to equal kinship affiliation. Thus, most of those who live within the same village or encampment are believed to be related. Members may move out to form colonies, however, and in this way lose their original identity. Other individuals and even families move into the residential unit, and in time they or their descendants are accepted as relatives. Within any residential area, however, there is a core group of old families, so to speak, toward whom the others gravitate and claim relationship of some sort.

The last basic element of East Asian social organization is ancestor worship, especially of one's patrilineal ancestors. Shamanistic religious practices often related to ancestor worship are prominent (see below *Traditional belief and aesthetic patterns*).

Apparently most of Europe and northern Asia at one time maintained a social organization of the type depicted above. It is also found in northern and eastern Africa. East Asia is exceptional because not only have many of the features of this model been maintained until recently, even down to the present, but because they were also accompanied by the rise of a centralized state.

Sociopolitical organizations. As stated above, Chinese civilization began as a lineage state (one in which political subordinates were ideally relatives of inferior rank in the lineage) and one in which the patrilineal segment of a lineage was of particular importance. Japanese political structure was also a political system tending toward a state based upon the segmentary lineage. It is almost impossible to maintain a strong centralized system of government along with a segmentary lineage social organization because forces for centralization are countered by those for segmentation. In China this "familial feudalism" came to an end with the Ch'in dynasty (221 BC), when a bureaucratic, authoritative system of government was introduced for all China. Although China subsequently became fragmented, indeed for a time became a feudal society, it never reverted to the lineage state as a form of government.

Japan entered into its bureaucratic period under the impact of Chinese influence, which was at its height during the Taika reform era beginning in 645. By the 11th century, however, during the Fujiwara period, local family-centred warrior bands held Japan in de facto control. With the rise to power of Minamoto Yoritomo (died 1199), the welding into a national state of local centres of power based on residence and descent groups reached its climax.

Korean sociopolitical organization managed to combine a number of seemingly conflicting factors as late as the 12th century: a bureaucratic structure, in part oriented around a Chinese-like civil service examination system, combined with a very class-conscious society in which local power rested largely in the hands of aristocratic estate holders. The residents on these estates—slaves, serfs, and nobles—were all united by common genealogical charters. Unlike Shang dynasty China, however, these lineage estates did not integrate to form a lineage state. Linguistic evidence for medieval Korean social organization can be found in the use of place-names along with patronymics. There are, for example, 84 place-names that qualify the Kim surname.

The traditional social structure in all three nations is similar in one respect: although segmentary lineages continued to exist, they were unable to dominate and determine the organization of the state. Nor can these be called feudal societies.

Significance of the tax system

Taxation and tax reforms and their relation to land tenure were important factors in traditional Chinese society. Reforms were initiated by the Northern Wei dynasty, which controlled North China from AD 386–534. At first, the reforms consisted of limitations to the amount of land any individual could control and of qualifications on inheritance rights. During the T'ang dynasty (618–907) this system was changed to a direct and, as compared to the past, heavy tax on land. The emphasis shifted from taxing each person equally, as in a poll tax, to a tax on resources. As a result, large estates apparently were broken up into small, independently owned farms and relatively small landlord-owned estates.

A second factor of great importance in shaping Chinese traditional society was the commercialization and urban orientation that developed in China. The percentage of persons living in urban centres in China even today is small, but by at least the Ming dynasty (1368–1644) and probably already by the Sung (906–1279) the influence of city life upon the nation was very strong.

Gentry society. This period in Chinese history is usually referred to as that of a "gentry society," a term of considerable ambiguity. On the one hand, one can speak of the scholar gentry or, more accurately, the degree-holding gentry—those called *shen-shih* in Chinese. Such individuals were granted a special legal as well as social status because of their success in the examination system. Some few members of this group, by continuing up the degree ladder, received bureaucratic appointments. These may be called the bureaucratic scholar gentry. Then there were others who, because of their position as landlords, may be termed landlord gentry.

To understand traditional Chinese society one should translate gentry simply as important and influential persons and then attempt to understand in what manner their pre-eminence was obtained and by what means their influence was exerted. Government service, the examination system, education, landed wealth, wealth in general, tenantry, and social mobility can best be examined as interrelating within a system of government, as well as of society. The summit of the system was the Imperial court supported by a minute elitist bureaucracy. The court and civil service system were organized as though the government was an autocratic, although benevolent, despotism. In a formal sense this was true. There was little an individual could do to counter the will of the central government if he met with its full displeasure. It is not fully understood how the theoretical or formal structure of the government, which can be deduced from examining old statutes, actually operated. It is, however, evident that the government of the various dynasties depended upon a client–patron system of structured relationships and on informal government to maintain stability in the countryside.

By late Ch'ing (1644–1911) and Republican times this relationship was called *kan-ch'ing*. To have good *kan-ch'ing* is to have a sense of well-being, a feeling of being at ease, especially in relationships between parties of unequal status who are not kinsmen. Those who have good *kan-ch'ing* are in a position to help each other rather than to compete with each other. In other words, it is a personalization of otherwise contractual relationships.

The personalization of contractual relationships

Landlord–tenant relations. Despite the superficially despotic central government, the landlord was primarily dependent upon the goodwill of the tenant if he was to get his rent. It is true that, should the tenant refuse to pay the rent, the landlord could ask for help from the magistrate, but such aid, in the short run at least, might prove to be very costly, as the landlord would be saddled with all court costs besides having to satisfy those greedy lower officials upon whose goodwill he had made himself dependent. Thus it was better for both parties, tenant and landlord, to keep the central government at a distance—especially military officials. The tenant, of course, normally paid the rent. For him not to do so and present no excuse would be tantamount to rejecting the landlord's right to the land. But the actual amount to be paid was open to negotiation. If drought, flood, too much rain at the wrong time of year, insect plagues, or other factors adversely affected the harvest, it was the landlord's obligation to remit as much of the rent as necessary for the tenant to live. The tenant was in a better position to know the actual growing conditions and the real condition of the harvest. If good *kan-ch'ing* existed, the landlord would not press overly for the rent, and the tenant would be fairly honest about paying it in good years.

The lack of security in rural areas meant that good relations between landlord and villager were necessary to protect the landlord against bandits. In an area in which the gentry were well respected, they were able to maintain an effective militia (mostly composed of villagers) for the defense of the village and their own property. But if the villagers hated the landlord, residents of the rural area where he lived might offer him no protection against bandits coming from a neighbouring area or might simply attack him themselves.

More symbolic contributions made by tenants to the landlord consisted of gifts of food and produce presented at festivals. During rites of passage (at birth, marriage, death, etc.) in the landlord's house, tenants as well as freeholders would contribute labour. The landlord would make monetary contributions to his neighbours when they needed help. Tenant children often worked as domestics in the "big house," and sometimes a landlord would take a tenant girl to be his "little wife" (second, subordinate spouse). The tenant was courteous to the landlord, calling him "master" or "elder."

In addition to forgiving rents at times of distress to the tenant who fulfilled his obligations, the landlord acted as an intermediary between the rural area and the functionaries of the central government. He had the poise, education, and background that made it possible for him to argue the case for an accused villager or attempt to have the tax rate adjusted or obtain a *pai-lou* ("memorial") in honour of a faithful widow or earnest local historian. It was also expected of landlords to obtain financing for bridges, schools, temples, and other semi-public buildings. With the aid of the village headman, the landlord organized the maintenance of public works by means of corvée labour (labour exacted in lieu of taxes). At the village level this was probably more like a series of days of cooperative community effort than unrewarded drudgery. This unofficial body of village headman and landlord was also responsible for morality in the community. They often helped to work out a compromise in a dispute or even acted as judges. During the Ch'ing dynasty they were responsible for bimonthly public readings of the emperor K'ang-hsi's "Sacred Edict" (*Sheng yü*):

The "Sacred Edict" of K'ang-hsi

> Be filial and respect the social relationships, be frugal and diligent, esteem scholarship and eschew unorthodoxy, be law abiding and pay your taxes.

Sometimes local children were taught along with the children of the "big house" by a tutor, or a school was established elsewhere for the neighbourhood, usually at the Classical (Confucian) temple. These illustrations indicate only some of the functions of the client–patron system of government.

The burdens of this system lay initially upon the tenant but tended to drain the resources of the landlord. It is difficult to imagine a landlord maintaining good *kan-ch'ing* and making a great deal of profit from his landholdings. But, by investing in urban-based enterprises, such as pawnshops, grain shops (in which a surplus could be sold at times of greatest demand), and small industries, the gentry could recoup its losses.

It was difficult to become wealthy through the ownership of land alone and thereby to acquire gentry status because of the rules of equal inheritance by all the male heirs. Wealth was often initially acquired in the cities or, if acquired in the countryside, frequently by such dubious means as banditry. Later this wealth was transferred to land both for economic security and for social prestige.

Families and lineages. The extended families of the "big house" were complex organizations including often only remotely related individuals seeking patronage. The peasant families, on the other hand, tended to be small, approximating a nuclear family (parents and children), although the large, extended pattern was the ideal. For many the cyclical joint (nuclear-extended) family corresponded closest with reality. This pattern, which is a basic feature of East Asian social organization, assumes the dissolution of the extended family after the death of the parents. To the individual the pattern is cyclical, as he is born into a household composed of grandparents and their married sons, which breaks up into nuclear households upon the death of the grandparents. As sons mature it is recreated, only to dissolve with the father's death.

In South China, especially in the provinces of Kwangtung, Kwangsi, and Fukien, the client–patron relationship was solidified by the continued power of segmentary lineages, the *tsu*. In Taiwan large lineage organizations were rare. Most individuals of Chinese descent resident on the island maintained only shallow lineage organizations and remembrances of ancestors.

The kindred form of kinship organization was an element within Chinese and thus Taiwanese kinship organization, but it was not as important for the Chinese as it was for the Koreans and certainly not as important as it was for the Japanese.

Korean Yi dynasty society developed a gentry similar to that of China, but, while in China the importance of the gentry lay in their function as community leaders in villages where they owned only a small percentage of the land, in Korea the gentry (known in Korea as *yangban*) owned most of the land. Koreans possessed a stronger class consciousness, and land ownership was limited mostly to the bureaucratic class.

In recent times at least, the Koreans have tended to practice primogeniture rather than equal inheritance by all sons. The joint family described for the Chinese has thus not been common for the Koreans, although the eldest son, after receiving his inheritance, is responsible to some extent for the welfare of his younger male siblings. The result is a weakly united extended family, a family that does not live together but still feels responsible for its members. The system of kinship terminology indicated by Korean terms of address is much like that of western Europe. It indicates the importance of the nuclear family and bilateral (paternal and maternal) kindred, while the Chinese terms of address indicate an emphasis on patrilocal residence. Other systems of kinship terminology in Korea show the importance of patrilineal ties, as well as the former presence of segmentary lineages.

Tokugawa Japan (1603–1867) was a highly bureaucratic state working within a feudal framework. During this time there were probably as many civil servants in Japan as there were in all of China at the same period, despite the difference in size and population. Admittance

to the bureaucracy was limited to the former warrior class, Samurai or *bushi*, who were placed on stipends in times of peace and whose caste position was protected by law.

Because of the exercise in Japan at this time of tighter political controls, especially vigilance by the Tokugawa and daimyo (hereditary feudal lord) for signs of disloyalty, which might be punished by confiscation of land, there was less need for a client–patron system to emerge, although the Japanese form of the segmentary lineage, the *dozuku*, only gradually declined in importance. A client–patron relationship existed naturally between the daimyo-executive and *bushi*-bureaucrat, but this relation varied from area to area. It tended to be thought of more in terms of formal obligations and efficiency rather than as one based on personalities. While in China there had been a personalization of contractual relationships, in Japan there was a ritualization and formalization, if not to say contractualization, of personal relations.

Socio-economic change in Tokugawa Japan

The Tokugawa period was one of increasing urbanization and commercialization. There was a development of small industries and an improvement of agricultural techniques, based in part upon specialization and the partial commercialization of agriculture. It became more profitable to work the land in small nuclear family groups now that farm management demanded more care and a growing demand for labour existed in the urban centres. As a consequence, the nuclear family came to be the dominant form in rural Japan. The position of the nuclear family in traditional Japanese society was also strengthened by the gradual emergence of a pattern of primogeniture. Primogeniture is relatively less painful in Japan because of the respect given adopted sons-in-law, who often are the younger brothers who did not inherit the estate into which they were born but whose children inherit their wives' estates.

The other groups covered in this article (except the independent Lolo) were dominated by or integrated into the sociopolitical organizations of other East Asian groups or cultures during the traditional period.

The Hui-hui, for example, are very similar in social and familial form to the Chinese, differing only in those aspects in which religion has been influential. One finds in China Chinese-Islāmic communities existing as compact segregated enclaves, focussing on a single mosque. There is more community spirit than among the Chinese, and the Islāmic minister, *chiao-chang*, is also the leader of the community.

The situation of the independent Lolo of the Ta-liang Shan is complex because of the interrelation between caste, class, and lineage affiliation. Only about one-tenth of the population of the Ta-liang Shan were Mosu or Black Lolos—that is, the upper caste of "pure" Lolos. The sociopolitical organization of the Mosu was the segmentary lineage with confederations, the latter continually rearranging because of feuding over "subjects," household attendants, and slaves. The tripartite grouping into subject or White Lolo, attendant, and slave was the result of contact with Chinese. Slaves were recently captured Chinese who after several generations came to regard themselves as Lolo and became household retainers. Their master then would permit them to become White Lolo with the status of subject. Members of the lower caste were apparently not integrated as kin with the Black Lolo but formed their own patrilineages. The relations between Black Lolo and subjects and retainers were superficially relaxed and egalitarian. They ate the same food, slept in the same house, and observed the same rules of hospitality. One might say that the greatest concern of a Black Lolo was for the welfare of his subject, because, if he acted wisely, kindly, and generously, he could attract followers. This became, of course, a point of discord between himself and other Black Lolos, as the men he might attract already had ties as subjects, attendants, or slaves with other Black Lolo.

Socialization and education. East Asian traditional society was dominated by middle-aged men and women. Within the joint family it was the wife—a former daughter-in-law and later a mother-in-law—whose voice was paramount. In the outside world the middle-aged man directed affairs after years of apprenticeship. The transitions from one stage of life to the next were all gradual, except for retirement. Adulthood was not achieved by passing some initiation rite, taking a head, or getting married—and certainly not by reaching a certain age—but only by acting responsibly. Retirement marked a sharp break: within a short time a powerful and authoritative adult might be converted into a gentle grandparent.

Children were closely integrated into the household. In China, Korea, and Japan especially it was believed that they were never able to repay the debt to their parents, and thus they strove to succeed and by this means win parental approval. This was especially true of brothers who had to cooperate in the joint family but who were also competing individually for parental approval.

TRADITIONAL ECONOMIC LIFE

Settlement patterns and housing. There are basically two house types in East Asia. One type is exemplified in its simplest form by the Ainu hut. Uprights support a ridgepole connected by rafters to the corners. Reed matting is used both for walls and roofing, as well as for flooring. The essential point is that the uprights, not the walls, support the roof. The other type may be exemplified by the Lolo house, which is constructed of wooden planks that, together with uprights, support the roof. The roof is made of planks held down by stones.

The North Chinese house is fundamentally the Ainu hut with elaborations. Large pillars may replace the simple uprights of the Ainu, fired bricks the mat walls, and tiles the mat roof, but the plan of construction remains the same. It is possible for an entire wall of a Chinese house to fall away without affecting the stability of the remaining sections. This is also the traditional house type of the Manchus, Hui-hui, Minchia, Koreans, Taiwanese, Miao, and Yao. Significant elaborations include the construction of a raised sleeping platform heated by flues from the stove. The Koreans prefer a heated floor instead. The house may be enclosed within a courtyard among Manchus, Chinese, Minchia, Hui-hui, and sometimes Miao and Yao. Or a smooth, hardened earth area, a *matang*, may be found in front of the house, as among the Koreans.

The Japanese house may be seen as a highly original synthesis of basic Ainu hut and Lolo house. Uprights are used, not necessarily pillars, so that the walls carry some of the weight. The mat flooring again suggests the Ainu type.

In the rural areas, houses may be grouped in tight clusters or as isolated farmsteads. By and large the Chinese, Manchus, Minchia, Koreans, Ainu, and Hui-hui live in tightly clustered settlements, while the other peoples have both. On Taiwan the Chinese-derived population tends to live more often in isolated farmsteads reminiscent of the settlement patterns of the United States Middle West.

Agriculture and trade. Every one of these societies is to some extent dependent upon agriculture. The Ainu have perhaps been mostly dependent upon fishing, gathering, capturing falcons for sale, trapping, and hunting—especially to obtain trade goods from the Japanese.

Most Chinese, Minchia, Koreans, Taiwanese, Hui-hui, and Japanese practiced a labour-intensive/land-scarce type of agriculture during the traditional period in which the primary beast of burden was man.

For South China, Korea, Japan, Taiwan, and among the Minchia rice is the dominant crop. The traditional method of growing rice requires the use of a water buffalo for preparing the soil, in addition to tremendous amounts of human energy for transplanting, weeding, and harvesting. In order to grow paddy, or wet rice, the farmer must have more control over his water supply than nature generally assures. To satisfy this need, countless small irrigation systems have been constructed throughout East Asia. Only some of the marginally arable land of the Hui-hui and adjacent regions in China's Northwest are totally dependent on irrigation. Here wa-

terwheels, placed along the riverbank and canals, are used.

The Miao, Yao, Manchus, and Lolo made more use of animals and undomesticated plants. The Lolo depended as much on pastoralism as on agriculture. The Manchus definitely depended primarily upon agriculture, but at nearly every point a beast of burden assisted man in working the soil. Although the Manchu today grow the same crops as the Chinese farmers of the North China Plain (maize, kaoliang, wheat, oats, millet, and buckwheat), their fields are worked by oxen or horses. Goods are transported in carts pulled by animals. Animals are fed grain rather than left entirely to scavenge. Only in the kitchen garden does Manchu agriculture resemble the intensive cultivation of the Chinese.

In all of East Asia during the traditional period a commercial and monetary economy was manifest. Farmers produced more than was necessary for subsistence, selling their surplus to buy goods at a market or to pay taxes and rents or repay loans. It is difficult to arrange the traditional economies of East Asia along a scale, but certainly by the beginning of the 19th century Japan was the most commercialized and industrialized. The power of the Chinese gentry and the centralized state, always jealous of their prerogatives, stifled industrial development in China. The same was apparently the case in Korea, whereas Japan's postfeudal society was in this respect more like that of Europe.

Degrees of economic development prior to modernization

TRADITIONAL BELIEF AND AESTHETIC PATTERNS

The syncretic religions found throughout the Far East developed through the interweaving of several belief systems. Ancient contributions were shamanism—that is, belief in an unseen world of gods, demons, and ancestral spirits responsive only to the shaman, or priest—and a belief in an impersonal supernatural force. In anthropological literature this force is often called *mana*, but in the Orient the term used is *tao*, the "way." This force has two aspects, an active and a passive, in Chinese known as *yang* and *yin*, respectively (see CHINESE PHILOSOPHY; TAOISM). Perhaps such beliefs derive from the areas to the south, but such a conceptualization of nature could also have derived from the philosophical underpinning of shamanism. A third ancient element is ancestor worship. Important later ingredients have been Buddhism and, in Korea, Christianity, which has been closely associated with Korean nationalism.

Features of East Asian shamanism

Twentieth-century Tungus (including Manchu) shamanism is probably as close to the ancient shamanistic foundation of East Asian beliefs as can still be found. There is a tendency for a shaman to represent his own lineage, although a shaman does not have to limit his services to his kin group. A feature of shamanistic practice is the séance, in which the shaman sends one of his souls out to meet with spirit helpers whose job it is to induce the lost soul, or fraction of a soul, of a patient to return. The séance demands both control and ecstasy. It is a dangerous occupation, psychologically demanding. In one variation, the shaman, instead of sending out one of his souls, becomes "possessed" by the spirit he has contacted. Much of the popular religious Taoism of China uses shamanistic séances of the latter type. Sometimes, a priest—that is, a person primarily concerned with ritual and doctrine rather than with personalized contact with spirits—is prominent, as in Japanese Shintō.

In religious terms *yang* is decidedly better than *yin*. Chinese saints such as Kuang Ti (supposedly a general who lived during the period of the Three Kingdoms, about the 3rd century after Christ) had an abundance of *yang*. Graveyard trees, the ghosts of those who died in childbirth, or those without male heirs have too much *yin*. The latter, called *kuei* in Chinese, supposedly caused much of the misfortune in traditional China. It therefore behooves people to propitiate the *kuei* at the same time that they take care of their own ancestral spirits. If the *kuei* cannot be placated by offerings made at crossroads or by a special festival celebrated at midsummer, then they may hopefully be frightened away by "hot noise," a literal translation of the Chinese word for happiness, with firecrackers, red-coloured paper, and by chanting Classical literature.

The three-part soul of one's own ancestor requires care after death lest it become a *kuei*. Generally, one's own ancestors are remembered by burning incense at the family altar. Ancestor worship is very ancient among the Chinese and probably among some of the other peoples in Asia, but it apparently became important in Japan only after the importation of Chinese culture. Before that time the Japanese worshipped only the deceased founder of the lineage. The reverence bestowed upon the emperor may be seen as deriving from this custom.

The social and intellectual life of the peoples of East Asia has affected their interpretation of the nature of religion. The Chinese learned gentleman has tended to be an agnostic, whereas his Japanese counterpart is generally a Buddhist of the Zen sect. In China and Korea there has been both a Confucian activism and a Taoist passivism. In Japan, on the other hand, Zen encouraged its *bushi* adherents to find their way within the world rather than by withdrawing to some lonely and beautiful spot, as in the Taoist ideal.

Aesthetically the Chinese gentry and their Japanese counterparts expressed themselves along similar lines. Fundamental to their visual art is the skill perfected in practicing calligraphy with brush and ink stone. The novel, a literary form dependent on a "middle class" having leisure time and an interest in details of personality rather than simply in characters of epic proportion, developed much earlier in both China and Japan than it did in the West. Stylized operatic theatrical productions, the *Ching-hsi* of China and the Nō of Japan, were enjoyed by the literati but were in form and content simply the most polished of a series of musical theatrical productions found throughout the area in the form of shadow plays, puppet shows, and tales of itinerant storytellers. It is in pornography that a difference may be found, the Japanese celebrating an exuberant phallicism, the Chinese being more sensual and playful.

MODERN DEVELOPMENTS

For the peoples of East Asia the 20th century has been a time of quickening change. The Taiwanese have emerged as a distinct ethnic group and nation, whereas the Manchus, once the rulers of China, have become eclipsed. By the time of the fall of the Ch'ing dynasty in 1911, most Manchus had become so Sinified that they were simply absorbed into the Chinese population, though some pockets of Manchus (the Bannermen) who had developed a strong sense of national identity and who resisted absorption by the Chinese remained. The establishment and sponsorship in Manchuria (Northeastern Provinces) of Manchukuo by the Japanese in 1932 gave such groups a respite. Now three generations removed from the fall of the Ch'ing dynasty and one from the unification of China under the Communists, there is probably little left of the Manchus as a distinct people.

The Ainu of Hokkaido have in a sense been fighting a losing battle against the better organized Japanese since the 1st millennium of the Christian Era. The Ainu, until Russian penetration of the Far East, were valued by the Japanese as a market. The Russian advance led to closer Japanese control over the Ainu and, after the Meiji Restoration (1868), to much closer supervision of Ainu life. The Ainu were encouraged to become sedentary farmers rather than moving on from plot to plot. This often led to their neglect of fishing and other traditional occupations. Large numbers of Japanese have since settled on Hokkaido, which has led to intermarriage, and for over 100 years now the Ainu have been encouraged to become successful within the framework of modern Japan. Despite discrimination by some Japanese, especially up to the time of World War II, the Ainu have accepted assimilation into Japanese society. To what extent the old ways will continue to be observed by some families cannot be ascertained, but as a distinct people the Ainu may soon disappear except in the ethnographic record.

The fate of the Minchia was sealed much earlier, in the Yüan dynasty (1279–1368), when Kublai Khan con-

quered the Nan Chao state. The Minchia were encouraged to become Chinese literati, and they have since then competed for Chinese honours with even greater fervour than the Chinese themselves. They achieved a high measure of success in Chinese society so that over the centuries they have become very Sinified. At the present time no political, social, or cultural situation of a nature that would slow the Minchia's rapid assimilation into the Chinese population seems likely to come into being.

Ethnic awareness of the Muslim Hui-hui in China

One might assume that the Hui-hui are also on the way to losing their distinct identity, but in fact the victory of the atheistic Communist Chinese has heightened the ethnic awareness of the Islāmic Hui-hui, who have maintained their religious bonds. During the last quarter of the 19th century they were the victims of extreme religious persecution, in the course of which millions of them were killed. Now only tolerance and a real end of discrimination by the Chinese will lessen the Hui-hui's resistance to being assimilated. They have apparently been allowed to play a part as a nominally autonomous group by the Chinese Communists.

In one sense the Ta-liang Shan (independent) Lolo have created one of the more successful counter-cultures to the Chinese. They have maintained their independence and identity during 2,000 years of Chinese pressure. During this time they were able to elaborate a social and ceremonial organization of their own and to develop a non-Chinese and non-alphabetic writing system. But also during the years, other Lolo groups, closely related to the independent Lolo in speech and culture yet living outside the mountain fastness of the Ta-liang Shan and under Chinese jurisdiction, have increased in number until there are about 3,000,000 of them, not including the Nakhi, Lisu, Lahu, and Akha. But there are only some 500,000 independent Lolo left: Chinese control is obviously gaining.

The so-called acephalous political organization (*i.e.*, lacking a governing head or chief) of the Lolo, Miao, Yao, and other groups in southern and southwestern China has given them certain advantages. The primary advantage lay in the inability of the Chinese to be done with them by one decisive battle or campaign. But it has proved a disadvantage as well, as it has left them unable to deal with the gradual encroachment of the Chinese onto their lands, first as individuals, later as officials. Only by enslaving the Chinese and destroying their settlements were the Lolo along the Szechwan–Yunnan border able to hold their own. Once deprived of the strength to carry out such drastic measures and forced to deal with the powerful government of the People's Republic of China, the Lolo, like the other non-Chinese peoples of southern and southwestern China, will probably find within a generation or two that all that remains of their ethnic uniqueness are some folk-art motifs and a few officially sponsored folk festivals.

Paradoxically, the 30,000,000 non-Chinese of southern and southwestern China have been able to maintain their own culture and language for thousands of years; yet, now that a government of China exists that pays special attention to them and that is sometimes sympathetic to them, they are likely to become totally acculturated. The reason for this is that they live scattered in small enclaves among the Chinese population.

Relations between the Taiwanese and the "mainlanders"

As pointed out already, the Taiwanese control most aspects of their lives and, through their domination of the provincial government, the careers of many "mainlanders" on the island. The latter are attempting to re-Sinify the Taiwanese by teaching Mandarin Chinese in the schools, by the cultural-restorations movement exemplified by the building of a beautiful new national museum, and by other government services and programs. But the fact that the Taiwanese own the land and control the resources, plus their greater numbers, suggests a different direction of development. If Taiwan is allowed to settle its own affairs, it is more likely that the Taiwanese will absorb the "mainlanders" than vice versa.

China and the West. Traditional East Asian culture, based on the tribute system and the respect for Chinese intellectual values, ended when it proved impossible to ignore the West and when the West would not agree to be just a somewhat different type of barbarian to be incorporated into the established order. Had the demands of the West been only those of imperialistic barbarians, they could have been dealt with in the classical manner. As it was, the dominant powers of the Far East had to see themselves as students instead of teachers. To accept this meant the destruction of the mythology underpinning the tribute system. The Westerners refused to kowtow and insisted on recognition at the national level. They defeated the Chinese militarily but did not thereupon attempt to conquer China and set up a new dynasty. Within a short time China lost suzerainty over Korea, over the Tungus on the northern watershed of the Amur, over the Khalkha Mongols, the Tibetans, the Vietnamese, the Ryukyuians, the people of Tanna Tuva, and the majority of Kazakhs and Kirgiz.

The response of the Manchu court to this situation was an attempt at antagonistic acculturation; that is, an attempt at learning the technology of the West without accepting Western values or allowing any changes in Chinese social, political, or economic organization. This response allowed the court to survive during the initial stages of the revolutionary period, which began in China partly because of the weakness of the court and its foreign origin but also because of a growing awareness that the gentry system was inadequate to supply services felt to be essential to a modern state. The use of modern arms at first enabled the court to put down rebellion, but by the 20th century the buildup of foreign mercantile and industrial centres in the major coastal cities and the activity of Western missionaries in the interior had awakened a growing desire for modernization and a reassertion of China's identity. It was only natural that the original leaders in the anti-Ch'ing movement should have come from those areas in closest contact with the West. The government tried to meet their demands by changing from the Classical system of education to one stressing Western thought, by allowing the development of industry, and even by accepting the idea of a constitutional monarchy—in fact, abandoning the earlier attempt at antagonistic acculturation. But the anti-Manchu sentiment that had been released was too strong to halt the fall of the Ch'ing dynasty in 1911.

China from the fall of the Manchus until 1950 found itself bound by a number of severe contradictions. Those who had given the revolution intellectual force stressed individualism, Western intellectualism, science, universal education, democracy, national reconstruction, and an improvement in the peoples' livelihood, as well as other liberal and popular measures. These measures were all suited to the needs of the times. During previous periods of Chinese history, such as the Ch'in (221–206 BC) and the Sui (AD 581–618), the Chinese had been quite able to rework their institutions drastically. The new reformers, however, had no real power base in the countryside. Their strength lay in the Western-influenced treaty ports and was suspect to the majority of Chinese. Those who soon came to have real power, the warlords who from 1912 to 1949 controlled most of China independently of the central government, did not understand the nature of the changes that were needed. Most of the warlords had abandoned Classical ideals, it is true, but they had not replaced them with those of the West. In fact, they were primarily opportunists or chauvinistic nationalists. The head of the Kuomintang, Chiang Kai-shek, reflected the desires of the nation to reconcile the different factions, and he might have been successful in doing so had the Japanese not sought to prevent the emergence of a modern China.

In some areas modernization did occur. There was limited industrialization; a socially conscious literary movement exemplified especially by the *pai-hua* (vernacular-language) movement led by Hu Shih and the bitter essayist Lu Hsün; the building of railroads and motor roads; the organization of one of the more efficient postal services in the world; and a nationwide, although not compulsory, school system. But the basic problem was that the leaders lacked the power to deal with the patron–

Breakdown of traditional relationships

client relationship that had held the traditional society together. As the warlords of China increased services, as industrialization continued, as classical principles well adapted to the maintenance of good *kan-ch'ing* were abandoned in favour of individualism, and, most importantly, as the old-fashioned gentry lost their ability to intercede for the welfare of the community, the traditional institutions became means of exploiting the farmers. This was the case because, as the power of the government increased, the restraint on the landlord that had made it essential that he keep the respect and goodwill of his neighbours and tenants was removed. The government gave the landlord protection from bandits of whatever derivation and assured the collection of rents. It became no longer necessary for the landlord to maintain a good standing in the community in which he owned land. In the area near major cities in which this process had evolved furthest, landlords, now often urban industrialists, divorced themselves entirely from the problems of the land and appointed an estate manager who collected a set amount of rent and kept whatever else he could squeeze out of the farmers.

The client–patron system had functioned amazingly well in traditional China. Few such holistic systems, encompassing political, educational, artistic, social, ethical, and economic goals, have lasted so long and with such vigour. Its major weakness—its lack of consistent service (in regard to the provision of regular admittance to schools, for example) and justice—was also a major virtue, as it accompanied a government that lay lightly upon the citizenry. But it became impossible to retain only a part of the system—namely, privileges for the gentry and nepotism in government. These were not destroyed until the Chinese Communist Party had fled to the countryside to lead a revolution in the classical Chinese manner.

The Communists' main thrust was a reorganization of society from the village level upward, with the cooperation of all "progressive" elements in an attempt to do away with "feudalism." This involved the elimination of vestiges of the client–patron system, along with many other associated traditional values, such as the hierarchical position of men in Chinese family life. Emphasis was placed upon the services individuals could offer the community and state regardless of the status of the person and his connections (*kuan-hsi*) or how those of higher rank felt about him (*kan-ch'ing*). In summary, the personalized, traditional society was considered exploitive and inefficient. Thus, the old lines of structural personalization were discarded and new ones established, such as farm cooperatives, women's clubs, literary movements, and anti-Japanese militia and crop improvement committees.

Non-Communist East Asia. Korea became gradually weaker under the Yi dynasty (1392–1910). The Yangban (gentry) took over once public lands and then did not pay taxes. To make up for the deficit the freeholders were taxed more heavily. They could not afford the taxes and lost the land, which thereupon passed into the hands of the bureaucratic landlord class. When famine occurred the central government had no reserves to alleviate the situation. Meanwhile, the intelligentsia, unaware of the real peril, indulged themselves in factional disputes more serious perhaps than those that had contributed to the fall of the Ming dynasty in China (1368–1644). The West largely bypassed Korea, which remained oriented along traditional lines after China had long been opened up to Western trade, missionizing, and interference and after the Meiji Restoration had set Japan on a path of modernization and industrialization. The Yi dynasty would probably have been swept aside in due time by a Christian- or Tonghak- (a syncretic revitalistic religious response to the West including elements of both Eastern religion and Christianity) led rebellion if Japan had not invaded Korea first and conquered it.

The Japanese conquest increased the Korean sense of national unity and in many ways modernized the country. South Korea is one of the more industrialized states in Asia, and a land-reform program is in effect.

Japanese society at the beginning of the 19th century had the strengths of feudal values interwoven into a bureaucratic system of government. Its people were ready, however, to discard the remnants of the feudal class system. It seemed better to be a prosperous businessman than a penniless samurai.

Recent social changes in Japan

In recent times some novel social forms have emerged in Japan, in the development of which the Japanese have been able to draw upon a number of value systems. One of these has been Bushido, the hierarchical and authoritarian conception of the role and status of the *bushi* service bureaucrat, based on a mixture of classical Chinese, feudal Japanese, and bureaucratic values. With its strong emphasis on loyalty in a vertically ordered system of two-person reciprocity, this way of the samurai is one of the important values that have shaped modern Japan.

Another hierarchically structured model dominant in some parts of Japan has been the *dōzoku*, the combination of kith and kin with landlord and tenant. In other areas, relations between landlord and tenant, although influenced by the *dōzoku* model, tended toward abuse by the landlord after a strong central government had assured his rights. This led to the growth of unrest and militancy among the rural population, finally suppressed in the 1930s.

The paternalistic model of organization in Japanese industry, known as *oyabun-kobun*, is probably inspired by both the Bushido system of values and the *dōzoku* (segmentary lineage). The result has been security for the worker, full employment, and ordered advancement with a minimum of division along class lines and in the professions.

The third organizational model has been drawn from the local kindred kinship group and the cooperating local group, the *buraku* (hamlet). These local units have become especially important since a land reform that occurred after World War II brought an end to landlordism in rural Japan. These two sources have provided the inspiration for egalitarianism and a desire for consensus found among the Japanese.

The populace is also divided into associational frames of reference such as industrial firms and villages. Differences in rank and status are important, but not class, except for former outcaste groups such as the Eta. Economically, the system probably works as well if not better than that of the West, as it does not tend to cause social alienation.

The interaction of these various concepts in the political arena has been a mixed blessing. Perhaps some unique adjustment—allowing for efficiency in government, the desire for consensus, and homage to rank while furthering egalitarianism—will be achieved in the future.

In the 20th century East Asia as a cultural entity, as defined and described at the beginning of this article, was badly shaken by the collapse of traditional China. At times it has seemed that Japan was destined to take China's place, but Japan's defeat in 1945 changed this. Up to the early 1970s China has directed its attention to its Inner Asian frontiers and to internal social, cultural, and economic change, while Japan, South Korea, and Taiwan have concentrated more on industrialization and on developing their international trade. Given a continuation of present circumstances, one might predict the end of East Asia as a psychological reality within another generation.

BIBLIOGRAPHY. GEORGE B. CRESSEY, *Asia's Lands and Peoples*, 3rd ed. (1963); and JOSEPH E. SPENCER, *Asia East by South*, 2nd ed. (1971), are comprehensive cultural geographies. The best balanced and most thorough history of East Asia is EDWIN O. REISCHAUER and JOHN K. FAIRBANK, *A History of East Asian Civilization*, vol. 1, *East Asia: The Great Tradition* (1961) and vol. 2, *East Asia: The Modern Transformation* (1965). The archaeological report *Kwang-chih Chang, The Archaeology of Ancient China* (1963), is comprehensive but unduly polemical concerning the possibility of Chinese borrowing from the West during the Bronze Age. HERRLEE G. CREEL, *The Birth of China* (1954), depicts the early civilization in China. FREDERICK W. MOTE, *Intellectual Foundations of China* (1971), is a concise, audacious, scholarly book on the classical period of East

Asian philosophy. The short pocketbook by PETER DUUS, *Feudalism in Japan* (1969), is a good introduction to the distinctive features of Japanese sociopolitical development. There are no works equivalent to this for other areas in East Asia, but KARL A. WITTFOGEL, *Oriental Despotism* (1957), and WOLFRAM EBERHARD, *Conquerors and Rulers*, 2nd rev. ed. (1965), are of interest. JOHN K. FAIRBANK (ed.), *The Chinese World Order: Traditional China's Foreign Relations* (1968), contains a discussion of China's tribute system. Opinions concerning Japanese prehistory are found in ROBERT J. SMITH and RICHARD K. BEARDSLEY (eds.), *Japanese Culture: Its Development and Characteristics* (1962). FRANK M. LEBAR, GERALD C. HICKEY, and JOHN K. MUSGRAVE, *Ethnic Groups of Mainland Southeast Asia* (1964), is a comprehensive work concerning not only the peoples of southern and southwestern China but also those of Southeast Asia. The statements contained within it are based upon an evaluation of various primary sources. The contradictory opinions are passed on to the reader along with an annotated working bibliography. The monograph does not cover the non-Chinese peoples of most of Szechwan Province. For this area the reader should consult HENRI M. D'OLLONE, *Mission d'Ollone 1906–1909*, 2nd ed. (1911; Eng. trans., *In Forbidden China: The d'Ollone Mission, 1906–1909*, 1912); DAVID C. GRAHAM, "The Customs of the Ch'uan Miao," and "The Ceremonies of the Ch'uan Miao," *Journal of the West China Border Research Society*, Series A, 9:13–119 (1937), and "The Customs of the Ch'iang," *ibid.*, 14:65–99 (1942). For Taiwan GEORGE W. BARCLAY, *Colonial Development and Population in Taiwan* (1954, reprinted 1972), is good; also FRANK B. BESSAC, "Cult-unit and Ethnic Unit: Processes and Symbolism," in the American Ethnological Society *Proceedings of the 1967 Annual Spring Meeting*, pp. 58–71 (1968). A sociological and ethnographic approach to the question of gentry society in China is treated in HSIAO-T'UNG FEI and CHIH-I CHANG, *Earthbound China: A Study of Rural Economy in Yunnan*, rev. ed. (1945); and HSIAO-T'UNG FEI, "Peasantry and Gentry: An Interpretation of Chinese Social Structure and Its Changes," *Am. J. Sociology*, 52:1–17 (1946); FRANCIS L.K. HSU, *Under the Ancestors' Shadow: Kinship, Personality, and Social Mobility in China* (1948, reprinted 1971); YUNG-TEH CHOW, *Social Mobility in China* (1966); MORTON H. FRIED, *Fabric of Chinese Society* (1953, reprinted 1969); and FRANK B. BESSAC, "Change in the Meaning of Kanch'ing in Taiwan Due to the Land Reform," *Proceedings of the VIIIth International Congress of Anthropological and Ethnological Science*, vol. 2, pp. 245–247 (1968). The influence of the segmentary lineage upon Chinese life is analyzed by MAURICE FREEDMAN in *Lineage Organization in Southeastern China* (1958, corr. reprint 1965). RICHARD K. BEARDSLEY, JOHN W. HALL, and ROBERT E. WARD, *Village Japan* (1959), is a well-balanced discussion of rural Japan. HARUMI BEFU, *Japan: An Anthropological Introduction* (1971), attempts to sketch the totality of Japanese life including introductory chapters on prehistory and the traditional period. Ethnographies or reports that reflect the revolution in China are C.S. CHEN, *Rural People's Communes in Lien-Chiang* (1969); ISABEL and DAVID CROOK, *Revolution in a Chinese Village: Ten Mile Inn* (1959); JAN MYRDAL, *Rapport från kinesisk* (1963; Eng. trans., *Report from a Chinese Village*, 1965); CH'ING-K'UN YANG, *A Chinese Village in Early Communist Transition* (1959). Chen's work is an analysis of captured documents kept by local cadre men. Myrdal's report is largely the presentation of notes from interviews with cadres and those committed to the revolution. The Crooks attempt to reconstruct the revolution on the basis of interviews. Yang writes as a trained observer. Concerning religion and the arts, S.M. SHIROKOGOROV, *Psychomental Complex of the Tungus* (1935), is a classic discussion of Siberian and East Asian shamanism; and *Mai-mai Sze, The Tao of Painting: A Study of the Ritual Disposition of Chinese Painting, with a Translation of the Chieh Tzu Yüan Hua Chuan; or, Mustard Seed Garden Manual of Painting, 1679–1701*, 2nd ed., 2 vol. (1963), is an excellent basic text on traditional East Asian art. RYUSAKU TSUNODA, WILLIAM THEODORE DE BARY, and DONALD KEENE (eds.), *Sources of the Japanese Tradition* (1958; 2-vol. text ed., 1964), is a comprehensive introduction to Japanese humanism. EVELYN MCCUNE, *The Arts of Korea* (1962), provides a collection of prints in part portraying not simply Korean but also East Asian styles in general. MICHAEL SULLIVAN, *Chinese Art in the Twentieth Century* (1959), brings the subject up to date. CH'ING-K'UN YANG, *Religion in Chinese Society: A Study of Contemporary Social Functions of Religion and Some of Their Historical Factors* (1961), combines good factual knowledge with sociological interpretations. Finally, JAMES B. CROWLEY (ed.), *Modern East Asia: Essays in Interpretation* (1970), is an eclectic but helpful and thoughtful collection.

(F.B.B.)

Easter Island

Easter Island (Isla de Pascua), a Chilean dependency in the eastern Pacific Ocean, famous for its giant stone statues, represents the easternmost outpost of the Polynesian island world. It stands in isolation 1,200 miles (1,900 kilometres) east of lonely Pitcairn Island and 2,300 miles (3,700 kilometres) west of Chile. Forming a triangle 14 miles long by 7 miles wide, the island has an area of 45 square miles (117 square kilometres); its highest point is 1,969 feet (600 metres) above sea level. To its original inhabitants the island is known as Rapanui (Great Rapa) or Te Pito te Henua (Navel of the World); its Dutch discoverers named it Paaseiland (Easter Island) in memory of their own day of arrival. Its mixed population, predominantly of Polynesian blood, numbers slightly over 1,000; almost all live in the village of Hanga-Roa on the sheltered west coast. The island is administered as part of the province of Valparaíso, Chile (for coverage of the region as a whole, see PACIFIC ISLANDS; and PACIFIC OCEAN; for its history, see OCEANIA, HISTORY OF).

The landscape. The small and hilly island is not part of a sunken landmass but is a typical oceanic high island formed by a series of separate underwater volcanic eruptions. Geological and oceanographic evidence shows that no perceptible emergence or submergence of the island's coastline has taken place since the last fall in sea level, which occurred less than 10,000 years ago. Three extinct volcanoes chiefly composed of tuff (a rock formed of compacted volcanic fragments) and joined by their own lava flows give the island its characteristic triangular shape. Parasitic tuff craters and cones (*i.e.*, craters and cones formed on the side of, or near, volcanoes after the original vent has become plugged up) are interspersed in the landscape, which is otherwise dominated by eroded lava fields. Most of these fields are rugged and are often thickly packed with both large and small lumps of cellular and tuffaceous lava that is either black or rusty in colour. Soil is sparse and suitable for extensive cultivation mainly in the Hanga-Roa and Mataveri area in the southwest, at Vaihu and on the plain southwest of the volcano Rano Raraku, and on the prehistorically cleared Poike peninsula in the eastern corner of the island. The arid landscape has no rivers or streams, but rain collects in the partly bog-covered crater lakes of the volcanoes Rano Kao, Rano Raraku, and Rano Aroi. Water from the extremely deep crater of Rano Kao, which is about 1,000 yards (one kilometre) wide, is piped to Hanga-Roa. The coast is formed by soft, eroded, ashy cliffs, with a vertical drop of about 500 to 1,000 feet; the cliffs are intercepted by long stretches of low, hard, and rugged lava formations. There is no natural harbour, but anchorage is found off Hanga-Roa on the west coast; off Vinapu and Hotu-Iti on the south coast; and off Anakena and in the Bahía la Perouse on the north coast. Notable among the few small offshore islets are Motu-Nui, Motu-Iti, and Motu-Kaokao (which figured in a local bird cult) near the southwest cape. The only real sandy beach is at Anakena; most other beaches are of gravel. Caves abound, many consisting of subterranean rooms joined by narrow tunnels extending far into the lava beds.

Anchorages

Climate. The climate is subtropical, with an average annual temperature of about 72° F (22° C), varying between about 77° F (25° C) in January and 70° F (21° C) in August. Average annual precipitation is about 40 inches, but with considerable annual variation. September is the driest month, and the heaviest rainfall occurs in June and July. Winds in June and August are irregular; during the rest of the year trade winds from the east and southeast are dominant. From September through March the Peru (or Humboldt) Current, which has an average temperature of about 70° F (21° C), flows against the island.

A subtropical climate

Vegetation. Indigenous plants and animals are few. The toromiro tree is the only wild tree and the Carolina wolfberry the only shrub; the vegetation is predominantly herbaceous. Analysis of pollen deposits has revealed that other trees and shrubs, among them a palm, were formerly present on the island until exterminated by extensive fires occurring at the time of aboriginal human

settlement. Today only 31 wild flowering plants, 14 ferns, and 14 mosses are reported. Grass and small ferns dominate the barren landscape, whereas the boggy crater lakes are thickly covered by two imported American species, the totora reed (an important building material) and *Polygonum acuminatum* (a medicinal plant). A number of cultivated species of plants was also introduced partly from America and partly from Polynesia before the arrival of Europeans; of these the principal species was the sweet potato, which was cultivated in extensive plantations and formed the staple diet. Bottle gourds, sugarcane, bananas, taro, yams, chili peppers, and two useful trees (*i.e.*, the Asiatic paper mulberry, with bark used for cloth manufacture, and the American *Triumfetta semitriloba*, with bark used for rope making) were of aboriginal importation, as also probably were the husk-tomato, a small variety of pineapple, and the coconut. The Chilean government has begun a program of reforestation.

Animal life. Before the arrival of human beings, the only vertebrates were either fish or seabirds capable of long flights. The animal life on land was otherwise restricted to a very few species of isopods (an order of crustaceans, which are aquatic animals with shells), spiders, insects, worms, a snail, and a centipede. Vast quantities of flies, large cockroaches, and a small scorpion were introduced recently. A small, long-legged chicken reported to lay blue eggs was introduced in pre-European times but later interbred with European varieties. The aboriginal edible Polynesian rat was subsequently replaced by larger European species. Sheep, horses, cattle, and pigs were introduced into the islanders' economy by the missionaries who established themselves ashore in 1866. Sheep have been especially numerous since a French sheep rancher began commercial ranching in 1870. A large wild cat, living in caves, is of unknown introduction. A Chilean partridge, a quail, and a small hawk have been added to the wildlife since 1880. Sea turtles and seals that formerly visited the island are now rare curiosities, but crayfish and various coastal and deep-sea fishes abound around the coast.

The inhabitants. The island population represents the easternmost settlement of a basically Polynesian subgroup, although non-Polynesian physical and linguistic traits have been noted among them since the time of European discovery. The original Rapanui vocabulary has been lost except for some mixed Polynesian and non-Polynesian words recorded before the Tahitian dialect was introduced to the decimated population by missionaries in 1864. Today Spanish is generally spoken. The islanders consistently divide themselves into descendants of two distinct ethnic groups, the "Long-Ears" from South America, and the "Short-Ears" from Polynesia (see below); intermarriage is nevertheless common, and an influx of foreign blood has become increasingly dominant in recent years. Whereas the aboriginal economy was based on the cultivation of sweet potato, chicken raising, and coastal fishing, the islanders are at present in the process of shifting to a cash economy following their employment at hourly wages after an airfield was opened at Mataveri, where a large settlement of Chilean labourers, technicians, and civil servants has been established.

History. The first European to discover Easter Island was the Dutch admiral Jacob Roggeveen, who paid it a single day's visit in 1722. He and his crew found a racially mixed population worshipping the sun in front of huge standing statues. An expedition dispatched by the Spanish viceroy of Peru rediscovered the island in 1770. The Spanish spent four days ashore and reported a population of 3,000 persons of extremely mixed physical appearance. A civil war seems to have raged on the island before the arrival of the English navigator Captain Cook in 1774; a decimated, poverty-stricken Polynesian population of only about 600 or 700 men and less than 30 women was found by the Englishmen, who also observed that the large statues were no longer venerated, most of them having been deliberately overthrown. In 1786 the French navigator Jean-François de Galaup, comte de La Pérouse arrived and tried in vain to introduce domestic animals. At the beginning of the 19th century a number of slave raiders, attempting to use slave labour in the establishment of seal-hunting colonies elsewhere in the Pacific, visited Easter Island, causing subsequent visitors to receive a hostile reception. A major slave raid launched from Peru in 1862, followed by smallpox epidemics, reduced the population to 111 before, at the end of the last century, it began to increase once more. In 1864 Brother Eugène Eyraud, a French Catholic missionary, became the first foreigner to settle on the island; as a result, the population became converted to Christianity by 1868. Settlers from Tahiti began to raise sheep in 1870. In 1888 the island was annexed by Chile, which leased nearly all its territory for sheep raising; in 1954 the Chilean navy administration took over the sheep range. Recently a civilian governor was appointed by the Chilean government. The island is now experiencing rapid change. There is a commercial airport, and a tourist hotel has been opened near the Hanga-Piko anchorage on the west coast. There is also a school, a hospital, and a leper station.

The stone statues

Archaeology. The lonely island is famous for its gigantic stone statues, of which there are more than 600, and for the ruins of giant stone walls, which show masterly construction. Archaeological surveys were carried out in 1914 and in 1934; archaeological excavations were undertaken in 1955. The excavations revealed that three distinct cultural periods are identifiable on the island. The early period is characterized by a solar observatory, megalithic walls of exquisitely fitted stone masonry astronomically oriented to the annual movements of the sun, and a heterogeneous variety of small- to medium-sized stone statues in human form. The middle period is characterized by a single conventionalized type of long-eared and legless busts erected on top of stepped stone platforms known as *ahu*. Existing early-period temple terraces were destroyed and rebuilt with no regard to solar orientation but for the sole purpose of supporting the tremendous weight of the giant stone statues of the new type. The sizes of the statues made were increased until they reached stupendous dimensions; the slim and lofty busts also had huge cylindrical *pukao* (topknots) of red tuff placed on top of their slender heads. Most middle period statues range from about 10 to 20 feet in height, but the biggest among those formerly standing on top of an *ahu* was about 32 feet tall, consisted of a single block weighing about 82 tons, and had a *pukao* of about 11 tons balanced on its apex. The largest statue still standing partly buried in the deep silt below the quarries is about 37 feet tall, and the largest unfinished one with its back attached to the rock is about 68 feet tall. Early-period sculptures were variously made of basalt (a fine-grained, dark-coloured rock solidified from a molten state), scoria (volcanic slag), and tuff, but the middle-period sculptures were all quarried from the special yellow-gray tuff found in the crater walls of Rano Raraku. Inside and outside the crater bowl numerous unfinished statues and thousands of crude stone picks are scattered about, bearing witness to a sudden interruption of the sculptors' work. The unfinished images show that each statue had its front and sides completed to a polish before the back was detached from the bedrock. The image was then slid away to be raised at random in the rubble below the quarries to have the back finished before being moved to some distant *ahu*. Deep oval eye cavities and red topknots were added only after the monument had been finally erected. From one to a dozen statues would stand in row on a single *ahu*, always facing inland. Experiments made by the islanders in 1955 to 1956 showed that 180 persons could pull a medium-sized statue over the ground. Twelve islanders were able to lift a 25-ton statue about ten feet off the ground and to tilt it on end on top of an *ahu;* this work took 18 days with no tools other than two wooden logs that were used as levers. Stones of all sizes were wedged under the statue one by one to form a slowly rising cairn in order to lift the giant monoliths upright. Traditions, supported by archaeology, suggest that the images represented important personalities who were deified after death. The three early period types of statue lack counterparts in Oceania, but have close affinities to

Unfinished carvings

the three specialized forms of monuments erected by an unknown people in the highlands of South America during the Tiahuanaco Period, which occurred in the 1st millennium AD. The middle-period busts, however, clearly evolved from a local prototype and have no counterpart elsewhere. Also peculiar to the middle period was a non-Polynesian bird cult with attendant birdman rites that survived into the third, or late, period. Its ceremonial centre was the village of Orongo on top of Rano Kao, which consisted of stone houses of a non-Polynesian type with roof vaults built as false arches. These houses and contiguous circular masonry dwellings with roof entrances are characteristic of the two earlier archaeological periods on the island; while unknown elsewhere in Polynesia they are common in the adjacent area of South America. The late-period Easter Islanders dwelt in boat-shaped pole-and-thatch houses, or in caves. This period was marked by internal wars, general destruction, and cultural decadence. The *mataa*, or obsidian spearpoint, which was mass-produced, is the characteristic artifact of this period. Wood carving and small crude stone figurines replaced monumental art. Written wooden tablets covered with incised signs (called *rongo-rongo*) placed in boustrophedon (method of writing in which the lines run alternately from right to left and from left to right) were copied from earlier specimens merely for ritual purposes; their proper reading was forgotten, and—despite many claims—modern attempts at deciphering them have failed. During this period art treasures were hidden in secret family caves, while the upright *ahu* images were successively overthrown. Silt from the abandoned quarries descended to the chests of the blind and unfinished busts standing at the foot of the volcano, rendering their overthrow impossible and thus securing for posterity the eyeless heads that have given the island its fame.

The wars of the late period

Tradition insists that destruction began after a period of peaceful coexistence between two people of different culture and language—the Long-Ears and the Short-Ears. The latter, tired of toiling for the former, all but exterminated them in a pyre along an ancient defense ditch at Poike on the far northeastern coast. Carbon dating and genealogies concur in placing this event and the beginning of the late period at about AD 1680. The middle period is estimated to have begun in about AD 1100. The original construction of the artificial Poike ditch, according to carbon dating, took place in about AD 380, but original settlement may well have occurred earlier.

Prospects for the future. The non-Polynesian vestiges on Easter Island have given rise to much speculation. A unanimous resolution adopted by 3,000 scientists at the Tenth Pacific Science Congress in 1961 affirmed that South America, as well as Southeast Asia, is a major source area for the peoples and cultures of the Pacific islands; Easter Island is the most apparent example of this cultural amalgamation. Today island life is increasingly assimilating Chilean influences. Easter Island is also gaining a new importance as a stepping-stone in modern aviation routes east and west across the South Pacific. The introduction of tourism, as well as the replanting of the forests, is likely to signal the opening of an entirely new era in local life.

GONZALEZ, *The Voyage of Captain Don Felipe Gonzalez in the Ship of the San Lorenzo . . . to Easter Island in 1770–71, ibid.*, two annotated syntheses of logs and documents; W.J. THOMSON, *Te Pito te Henua, or Easter Island* (1889), an early survey of the archaeology and culture; K. ROUTLEDGE, *The Mystery of Easter Island* (1919), a popular account of the first major expedition; A. METRAUX, *Ethnology of Easter Island* (1940), a comprehensive ethnological survey; P.S. ENGLERT, *La Tierra de Hotu Matua* (1948), observations by a resident missionary; THOR HEYERDAHL, *Aku-Aku: The Secret of Easter Island* (1958), an account of the adventures of an archaeological expedition, "The Statues of Easter Island" and "The Composite Culture of Easter Island," in *Sea Routes to Polynesia* (1968), a popular report on present knowledge of pre-European activities, and edited with E.N. FERDON, JR., *Report of the Norwegian Archaeological Expedition to Easter Island and the East Pacific*, 2 vol. (1961–65), a general introduction to the island, followed by illustrated reports by a team of American and Norwegian archaeologists.

(Th.H.)

Eastern Arctic Cultures

In the eastern, or Eurasian, Arctic there is a diversity of ethnic groups distributed across the great expanses of land from northern Scandinavia to the Asian shores of the Bering Sea. All occupy either one or both of the principal ecological zones of the north, the far northern tundra (cold, desert lowland) and the taiga (swampy, coniferous forest). This bizonal distribution of people stands in marked contrast to the ethnic distribution in North America, where traditionally the tundra was occupied only by Eskimo (including Aleut) and the taiga only by Indians. (For a map of the distribution of eastern and western Arctic ethnic groups, see ARCTIC PEOPLES AND CULTURES.)

PEOPLES AND LANGUAGES

The major cultural groups of the eastern Arctic may conveniently be classed into five categories: (1) the Lapp and Komi, living in far northern Europe; (2) the Samoyed, Ostyak, and Mansi, living west and east of the Ural Mountains; (3) the Tungus, living across much of Northern Siberia; (4) the Yakut, of Northeastern Siberia; and (5) the Paleosiberians (Yukaghir, Koryak, Chukchi, Kamchadal, Asiatic Eskimo, Aleut, and Ket), most of whom live in Far Eastern Siberia and on the Bering shores. It should be noted that some of these peoples, living in the Soviet Union, have adopted new names (cited below).

Lapp, Komi, and Samoyed

Of northern Finno-Ugrian-speaking peoples west of the Urals, the Lapp and the Komi are the only recognizable entities remaining today. The Lapp comprise small minorities in northern Norway, Sweden, Finland, and on the Kola Peninsula in Russia; their total population is 35,000; their principal livelihoods are fishing and reindeer breeding. The Komi, by contrast, are concentrated in northern Russia between the Pechora and Vychegda rivers (southeast of the White Sea); most are agriculturalists, but in the northern part of their area, some are hunters and reindeer breeders. They number 280,000. The Komi Autonomous Soviet Socialist Republic has been in existence since 1936.

East of the Komi and on both sides of the Urals lies the traditional area of the Samoyed peoples. Their languages and those of the Finno-Ugrians make up the Uralian language stock. The majority of the Samoyed are located along the coast and lower reaches of rivers between the White Sea and Taymyr, where they have adapted to a tundra ecology based principally on reindeer breeding, hunting, and fishing. These groups are now known in the Soviet Union as the Nentsy (20,000 persons), Nganasan (1,000), and Entsy (500). A fourth group of Samoyed, the Selkup (4,000 persons), is settled well to the south of the others and along the upper reaches of the Ob River. Their nearest non-Russian neighbours are two Finno-Ugrian-speaking peoples who moved to the east of the Urals: the Ostyak, now called the Khanty, who number 20,000, and the Vogul, now called the Mansi, who number 6,000. Earlier, the Selkup, Khanty, and Mansi were hunters and fishers only; later, they adopted reindeer breeding (Nentsy influence), fur trapping (tsarist influence), and fur farming (Soviet influence).

Tungus and Yakut

The Siberian home of most of the Tungus people, who speak what is called a Tunguso-Manchurian language, is in the vast area between the Yenisey and Lena rivers, to the east and south of the Samoyed. These Tungus are now known in the Soviet Union as Evenki; they number 25,000 persons. Like the Nentsy, they are traditionally reindeer breeders, hunters, and fishers principally; Evenki culture, however, is adapted to the taiga and not to the tundra. There are also the Dolgan, a small Tungus group of 4,000 persons, living north of the Evenki and in the southern part of Taymyr in ecologic conditions approaching those of Samoyed groups. The Dolgan are now Yakut speakers. One group of Siberian Tungus lives well to the east of the Yenisey–Lena area; they are the 9,000 Lamut,

now called Even, whose culture and language are held to be closely similar to the Evenki. The dispersed Tungus, or Evenki, population continues east and south beyond the Lena River to the Sea of Okhotsk and the Amur River; it is particularly in these areas that Evenki culture becomes blended with Yakut.

The Yakut, who number 230,000 persons, are distributed on both sides of the middle basin of the Lena and on to the Kolyma River in Northeastern Siberia. The Yakut speak a Turkic language, and it and the Tungus-Manchurian language of the Tungus combine to form the so-called Altaic linguistic family. Only a minority of the Yakut are reindeer breeders, most of them having kept cattle and horses; agriculture and hunting also are traditional practices. The Yakut may have moved northward into their present locations not long before the Russians arrived in that part of Siberia in the 17th century; local groups of other ethnic populations (besides Dolgan and Evenki, also Yukaghir and even Russian settlers) were assimilated by the Yakut, who have always had an important role as traders. Since 1922 there has been a Yakut Autonomous Soviet Socialist Republic.

Paleosiberians

Far Eastern Siberia is the ancestral home of some of the different peoples known collectively as Paleosiberians. They do not form a linguistic group of their own, and, unlike all other Arctic peoples of the Eastern Hemisphere, they do not have linguistic affinities with peoples to the south. They appear to have been in Siberia much longer than the other peoples, who are sometimes therefore designated collectively as Neosiberians. The Yukaghir, immediately to the northeast of the Yakut, are Paleosiberians who used to practice a primitive hunting economy over wide areas of tundra. Privation, disease, and assimilation (particularly to the Even, Yakut, and Russians) have since taken a severe toll, and there are now under 500 persons who call themselves Yukaghir. Many of them are reindeer breeders, and a third of them regard Russian as their native tongue. East of the Yukaghir are the Koryak and the Chukchi, both of whom are traditionally adapted to the tundra (reindeer breeding and hunting) as well as to the sea (hunting and fishing). Both offered relatively severe opposition to the Russians, the Chukchi not becoming Russian subjects until as late as 1789. Only the Chukchi expanded their territory and numbers in historical times, however, and this was at the expense of the Koryak as well as of the Yukaghir. The Koryak number about 6,000 and the Chukchi over 11,000.

Along the Bering Sea are 1,000 Asiatic Eskimo interspersed with Chukchi settlements. There are also about 1,000 Kamchadal, now called Itelmen, along the west coast of the Kamchatka Peninsula; the economies of both peoples are marine. The languages of the Koryak, Chukchi, and Itelmen are related. Finally, there are a few hundred Russian Aleut on Commander Island off the Kamchatka coast, and far to the west there are 1,000 Ket, who are hunters, trappers, and fur farmers living along the middle reaches of the Yenisey. Both of these peoples are included among the Paleosiberians; the language of the Ket is the sole survivor of a linguistic group earlier present in the area.

TRADITIONAL CULTURE PATTERNS

Ecological and economic systems. From earliest times to the present day, the way of life of many of these peoples has centred upon the reindeer; indeed, they have had to adjust their lives to the peculiarities of the species. Important in this regard are the seasonal migrations of reindeer between tundra and taiga; their movement in herds; their seasonal preferences for certain grasses, mosses, and other fungi; their dependence upon salt; their relative helplessness—and panic—when attacked by mosquitoes and other flying insects in the summer and such predators as the wolf and wolverine in the winter. The situation has always given rise to a number of similarities in all types of reindeer economy, among the more important of which are the seasonal movements of camps and the seasonal differences in their size and composition.

There are, however, distinctive ecological and economic differences among the Arctic peoples of the Old World, relating to each of the three principal ways in which they utilize reindeer. The traditional Paleosiberian Yukaghir, for example, were simply reindeer hunters. Although they "monitored" the seasonal movements of the reindeer, they made no effort to herd the animals or to use them for transportation (the Yukaghir adopted both these practices later, however, after contact with neighbouring peoples, particularly the Even). They used decoy reindeer in the hunt and travelled on foot or ski, by dogsled (though this was never general), and by canoe or raft. Reindeer were by far their most important source of food and of skins for clothing and tent covering, so that their lack of control over the condition and movement of the herds left the Yukaghir susceptible to unpredictable periods of privation. Fishing, the hunting of other species, and berry gathering were also essential to the economy.

Reindeer hunting, breeding, and herding

Another basic way of using reindeer is represented by the many Tungus groups that partly controlled reindeer breeding as an adjunct to a basic economy of hunting and fishing in the taiga. Geldings were ridden, used as pack animals, and sometimes harnessed to sleds; females were milked, making possible various dairy products; dead reindeer were an important source of skins, bone, antler, and sinew for clothing, shelter, and simple utensils. These Tungus secured their meat, however, not from their domesticated reindeer but from wild reindeer, Asiatic red deer, and elk that they hunted. The domesticated herd was always small (herds of up to 25 reindeer per household were usual); the animals usually pastured in the vicinity of the camp, securing protection from wolves there in the winter and finding relief from the summer mosquitoes in the smudge fires provided by the camp for that purpose. These hunting and herding Tungus, it may be noted, also used dogs—as camp sentinels to warn against predators or strangers and as "pointers" in hunting small game such as sable or squirrel.

The third basic method of using reindeer was controlled breeding and herding. This was the principal or sole livelihood of several other Tungus groups (many Nentsy and Entsy and some Nganasan), of the tundra Chukchi and Koryak in Northeastern Siberia, of the northern Samoyed in Western Siberia, and of many Lapp. All these groups depended upon the herded reindeer for food, and many used dogs to shepherd the herds, which sometimes were large in number. Prestige and social status, indeed, were measured by the size of a household's herd; and competition for prestige sometimes had damaging ecological consequences: pastures would be overgrazed or aggressively expanded, or epidemics would decimate large, closely packed herds. As a result, impoverished reindeer owners would be driven to find alternative livelihoods in villages or elsewhere; some would revert to reindeer nomadism. (Today there are state-imposed regulations in both the Soviet Union and Scandinavia ameliorating such problems.) As a supplement to herding, most of these peoples pursued fishing in the summer, and they bartered extensively with urban, village, and agricultural populations.

Social systems. The peoples of the eastern Arctic have been studied and written about far less than the Eskimo of the western Arctic. In tsarist Russia and the Soviet Union, in particular, there has always been some tendency to play down any attention to national differences. Most investigations have thus depended on inferential sources. They have tried, that is, to reconstruct the social relations of certain eastern Arctic peoples by piecing together information derived from myths, legends, and other folklore that have been published. They have also tried to infer the social systems of Arctic peoples by reference to the social structures of their Turkic and Mongol neighbours and kinsmen farther south, who have been more thoroughly studied—the assumption being that the systems are probably similar.

Tribes and clans

Among all the eastern Arctic peoples, there appear to have been large territorial groups that may be called tribes—*i.e.*, clusters of communities that could act together for such common purposes as warfare and trade. One tribe could make alliances and establish systems of exchange with other tribes. Below the level of the tribe,

at least among the Neosiberians, there were probably clans, groups of people having a stricter sense of kinship. Normally, clans would be exogamous; that is, marriage within the clan would be forbidden. Further, a person's lineage within the clan would be important in determining his residence, role, and inheritance.

From the 17th century onward, however, clans—and even tribes—had to leave their traditional territories and disperse in smaller units and "mixed" kin units to search for new territories. This happened to the Tungus when they were faced with the exhaustion of reserves of fur that had to be supplied to the Russians and when they were faced with the continual encroachment of Russian settlement. The movement of Tungus groups created pressures on the territories of other neighbouring peoples; the northern movement of the Yakut had similar effects in Northeastern Siberia. The competitive expansion of grazing lands could also disrupt traditional social relations, as it apparently did among the northern Samoyed. Various demographic and economic changes, in short, could have serious social consequences. Finally, there was the political influence. The tsarist Russian government tried to consolidate the tribe–clan system and use it to administer all northern peoples, but the administrative use of tribe and clan, being a foreign idea, tended paradoxically to sever the already weakening association between kinship and territorial organization. Among most groups, therefore, the village or camp emerged as the relevant territorial and social unit in the 19th and early 20th century.

Dominance of village and camp

Village or camp enterprises of a seasonal nature generally involved each of the three principal livelihoods: reindeer breeding, hunting, and fishing. When hunting and fishing was pursued collectively, the game or catch was distributed collectively. When production was not collective, responsibilities for distribution were limited, and they were minimal or absent when furbearing animals were caught for trade with foreigners. Villages and camps (and subdivisions made within these units) claimed rights to the produce from hunting and fishing grounds usually on an annual or lifetime basis. Among reindeer breeders, herding was undertaken collectively, and rights to pasture were claimed collectively, also. The animals, however, were owned individually. The size and composition of herding camps could be adjusted at each season of the year.

In all ethnic groups, close interpersonal bonds of friendship arose between non-kinsmen within the village or camp. Kinship nevertheless remained in many ways the most important principle of interpersonal and group relations, and many privileges and obligations of kinship were recognized. Among the more onerous was the prosecution of the blood feud, a retaliatory killing and counterkilling between different kin groups that might continue for generations. Blood feuds seem to have been widespread even at the end of the 19th century, indicating that clanship was still a recognizable principle but without any territorial meaning, for villages and camps were then composed of persons from different clans.

The incidence of cross-cousin marriage, in which certain categories of first cousins were obliged to marry, remained notable among many of the eastern Arctic peoples. Practiced in conjunction with the general rule of patrilocal residence, this marriage preference had earlier supported the territorial groupings of persons in clans; the preference remained even after the development of villages and camps in which cousins remained anyway, without the compulsion of marriage. The matching of several siblings of one family with those of another and a close bond between husbands of sisters—sometimes denoted as closer than that between brothers—were prevalent among the northern Eurasians. So, too, was the injunction that a bridegroom provide several years' "service" to his father-in-law before being allowed to set up his own marital household. Common among the reindeer breeders only was the establishment of marriages through contributions of wealth (including reindeer) from both the parties (bride price from the groom, dowry from the bride). Having two or more wives was a privilege of personal rank and occurred most frequently among preeminent hunters or warriors, shamans and smiths, and well-to-do reindeer owners. These marriage practices (except those prohibited by law) persist among some contemporary Lapp groups in Scandinavia. Among the Lapp, building a herd was probably the most influential factor governing marital patterns.

In all these societies there have been strains of social and economic inequality. At the very least, the need for authority in organizing work teams promoted village or camp elders, local headmen, lead hunters, and so on; among some peoples—the Chukchi are notable—an ethic of success and of male reputation licensed the presence of "strong men" and aggressive behaviour. Intertribal warfare, fairly general though sporadic throughout northern Eurasia, led to the use of captives as slaves. Among the reindeer breeders, differential accumulation of herd capital placed some herdsmen in employer–employee relationships.

Animism and shamanism

Belief systems. Traditionally, there were broad similarities among the spiritual cultures of all the northern Eurasians. All tended toward animism—*i.e.*, a belief that everything in nature, every beast and bird, stone and earth, wind and snow, is alive with soul or spirit—and all believed in shamanism; indeed, the word shaman is of Tungus origin (*šaman*). The shaman was priest, medicine man, and prophet; that is, he directed communal sacrifices and ceremonies; he cured illnesses, and he foretold the future. He acquired his profession either by inheritance or by what might be called spontaneous calling or "election," but in any event he ordinarily had to go through initiations or trials of self-abnegation and a kind of hysteria before he acquired the ability to "see" spirits, behave like a spirit, and leave his body and travel in all cosmic regions like a spirit. It was these presumed abilities that were thought to qualify him as a healer, for the cause of illness was thought to be the straying of one's soul, and only the shaman was deemed able to search out the soul and return it to the patient's body. Siberian shamans were frequently women; male and female transvestism in shamans was common.

The shaman's power was often associated with the properties of iron, and there was a corresponding association of the profession of shaman with that of smith. The role of the smith had particular prestige among the Tungus and Yakut.

Christianity reached these peoples at different historical periods; some Lapp were converted as early as the 16th century, whereas some Chukchi probably were never converted, even before the Russian Revolution discouraged religious faith. Christianity, when it was adopted, usually came in the wake of trade with the Western world and with the West's imposition of taxes. In any event, animism and shamanism rarely died completely but became blended with Christian beliefs, rituals, and liturgy. Christian motifs, for instance, appeared in the drawings on Lapp shamans' drums; Christian crosses and crucifixes were worn together with amulets and other talismen of animistic belief.

CONTEMPORARY TRENDS

Collectivization and russification

Ethnic changes in the Soviet Union. The abolition of serfdom in 1861 brought millions of Russian peasants to Siberia in a comparatively short time; Soviet settlement, development, and industrialization during the 20th century has affected the demographic structure of Northern Siberia even more. Although it must be recognized that no non-Soviet observer has been permitted to study any of the northern peoples since the 1930s or even earlier, some historical trends and events are clearly evident. First, it can be noted that attempts to deal administratively with northern peoples began as early as 1922. Then, between 1924 and 1935, a Committee for Assistance to the Peoples of the Northern Regions (the Committee of the North) sought determinedly to bring the native peoples into the Soviet administrative structure and to establish among them "integral cooperatives," collective farms, and educational, medical, technical, and social programs. In 1925 Leningrad State University accepted the first stu-

dents from among the northern peoples, and in 1930 the Institute of Northern Peoples was established at the university with 195 pupils in attendance from 19 ethnic groups. The institute closed in 1941, but its work was continued after the war at several regional institutions. Among its principal objectives has been the training of native persons as teachers and administrators.

The editors of the monumental Soviet work *Narody Sibiri* (published 1956; Eng. trans., *The Peoples of Siberia*, 1964) stated that, "By the present time, the village soviet has become the principal local unit of Soviet administration among the peoples of the North, while the collective farm now is universally the fundamental economic unit." The progress toward this state of affairs, however, was beset by difficulties and controversies. The Committee for Assistance to the Peoples of the Northern Regions, for instance, ruled, in 1926, in favour of "clan-based native soviets," but this arrangement proved unworkable because the clan elders were not too willing to support, explain, and enforce Soviet policies. Accordingly, the native soviets were redesigned between 1929 and 1932 as territorial units at the bottom rung of the standard Soviet administrative structure; above the soviet was established the region (*rayon*) and then the district (*okrug*). The northern *okruga* were named after the dominant minority people of the region; by the end of 1932 there were nine such *okruga* of northern peoples, 82 *rayony*, and 462 soviets. Native membership in the executive committees of these *okruga* and *rayony* has varied from 33 to 97 percent.

The progress of collectivization among the northern peoples was recorded as 12 percent of households in 1931, 36 percent in 1934, 75 percent in 1940, and 97 percent in 1948. The program met its chief resistance from reindeer breeders. The problem at heart is a conflict between ideology and ecology or economics. Official Soviet ideology holds that nomadism is an unworthy way of life in a Socialist society, but this is not easily reconciled with the ecological fact that reindeer pastoralism can be conducted successfully only on a nomadic basis, for reindeer must move seasonally. These difficulties have adversely affected not only production in the Soviet reindeer industry but also recruitment to it. Lately, however, ethnographers have tried to persuade administrators and other officials that "production nomadism" is necessary and is compatible with an otherwise stable or sedentary way of life. Probably of greater significance for the future is the issue of whether northern peoples should be encouraged to join the Siberian industrial force or, on the contrary (as Soviet ethnographers seem to urge), be encouraged to remain in their traditional pursuits and to retain their traditional skills.

In education, a number of native grammars were published and used in schools in the early 1930s. The change from a Roman-based to a Cyrillic-based alphabet in 1937, however, presaged greater Russian influence. This seems to have continued, and Russian is now the lingua franca of much of the north, although the Komi and Yakut languages still appear to retain a respected status.

One of the most notable aspects of ethnic relations in the Soviet north today is its complexity. Even at the level of the village soviet, there can be polyethnic membership, and this mixture of representatives from various ethnic groups increases at the levels of the *rayon* and the *okrug*; there are polyethnic collectives such as the Nentsy–Entsy–Nganasan–Dolgan collective in the Taymyr and the Yukaghir–Lamut–Chukchi one in the northeast; Russians also sometimes belong to northern peoples' soviets and collectives. Some ethnic groups—the Yakut and the Komi—are deemed to have reached the level of "Socialist nation"; others, having national *okruga* and written languages, are perhaps progressing in that direction. But the majority are unlikely ever to achieve nationhood. It seems clear that they will either remain as minorities or disappear. Russification is the dominant trend.

The Lapp in Scandinavia. The Lapp of Norway, Sweden, and Finland today form small minorities even in the northern regions of these countries, but they are receiving greater recognition than ever before. The explanation may lie more in the changing attitudes of Scandinavians, who are becoming more tolerant of diversity, than it does in any activism on the part of the Lapp themselves. In any event, the Lapp of Sweden, for instance, have their own ombudsman, whose work is particularly concerned with the legal position of Lapp groups faced by public or private encroachments on their reindeer pastures. There are Lapp language primers, and school readers now available in each of the three countries (though by no means are all schools with Lappish-speaking children using them); and there are Lappish high schools, Lapp-language newspapers and radio programs, and Lapp-language courses in several Scandinavian universities.

Combined ethnic and national trends among the Lapp

The reindeer-breeding industry is, in general, in good condition. In Norway it is predominantly a Lappish livelihood, and in Sweden it is exclusively so (in Finland, however, the Finns predominate in most reindeer breeding localities). The nomadic way of life associated with reindeer pastoralism is becoming seriously modified, but most of the modifications either are initiated by individual households or camps (and hence vary locally) or emanate from the regional and national associations that have been formed by the reindeer owners themselves. Direct legislation by the state is less important in this process, though the indirect influence of the state—as the principal source of capital loans, subsidized housing, and infrastructure amenities—should not be minimized. Cooperatives for the purchase and marketing of reindeer products are established in many areas.

Lappish individuals and communities today, without exception, have a heightened sense of national citizenship, and all persons except the very old and perhaps the very young are conversant in the language of the country of their citizenship. Indeed, individuals who leave reindeer breeding are likely to assume a non-Lappish identity: in Sweden such persons usually join the northern industrial labour force or move to Stockholm. In Norway, where the majority of Lapp reside, most families of Lappish descent have never been involved in reindeer herding; most of them have been and are fishermen. Among these people, Lappish culture, in all its respects, is fast being replaced by Norwegian culture.

BIBLIOGRAPHY. The outstanding work of reference compiled by Soviet ethnographers is *The Peoples of Siberia*, ed. by M.G. LEVIN and L.P. POTAPOV (1964; orig. pub. in Russian, 1956). Two earlier general works that retain their importance are MARIE ANTOINETTE CZAPLICKA, *Aboriginal Siberia: A Study in Social Anthropology* (1914); and WALDEMAR JOCHELSON, *Peoples of Asiatic Russia* (1928). Siberian ethnographies are few and, for the most part, date from the turn of the century; outstanding are *The Chukchee* (1904–09) and *The Eskimo of Siberia* (1913), both by WALDEMAR BOGORAS; *The Koryak* (1905–08), *The Yukaghir and the Yukaghirized Tungus* (1910–26), and *The Yakut* (1933), all by WALDEMAR JOCHELSON. These five titles are publications of the American Museum of Natural History. An early report from the Samoyeds is KAI DONNER, *Bei den Samojeden in Sibirien* (1926; Eng. trans., *Among the Samoyed in Siberia*, 1954). The indispensable work on the Tungus is S.M. SHIROKOGOROFF, *Social Organization of the Northern Tungus* (1933, reprinted 1966); the author, however, is concerned with Tungus of the Manchurian–Chinese–Russian border area. Important reviews of aspects of the contemporary situation are TERENCE ARMSTRONG, "The Administration of Northern Peoples: The USSR," in R.ST.J. MACDONALD (ed.), *The Arctic Frontier* (1966); STEPHEN and ETHEL DUNN, "The Transformation of Economy and Culture in the Soviet North," *Arctic Anthrop.*, 1:1–28 (1963); and ETHEL DUNN, "Educating the Small Peoples of the Soviet North: The Limits of Cultural Change," *ibid.*, 5:1–31 (1968). A great deal of ethnography has been, and continues to be, written about the Lapp of Scandinavia. Two outstanding general works are BJORN COLLINDER, *The Lapps* (1949), particularly strong on the culture of the Lapps of Sweden; and ORNULV VORREN and ERNST MANKER, *Samekulturen*, 2nd ed. (1958; Eng. trans., *Lapp Life and Customs: A Survey*, 1962), an overview of all the Lapp groups of Scandinavia with particular attention to the various ecologic divisions. The contemporary situation of the Lapp in Finland is outlined in KARL NICKUL, *Report on Lapp Affairs* (1952). HARALD EIDHEIM, *Aspects of the Lappish Situation* (1971), provides a social anthropological analysis of the Lapp minority situation in Norway.

(R.P.B.P.)

Eastern Christianity, Independent Churches of

Historical and cultural importance

The Eastern Christian churches that do not recognize the authority of the pope in Rome or the ecumenical patriarch in Istanbul, such as the Syrian, Armenian, Coptic, and Ethiopian churches, are of great historical and religious importance (see also EASTERN ORTHODOXY, HISTORY OF; CHRISTIANITY BEFORE THE SCHISM OF 1054; EASTERN RITE CHURCHES). Most of them are of very ancient origin, reaching back to the subapostolic (late 1st to early 2nd centuries AD) or even to the apostolic age (1st century AD)—to the time of the first Christian communities. Syrian Christianity possesses special significance, since primitive Syrian Christianity derived its traditions not via Antioch (in Syria) and the Hellenistic (post-Alexandrian Greek) Christianity of St. Paul but directly from Palestine, taking over tenets from Palestinian (Aramaic-speaking) Christianity.

A very important access to the understanding of early Palestinian Christianity is thus opened to scholars that would otherwise be closed. Moreover, with the emergence of the Christian faith in the early Christian centuries among the Eastern peoples from Egypt to India, the Eastern churches contributed to a transformation of popular and national life and thought—by inventing alphabets, translating biblical and Christian writings, and inaugurating an era marked by national literatures and cultures. The development of many of the Eastern nations is bound up with the development of the independent Eastern churches. The profound spirituality of these churches, which was expressed in asceticism, mysticism, a deep vision of the Christian life, and a burning zeal for the missionary enterprise, reached out beyond regional boundaries and enriched the lives of other nations. The influence of their intellectual creativity also extended to Europe and to non-Christian cultures.

Yet, despite their indubitable historical and cultural significance, the history of the Eastern Christian independent churches has been relatively neglected by Western scholars. Various interests, biases, and technical problems have contributed to a dearth of knowledge of the Eastern independent churches. Western-centred views of the history of culture, such as the view of the 19th-century German philosopher G.W.F. Hegel—that the spiritual sun, unlike the physical sun, rises in the West and then radiates its light to the Eastern sphere—have contributed to this neglect, as have the difficulties in mastering the Eastern languages (Syriac, Armenian, and others). The result is that for most of these churches there is no real history beyond that of a general, sketchy survey. Historical research concerning these churches is still in a preparatory stage, since manuscript sources must first be unearthed and gathered before historical judgments based on documentary evidence can be made.

The Western approach to church history has been dominated by the study of the Western Church and hence lacks the perspective and breadth necessary to grasp all of Christianity in its fullness in thought and action. This deficiency can, in part, be rectified by increased knowledge of the Eastern branches of Christianity through more research and study.

THE WEST SYRIAN CHURCH: THE SYRIAN ORTHODOX CHURCH OF ANTIOCH

Origins in the doctrines of Monophysitism. The 5th-century Monophysite doctrine—that Christ is not in two separate natures (divine and human) but is one nature out of two natures—found a zealous following among the Syrians. The decision of the ecumenical Council of Chalcedon (451) against Monophysitism rallied a large body of Christians in Syria and adjacent areas who were against Greek dominance to support the Monophysite movement, although the towns, because of their Hellenistic elements, remained loyal to the orthodox two-nature doctrine of Christ formulated at Chalcedon. During

Distribution of independent Eastern Christian churches.

the Acacian Schism (484–519), created by the doctrinal conflict over the decision of the Council of Chalcedon between the patriarch Acacius of Constantinople and the Roman pope Felix III (483–492), the Syrian Church became Monophysite.

Severus and John bar Qursos (John of Tella)

The founder of Syrian Monophysitism was Severus, patriarch of Antioch (512–518). After a temporary victory of Severus over the exponents of orthodoxy, the situation became very critical for the Syrian Church. During the reign (518–527) of Emperor Justin I, a synod in July 518 made a decision to condemn Severus. In the following year, intensive persecution of the Monophysites swept through the Syrian patriarchate, and diocese after diocese lost its bishop. The acute shortage of clergy became a life-and-death issue for virtually every Monophysite community. At conclaves of bishops, they all refrained from ordaining priests for fear of official governmental and ecclesiastical reprisals. At this juncture, John Bar Qursos, bishop of Tella, volunteered to undertake the risk of ordaining priests without support from Constantinople. From the Persian frontiers to Armenia, Cappadocia, and Phoenicia, he encouraged, instructed, and examined candidates for ordination and performed mass ordinations. His heroic efforts soon began to show results. Depressed communities felt a quickening spirit. Candidates for ordination came to him "like a flood that is produced in a river by thick clouds" (John of Ephesus) wherever he appeared—in monasteries, on the roads, and even in the desert. The Syrian Oriental churches thus successfully withstood this first harsh test that threatened their existence.

When, under Emperor Justinian I (527–565), Pope Agapetus personally took the problem of the Syrian churches into his expert hands, the outlook for the Monophysites became bleak. The renewed persecutions brought consequences of the utmost gravity—the Syrian flock found itself once again without shepherds. When the Monophysite cause was at its lowest ebb, Ḥārith ibn Jabalah, king of the Arabs, appeared in Constantinople in 542–543, determined to create a closely knit Monophysite realm. He demanded two or three bishops from Justinian's wife, the empress Theodora, who favoured the Monophysite cause, and she complied.

The reorganization under Jacob Būrd'ānā (Baradaeus). One of the most decisive events in the history of the Monophysite movement then occurred when Patriarch Theodosius of Alexandria (536–567), a follower of the views of Severus, intoned the ceremony of episcopal consecration for two monks: Theodoros of Arabia as bishop for the Arabs (542/543–571/572) and Jacob Būrd'ānā ("garbed in a patchwork garment") as bishop of Edessa (542/543–578), which actually included all the area of the Syrians.

The number of ordinations Jacob Būrd'ānā (latinized as Baradaeus) performed in a necessarily clandestine fashion is reported to have been extremely large (100,000). Though he was pursued and had a price on his head, he was never caught by Byzantine imperial or church agents. His tireless work forged the reorganized communities into a church body, creating the national Syrian Church.

Role of monasticism in the organization of the church

In this process, a large share of credit belongs to the monastic movement that was fostered by such leaders as Rabbula of Edessa (411/412–435), John bar Qursos (519–538), and particularly by Philoxenos of Mabbug (485–523). This Syrian type of monasticism was characterized by the enthusiasm, zeal, and rigour manifested by such personages as the stylites (ascetics living on a pillar) and recluses. The huge, enthusiastic army of ascetics and monks rendered extremely important services to the work of the organization. Jacob Būrd'ānā then established the hierarchy: two metropolitans each were appointed in Asia Minor (Seleucia, in Isauria, and Taurus) and in Syria (Laodicea, Seleucia), and one for Mesopotamia (Amida). In consecrating the patriarch Sergios of Tella, Jacob filled the highest post in the ecclesiastical hierarchical structure of the Syrian Monophysites. Because of the merits of Jacob, the Syrian Monophysites after the 8th or 9th century began to call themselves Jacobites, but the designation is no longer preferred.

Developments after the Arab conquest. The Arab conquest in the 7th century was hailed by the Syrians because it freed them from the oppression and tyranny of Byzantium. Since the new situation was a blow to the Hellenistic elements in the towns, the indigenous Syrian Church benefitted. The native church began to develop its own way of life without restrictions. It expanded into northern Mesopotamia, with a centre in Mosul, where its efforts could be pursued under new conditions. The seat of the primate (called maphrian in Syriac and also catholicos) of the Orient was established in Tagrit, with Marutha (629–649) as the first maphrian. The spiritual life of the area also benefitted from the new situation. Literary works began to be produced freely, especially works on the Bible, asceticism, spirituality, and the liturgy. The liturgy of the Syrian Church is one of the oldest and richest in Christendom. The oldest collection of liturgical manuscripts in the monastery of Za'farān contains many Anaphoras (prayers of consecration in the liturgy). The Syrian Liturgy of St. James (which is still one of the forms of worship of the Syrian Church) has its roots deep in antiquity. In addition to liturgical renewal, a number of monastic communities became involved in education, literary life, and scholarly work. Scholars such as Severus Sebokht (died 666/7), Jacob of Edessa (died *c.* 708), Dionysios Tell Mahre (died 845), and later Michael the Great (died 1199) and Bar'Ebrāyā (died 1286) enabled the Syrian Church to assume leadership in theological thought in Monophysitism, a role that it retained until the end of the Middle Ages. All of this was fostered by conditions which, under the Arab rule during the dynasty of the Umayyads (661–750), were liberal and which remained tolerable under the 'Abbāsids (750–1258). During the dynasty of the 'Abbāsids, the Jacobites enjoyed an influential position at the court of the caliphs at Baghdad.

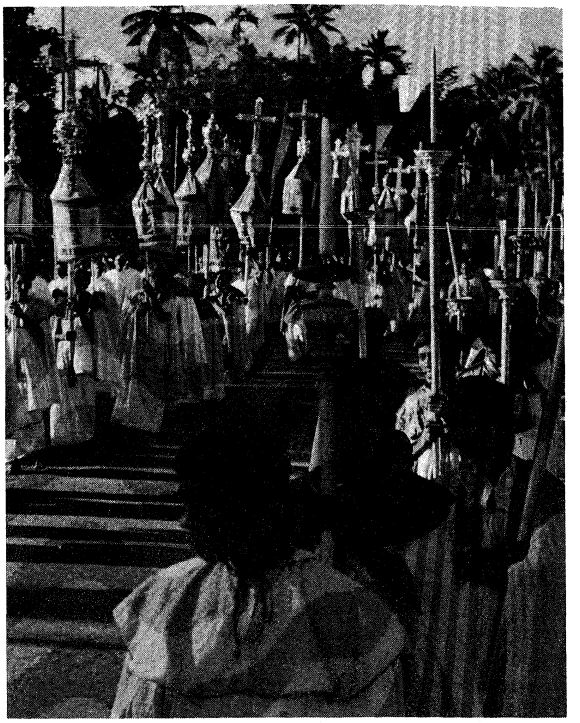
Liturgical and theological developments

In the 12th century the Jacobite Church reached its widest expansion: 20 metropolitan seats and 103 eparchies (bishoprics) in Syria, Mesopotamia, and Cyprus, with about 2,000,000 believers. The decline in importance and numbers, however, came quite rapidly. Islām took its toll by conversions that were fostered by internal disputes and strifes, including a schism (1364–94), and the catastrophes (the Mongol invasions) in the 13th and 14th centuries reduced the number of adherents; by the 17th century there were only 20 bishoprics. In the same century the Syrian Church succeeded in winning a part of the Christians of St. Thomas in Malabār (Kerala), South India, namely those who were not incorporated under the jurisdiction of Rome when the church in Malabār, which had been under the Catholicos of Seleucia–Ctesiphon, was thrown into conflict because the Roman Catholic Curia had given to the Portuguese jurisdiction over all the Christians of that area. This gain, however, was quickly balanced by the loss to Rome of a part of the Jacobites, who became Syrian Catholics. The remaining body has been known as the Syrian Orthodox church.

Modern developments. Until World War I, most members of the church lived in northern Mesopotamia, in the region of Mardin, Midyat, Diyarbakır, and Urfa (all in Turkey). These compact communities were subjected to savage persecution and massacre in 1914–18 by the Turks. Those who escaped from the persecution established communities in Syria, Lebanon, and Iraq. Today, about 80,000–90,000 Syrian Orthodox are scattered in communities in Iraq, Lebanon, Syria, Jordan, Egypt, Turkey, and the United States. Of the once flourishing communities in north Mesopotamia, Midyat is the only town that has retained its Christian character. Other Syrian Orthodox communities, except the one in Istanbul, are very small.

Modern persecutions

The patriarchal see that was located in Mardin was moved to the monastery of Za'farān, then to Mosul, Iraq, to Homs, Syria (1921), and finally established in Damascus, Syria (1959). Since 1293 all the patriarchs bear the surname Ignatios in honour of Ignatius of Antioch (the early martyred bishop). The present patriarch, Ignatios XXXIX Jacob III, rules from Damascus over 11 metropolitans and three bishops and over the Syrian Orthodox Church in Malabār. His actions toward healing a 50-



Procession of Christians of St. Thomas (Syrian Church) bearing silver crosses, Kerala, India.
Bernhard Moosbrugger

year-old rift with the church in India reached success in 1958. He has fostered education (for example, the St. Aphrem theological school at Atshaneh, Lebanon), and through his visits to the congregations in several continents strengthened the life and unity of the church.

THE EAST SYRIAN CHURCH

Origins in the doctrines of Nestorianism. The belief that there were two separate natures in Christ—the one divine and the other human—was a deep-rooted conviction in the Antiochian (Syrian) school of biblical interpretation. The movement that rallied behind this doctrine is connected with the name of Nestorius, patriarch of Constantinople (428–431), who was involved in a violent theological controversy that ended with his deposition by the Council of Ephesus (431). His adversaries were so successful that five years later Nestorius—the least besmirched figure in the whole net of ecclesiastical and political intrigues—was banished to Upper Egypt to end his life in obscurity (*c.* 451). The decrees of the Council of Ephesus, however, were not able to wipe out the opposition movement (later called Nestorianism).

After the theological settlement of 433 between the patriarchs Cyril of Alexandria (reigned 412–444) and John of Antioch (died 441/2), the bishops who could not accept this agreement were driven closer to the Christians outside the Byzantine (Orthodox) territory, namely, in Persia. This party found a centre in the Christian School of Edessa that had been founded by Syrian refugees from Persia and was under the leadership of Ibas (or Hiba; died 457), who had supported Nestorius at Ephesus. Renewed theological disputes flared up at Edessa, and due to agitation by the Monophysites, the teachers and a number of students were compelled to flee and to seek refuge in Persian territory, mainly at Nisibis. This gave another impetus to various movements to form a church independent of Antioch.

Organization of the Nestorian Church. The Persian Church in 486, at the synod of Seleucia–Ctesiphon, officially accepted the Nestorian creed, and the Nestorian Church was established under the leadership of the catholicos at Seleucia–Ctesiphon. This move was motivated by ecclesiastical and political considerations in order to dissipate Persian suspicions regarding links with Byzantium. At a synod in 612, the dogmatic position of the Nestorian Church was definitely fixed according to the formulations of Babai the Great (died after 627/8). The church rejected the condemnation of Nestorius at Ephesus and elevated him, together with Diodorus of Tarsus (died *c.* 390) and Theodore of Mopsuestia (*c.* 350–428/429), to the position of its major authorities. A vigorous church emerged and flourished, in spite of periods of persecutions under the Zoroastrian Sāsānids (226–657), until 643, developing its own way of life.

Developments after the Arab conquest. These conditions continued after the Arab conquest as long as the Umayyad dynasty lasted. Conditions changed to some degree, however, with the ʿAbbāsids. There were occasional outbursts of oppression, but the church was able to continue without any serious danger to its basic structure and concerns. Under the Islāmic caliphs, the Nestorians became spokesmen for all Christians in their empire; and under some caliphs, church leaders enjoyed a favoured position. Catholicos Timotheos I (780–823) was regarded as a protector of a considerable number of Nestorian elite: physicians, pharmacists, merchants, and scholars. The Nestorians utilized the favourable conditions to their advantage.

Ancient liturgical traditions

The Nestorian Church has retained many of its ancient traditions. The canon of the New Testament reflects an early stage in development by its exclusion of all the Catholic Epistles (those attributed to James, Peter, John, and Jude) and the Apocalypse (Revelation). The liturgy, due to the Nestorians' isolation, has preserved its very primitive character. The chief liturgies are those of Mār Addai and Mār Mari, Theodore of Mopsuestia, and Nestorius. The celebration of the Eucharist begins with the ritual of making the eucharistic bread for which the "holy leaven" has been used. The Nestorians believe that the holy leaven literally can be traced back to apostolic times. Their avoidance of pictures and icons in the churches puzzled the first visitors from the West after the Reformation and left them with the impression that the Nestorians were "Protestants of the East."

The establishment of the Nestorian Church as a reaction against the West also included a reaction against the predominance of ascetic forces, so that marriage was required even of the ecclesiastical hierarchy, thereby alienating the ascetic circles and driving them into the Monophysite fold. But in 544 the church revived its stand in favor of celibacy, thereby paving the way for reconciliation with monasticism.

Abraham of Kashkar (died 588) founded the monastery of Izlā (near Nisibis), which became a centre of reform monasticism. Under its aegis, a network of monastic communities was established. Spiritual, ascetic, and mystical literature was produced in these monastic centres that nurtured piety, education, charity, and intellectual culture.

Missionary activity

The religious zeal of the Nestorians is indicated by their missionary outreach. Through the centuries, this church became the most widespread of the Eastern Christian churches. Not only Syria and Persia but also Arabia, Media (Holvan), Khorāsān (Merv), Herat, Samarkand, and Turkistan were included in its mission field. Nestorian missionaries early reached India. The use of Syriac as the ecclesiastical language of the Christians in South India, known as the Christians of St. Thomas, indicates their origin, and for centuries they were under the jurisdiction of the catholicos in Seleucia–Ctesiphon. Remnants of Nestorian manuscripts testify to their missionary work in Chinese Turkistan and Turfan, and literary data to that in Tibet. The monument of Hsi-an (Ch'ang-an) of 781 gives a summary report of the success of Nestorianism in China. In the 13th century, various tribes of Mongols were converted to Christianity. At the beginning of the 14th century, there were ten metropolitan sees in Central Asia, developing an indigenous clergy. The missionary activity of the Nestorians indicates its tremendous spread: the catholicos in Seleucia–Ctesiphon presided over an area that covered an immense territory from Cairo to Peking.

The Nestorian churches also produced important centres of learning. The School of Nisibis supplanted the

School of Edessa as the main centre of Nestorian culture; it influenced the founding of many other schools and the development of higher education in Europe. These schools became the focuses for the cultivation of a literary life that was marked by its manifoldness and its creation of new genres. Its amplitude was marked by such names as Narsai (died 503), Babai (died after 627/8), Ḥenānā (died *c.* 610), and Ḥunain ibn Isḥāq (died 873). The Nestorians thus have secured an important position in the history of culture by transmitting to the Arabs the heritage of late antiquity in philosophy, medicine, and natural sciences.

After the 10th and 11th centuries, the Nestorian Church suffered increasing losses to Islām; the Syrian renaissance, which, however, produced such a manysided Nestorian scholar as ʿAbdīšōʿ (died 1318), was very influential before its extinction. The Mongol invasion, with its massacres and destruction under Timur (1336–1405) in 1380, nearly annihilated the Nestorian Church. A remnant escaped the destruction under Timur and found a place of refuge in the mountains of Kurdistan, where its descendants, known as Assyrian Christians, continued their existence. A union with the Roman Catholic Church in the 16th century threw their communities into an internal crisis that subsequently weakened the position of the Christians with the Muslims. As a result, the Chaldean Church was constituted, embracing the Nestorian faithful in Iraq, Iran, and Syria. (Its membership today is about 96,000.) The efforts of the present patriarch, Paul II Cheikho, are marked by lively fostering of church life, monasticism, and education as well as by endeavours toward healing of deep wounds, which have destroyed several bishoprics in the north, caused by the war between the Iraqi government and the Kurds. The vigour of the church is manifested by the expansion of church work and the establishment of several new eparchies. The Nestorians in Malabār entered into a union with Rome in 1599 and today number about 1,800,000.

The Chaldean Church

Modern developments. In the 19th century, Anglican missionaries attempted to revive the Assyrian Christians, and the Nestorian Church came under Anglo-Saxon influence. In World War I, a new tragedy struck the Assyrian Christians with their expulsion from the territory of the Kurds in the old Ottoman (Turkish) Empire. They were persecuted by the Kurds and, according to some estimates, more than a half of them died. Their hopes to found their own state collapsed, and the remnants gathered in Caucasia, Iran, Syria, and particularly in Iraq. After 1933 new bloody conflicts brought new sufferings to the Assyrian refugees. Attempts to practice full autonomy in matters of civil authority evoked most serious conflicts with the new state of Iraq, which could not tolerate a state within a state. This caused an exodus to America. Since 1940 even the patriarch, Simon XXI (from a family in which the office has been hereditary for centuries), has made his residence in the United States (San Francisco). The church has more than 80,000 believers in Iraq, in Syria about 30,000, in Iran about 20,000, in Malabār about 8,000, and in America about 25,000.

THE ARMENIAN CHURCH

Origins under Gregory the Illuminator. The Armenians look to Gregory the Illuminator (240–*c.* 325) as their apostle. Consecrated by the metropolitan of Caesarea, Cappadocia, Gregory converted King Tiridates (Trdat) III and through him introduced Christianity to Armenia (before 300). Though Christianity barely penetrated to the lower levels of Armenian society, the reputation for having established the first Christian state belongs to the Armenians. In his work, Gregory was supported by Armenians under Hellenistic as well as Syrian influence and by a contingent of Syrians. The Syrians were particularly instrumental because they introduced a zeal for monasticism as well as for evangelistic work that inspired the Armenians to carry the missionary work over into Georgia. At the beginning, all worked peacefully together, and Greek and Syriac became the ecclesiastical languages.

In 374 the Armenians rejected their dependence on the Church of Caesarea. Repudiation of Greek and Syriac, adoption of their own idiom, creation of their own alphabet, and translation of the Scriptures under Catholicos Sahak (390–441) and Mesrob (Mashtots; died 439/440) all created conditions to weld together a religion, culture, and nationality. The Armenians were not represented at the Council of Ephesus (431), but when the acts were sent to Armenia, they were approved by Sahak. They also were not represented at the Council of Chalcedon (451) because at that time they were involved in mortal struggle with the Persians, and it was not before the end of these battles in 484 that they could resume contact with the Byzantine Church.

Rise of the indigenous Armenian Church

At this time, the Byzantine emperor Zeno (died 491) propagandized his letter to the Egyptian Church, the *Henotikon*, which was similar to the Monophysite formulations. During the Synod of Dvin (505/6), relations were established with the Monophysites in Syria and Persia. The formula, *mia physis tou theou sesarkomenē* (one incarnate nature of the godhead), coined by Cyril of Alexandria, was accepted; but it is not clear how Monophysitism was understood at that time, except that the positions of the early proponents of the Monophysite view, Eutyches, the patriarch of Antioch, and Severos, were rejected. Ancient Armenian Christology (doctrines about Christ) apparently was under the influence of Julian of Halicarnassus (died before 538). Most of the theologians, however, were not interested in Christological problems, and those who were were not in agreement as to whether Monophysitism should be interpreted according to its definition or according to its content. The formulations in the Armenian liturgical texts indicate, however, that the Armenians were more tolerant with the diophysite (two natures) terms than the West Syrians.

Developments after the Arab conquest. After the end of the persecutions under the Persians, the existence and development of the Armenian Church were guaranteed under the Arab rule, owing to the more tolerant position of Arabs toward the Christians—regardless of conflicts and occasional persecutions under the ʿAbbāsids in which churches and monasteries were destroyed. Frequent insurrections aggravated the condition of the Armenians, but in spite of their sufferings, their faith and nationality grew into an inseparable unity that became a protective wall preventing apostasy to Islām.

In the 9th century, when the Muslim rule became weaker, the Armenians succeeded in gaining some independence; and under the native dynasty of the Bagratids (885–1046), a cultural renaissance was initiated, and many exiled Armenians returned to their country. The Armenians devoted themselves to the cultivation of their own national life, manners, and customs. In their liturgical traditions, they were in debt to Greek and Syrian sources; but in their ritual, they developed their own idiosyncratic forms that became objects of heated controversies with the Syrians. In their Eucharist rite, the Armenians, alone among the Oriental churches, had adopted the use of unleavened bread. They did not mix water with wine in the Eucharist or use olive oil for the myron (oil of chrism or confirmation). They brought sacrificial animals into the church at Easter time—explaining this custom as a heritage from the days of Gregory—and celebrated the Nativity of Christ and the Epiphany together on January 6 according to an archaic Christian tradition. Disregarding the practice of such idiosyncratic customs, a not insignificant number of Armenians were inclined toward union with the Orthodox Church, and one overanxious catholicos (Vahan I [967–969]) even lost his office in the attempt. The great masses, however, remained loyal to their own church and its ways.

Liturgical practices

After this period of national efflorescence, Armenia experienced a long period of sufferings and trials under Byzantium and the Turks, and many were compelled to leave the country. In the 14th century, Armenia was subjected to a horrible holocaust of mass destruction under Timur, and only a remnant of the nation survived. Flight and exile remained the lot of the Armenians in subsequent centuries, so that the communities in dispersion in

Syria, Egypt, and Iran grew steadily. Even the catholicate was transferred to Isfahan, Persia, between 1614 and 1638.

In the 16th and 17th centuries, the catholicos of Echmiadzin (now Armenian S.S.R.) showed inclinations to union with the Roman Catholic Church. These attempts, which had been given an earlier expression in the 11th century, finally resulted in the celebration of a uniate service (the local rite with approval from Rome) in 1740 in Turkish territory. A uniate patriarchate (under Roman Catholic jurisdiction) was established in Sis (now in Beirut), and in developing communities in Cilicia, Syria, Palestine, Mesopotamia, and Egypt. Today the uniate church has about 100,000 believers.

Modern developments. In the late 18th century, when Russia conquered Armenia, new sufferings occurred because of the policy to coerce the Armenians into the Russian state church. The massacres in Turkey in 1895–96, 1909, and 1914–15 by Turks and Kurds exceeded all other persecutions. In the first massacre, about 200,000 Armenians were killed; in the second, in the district of Adana, about 30,000; and in the third about 600,000, together with those who were deported. Those who escaped (about 150,000) and were not dragged into harems (about 100,000 wives and girls) were compelled to leave the country.

Present organization of the Armenian church

There are thought to be about 2,500,000–3,500,000 Armenians today scattered all over the world (in the Middle East, Europe, North and South America) under two catholicates (Echmiadzin and Sis) and two patriarchates (Jerusalem and Constantinople). The catholicate of Echmiadzin was vacant from 1938 until 1945, when a catholicos, approved by the Soviet government for propaganda purposes (according to many ecclesiastical authorities), filled the position. The catholicos of Sis has his residence in Anṭilyās, Lebanon (since 1921). There are two classes of clergy. The ordinary priests, who must marry before ordination into the diaconate, are recruited from monks or lay people, mainly from the cantors and teachers, and thus the influence of the lay people on the affairs of the church is great. Another class of priests is represented by the *vartabeds*, or doctors, who must remain unmarried. From this class of elite are produced the bishops. These celibates are generally members of a clerical community (*ucht*) who live together in a religious establishment (*vanq*). Monasteries exist only as seminaries for preparing the clergy.

THE COPTIC CHURCH

Origins and early development of Coptic Christianity. Remnants of many apocryphal gospels and papyri discovered in Egypt testify to an early form of Egyptian Christianity (first part of the 2nd century) that must have developed quite rapidly.

During the Council of Chalcedon (451), Dioscurus, patriarch of Alexandria (444–451), defended the Monophysite position and was deposed and banished. This act aroused the Egyptians, who were mindful of their national and ecclesiastical autonomy. The attempts to impose the Chalcedonian decrees on the Egyptian Church fanned the anti-Byzantine sentiments among the native population, and thus the thesis of Cyril of Alexandria ("one nature of the incarnate Word") became a slogan for their fight against Byzantine rule. Proterius, the new Orthodox patriarch, was recruited from the Egyptian clergy; but because he had been consecrated in Constantinople, he could find few adherents (branded as Melkites, "emperor's men").

The great majority remained faithful to Dioscurus and looked upon him as a martyr. Bishops loyal to Dioscurus elected a rival patriarch, Timotheus Aelurus. The riots that followed his consecration precipitated various atrocities, including the mob murder of Proterius on Good Friday, 457. As champions of the interests of the indigenous people, the monks took over the leadership of the masses. Christian monasticism was not generated in Alexandria, a centre of Greek culture, but in the indigenous Coptic (Arab Ḳibṭ, denoting the descendants of the original inhabitants of Egypt) Christian settlements of Upper Egypt. It developed rapidly into a significant movement, able to produce such figures as Shenute (*c.* 348–451/466), a reformer of monastic life and a celebrated leader of the people. The role of the monks is attested by the many Coptic "Lives of the Saints" and the large number of ruins of their monasteries. Under their leadership, almost the entire indigenous population embraced the Monophysite belief. The definitive acts in separating the Egyptian Church from the jurisdiction of Byzantine-oriented ecclesiastics were carried out by Patriarch Timotheos Aelurus (died 477) and Petrus III Mongus (477/482–490). The doctrine that the Egyptian Church adopted represented a modified position, rejecting the concept of the fusion of the divine and human nature of Christ similar to the mixing of water and wine (Eutyches) but understanding the union as similar to the union between the soul and the body. Thereby the absolute form of Monophysitism of Eutyches was rejected in favour of the pre-Chalcedonian Christology of Cyril. Theological writings, however, left room for rapprochement in one or another direction.

Influence of monasticism and doctrinal position of Coptic Christianity

Developments after the Arab conquest. Embittered by the attempts to force them to accept the Chalcedonian decrees, the native Egyptians tried to free themselves from the Byzantine yoke. When the Arabs invaded Egypt in 642, they were greeted at first as liberators. The Umayyad period (661–750) gradually brought restrictions, but what became intolerable was the taxation. In order to simplify control, marks were burned on the hands of the Christians, including the clergy and monks. The heavy burdens caused many native Christians to become apostates. The sufferings increased under the ʿAbbāsids (750–868). In 837 Christians were ordered to wear five-pound crosses around their necks, all new churches were demolished, and Christian education, as well as solemn celebration of festivals, was forbidden. These oppressions seldom led, however, to bodily harm. The Synaxaria (collections of extracts from biographies of saints) show that the number of martyrs under the Byzantines was much greater than that under the Arabs.

Repeated insurrections, however, caused bloody reprisals that in turn caused losses through conversions to Islām. But the church drew courage from the spiritual heritage that had found its expression in monasticism, and in this way preserved its national character, traditions, and idiosyncrasies. Because of the disappearance of the Greek elements during these centuries, however, independent theological thought in the Coptic Church became increasingly barren. A comparison with Syrian thought makes this manifest. There is nothing in Coptic Christianity comparable to the enrichment of life through the extensive translations from the Greek theological works into Syriac and their numerous original literary accomplishments. As a result, the Coptic Church became a borrower of Syrian theological works.

Preservation of the national character of the Coptic Church

With the Shīʿite Fāṭimids (969–1171), a flourishing period for the Egyptian Church occurred—interrupted, however, by the persecutions of al-Ḥākim (996–1021), whose name is connected with the destruction of thousands of churches and chapels and forced conversions to Islām. Many monasteries were also destroyed under the Ayyūbids (1171–1250), and in 1321, under the Mamlūks (1257–1517), most of the remaining churches and monasteries were destroyed. The Copts took vengeance by burning down the mosques, which in turn resulted in mass executions of the Copts. The Turkish period (16th to 19th centuries) brought new persecutions and massacres. All this intermittent bloodletting decimated the number of the Christians. As against 168 bishops in the 6th century, ruling over four ecclesiastical provinces (Pentapolis, Libya, Aegyptus Inferior, and Thebais), in the 10th century the number of bishops had fallen to 110, and dropped to 47 within a century; and in the 17th century, there were only 17 left. Only a very small number (4,000) of the Coptic Christians accepted the jurisdiction of the Roman pope in 1741 under the leadership of the bishop of Jerusalem.

Modern developments. More peaceful times did not come until the reign of the tolerant Muḥammad ʿAlī (1805–48) and the occupation of Egypt by the French and

the British. Some reform movements were initiated, particularly by Patriarch Cyril IV (1854–61), who was celebrated as a promoter of education and literature and a restorer of the churches.

Coptic liturgy and other religious practices

The liturgy, namely, that of Basil, Gregory Nazianzus, and St. Mark, has remained the same, even though the centuries have brought about numerous changes in the life of the church. The Coptic language lives only in the liturgical books. In the manuscripts and printed materials, a Coptic column is furnished with a parallel column in Arabic. Confession, regarding which a reform movement in the 12th century had fought a bitter battle, today is hardly required. Besides the anointing of the sick, there is also an anointing of the healthy as a kind of strengthening of repentance. Monasticism has declined drastically. Today there are eight monasteries with 300 monks and five convents with 80 to 100 nuns.

According to various estimates, today there are about 1,300,000–3,000,000 Coptic Christians, with 19 archbishoprics in Egypt, headed by the patriarch. Outside Egypt there are archbishops in Jerusalem (one), in The Sudan (two), in Uganda (two), in South Africa (one), and in Kuwait (one). Of the Coptic Christians who now accept the jurisdiction of the Roman pontiff, there are about 80,000.

THE ETHIOPIAN CHURCH

Origins and early developments. The earliest phases in the Christianization of Ethiopia are unknown. The first definite historical figure was Frumentius, bishop of Axum (*c.* 356). ʿĒzānā, the king of Aksum, was converted to the Christian faith, and this event was reflected in numismatic and epigraphic sources. The same sources indicate, however, that a large number of the people apparently resisted the new religion so that the king had to follow a policy of opportunism. As a consequence, the endeavours of Frumentius apparently slowed down almost to the point of stagnation. The renewal of Christian missionary activity began with the arrival of the Syrian monks (6th century) whose names have been immortalized in the "Chronicle of the Kings" and the Synaxarium. This revival also introduced Monophysitism. When the patriarchate of Alexandria was transferred to Cairo (*c.* 640), the Ethiopian Church became entirely dependent on it.

The "Dark Ages" of Ethiopian Christianity

Developments after the Arab conquest. From the Arab invasion until the 13th century, the history of Ethiopian Christianity is almost entirely unknown. Conditions probably were deplorable for Christianity since pagan traditions, polygamy, and low standards plagued rulers and clergy alike, as well as the people. Some rulers of the 12th century, however, are celebrated as saints; *i.e.*, they were regarded as champions of Christian faith still wrestling with grave dangers. One of them, Lālibelā (1190–1225), is regarded as the founder of the large rock churches. The common type of church building was the round church, the basic form of which was derived from the huts that were the dwellings of the people. Ties with the Coptic Church were intimate, and in the 12th century the head of the Ethiopian Church, Abuna, was chosen by the Coptic patriarch from the Coptic hierarchy. This connection was particularly valuable for the Copts since after the Arab conquest of the Nile Valley and after the gradual disappearance of Christianity in Nubia (14th century), the Christians in Ethiopia could serve as leverage for the Egyptian Christians. Destruction of churches in the Nile Valley encouraged repercussions in the form of destruction of mosques in Ethiopia.

With the emergence of the Solomonid dynasty (1270), the centre of the state was moved to the south, and an intensified struggle with Islām was initiated. A period of ecclesiastical efflorescence associated with the work of the vigorous and able patriarch Takla Hāymanōt was inaugurated, especially in the areas of Coptic–Arabic literature and monasticism. The position of the head of the monks became strengthened so that it even exceeded that of the Coptic Abuna. In the 14th century, two monastic orders devoted to missionary work were created, and monasticism increased in importance. During the reign of Zarʿa-Yaʿcōb (1434–68), the Ethiopian Church reached its zenith. He was celebrated as a religious reformer and promoter of schools and monasteries.

Contacts with the Roman Catholic Church

Muslim invasions (1520–51) encouraged new attempts aimed at communion with the Roman Catholic Church in order to obtain military help from the Portuguese. Though the 13th-century attempts had ended with the murder of Dominican missionaries, the 16th-century endeavours brought success. Jesuit missionaries arrived in Ethiopia, Negus Susenyos (Malak Sagad III) accepted the Catholic (Chalcedonian) creed in 1621 or 1622, a Catholic patriarch, Atonso Mendes, was sent from Rome in 1624 or 1625, and in 1626 the Catholic religion was elevated to official status. All this, however, proved to be ephemeral. In 1632 Susenyos was succeeded by his son Fasiladas, who reversed his father's policies. The Jesuits were expelled, and attempts made by the Franciscans ended tragically—most of them were martyred. Since the early 19th century Roman Catholic Lazarist and Capuchin missionaries have been more successful, and the number of the uniates (those who accept the jurisdiction of Rome) is now about 76,000.

Modern developments. Changes in the church administration came in the 20th century. The emperor Haile Selassie reorganized the church in 1929, and the number of bishops was increased to 12. The quest for independence from the Coptic Church was achieved in 1948 when the Ethiopian archbishopric received recognition of autocephalic (independent) status from the Coptic patriarch. Though the Coptic patriarch retains a primacy of honour, the patriarch of Ethiopia has primacy of jurisdiction. After 1955 the Ethiopian Church became the state church. It has about 8,000,000 members, including 500,000 in Eritrea, and therefore is the largest among the Eastern independent churches.

Customs and practices. Throughout the centuries, the Ethiopian Church has retained its own traditions. Its canon of the Bible is the largest of Christian biblical canons, containing such apocryphal books as the Jubilees, the Ethiopic Enoch, IV Esdras, the Rest of the Words of Baruch, the Ascension of Isaiah, the Shepherd of Hermas, and others. The Apostles' Creed is not used. These differences, however, are overshadowed by idiosyncrasies that come from Jewish influences, which probably arrived in the kingdom of Aksum from South Arabia and from archaic Semitic elements. Jewish customs and traditions include the Zion (holy hill) of the Ethiopians in Aksum, the seat of the Ark of the Covenant—depicted in the national saga *Kebra Nagast* ("Glory of the Kings"), a replica of which is an essential cult object in every church—the keeping of the sabbath, circumcision, distinction between ritually clean and unclean meats, purification laws, and the architectural design of churches that reflects the threefold division of the Hebrew temple. Pagan customs also survive, such as redemption ceremonies, including the sacrifice of a goat or a lamb for sick persons, and magical customs and prayers that retain their thinly veiled pagan substratum.

The clergy of the Ethiopian Church

There are two kinds of clergy in the Ethiopian Church. The priests who administer the sacraments receive little preparation, and their standards for ordination are low. Little is expected from them by the masses, among whom polygamy, free love, and even infanticide are not uncommon. They are expected to be able to manage the ancient Geʿez language (not understood by the people who speak Amharic) enough to read the liturgy. The *dabtaras* are educated lay clerks entrusted with the chant in the churches and teaching in the schools. Until about 1900, church schools were the only places for education.

Monasticism in the Ethiopian Church is numerically the strongest among the Eastern independent churches. Due to a very low level of achievement of the priesthood, the monks exercise the major religious, moral, and intellectual influence on the faithful.

Eastern Orthodoxy

Eastern Orthodoxy, characterized by its continuity with the apostolic church, its liturgy, and its territorial churches, is one of the three major branches of Christianity.

This article is divided into the following sections:

I. Nature and significance
- Significance
- The norm of church organization

II. History
- Causes of the East-West schism
- The Schism of 1054 and its aftermath

III. Doctrine
- Councils and confessions
- God and man
- Christ
- The Holy Spirit
- The Holy Trinity
- The transcendence of God
- Modern theological developments

IV. The structure of the church
- The canons
- The episcopate
- Clergy and laity
- Monasticism

V. Worship and sacraments
- The role of the liturgy
- The eucharistic liturgies
- The liturgical cycles
- The sacraments
- Architecture and iconography

VI. The church and the world
- Missions: ancient and modern
- Orthodoxy and other Christians
- Church, state, and society
- The Orthodox Church today

I. Nature and significance

The term Eastern Orthodoxy designates the large body of Christians who follow the faith and practices that were defined by the first seven ecumenical councils. The word orthodox, meaning "right believing," has traditionally been used, in the Greek-speaking Christian world, to designate those communities, or individuals, who preserved the true faith (as defined by those councils), as opposed to those who were declared heretical. The official designation of the church in Eastern Orthodox liturgical or canonical texts is "the Orthodox Catholic Church." Because of the historical links of Eastern Orthodoxy with the Eastern Roman Empire and Byzantium (Constantinople), however, in English usage it is referred to as the "Eastern" or "Greek Orthodox" Church. These terms are sometimes misleading, especially when applied to Russian or Slavic churches and to the Orthodox communities in western Europe and America.

SIGNIFICANCE

The Schism of 1054

The schism between the churches of the East and the West (1054) was the culmination of a gradual process of estrangement that began in the very first centuries of the Christian era and continued through the Middle Ages. Linguistic and cultural differences, as well as political events, contributed to the estrangement in various degrees. From the 4th to the 11th centuries, Constantinople, the centre of Eastern Christianity, was also the capital of the Eastern Roman, or Byzantine Empire, while Rome, after the barbarian invasions, fell under the influence of the Holy Roman Empire of the West, a political rival of Byzantium. In the West theology remained under the prevailing influence of St. Augustine of Hippo (354–430), while in the East doctrinal thought was shaped by the Greek Fathers. Theological differences could have been settled if the two areas of Christendom had not simultaneously developed different concepts of church authority. The growth of Roman primacy, based on the concept of the apostolic origin of the Church of Rome, was incompatible with the Eastern idea that the importance of certain local churches—Rome, Alexandria, Antioch, and later, Constantinople,—could be determined only by their numerical and political significance and not by apostolic foundation. For the East, the highest authority in settling doctrinal disputes was the ecumenical council.

At the time of the Schism of 1054 between Rome and Constantinople, the membership of the Eastern Orthodox Church was spread throughout the Middle East, the Balkans, and Russia, with its centre in Constantinople, also called "New Rome" and a recognized metropolis of Christian civilization. The vicissitudes of history have greatly modified the internal structures of the Orthodox Church, but, even today, the bulk of its members live in the same geographic areas. Missionary expansion toward Asia and emigration toward the West, however, have maintained the importance of Orthodoxy worldwide.

The total membership of the Orthodox Church today is, in varying estimations, between 100,000,000 and 150,000,000.

THE NORM OF CHURCH ORGANIZATION

Autocephalous and autonomous churches

The Orthodox Church is a fellowship of "autocephalous" churches (governed by their own head bishops), with the Ecumenical Patriarch of Constantinople holding titular or honorary primacy. The number of autocephalous churches has varied in history. Today there are 15: the Church of Constantinople (Istanbul, Turkey), the Church of Alexandria (Egypt), the Church of Antioch (with headquarters in Damascus, Syria), the Church of Jerusalem, the Church of Russia, the Church of Georgia, the Church of Serbia, the Church of Romania, the Church of Bulgaria, the Church of Cyprus, the Church of Greece, the Church of Albania, the Church of Poland, the Church of Czechoslovakia, and the Church of America.

There are also "autonomous" churches (retaining a token canonical dependence upon a mother see) in Crete, Finland, and Japan. Among the autocephalous churches, the first nine are headed by "patriarchs," the others by archbishops or metropolitans. These primatial titles are strictly honorary.

The order of precedence in which the autocephalous churches are listed does not include any reflection on their actual influence or numerical importance. The ancient patriarchates of Constantinople, Alexandria, and Antioch, for example, present only shadows of their past glory. There remains, however, a consensus within the Orthodox Church that Constantinople's primacy of honour, recognized by the ancient canons because it was the capital of the ancient empire, should remain as a symbol and tool of church unity and cooperation. The recent pan-Orthodox conferences were thus convoked by the ecumenical patriarch of Constantinople. Several of the autocephalous churches are de facto national churches, by far the largest being the Russian Church; however, it is not the criterion of nationality but rather the territorial principle that is the norm of church organization.

In recent times, and especially since the Russian Revolution, there has been much turmoil and administrative conflict within the Orthodox Church. In western Europe and in the Americas, in particular, overlapping jurisdictions have been set up and political passions have led to the formation of ecclesiastical organizations without clear canonical status. Though it has provoked controversy, the recent establishment (1970) of the new autocephalous Orthodox Church in America by the patriarch of Moscow has as its stated goal the resumption of normal territorial unity in the Western Hemisphere.

II. History

CAUSES OF THE EAST–WEST SCHISM

The underlying issue in the schism between East and West was, and is, whether in New Testament times and in

the following centuries the Church of Rome possessed a God-given primacy, based on the words of Christ to Peter (Matt. 16:18), or whether each Christian Church was fundamentally identical in status with all the others, provided it kept with them the unity of faith and love. Clear polarization of thought on this issue became evident after the transfer of the Roman Empire's capital from Rome to Constantinople (dedicated in 330) by Constantine I. The Trinitarian and Christological controversies that raged from the 4th to the 8th century were resolved by ecumenical councils meeting in the East and convoked by the emperors. The second ecumenical Council (Constantinople, 381) issued the following ruling: "The bishop of Constantinople shall have the prerogative of honor after the bishop of Rome, because Constantinople is New Rome" (canon 3). In 451 the fourth ecumenical Council of Chalcedon expanded the same view, explaining the concept of the primacy of the "Old Rome" in terms of its having been the old imperial capital and reaffirming the patriarchal authority of the "New Rome" (canon 28). In 599 the archbishop of Constantinople, on the basis of the same theory, assumed the title of ecumenical patriarch. The accepted criterion of primacy in the East was the de facto authority assumed by some churches because of historical circumstances. In order to be fully legitimate, however, this authority must be sanctioned by church councils.

The ecumenical patriarch

Political and cultural factors also contributed to the schism. The Persian wars of Emperor Heraclius (610–641) and the subsequent challenge of Islām forced the Byzantines to concentrate their entire attention on problems of survival in the East. Deprived of the Byzantine emperor's protection against the Lombard invasions, Pope Stephen II (reigned 752–757) asked for the support of the Frankish king Pepin (754); and a later successor, Pope Leo III (reigned 795–816), crowned Pepin's son, Charles, as emperor in Rome. The Frankish influence at the papal court greatly contributed to the breaking of the last bridges with the East.

THE SCHISM OF 1054 AND ITS AFTERMATH

The conflict between Patriarch Photius and Pope Nicholas I ended with a reconciliation under Nicholas' successor, John VIII (872–882). The estrangement, however, grew more intense in the 10th and 11th centuries, due to the growing German influence in Rome and, also, the insertion of the word Filioque (and the Son) into the Nicene Creed (probably in 1014). The Schism of 1054 was nothing more than an unsuccessful attempt at reconciliation between Roman legates and Patriarch Michael Cerularius. The attempt ended in mutual anathemas.

The mistreatment of Eastern Christians by the Crusaders deepened the rift even more, so that the numerous attempts at reunion, and especially the councils of Lyons (1274) and Florence (1439), ended in failure.

Almost simultaneously with the rift with Rome, the Byzantine Church greatly expanded its missionary activity. The mission to the Slavs, initiated by St. Cyril and St. Methodius (863), led to the conversion of Bulgaria (864), Kievan Russia (988), and the establishment of the Serbian Church (1220).

The fall of Constantinople under the Turks (1453) did not put an end to the prestige of the patriarchate. The Ottomans entrusted to it the civil administration of all the Christians of the Turkish Empire. The Russian Church, however, developed full independence and viewed itself as the "Third Rome," successor of Byzantium.

Moscow, the Third Rome

With the gradual disintegration of the Turkish Empire in the 19th and the 20th centuries, independent autocephalous churches were established in the Balkans. Meanwhile, the Russian Church developed a system of education, expanded through its missionaries to Asia, Japan, and Alaska, and played a leading role in the Orthodox world.

The Russian Revolution of 1917, the temporary eclipse and the modern re-emergence of the Russian Church, the institution of Communist regimes in the Balkans after World War II, the establishment of relatively strong Orthodox communities in western Europe and the Americas, as well as the involvement of all Orthodox Churches in the ecumenical movement are the main factors that influence the life of the Orthodox Church today (see also EASTERN ORTHODOXY, HISTORY OF).

III. Doctrine

COUNCILS AND CONFESSIONS

All Orthodox credal formulas, liturgical texts, and doctrinal statements affirm the claim that the Orthodox Church has preserved the original apostolic faith, which was also expressed in the common Christian tradition of the first centuries. The Orthodox Church recognizes as ecumenical the seven councils of Nicaea I (325), Constantinople I (381), Ephesus (431), Chalcedon (451), Constantinople II (553), Constantinople III (681), and Nicaea II (787) but considers that the decrees of several other later councils also reflect the same original faith (*e.g.*, the councils of Constantinople that endorsed the theology of St. Gregory Palamas in the 14th century). Finally, it recognizes itself as the bearer of an uninterrupted living tradition of true Christianity that is expressed in its worship, in the lives of the saints, and in the faith of the whole people of God.

The first seven ecumenical councils

In the 17th century, as a counterpart to the various "confessions" of the Reformation, there appeared several "Orthodox confessions," endorsed by local councils but, in fact, associated with individual authors (*e.g.*, Metrophanes Critopoulos, 1625; Peter Mogila, 1638; Dosítheos of Jerusalem, 1672). None of these confessions would be recognized today as having anything but historical importance. When expressing the beliefs of his church, the Orthodox theologian, rather than seeking literal conformity with any of these particular confessions, will rather look for consistency with Scripture and tradition, as it has been expressed in the ancient councils, the early Fathers, and the uninterrupted life of the liturgy. He will not shy away from new formulations if consistency and continuity of tradition are preserved.

What is particularly characteristic of this attitude toward the faith is the absence of any great concern for establishing external *criteria* of truth—a concern that has dominated Western Christian thought since the Middle Ages. Truth appears as a living experience accessible in the communion of the church and of which the Scriptures, the councils, and theology are the normal expressions. Even ecumenical councils, in the Orthodox perspective, need subsequent "reception" by the body of the church in order to be recognized as truly ecumenical. Ultimately, therefore, truth is viewed as its own criterion: there are signs that point to it, but none of these signs is a substitute for a free and personal experience of truth, which is made accessible in the sacramental fellowship of the church.

The criterion of truth

Because of this view of truth, the Orthodox have traditionally been reluctant to involve church authority in defining matters of faith with too much precision and detail. This reluctance is not due to relativism or indifference but rather to the belief that truth needs no definition to be the object of experience and that legitimate definition, when it occurs, should aim mainly at excluding error and not at pretending to reveal the truth itself that is believed to be ever present in the church.

GOD AND MAN

The development of the doctrines concerning the Trinity and the incarnation, as it took place during the first eight centuries of Christian history, was related to the concept of man's *participation* in divine life.

The Greek Fathers of the church always implied that the phrase found in the biblical story of the creation of man (Gen. 1: 26), according to "the image and likeness of God," meant that man is not an autonomous being and that his ultimate nature is defined by his relation to God, his "prototype." In paradise Adam and Eve were called to participate in God's life and to find in him the natural growth of their humanity "from glory to glory." To be

"in God" is, therefore, the *natural* state of man. This doctrine is particularly important in connection with the Fathers' view of human freedom. For theologians such as Gregory of Nyssa (4th century) and Maximus the Confessor (7th century) man is truly free only when he is in communion with God; otherwise he is only a slave to his body or to "the world," over which, originally and by God's command, he was destined to rule.

Human freedom and sin

Thus, the concept of *sin* implies separation from God and the reduction of man to a separate and autonomous existence, in which he is deprived of both his natural glory and his freedom. He becomes an element subject to cosmic determinism, and the image of God is thus blurred within him.

Freedom in God, as enjoyed by Adam, implied the possibility of falling away from God. This is the unfortunate choice made by man, which led Adam to a subhuman and unnatural existence. The most unnatural aspect of his new state was death. In this perspective, "original sin" is understood not so much as a state of guilt inherited from Adam but as an unnatural condition of human life that ends in death. Mortality is what each man now inherits at his birth and this is what leads him to struggle for existence, to self-affirmation at the expense of others, and ultimately to subjection to the laws of animal life. The "prince of this world" (*i.e.*, Satan), who is also the "murderer from the beginning," has dominion over man. From this vicious circle of death and sin, man is understood to be liberated by the death and Resurrection of Christ, which is actualized in Baptism and the sacramental life in the church.

The general framework of this understanding of the God–man relationship is clearly different from the view that became dominant in the Christian West—*i.e.*, the view that conceived of "nature" as distinct from "grace" and that understood original sin as an inherited guilt rather than as a deprivation of freedom. In the East, man is regarded as fully man when he participates in God; in the West, man's nature is believed to be autonomous, sin is viewed as a punishable crime, and grace is understood to grant forgiveness. Hence, in the West, the aim of the Christian is justification, but in the East, it is rather communion with God and deification. In the West, the church is viewed in terms of mediation (for the bestowing of grace) and authority (for guaranteeing security in doctrine); in the East, the church is regarded as a communion in which God and man meet once again and a personal experience of divine life becomes possible.

Deification

CHRIST

The Orthodox Church is formally committed to the Christology (doctrine of Christ) that was defined by the councils of the first eight centuries. Together with the Latin Church of the West, it has rejected Arianism (a belief in the subordination of the Son to the Father) at Nicaea (325), Nestorianism (a belief that stresses the independence of the divine and human natures of Christ) at Ephesus (431), and Monophysitism (a belief that Christ had only one divine nature) at Chalcedon (451). The Eastern and Western churches still formally share the tradition of subsequent Christological developments, even though the famous formula of Chalcedon, "one person in two natures," is given different emphases in the East and West. The stress on Christ's identity with the pre-existent Son of God, the Logos (Word) of the Gospel According to John, characterizes Orthodox Christology. On Byzantine icons, around the face of Jesus, the Greek letters ὁ ὤν—the equivalent of the Jewish Tetragrammaton YHWH, the name of God in the Old Testament—are often depicted. Jesus is thus always seen in his divine identity. Similarly, the liturgy consistently addresses the Virgin Mary as Theotokos (the "one who gave birth to God"), and this term, formally admitted as a criterion of orthodoxy at Ephesus, is actually the only "Mariological" (doctrine of Mary) dogma accepted in the Orthodox Church. It reflects the doctrine of Christ's unique divine Person, and Mary is thus venerated only because she is his mother "according to the flesh."

Logos as the Christ

This emphasis on the personal divine identity of Christ, based on the doctrine of St. Cyril of Alexandria (5th century), does not imply the denial of his humanity. The anthropology (doctrine of man) of the Eastern Fathers does not view man as an autonomous being but rather implies that communion with God makes man fully human. Thus the human nature of Jesus Christ, fully assumed by the divine Word, is indeed the "new Adam" in whom the whole of humanity receives again its original glory. Christ's humanity is fully "ours"; it possessed all the characteristics of the human being—"each nature (of Christ) acts according to its properties," Chalcedon proclaimed, following Pope Leo—without separating itself from the divine Word. Thus, in death itself—for Jesus' death was indeed a fully human death—the Son of God was the "subject" of the Passion. The theopaschite formula ("God suffered in the flesh") became, together with the Theotokos formula, a standard of orthodoxy in the Eastern Church, especially after the second Council of Constantinople (553). It implied that Christ's humanity was indeed real not only in itself but also for God, since it brought him to death on the cross, and that the salvation and redemption of humanity can be accomplished by God alone—hence the necessity for him to condescend to death, which held humanity captive.

Theology of salvation and redemption

This theology of redemption and salvation is best expressed in the Byzantine liturgical hymns of Holy Week and Easter: Christ is the one who "tramples down death by death," and, on the evening of Good Friday, the hymns already exalt his victory. Salvation is conceived not in terms of satisfaction of divine justice, through paying the debt for the sin of Adam—as the medieval West understood it—but in terms of uniting the human and the divine with the divine overcoming human mortality and weakness and, finally, exalting man to divine life.

What Christ accomplished once and for all must be appropriated freely by those who are "in Christ"; their goal is "deification," which does not mean dehumanization but the exaltation of man to the dignity prepared for him at creation. Such feasts as the Transfiguration or the Ascension are extremely popular in the East precisely because they celebrate humanity glorified in Christ—a glorification that anticipates the coming of the Kingdom of God, when God will be "all in all."

Participation in the already deified humanity of Christ is the true goal of Christian life, and it is accomplished through the Holy Spirit.

THE HOLY SPIRIT

The gift of the Holy Spirit at Pentecost "called all men into unity," according to the Byzantine liturgical hymn of the day; into this new unity, which St. Paul called the "body of Christ," each individual Christian enters through Baptism and "chrismation" (the Eastern form of the Western "confirmation") when the priest anoints him saying "the seal of the gift of the Holy Spirit."

This gift, however, requires man's free response. Orthodox saints such as Seraphim of Sarov (died 1833) described the entire content of Christian life as a "collection of the Holy Spirit." The Holy Spirit is thus conceived as the main agent of man's restoration to his original natural state through Communion in Christ's body. This role of the Spirit is reflected, very richly, in a variety of liturgical and sacramental acts. Every act of worship usually starts with a prayer addressed to the Spirit, and all major sacraments begin with an invocation to the Spirit. The eucharistic liturgies of the East attribute the ultimate mystery of Christ's Presence to a descent of the Spirit upon the worshipping congregation and upon the eucharistic bread and wine. The significance of this invocation (in Greek *epiklēsis*) was violently debated between Greek and Latin Christians in the Middle Ages because the Roman canon of the mass lacked any reference to the Spirit and was thus considered as deficient by the Orthodox Greeks.

The Holy Spirit as the agent of restoration

Since the Council of Constantinople (381), which condemned the Pneumatomachians ("fighters against the Spirit"), no one in the Orthodox East has ever denied that

the Spirit is not only a "gift" but also the giver—*i.e.*, that he is the third Person of the holy Trinity. The Greek Fathers saw in Gen. 1:2 a reference to the Spirit's cooperation in the divine act of creation; the Spirit was also viewed as active in the "new creation" that occurred in the womb of the Virgin Mary when she became the mother of Christ (Luke 1:35); and finally, Pentecost was understood to be an anticipation of the "last days" (Acts 2:17) when, at the end of history, a universal communion with God will be achieved. Thus, all the decisive acts of God are accomplished "by the Father in the Son, through the Holy Spirit."

THE HOLY TRINITY

By the 4th century a polarity developed between the Eastern and Western Christians in their respective understandings of the Trinity. In the West God was understood primarily in terms of one essence (the Trinity of Persons being conceived as an irrational truth found in revelation); in the East the tri-personality of God was understood as the *primary* fact of Christian experience. For most of the Greek Fathers, it was not the Trinity that needed theological proof but rather God's essential unity. The Cappadocian Fathers (Gregory of Nyssa, Gregory of Nazianzus, and Basil of Caesarea) were even accused of being tri-theists because of the personalistic emphasis of their conception of God as one essence in three hypostases (the Greek term *hypostasis* was the equivalent of the Latin *substantia* and designated a concrete reality). For Greek theologians, this terminology was intended to designate the concrete New Testamental revelation of the Son and the Spirit, as distinct from the Father.

Modern Orthodox theologians tend to emphasize this personalistic approach to God; they claim that they discover in it the original biblical personalism, unadulterated in its content by later philosophical speculation.

The Filioque controversy

Polarization of the Eastern and the Western concepts of the Trinity is at the root of the *Filioque* dispute. The Latin word *Filioque* ("and from the Son") was added to the Nicene Creed in Spain in the 6th century. By affirming that the Holy Spirit proceeds not only "from the Father" (as the original creed proclaimed) but also "from the Son," the Spanish councils intended to condemn Arianism by reaffirming the Son's divinity. Later, however, the addition became an anti-Greek battle cry, especially after Charlemagne (9th century) made his claim to rule the revived Roman Empire. The addition was finally accepted in Rome under German pressure. It found justification in the framework of Western conceptions of the Trinity; the Father and the Son were viewed as one God in the act of "spiration" of the Spirit.

The Byzantine theologians opposed the addition, first on the ground that the Western Church had no right to change the text of an ecumenical creed unilaterally and, second, because the *Filioque* clause implied the reduction of the divine persons to mere relations ("the Father and the Son are two in relation to each other, but one in relation to the Spirit"). For the Greeks the Father alone is the origin of both the Son and the Spirit. Patriarch Photius (9th century) was the first Orthodox theologian to explicitly spell out the Greek opposition to the *Filioque* concept, but the debate continued throughout the Middle Ages.

THE TRANSCENDENCE OF GOD

Apophatic theology

An important element in the Eastern Christian understanding of God is the notion that God, in his essence, is totally transcendent and unknowable and that, strictly speaking, God can only be designated by negative attributes: it is possible to say what God is not, but it is impossible to say what he is.

A purely negative, or "apophatic" theology—the only one applicable to the *essence* of God in the Orthodox view—does not lead to agnosticism, however, because God reveals himself personally—as Father, Son, and Holy Spirit—and also in his *acts*, or "energies." Thus, true knowledge of God always includes three elements: religious awe; personal encounter; and participation in the acts, or energies, which God freely bestows on creation.

This conception of God is connected with the personalistic understanding of the Trinity. It also led to the official confirmation by the Orthodox Church of the theology of St. Gregory Palamas, the leader of Byzantine hesychasts (monks devoted to divine quietness through prayer), at the councils of 1341 and 1351 in Constantinople. The councils confirmed a real distinction in God, between the unknowable essence and the acts, or "energies," which make possible a real communion with God. The deification of man, realized in Christ once and for all, is thus accomplished by a communion of divine energy with humanity in Christ's glorified manhood.

MODERN THEOLOGICAL DEVELOPMENTS

Until the conquest of Constantinople by the Turks (1453), Byzantium was the unquestioned intellectual centre of the Orthodox Church. Far from being monolithic, Byzantine theological thought was often polarized by a Humanistic trend, favouring the use of Greek philosophy in theological thinking, and the more austere and mystical theology of the monastic circles. The concern for preservation of Greek culture and for the the political salvation of the empire led several prominent Humanists to adopt a position favourable to union with the West. The most creative theologians (*e.g.*, Symeon the New Theologian, died 1033; Gregory Palamas, died 1359; Nicholas Cabasilas, died *c.* 1390), however, were found rather in the monastic party that continued the tradition of patristic spirituality based upon the theology of deification.

The dark age of Orthodox theology

The 16th, 17th, and 18th centuries were the dark age of Orthodox theology. Neither in the Middle East nor in the Balkans nor in Russia was there any opportunity for independent theological creativity. Since no formal theological education was accessible, except in Western Roman Catholic or Protestant schools, the Orthodox tradition was preserved primarily through the liturgy, which retained all its richness and often served as a valid substitute for formal schooling. Most doctrinal statements of this period, issued by councils or by individual theologians, were polemical documents directed against Western missionaries.

After the reforms of Peter the Great (died 1725), a theological school system was organized in Russia. Shaped originally in accordance with Western Latin models and staffed with Jesuit-trained Ukrainian personnel, this system developed, in the 19th century, into a fully independent and powerful tool of theological education. The Russian theological efflorescence of the 19th and 20th centuries produced many scholars, especially in the historical field (*e.g.*, Philaret Drozdov, died 1867; V.O. Klyuchevsky, died 1913; V.V. Bolotov, died 1900; E.E. Golubinsky, died 1912; N.N. Glubokovsky, died 1937). Independently of the official theological schools, a number of laymen with secular training developed theological and philosophical traditions of their own and exercised a great influence on modern Orthodox theology (*e.g.*, A.S. Khomyakov, died 1860; V.S. Solovyev, died 1900; N. Berdyayev, died 1948), and some became priests (P. Florensky, died 1943; S. Bulgakov, died 1944). A large number of the Russian theological intelligentsia (*e.g.*, S. Bulgakov, G. Florovsky) emigrated to western Europe after the Russian Revolution (1917) and played a leading role in the ecumenical movement.

With the independence of the Balkans, theological schools were also created in Greece, Serbia, Bulgaria, and Romania. Modern Greek scholars contributed to the publication of important Byzantine ecclesiastical texts and produced standard theological textbooks.

The Orthodox diaspora

The Orthodox diaspora—the emigration from eastern Europe and the Middle East—in the 20th century has contributed to modern theological development through their establishment of theological centres in western Europe and America.

Orthodox theologians reacted negatively to the new dogmas proclaimed by Pope Pius IX: the Immaculate Con-

ception of Mary (1854) and papal infallibility (1870). In connection with the dogma of the Assumption of Mary, proclaimed by Pope Pius XII (1950), the objections mainly concerned the presentation of such a tradition in the form of a dogma.

In contrast to the recent general trend of Western Christian thought toward social concerns, Orthodox theologians generally emphasize that the Christian faith is primarily a direct experience of the Kingdom of God, sacramentally present in the church. Without denying that Christians have a social responsibility to the world, they consider this responsibility as an outcome of the life in Christ. This traditional position accounts for the remarkable survival of the Orthodox Churches under the most contradictory and unfavourable of social conditions, but, to Western eyes, it often appears as a form of passive fatalism.

IV. The structure of the church

THE CANONS

The permanent criteria of church structure for the Orthodox Church today, outside of the New Testament writings, are found in the canons (regulations and decrees) of the first seven ecumenical councils; the canons of several local or provincial councils, whose authority was recognized by the whole church; the so-called *Apostolic Canons* (actually some regulations of the church in Syria, dating from the 4th century); and the "canons of the Fathers," or selected extracts from prominent church leaders having canonical importance.

The nomocanon

A collection of these texts was made in the Byzantine nomocanon, attributed, in its final form, to the patriarch Photius (9th century). The Byzantine Church, as well as the modern Orthodox Churches, has adapted the general principles of this collection to its particular situation, and the local autocephalous churches govern themselves according to their own particular statutes, although all accept the ancient canons as their common canonical reference.

The canons themselves do not represent a system or a code. They do, however, reflect a consistent view of the church, of its mission, and of its various ministries; they also reflect an evolution of ecclesiastical structure—*i.e.*, the growth of centralization in the framework of the Christian Roman Empire. For the Orthodox Church today, only the original self-understanding of the church has a theologically normative value. Thus, those canons that reflect the nature of the church as the body of Christ have an unchanging validity today; other canons, if they can be recognized as conditioned by the historical situation in which they were issued, are subject to change by conciliar authority; others have simply fallen out of practice. The use and interpretation of the canons is therefore possible only in the light of some understanding of the church's nature. This theological dimension is the ultimate criterion through which it is possible to distinguish what is permanent in the canons from that which represents no more than a historical value.

THE EPISCOPATE

The Orthodox understanding of the church is based on the principle, attested to in the canons and in early Christian tradition, that each local community of Christians, gathered around its bishop and celebrating the Eucharist, is the local realization of the *whole* body of Christ. "Where Christ is, there is the Catholic church," wrote Ignatius of Antioch (*c.* AD 100). Modern Orthodox theology also emphasizes that the office of the bishop is the highest among the sacramental ministries and that there is therefore no divinely established authority *over* that of the bishop in his own community, or diocese. Neither the local churches nor the bishops, however, can or should live in isolation. The wholeness of church life, realized in each local community, is regarded as identical with that of the other local churches in the present and in the past. This identity and continuity is manifested in the act of the ordination of bishops, an act that requires the presence of several other bishops in order to constitute a conciliar act and to witness to the continuity of apostolic succession and tradition.

The bishop is primarily the guardian of the faith and, as such, the centre of the sacramental life of the community. The Orthodox Church maintains the doctrine of apostolic succession—*i.e.*, the idea that the ministry of the bishop must be in direct continuity with that of the Apostles of Jesus. Orthodox tradition—as expressed especially in its medieval opposition to the Roman papacy—distinguishes the office of the "Apostle" from that of the bishop, however, in that the first is viewed as a universal witness to the historic Jesus and his Resurrection, while the latter is understood in terms of the pastoral and sacramental responsibility for a local community, or church. The continuity between the two is, therefore, a continuity in faith rather than in function. This Orthodox concept of the doctrine of apostolic succession has received wider exposure in Western churches recently because of increased encounters and consultations between Orthodox and Anglican churchmen, the Orthodox always emphasizing unity of faith as a prerequisite for recognition, on their part, of the "validity" of Anglican orders.

Apostolic succession

No bishop can be consecrated or exercise his ministry without being in unity with his colleagues—*i.e.*, be a member of an episcopal council, or "synod." After the Council of Nicaea (325), whose canons are still effective in the Orthodox Church, each province of the Roman Empire had its own synod of bishops that acted as a fully independent unit for the consecration of new bishops and also as a high ecclesiastical tribunal. In the contemporary Orthodox Church these functions are fulfilled by the synod of each autocephalous church. In the early church the bishop of the provincial capital acted as chairman of the synod and was generally called "metropolitan." Today, this function is fulfilled by the local primate who is sometimes called "patriarch" (in the autocephalous churches of Constantinople, Alexandria, Antioch, Jerusalem, Russia, Georgia, Serbia, Romania, and Bulgaria), but he may also carry the title of archbishop (Cyprus, Greece) or metropolitan (Poland, Czechoslovakia, America). The titles of archbishop and metropolitan are also widely used as honorific distinctions.

Generally, but not always, the jurisdiction of each autocephalous synod coincides with national borders—the exceptions are numerous in the Middle East (*e.g.*, jurisdiction of Constantinople over the Greek islands, jurisdiction of Antioch over several Arab states, etc.)—and concerns also the national dioceses of the Orthodox diaspora (*e.g.*, western Europe, Australia, America), which frequently remain under the authority of their mother churches. The latter situation led to an uncanonical overlapping of Orthodox jurisdictions, all based on ethnic origins. Several factors, going back to the Middle Ages, have contributed to modern ecclesiastical nationalism in the Orthodox Church. These factors include the use of the vernacular in the liturgy and the subsequent identification of religion with national culture; this identification sometimes helps the survival of the church under adverse political conditions, but it also hampers missionary expansion and the sense of a specifically Christian identity of the faithful.

CLERGY AND LAITY

The emphasis on communion and fellowship, as the basic principle of church life, inhibited the development of clericalism. The early Christian practice of having the laity participate in episcopal elections never disappeared completely in the East. In modern times, it has been restored in several churches. The Moscow Council of 1917–1918 introduced it in Russia, even if the events of the Revolution prevented its full implementation. Bishops are also elected by clergy-laity conventions in America and in other areas of the Orthodox world.

Clerical marriage

The lower orders of the clergy—*i.e.*, priests and deacons—are generally married men. The present canonical legislation allows the ordination of married men to the diaconate and the priesthood, provided that they were married only once and that their wives are neither wid-

ows nor divorcees. These stipulations reflect the general principle of absolute monogamy, which the Eastern Church considered as a Christian norm to which candidates for the priesthood are to comply strictly. Deacons and priests cannot marry after their ordination.

Bishops, however, are selected among the unmarried clergy or widowed priests. The rule defining the requirement for an unmarried episcopate was issued at a time (6th century) when monks represented the elite of the clergy. The contemporary decrease in the number of monks in the Orthodox Church has created a serious problem in some territorial churches, in that new candidates for the episcopacy are difficult to find.

Besides being admitted, at least in some areas, to participation in episcopal elections, Orthodox laymen often occupy positions in church administration and in theological education. In Greece almost all professional theologians are laymen. Laymen also frequently serve as preachers.

MONASTICISM

The tradition of Eastern Christian monasticism goes back to the 3rd and 4th centuries of the Christian Era. From its beginning it was essentially a contemplative movement seeking the experience of God in a life of permanent prayer. This contemplative character has remained its essential feature throughout the centuries. Eastern Christianity never experienced the development of religious orders, pursuing particular missionary or educational goals and organized on a universal scale, as did Western Christianity.

Eremitic and cenobitic monasticism

Concern for prayer, as the central and principal function of monasticism, does not mean that the Eastern Christian monastic movement was of a single uniform character. Eremitic (solitary) monasticism, favouring the personal and individual practice of prayer and asceticism, often competed with "cenobitic" (communal) monastic life, in which prayer was mainly liturgical and corporate. The two forms of monasticism originated in Egypt and coexisted in Byzantium, as well as throughout eastern Europe.

In Byzantium the great monastery of Studius became the model of numerous cenobitic communities, including that of the Caves in Kiev in the 11th century. It is in the framework of the eremitic, or hesychast tradition, however, that the most noted Byzantine mystical theologians (*e.g.*, Symeon the New Theologian, Gregory Palamas, etc.) received their training. One of the major characteristics of the hesychast tradition is the practice of the "Jesus prayer," or constant invocation of the name of Jesus, sometimes in connection with breathing. This practice won wide acceptance in medieval and modern Russia.

Cenobitic traditions of Byzantium also were important in Slavic lands. The colonization of the Russian north was largely accomplished by monks who acted as pioneers of civilization and as missionaries.

In Byzantium, as well as in other areas of the Orthodox world, the monks were often the only upholders of the moral and spiritual integrity of Christianity, and thus they gained the respect of the masses, as well as that of the intellectuals. The famous Russian *startsy* ("elders") of the 19th century became the spiritual leaders of F. Dostoyevsky, N. Gogol, and L. Tolstoy and inspired many religious philosophers in their quest for religious experience.

Today, the most famous, though declining, centre of Orthodox monasticism is Mount Athos (Greece), where over a thousand monks of different national backgrounds form a variety of communities, grouped into a monastic republic.

V. Worship and sacraments

THE ROLE OF THE LITURGY

By its theological richness, spiritual significance, and variety, the worship of the Orthodox Church represents one of the most significant factors in this church's continuity and identity. It helps to account for the survival of Christianity during the many centuries of Muslim rule in the Middle East and the Balkans when the liturgy was the only source of religious knowledge or experience. Since liturgical practice is practically the only religious expression legally authorized in the Soviet Union today, the continuous existence of Orthodox communities there is also centred almost exclusively around the liturgy.

Worship as the primary experience of Eastern Christianity

The concept that the church is most authentically itself when the congregation of the faithful is gathered together in worship is a basic expression of Eastern Christian experience. Without that concept it is impossible to understand the fundamentals of church structure in Orthodoxy, with the bishop functioning in his essential roles of teacher and high priest in the liturgy. Similarly, the personal experience of man's participation in divine life is understood in the framework of the continuous liturgical action of the community.

According to many authorities, one of the reasons that helps to explain why the Eastern liturgy has made a stronger impact on the Christian Church than has its Western counterpart is that it has always been viewed as a total experience, appealing simultaneously to the emotional, intellectual, and aesthetic faculties of man. The liturgy includes a variety of models, or symbols, using formal theological statements as well as bodily perceptions and gestures (*e.g.*, music, incense, prostrations) or the visual arts. All are meant to convey the content of the Christian faith to the educated and the noneducated alike. Participation in the liturgy implies familiarity with its models, and many of them are conditioned by the historical and cultural past of the church. Thus, the use of such an elaborate and ancient liturgy presupposes catechetical preparation. It may require an updating of the liturgical forms themselves. The Orthodox Church recognizes that liturgical forms are changeable and that, since the early church admitted a variety of liturgical traditions, such a variety is also possible today. Thus, Orthodox communities with Western rites now exist in western Europe and in the Americas.

The Orthodox Church, however, has always been conservative in liturgical matters. This conservatism is due, in particular, to the absence of a central ecclesiastical authority that could enforce reforms and to the firm conviction of the church membership as a whole that the liturgy is the main vehicle and experience of true Christian beliefs. Consequently, reform of the liturgy is often considered as equivalent to a reform of the faith itself. However inconvenient this conservatism may be, the Orthodox liturgy has preserved many essential Christian values transmitted directly from the experience of the early church.

Throughout the centuries, the Orthodox liturgy has been richly embellished with cycles of hymns from a wide variety of sources. Byzantium (where the present Orthodox liturgical rite took shape), while keeping many biblical and early Christian elements, used the lavish resources of patristic theology and Greek poetry, as well as some gestures of imperial court ceremonial, in order to convey the realities of God's kingdom. The results are impressive and the liturgy thus has served as a powerful missionary weapon: *The Russian Primary Chronicle* reports that the envoys of the pagan prince Vladimir, visiting Constantinople in 988 and confronted with the liturgy in Hagia Sophia, did not know any more "whether they were in heaven, or on earth."

Normally, the content of the liturgy is directly accessible to the faithful, because the Byzantine tradition is committed to the use of any vernacular language in the liturgy. Translation of both Scriptures and liturgy into various languages was undertaken by the medieval Byzantines, as well as by modern Russian missionaries. Liturgical conservatism, however, leads de facto to the preservation of antiquated languages. The Byzantine Greek used in church services by the modern Greeks and the Old Slavonic still preserved by all the Slavs are at least as distant from the spoken languages as is the language of the King James Version—used in many Protestant Churches—from modern English.

THE EUCHARISTIC LITURGIES

Two eucharistic liturgies are most generally used in Orthodox worship—*i.e.*, the so-called liturgies of St. John Chrysostom and of St. Basil the Great. Both acquired their present shape by the 9th century, but it is generally recognized that the wording of the eucharistic "canon" of the liturgy of St. Basil goes back to the 4th century—*i.e.*, to St. Basil himself. The so-called Liturgy of St. James is used occasionally, especially in Jerusalem. During the period of Lent, a service of Communion, with elements (bread and wine) reserved from those consecrated on the previous Sunday, is celebrated in connection with the evening service of Vespers; it is called the "Liturgy of the Presanctified" and is attributed to St. Gregory the Great.

The liturgies of St. John Chrysostom and of St. Basil differ only in the text of the eucharistic canon: their overall structure, established in the high Middle Ages, is identical.

These eucharistic liturgies begin with an elaborate rite of preparation (*proskomidē*). A priest on a separate "table of oblation" disposes on a paten (plate) the particles of bread that will symbolize the assembly of the saints, both living and dead, around Christ, the "Lamb of God." Then follows the "Liturgy of the Catechumens," which begins with a processional entrance of the priest into the sanctuary with the Gospel (Little Entrance) and which includes the traditional Christian "liturgy of the word"—*i.e.* the reading from the New Testament letters and the Gospels as well as a sermon. This part of the liturgy ends with the expulsion of the "catechumens," who, until they were baptized, were not admitted to the sacramental part of the service. The "Liturgy of the Faithful" includes another ceremonial procession of the priest into the sanctuary. He carries the bread and wine from the table of oblations to the altar (Great Entrance); the following recitation of the Nicene Creed, the eucharistic canon, the Lord's Prayer, and Communion are—as in the West—the characteristic parts of the Byzantine "Liturgy of the Faithful." The bread used for the Eucharist is ordinary leavened bread; Communion is distributed under both kinds (bread and wine) with a special spoon (*labis*).

THE LITURGICAL CYCLES

Variety of hymnodical texts

One of the major characteristics of the Byzantine liturgical tradition is the wealth and variety of hymnodical texts marking the various cycles of the liturgical year. A special liturgical book contains the hymns for each of the main cycles. The *daily* cycle includes the offices of Vespers (Hesperinos), Compline (Apodeipnon), the midnight prayer, Matins (Orthros), and the four canonical "hours"—*i.e.*, offices to be said at the "First" (6:00 AM), "Third" (9:00 AM), "Sixth" (12:00 noon), and "Ninth" (3:00 PM) hours. The liturgical book covering the daily cycle is called the *Hōrologion* ("The Book of Hours"). The *Paschal* (Passover) cycle is centred on the "Feast of Feasts"—*i.e.*, of Christ's Resurrection; it includes the period of Great Fast (Lent), preceded by three Sundays of preparation and the period of 50 days following Easter. The hymns of the Lenten period are found in the *Triōdion* (Three Odes), and those of the Easter season in the *Pentekostarion* (called the "Flowery Triodion"). The weekly cycle is the continuation of the Resurrection cycle found in the *Triōdion* and the *Pentekostarion;* each week following the Sunday after Pentecost (50 days after Easter) possesses its own musical tone, or mode, in accordance with which all the hymns of the week are sung. There are eight tones whose composition is traditionally attributed to St. John of Damascus (8th century). Each week is centred around Sunday, the day of Christ's Resurrection.

The Easter and weekly cycles clearly dominate all offices of the entire year and illustrate the absolute centrality of the Resurrection in the Eastern understanding of the Christian message. The date of Easter, set at the Council of Nicaea (325), is the first Sunday after the full moon following the spring equinox. Differences between the East and West in computing the date exist because the Orthodox Church uses the Julian calendar for establishing the date of the equinox (hence a delay of 13 days) and also because of the tradition that Easter must necessarily follow the Jewish Passover and must never precede it or coincide with it. The *yearly* cycle includes the hymns for each of the 366 days of the calendar year, with its feasts and daily commemoration of saints. They are found in the 12 volumes of the *Menaion* ("Book of Months").

The golden age of Byzantine hymnody

From the 6th to the 9th centuries the Byzantine Church experienced its golden age of creativity in the writing of hymns by outstanding poets such as John of Damascus. In more recent times hymn writing has generally followed the accepted patterns set by these authors but rarely has it reached the quality of its models. Since the Eastern Orthodox tradition bans instrumental music, or accompaniment, the singing is always a cappella, with only a few exceptions admitted by Westernized parishes in America. The idea behind the ban is based upon the practice of worship in the New Testament; *i.e.*, only the natural aptitudes of the living congregation are viewed as capable of expressing praise that is worthy of God. In many Orthodox churches there is a wealth of new musical compositions for liturgical texts.

THE SACRAMENTS

Contemporary Orthodox catechisms and textbooks all affirm that the church recognizes seven *mystēria*, or "sacraments": Baptism, chrismation, Communion, holy orders, penance, anointing of the sick (the "extreme unction" of the medieval West), and marriage. Neither the liturgical book called *Euchologion* (prayer book), which contains the texts of the sacraments, nor the patristic tradition, however, formally limits the *number* of sacraments; they do not distinguish clearly between the "sacraments" and such acts as the blessing of water on Epiphany day or the burial service or the service for the tonsuring of a monk that in the West are called *sacramentalia.* In fact, no council recognized by the Orthodox Church ever defined the number of sacraments; it is only through the "Orthodox confessions" of the 17th century directed against the Reformation that the number seven has been generally accepted. The underlying sacramental theology of the Orthodox Church is based, however, on the notion that the ecclesiastical community is the unique *mystērion*, of which the various sacraments or *sacramentalia* are the normal expressions.

The Christian community as the *mystērion*

In the West, since the Scholastic period (Middle Ages) and, especially, since the Catholic Reformation (16th century), much emphasis has been placed on the vicarious juridical power of the minister to administer the sacraments validly. The Orthodox East, however, interprets each sacramental act as a prayer of the entire ecclesiastical community, led by the bishop or his representative, and also as a response of God, based upon Christ's promise to send the Holy Spirit upon the church. These two aspects of the sacrament exclude both magic and legalism: they imply that the Holy Spirit is given to free men and call for their responses. In the *mystērion* of the church, the participation of men in God is effected through their "cooperation" or "synergy"; to make this participation possible once more is the goal of the incarnation.

Baptism and confirmation. Baptism is normally performed by triple immersion as a sign of the death and Resurrection of Christ; thus, the rite appears essentially as a gift of new life. It is immediately followed by confirmation, performed by the priest who anoints the newly baptized Christian with "Holy Chrism" (oil) blessed by the bishop. Baptized and confirmed children are admitted to Holy Communion. By admitting children immediately after their Baptism to both confirmation and Communion, the Eastern Christian tradition maintains the positive meaning of Baptism—*i.e.*, as the beginning of a new life nourished by the Eucharist.

The Eucharist. There never has been, in the East, much speculation about the nature of the eucharistic mys-

tery. Both canons presently in use (that of St. Basil and that of St. John Chrysostom) include the "words of institution" ("This is my Body . . .," "This is my Blood . . ."), which are traditionally considered in the West as the formula necessary for the validity of the sacrament. In the East, however, the culminating point of the prayer is not in the remembrance of Christ's act but in the invocation of the Holy Spirit, which immediately follows: "Send down Thy Holy Spirit upon us and upon the Gifts here spread forth, and make this bread to be the precious Body of Thy Christ. . . ." Thus, the central mystery of Christianity is seen as being performed by the prayer of the church and through an invocation of the Spirit. The nature of the mystery that occurs in the bread and wine is signified by the term *metabolē* ("sacramental change"). The Western term transubstantiation occurs only in some confessions of faith after the 17th century.

Orders. The Orthodox Church recognized three major orders: the diaconate, the priesthood, and the episcopate (bishop), as well as the minor orders of the lectorate and the subdiaconate. All the ordinations are performed by a bishop and, normally, during the eucharistic liturgy. The consecration of a bishop requires the participation of at least two or three bishops, as well as an election by a canonical synod.

Penance. The sacrament of penance in the early church was a solemn and public act of reconciliation, through which an excommunicated sinner was readmitted into church membership. Historically it has evolved into a private act of confession through which every Christian's membership in the church is periodically renewed. In the Orthodox Church today there is a certain variety in both the practice and the rite of penance. In the churches of the Balkans and the Middle East, it fell into disuse during the four centuries of Turkish occupation but is gradually being restored today. In Greek-speaking churches only certain priests, especially appointed by the bishop, have the right to hear confessions. In Russia, on the contrary, confessions remained a standard practice that was generally required before communion. General or group confession, introduced by John of Kronstadt, a Russian spiritual leader of the early 20th century, is also occasionally practiced. The rite of confession in the *Euchologion* retains the form of a prayer, or invocation, said by the priest for the remission of the penitent's sins. In the Slavic ritual a Latin-inspired and juridical form of personal absolution was introduced by Peter Mogila, metropolitan of Kiev (17th century). Confession, in Orthodox practice, is generally viewed as a form of spiritual healing rather than as a tribunal. The relative lack of legalism reflects the Eastern patristic approach to sin—*i.e.*, as an internal passion and as an enslavement. The external sinful acts—which alone can be legally tried—are only manifestations of man's internal disease.

Practice of confession

Anointing of the sick. Anointing of the sick is a form of healing by prayer. In the Greek Church it is performed annually in church for the benefit of the entire congregation on the evening of Holy Wednesday.

Marriage. Marriage is celebrated through a rite of crowning, performed with great solemnity and signifying an eternal union, sacramentally "projected" into the Kingdom of God. Orthodox theology of marriage insists on its sacramental eternity rather than its legal indissolubility. Thus, second marriages, in cases of either widowhood or divorce, are celebrated through a subdued penitential rite, and men who have been married more than once are not admitted to the priesthood. Remarriage after divorce is tolerated on the basis of the possibility that the sacrament of marriage was not originally received with the consciousness and responsibility that would have made it fully effective; remarriage can be a second chance.

ARCHITECTURE AND ICONOGRAPHY

Since the time of Constantine I, Eastern Christianity has developed a variety of patterns in church architecture. The chief model was created when Emperor Justinian I completed the "great church" of Hagia Sophia in Constantinople in the 6th century. The architectural conception of that church consisted of erecting a huge round dome on top of the classical early Christian basilica. The dome was meant to symbolize the descent of heaven upon earth—*i.e.*, the ultimate meaning of the eucharistic celebration.

The iconostasis or screen, characteristically decorated with icon paintings, separates the sanctuary from the nave in an Orthodox church. In the Greek Orthodox Cathedral, London.

The screen, or iconostasis, which separates the sanctuary from the nave in contemporary Orthodox Churches, is a rather late development. After the triumph of orthodoxy over iconoclasm (destruction of images) in 843, a new emphasis was placed upon the permanent revelatory role of *images*. The incarnation implied that God had become man—*i.e.*, fully visible and thus describable in his human nature. The images of Christ and the saints, who had manifested in their lives the new humanity transfigured by the grace of God, were placed everywhere in full evidence before the congregation. A contrast was thus suggested between the visible manifestation of God through the pictural representation of Christ as man and his more perfect but mysterious and invisible presence in the Eucharist. The iconostasis, together with those parts of the liturgy that involve the closing and opening of the curtain before the altar, emphasizes the mysterious and "eschatological" (consummation of history) character of the eucharistic service. They suggest, however, that this *mystery* is not a "secret" and that the Christian is being introduced through the eucharistic liturgy into the very reality of divine life and of the kingdom to come, which was revealed when God became man.

The iconoclastic controversy

The long iconoclastic controversy (725–843), during which the Orthodox theology of icons was fully developed, concerned itself primarily with the problem of the incarnation; it was the direct continuation of the Christological debates of the 5th, 6th, and 7th centuries. The image of Christ, the incarnated God, became, for the Eastern Christian, a pictorial confession of faith: God was truly visible in the humanity of Jesus of Nazareth, and the saints—whose images surround that of Christ—are witnesses of the fact that the transfigured, "deified" humanity is accessible to those who believe in Christ.

Popular use of icons

Departing from tridimensional images or statues, which were reminiscent of pagan idolatry, the Christian East developed a rich tradition of iconography. Portable icons —often painted on wood but also using mosaics with enamel techniques—are always kept in houses or public places. Among the icon painters, who never signed their work, there appeared several artists of genius. Most of

them are unknown, but tradition and written documents have revealed the names of some, such as the famous 14th–15th-century Russian painter Andrey Rublev.

VI. The church and the world

The schism between the Greek and the Latin churches coincided chronologically with a surge of Christian missionary activity in northern and eastern Europe. Both sides contributed to the resultant expansion of Christianity but used different methods. The West imposed a Latin liturgy on the new converts and thus made Latin the only vehicle of Christian civilization and a major instrument of ecclesiastical unity. The East, meanwhile, as noted above, accepted from the start the principle of translating both the Scriptures and the liturgy into the spoken tongues of the converted nations. Christianity thus became integrated into the indigenous cultures of the Slavic nations, and the universal Orthodox Church evolved as a fellowship of national churches rather than as a centralized body.

MISSIONS: ANCIENT AND MODERN

The Christian East, in spite of the integrating forces of Christian Hellenism, was always culturally pluralistic: since the first centuries of Christianity, Syrians, Armenians, Georgians, Copts, Ethiopians, and other ethnic groups used their own languages in worship and developed their own liturgical traditions. Even though by the time of the Greek missions to the Slavs the Byzantine Church was almost monolithically Greek, the idea of a liturgy in the vernacular was still quite alive, as is demonstrated by the use of the Slavic language by the missionaries of SS. Cyril and Methodius in the 9th century.

The Turkish conquest of the Middle East and of the Balkans (15th century) interrupted the missionary expansion of the Orthodox Church. Throughout the Middle Ages Islām and Christianity had usually confronted each other only militarily, and the victory of Islām meant that the Christians could survive only in enclaves and were legally excluded from proselytizing among Muslims.

Russian missionary activity

The Russian Church alone was able to continue the tradition of SS. Cyril and Methodius, and it did so almost without interruption until today. In the 14th century St. Stephen of Perm translated the Scriptures and the liturgy into the language of a Finnish tribe of the Russian north and became the first bishop of the Zyrians. The expansion of the Russian Empire in Asia was accompanied by efforts of evangelization that—sometimes in opposition to the avowed policy of Russianization practiced by the government of St. Petersburg—followed the Cyrillo-Methodian pattern of translation. This method was utilized among the Tatars of the Volga in the 16th century and among the various peoples of Siberia throughout the 18th and the 19th centuries. In 1714 a mission was established in China. In 1794 monks of the Valamo Abbey reached Alaska; their spiritual leader, the monk Herman, was canonized by the Orthodox Church in 1970.

The Alaskan mission was under the direction of a modest priest sent to America from eastern Siberia, Ivan Veniaminov. During his long stay in America, first as a priest, then as a bishop (1824–1868), he engaged in the work of translating the Gospels and the liturgy into the languages of the Aleuts, the Tlingit Indians, and the Eskimos of Alaska.

In Japan an indigenous Orthodox Church was established by the recently canonized St. Nikolay Kasatkin (died 1913). The entirely indigenous character of this church enabled it to survive the political trials of the Russo-Japanese War (1904–1905), of the Russian Revolution, and of World War II. The new Church of Japan received its full autonomy from the Russian Church in 1970.

The missionary tradition is also being revived in Greece. Various Greek associations are dedicated to the pursuit of missionary work in East Africa, where sizable indigenous groups have recently joined the Orthodox Church.

ORTHODOXY AND OTHER CHRISTIANS

Since the failure of the unionist Council of Florence (1439) there have been no official attempts to restore unity between the Orthodox Church and Roman Catholicism. In 1484 an Orthodox council defined that Roman Catholics desiring to join the Orthodox Church were to be received through chrismation (or confirmation). In the 17th century, however, the relations deteriorated to the point that the ecumenical patriarchate of Constantinople decreed that all Roman Catholic and Protestant sacraments, including Baptism, were totally unauthentic. A parallel attitude prevailed in Russia until the 18th century, when large numbers of Eastern Rite Roman Catholics ("Uniates") were received back into Orthodoxy by a simple confession of faith, and this practice was adopted in the acceptance of individual Roman Catholics as well.

After the 16th-century Reformation, a lengthy correspondence took place between the Tübingen group of Reformers (German Lutheran) headed by P. Melanchthon and ecumenical Patriarch Jeremiah II. It led to no concrete results, for the East generally considered the Protestants as only a branch of deviation of the altogether erroneous Roman Church.

Various attempts at rapprochement with the Anglican Communion, especially since the 19th century, were generally more fruitful. Several private associations of churchmen and theologians promoted understanding between Eastern Orthodoxy and the "Anglo-Catholic" branch of Anglicanism. The Orthodox, however, were reticent in taking any formal step toward reunion before a satisfactory statement on the content of Anglican faith, taken as a whole, could be obtained.

Ecumenical movement

The contemporary ecumenical movement involved the Orthodox Church from the very beginning. Eastern Orthodox representatives took part in the various Life and Work (practical) and Faith and Order (theological) Conferences from the very beginning of this century. One by one the various independent Orthodox Churches joined the World Council of Churches, created in 1948. Often, and especially at the beginning of their participation, Orthodox delegates had recourse to separate statements, which made clear to the Protestant majorities that, in the Orthodox view, Christian unity was attainable only in the full unity of the primitive apostolic faith from which the Orthodox Church had never departed. This attitude of the Orthodox could be understood only if it made sufficiently clear that the truth—which historic Eastern

Orthodoxy claims to preserve—is maintained by the Holy Spirit in the church as a whole and not by any individual or any group of individuals on their own right and also that the unity of Christians—which is the goal of the ecumenical movement—does not imply cultural, intellectual, or ritual uniformity but rather a mystical fellowship in the fullness of truth as expressed in eucharistic Communion.

The ecumenical movement, especially since the second Vatican Council, is today much wider than the formal membership of the World Council of Churches. The principle of conciliarism and the readiness of the popes to appear publicly as equals of Eastern patriarchs—as in the recent meetings between Pope Paul VI and Patriarch Athenagoras—represent significant moves in the direction of a better understanding between Orthodoxy and Roman Catholicism.

The tendency, however, represented by those Western Christians who apparently identify Christianity with various political or social causes has the effect of again widening the traditional gap that has been, in the past, one of the major causes of the break between East and West.

CHURCH, STATE, AND SOCIETY

In the West, after the fall of the Roman Empire, the church assumed the unifying social function that no other individual or institution was able to fulfill. Eventually, the popes were formally invested with civil authority in Christendom. In the East the empire persisted until 1453 and in Russia until 1917; thus the church had to fulfill its social functions in the political framework of the Christian empire.

This historical contrast coincides with a theological polarization: the Eastern Fathers conceived the God–man relationship in terms of personal experience and Communion culminating in deification; Western theology, meanwhile, understood man as autonomous in the secular sphere, although controlled by the authority of the church, which was conceived as vicariously representing God.

Caesaropapism

The Byzantine and Eastern form of church–state relations has often been labelled as "caesaropapism," because the hierarchy of the church was, most of the time, deprived of the legal possibility of opposing imperial power. But this label is inaccurate in two aspects: first, it presupposes that the emperor possessed a recognizable power to define the content of the faith, comparable to that of the papacy; and, second, it underestimates the power of the church (as a corporate, transfiguring, and deifying power) that is effective without legal guarantees or statutes. The Byzantine ideal of church–state relations was a "symphony" between the civil and the ecclesiastical functions of Christian society. The abuses of imperial power were frequent, but innumerable examples of popular resistance to those imperial decrees that were considered as detrimental to the faith can be cited. Neither the strong emperors of the 7th century, trying to impose Monophysitism, nor the weakened Palaeologans (13th to 15th centuries), attempting reunion with Rome, were able to overcome the corporate opposition of Orthodox clergy and laity.

The Byzantine conception of church–state relations was not, however, without major weaknesses. It often led to a de facto identification of the interests of the church with those of the empire. Conceived when both the church and the empire were supranational and, in principle, universal, it gradually evolved into a system that gave a sacred sanction to *national* states. Modern ecclesiastical nationalism, which inhibits relations between Orthodox Churches today, is the outcome of the medieval alliance between the empire and the church.

Only after the Turkish occupation of the Balkans was civil authority directly assumed by the Orthodox Church hierarchy in the Middle East. It was granted to it by the new Muslim overlords, who chose to administer their Christian subjects as a separate community, or *millet*, ruled by its own religious leaders. The patriarch of Constantinople was thus appointed by the sultan as head (*millet-bachi*) of the entire Christian population of the Ottoman Empire. Understood by some, especially the Greeks, as the heir of Byzantine emperors and by others, especially the Balkan Slavs and Romanians, as an agent of the hated Turks, the patriarch exercised these powers until the secularization of the Turkish republic by Kemal Atatürk in 1921. By that time, however, he had lost most of his jurisdictional powers because of the establishment of autocephalous churches in Greece, Serbia, Bulgaria, and Romania.

The *millet* system of the Ottoman Empire

The *millet* system, however, survived in other areas of the Middle East. In Cyprus, for example, the church assumed a leading role in national liberation, and its prestige made Archbishop Makarios the natural leader of the young republic.

The *millet* system and the active political responsibilities that it implied for the church, it should be noted, originated in the Ottoman period only and is not in the spiritual tradition of the Christian East as such. The Russian Church is the most recent example of religious survival without practical social or political involvement.

The Orthodox attitude toward social responsibility in the world constitutes a distinct contribution to the contemporary ecumenical movement. But it will be meaningful only if it is understood in its proper framework—*i.e.*, as an understanding of the Christian faith as a personal spiritual experience of God, which is self-sufficient knowledge of God and which, as such, can lead to an authentically Christian witness in the secularized world.

The practical forms of that witness have varied greatly in history, and Orthodox tradition has placed among the church's saints both hermits and politicians, hesychast monks as well as emperors. According to Serge Bulgakov, a modern Orthodox theologian, the Orthodox Church accepts "a relativism of means and methods," provided there remains "an absolute and unique goal," which is the Kingdom of God still *to come* but also already *present* in the mystery of the church.

Codification and systematization of practical devices in the fields of personal or social ethics is foreign to Orthodoxy, which rather relies on free human conscience; each Christian, in his behaviour, stands before the judgment of the New Testament and of the great examples of the saints.

THE ORTHODOX CHURCH TODAY

The contemporary Orthodox Church is confronted with major problems of a structural, intellectual, and spiritual nature. On the world level its internal organization, while very decentralized, is still shaped by traditions going back to the Byzantine Empire. The ancient patriarchates of Constantinople, Alexandria, Antioch, and Jerusalem—which occupy the first four places among the autocephalous churches in virtue of their past as major centres of the empire—represent altogether no more than 1,000,000 faithful; and if the patriarch of Antioch still governs a sizable community of Arab Christians in Syria and Lebanon, his three colleagues are dependent upon the human and material support of Greece.

The violent persecutions suffered by the Russian Church after the Communist Revolution and the serious limitations placed upon religious activities by the Socialist states of the Balkans constitute another major test of Orthodoxy's ability to survive in the modern world. The Church of Russia, greatly reduced in numbers and deprived of means of educational, missionary, and intellectual development, has passed the test successfully thus far: the fact that major literary and intellectual figures like Boris Pasternak and Aleksandr Solzhenitsyn have been professed Christians and that millions of the faithful crowd the few churches which are still open, does give much hope to the Orthodox for the future.

Mere survival, however, is insufficient for a meaningful intellectual development, which requires a system of education and a tradition of scholarship. History has not favoured Eastern Orthodoxy in this respect. The Turkish conquest in 1453 brutally interrupted the potential en-

counter between the tradition of the Greek Fathers and the great Western Renaissance, for which Byzantine theologians seemed to be ready. Similarly, the Communist Revolution of 1917 put an end to the remarkable scholarly and spiritual creativity of Orthodox Russia, whose major Christian intellectual figures were either persecuted or emigrated to the West.

In spite of these events, the areas of potential growth and the signs of revival are not lacking. These can be seen not only in the remarkable capacity for survival under adverse conditions, which Orthodox Christianity has recently shown, but also in the efforts to strengthen the unity between the autocephalous churches—five pan-Orthodox conferences met recently in Rhodes (1961, 1963, 1964), Belgrade, and Geneva—and in the Orthodox expansion to Western countries, especially to the Americas. It remains to be seen what positive contribution this new presence will make in the midst of the contemporary crisis of Western Christianity.

Eastern Orthodoxy, History of

Eastern Orthodoxy, tracing its origins to the very beginning of Christianity, is one of the three major forces in Christianity, along with Roman Catholicism and Protestantism. Since the Schism of 1054, Eastern Orthodoxy —centred mainly in the Balkans, the Middle East, and Russia—has experienced unfavourable effects from various ethnic, political, social, and antireligious pressures. In spite of such pressures, which the Western churches have not experienced, Eastern Orthodoxy has not only survived but, at times, it also has thrived.

Throughout the medieval period and up to modern times, the Christian Church in the Middle East, in the Balkans, and in eastern Europe continued a historical development distinct from both the Western Latin world and from the ancient Monophysite (emphasizing the divine nature of Christ) or Nestorian (emphasizing the human nature of Christ) churches of the East that did not accept the decrees of the Council of Chalcedon in 451. Holding the faith of the seven ecumenical councils (from 325–787), it always defined itself as the "Orthodox" Church in distinction to Western Roman Catholicism and Eastern non-Chalcedonian churches. After the 16th century, Russian Orthodox missions developed in northern and eastern Asia and finally on the American continent. In the 20th century, numerous Orthodox communities appeared throughout the Western world and, more recently, in Africa.

The Schism in 1054 that separated East and West, the tragic confrontation with Western Crusaders (*e.g.*, the sack of Constantinople in 1204), the Mongolian conquest of Russia (13th century), and the Turkish occupation of the entire Middle East (15th–20th centuries) contributed to the estrangement between East and West, which was initiated in the first centuries of Christianity. With the emergence of Russia in the 16th century and the independence of the Balkan peoples in the 19th century, East and West met again, but their respective histories and religious beliefs were different. Eastern Orthodoxy, which had rejected the medieval papacy of Rome, had not known the Reformation. It had encountered modern secularism only recently. Its structures and organization had developed in the tight framework of the Byzantine, the Ottoman, and the Russian imperial systems. In matters of faith, however, it had preserved the idea that the entire body of the church (the "people of God"), as distinct from any particular institution such as the papacy, was the guardian of the truth. Also, its insistence on tradition, on the liturgy, on sacramental life, and on the mystical experience of God clearly distinguished its religious outlook from the major principles of Protestantism (*e.g.*, justification by grace through faith).

THE CHURCH OF IMPERIAL BYZANTIUM

Byzantine Christianity around AD 1000. At the beginning of the second millennium of Christian history, the church of Constantinople, capital of the East Roman (or Byzantine) Empire, was at the peak of its world influence and power. Neither Rome, which had become a provincial town and its church an instrument in the hands of political interests, nor Europe under the Carolingian and Ottonian dynasties could really compete with Byzantium as centres of Christian civilization. The Byzantine emperors of the Macedonian dynasty had extended the frontiers of the empire from Mesopotamia to Naples (in Italy) and from the Danube River (in central Europe) to Palestine. The church of Constantinople not only enjoyed a parallel expansion but also extended its missionary penetration, much beyond the political frontiers of the empire, to Russia and the Caucasus.

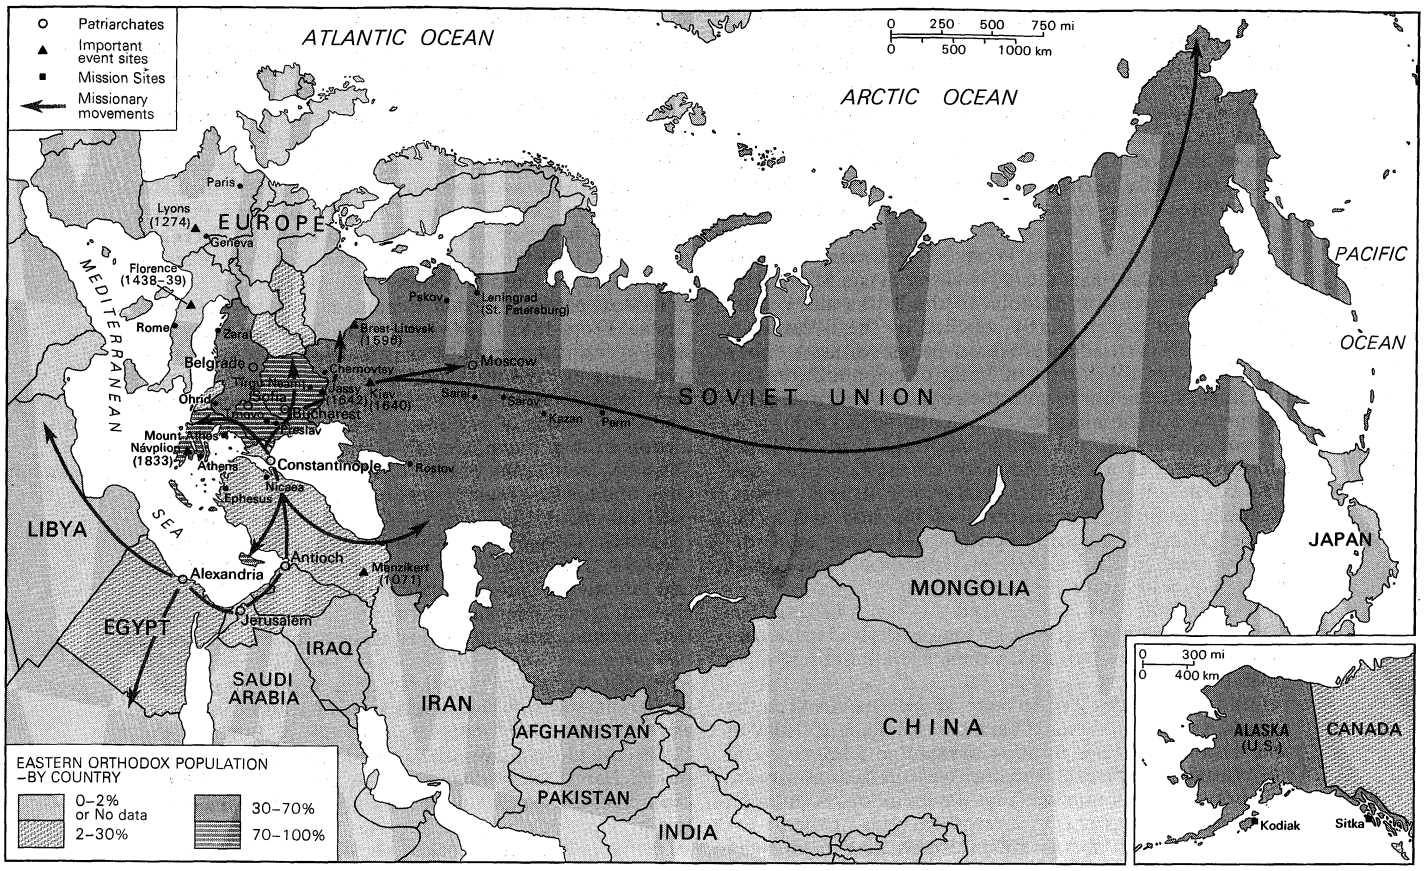
Expansion of Byzantine church and state

Relations between church and state. The ideology that had prevailed since Constantine (4th century) and Justinian I (6th century)—according to which there was to be only one universal Christian society, the *oikoumenē*, led jointly by the empire and the church—was still the ideology of the Byzantine emperors. The authority of the patriarch of Constantinople was motivated in a formal fashion by the fact that he was the bishop of the "new Rome," where the emperor and the senate also resided (canon 28 of the Council of Chalcedon, 451). He held the title of "ecumenical patriarch," which pointed to his political role in the empire. Technically, he occupied the second rank—after the bishop of Rome—in a hierarchy of five major primates, which included also the patriarchs of Alexandria, Antioch, and Jerusalem. In practice, however, the latter three were deprived of all authority by the Arab conquest of the Middle East in the 7th century, and only the emerging Slavic churches attempted to challenge, at times, the position of Constantinople as the unique centre of Eastern Christendom.

The relations between state and church in Byzantium are often described by the term caesaropapism, which implies that the emperor was acting as the head of the church. The official texts, however, describe the emperor and the patriarch as a dyarchy (government with dual authority) and compare their functions to that of the soul and the body in a single organism. In practice, the emperor had the upper hand over much of church administration, though strong patriarchs could occasionally play a decisive role in politics: Patriarch Nicholas Mystikus (patriarch 901–907, 912–925) and Polyeuctus (patriarch 956–970) excommunicated emperors for uncanonical acts. In the area of faith and doctrine, the emperors could never impose their will when it contradicted the conscience of the church: this fact, shown in particular during the numerous attempts at union with Rome during the late medieval period, proves that the notion of caesaropapism is not unreservedly applicable to Byzantium.

Significance of Hagia Sophia

The Church of the Divine Wisdom, or Hagia Sophia, built by Justinian in the 6th century, was the centre of religious life in the Eastern Orthodox world. It was by far the largest and most splendid religious edifice in all of Christendom. According to *The Russian Primary Chronicle*, the envoys of the Kievan prince Vladimir, who visited it in 987, reported: "We knew not whether we were in heaven or on earth, for surely there is no such



The extent of Eastern Orthodoxy in the Balkans, the Middle East, the Soviet Union, and Alaska.
Orthodox Christian population data from *Eastern Orthodox World Directory* by Joe Kuzmission, Copyright 1968 by Branden Press, Inc.

splendor or beauty anywhere upon earth." Hagia Sophia, or the "great church," as it was also called, provided the pattern of the liturgical office, which was adopted throughout the Orthodox world. This adoption was generally spontaneous and based upon the moral and cultural prestige of the imperial capital: the Orthodox Church uses the 9th-century Byzantine Rite.

Monastic and mission movements. Both in the capital and in other centres, the monastic movement continued to flourish as it was shaped during the early centuries of Christianity. The Constantinopolitan monastery of Studius was a community of over 1,000 monks, dedicated to liturgical prayer, obedience, and asceticism. They frequently opposed both government and ecclesiastical officialdom, defending fundamental Christian principles against political compromises. The Studite Rule (guidelines of monastic life) was adopted by daughter monasteries, particularly the famous Monastery of the Caves in Kiev (in Russia). In 963 Emperor Nicephorus II Phocas offered his protection to St. Athanasius, the Athonite, whose laura (large monastery) is still the centre of the monastic republic of Mt. Athos (under the protection of Greece). The writings of St. Symeon the New Theologian (949–1022), abbot of the monastery of St. Mamas in Constantinople, are a most remarkable example of Eastern Christian mysticism, and they exercised a decisive influence on later developments of Orthodox spirituality.

Missionary expansion

Historically, the most significant event was the missionary expansion of Byzantine Christianity throughout eastern Europe. In the 9th century, Bulgaria had become an Orthodox nation and under Tsar Symeon (893–927) had established its own autocephalous (administratively independent) patriarchate in Preslav. Under Tsar Samuel (976–1014) another autocephalous Bulgarian centre appeared in Ohrid. Thus, a Slavic-speaking daughter church of Byzantium dominated the Balkan Peninsula. It lost its political and ecclesiastical independence after the conquests of Byzantine emperor Basil II (976–1025), but the seed of a Slavic Orthodoxy had been solidly planted. In 988 the Kievan prince Vladimir embraced Byzantine Orthodoxy and married a sister of the same emperor Basil. After that time, Russia became an ecclesiastical province of the church of Byzantium, headed by a Greek or, less frequently, a Russian metropolitan appointed from Constantinople. This statute of dependence was not challenged by the Russians until 1448. During the entire period, Russia adopted and developed the spiritual, artistic, and social heritage of Byzantine civilization, which was received through intermediary Bulgarian translators.

Relations with the West. Relations with the Latin West, meanwhile, were becoming more ambiguous. On the one hand, the Byzantines considered the entire Western world as a part of the Roman *oikoumenē* of which the Byzantine emperor was the head and in which the Roman bishop enjoyed honorary primacy. On the other hand, the Frankish and German emperors in Europe were challenging this nominal scheme, and the internal decadence of the Roman papacy was such that the powerful patriarch of Byzantium seldom took the trouble of entertaining any relations with it. From the time of Patriarch Photius (patriarch 858–867, 877–886), the Byzantines had formally condemned the *Filioque* clause, which stated that the Spirit proceeded from the Father and from the Son, as an illegitimate and heretical addition to the Nicene Creed, but in 879–880 Photius and Pope John VIII had apparently settled the matter to Photius' satisfaction. In 1014, however, the *Filoque* was introduced in Rome, and communion was broken again.

The background of the Schism of 1054

The incident of 1054, wrongly considered as the date of the Schism (which had actually been developing over a period of time), was, in fact, an unsuccessful attempt at restoring relations, disintegrating as they were because of political competition in Italy between the Byzantines and the Germans and also because of disciplinary changes (enforced celibacy of the clergy, in particular) imposed by the reform movement that had been initiated by the monks of Cluny (in France). Conciliatory efforts of Emperor Constantine Monomachus (reigned 1042–1055)

were powerless to overcome either the aggressive and uninformed attitudes of the Frankish clergy, who were now governing the Roman Church, or the intransigence of Byzantine patriarch Michael Cerularius (1043–58). When papal legates came to Constantinople in 1054, they found no common language with the patriarch. Both sides exchanged recriminations on points of doctrine and ritual and finally hurled anathemas of excommunication at each other, thus provoking what has been called the Schism.

Invasions from East and West. *The Crusades.* After the Battle of Manzikert (1071) in eastern Asia Minor, Byzantium lost most of Anatolia to the Turks and ceased to be a world power. Partly solicited by the Byzantines, the Western Crusades proved another disaster: they brought the establishment of Latin principalities on former imperial territories and the replacement of Eastern bishops by a Latin hierarchy. The culminating point was, of course, the sack of Constantinople itself in 1204, the enthronement of a Latin emperor on the Bosporus, and the installation of a Latin patriarch in Hagia Sophia. Meanwhile, the Balkan countries of Bulgaria and Serbia secured national emancipation with Western help, the Mongols sacked Kiev (1240), and Russia became a part of the Mongol Empire of Genghis Khan.

The Byzantine heritage survived this series of tragedies mainly because the Orthodox Church showed an astonishing internal strength and a remarkable administrative flexibility.

Until the Crusades, and in spite of such incidents as the exchanges of anathemas between Michael Cerularius and the papal legates in 1054, Byzantine Christians did not consider the break with the West as a final schism. The prevailing opinion was that the break of communion with the West was due to a temporary take-over of the venerable Roman see by misinformed and uneducated German "barbarians," and that eventually the former unity of the Christian world under the one legitimate emperor—that of Constantinople—and the five patriarchates would be restored. This utopian scheme came to an end when the Crusaders replaced the Greek patriarchs of Antioch and Jerusalem with Latin prelates, after they had captured these ancient cities (1098–99). Instead of re-establishing Christian unity in the common struggle against Islām, the Crusades demonstrated how far apart Latins and Greeks really were from each other. When finally, in 1204, after a shameless sacking of the city, the Venetian Thomas Morosini was installed as patriarch of Constantinople and confirmed as such by Pope Innocent III, the Greeks realized the full seriousness of papal claims over the universal church: theological polemics and national hatreds were combined to tear the two churches further apart.

The sack of Constantinople and its aftermath

After the capture of the city, the Orthodox patriarch John Camaterus fled to Bulgaria and died there in 1206. A successor, Michael Autorianus was elected in Nicaea (1208), where he enjoyed the support of a restored Greek empire. Although he lived in exile, this patriarch was recognized as legitimate by the entire Orthodox world. He continued to administer the immense Russian metropolitanate. From him, and not from his Latin competitor, the Bulgarian Church received again its right for ecclesiastical independence with a restored patriarchate in Trnovo (1235). It was also with the Byzantine government at Nicaea that the Orthodox Serbs negotiated the establishment of their own national church; their spiritual leader, St. Sava, was installed as autocephalous (independent) archbishop of Serbia in 1219.

The Mongol invasion. The invasion of Russia by the Mongols had disastrous effects on the future of Russian civilization, but the church survived, both as the only unified social organization and as the main bearer of the Byzantine heritage. The "metropolitan of Kiev and all Russia," who was appointed from Nicaea or from Constantinople, was a major political power, respected by the Mongol Khans. Exempt from taxes paid by the local princes to the Mongols and reporting only to his superior (the ecumenical patriarch), the head of the Russian Church—though he had to abandon his cathedral see of Kiev that had been devastated by the Mongols—acquired an unprecedented moral prestige. He retained ecclesiastical control over immense territories from the Carpathian Mountains to the Volga River, over the newly created episcopal see of Sarai (near the Caspian Sea), which was the capital of the Mongols, as well as over the Western principalities of the former Kievan Empire—even after they succeeded in winning independence (*e.g.*, Galicia) or fell under the political control of Lithuania and Poland.

Attempts at ecclesiastical union and theological renaissance. In 1261 the Nicaean emperor Michael Palaeologus recaptured Constantinople from the Latins, and an Orthodox patriarch again occupied the see in Hagia Sophia. From 1261 to 1453 the Palaeologan dynasty presided over an empire that was embattled from every side, torn apart by civil wars, and gradually shrinking to the very limits of the imperial city itself. The church, meanwhile, kept much of its former prestige, exercising jurisdiction over a much greater territory, which included Russia as well as the distant Caucasus, parts of the Balkans, and the vast regions occupied by the Turks. Several patriarchs of this late period—*e.g.*, Arsenius Autorianus (patriarch 1255–59, 1261–65), Athanasius I (patriarch 1289–93, 1303–10), John Calecas (patriarch 1334–47), and Philotheus Coccinus (patriarch 1353–54, 1364–76)—showed great independence from the imperial power, though remaining faithful to the ideal of the Byzantine *oikoumenē*.

Extension of ecclesiastical jurisdiction

Without the military backing of a strong empire, the patriarchate of Constantinople was, of course, unable to assert its jurisdiction over the churches of Bulgaria and Serbia, which had gained independence during the days of the Latin occupation. In 1346 the Serbian Church even proclaimed itself a patriarchate; a short-lived protest by Constantinople ended with recognition in 1375. In Russia, Byzantine ecclesiastical diplomacy was involved in a violent civil strife; a fierce competition arose between the grand princes of Moscow and Lithuania, who both aspired to become leaders of a Russian state liberated from the Mongol yoke. The "metropolitan of Kiev and all Russia" was by now residing in Moscow, and often, as in the case of the metropolitan Alexis (1354–78), played a directing role in the Muscovite government. The ecclesiastical support of Moscow by the church was decisive in the final victory of the Muscovites and had a pronounced impact on later Russian history. The dissatisfied western Russian principalities (which would later constitute the Ukraine) could only obtain—with the strong support of their Polish and Lithuanian overlords—the temporary appointment of separate metropolitans in Galicia and Belorussia. Eventually, late in the 14th century, the metropolitan residing in Moscow again centralized ecclesiastical power in Russia.

Relations with the Western Church. One of the major reasons behind this power struggle in the northern area of the Byzantine world was the problem of relations with the Western Church. To most Byzantine churchmen, the young Muscovite principality appeared to be a safer bulwark of Orthodoxy than the Western-oriented princes who had submitted to Catholic Poland and Lithuania. Also, an important political party in Byzantium itself favoured union with the West in the hope that a new Western Crusade might be made against the menacing Turks. The problem of ecclesiastical union was, in fact, the most burning issue during the entire Palaeologan period.

The problem of ecclesiastical union

Emperor Michael Palaeologus (1259–82) had to face the aggressive ambition of the Sicilian Norman king Charles of Anjou, who dreamed of restoring the Latin empire in Constantinople. To gain the valuable support of the papacy against Charles, Michael sent a Latin-inspired confession of faith to Pope Gregory X, and his delegates accepted union with Rome at the Council of Lyons (1274). This capitulation before the West, sponsored by the Emperor, won little support in the church. During his lifetime, Michael succeeded in imposing an Eastern Catholic patriarch, John Beccus, upon the Church of Constantinople, but upon Michael's death an Orthodox council condemned the union (1285).

Throughout the 14th century, numerous other attempts at negotiating union were initiated by the emperors of Byzantium. Formal meetings were held in 1333, 1339, 1347, and 1355. In 1369 Emperor John V Palaeologus was personally converted to the Roman faith in Rome. All these attempts were initiated by the government and not by the church, for an obvious political reason; *i.e.*, the hope for Western help against the Turks. But the attempts brought no results either on the ecclesiastical or on the political levels. The majority of Byzantine Orthodox churchmen were not opposed to the idea of union but considered that it could only be brought about through a formal ecumenical council at which East and West would meet on equal footing, as they had done in the early centuries of the church. The project of a council was promoted with particular consistency by John Cantacuzenus, who, after a brief reign as emperor (1347–54), became a monk but continued to exercise great influence on all ecclesiastical and political events. The idea of an ecumenical council was initially rejected by the popes, but it was revived in the 15th century with the temporary triumph of conciliarist ideas (which advocated more power to councils and less to popes) in the West at the councils of Constance and Basel. Challenged with the possibility that the Greeks would unite with the conciliarists and not with Rome, Pope Eugenius IV called an ecumenical council of union in Ferrara, which later moved to Florence.

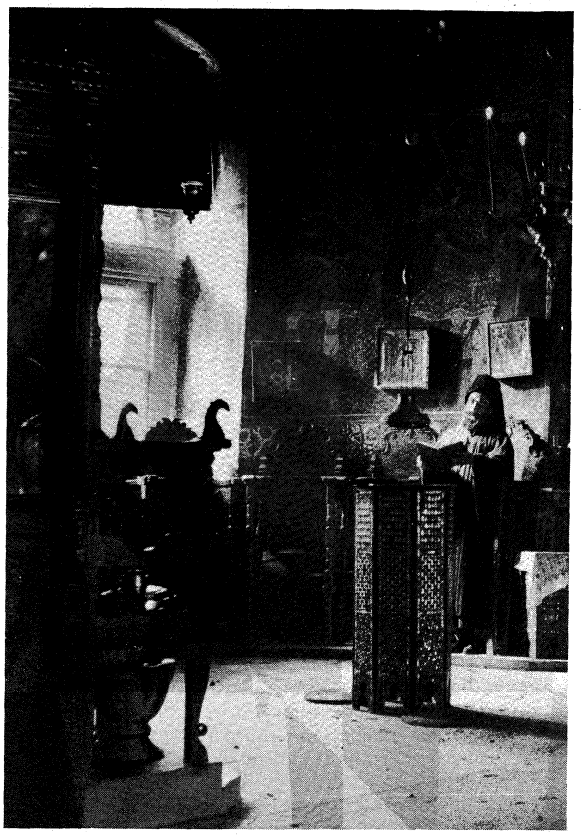
The Council of Ferrara–Florence

The Council of Ferrara–Florence (1438–45) lasted for months and allowed for long theological debates. Emperor John VIII Palaeologus, Patriarch Joseph, and numerous bishops and theologians represented the Eastern Church. They finally accepted most Roman positions—the *Filioque* clause, purgatory (an intermediate stage for the soul's purification between death and heaven), and the Roman primacy. Political desperation and the fear of facing the Turks again, without Western support, was the decisive factor that caused them to place their signatures of approval on the Decree of Union (July 6, 1439). The metropolitan of Ephesus, Mark Eugenicus, alone refused to sign. Upon their return to Constantinople, most other delegates also renounced their acceptance of the council and no significant change occurred in the relations between the churches.

The official proclamation of the union in Hagia Sophia was postponed until December 12, 1452; however, on May 29, 1453, Constantinople fell to the Ottoman Turks. Sultan Mehmed II transformed Hagia Sophia into an Islāmic mosque, and the few partisans of the union fled to Italy.

Theological and monastic renaissance. Paradoxically, the pitiful history of Byzantium under the Palaeologan emperors coincided with an astonishing intellectual, spiritual, and artistic renaissance that influenced the entire Eastern Christian world. The renaissance was not without fierce controversy and polarization. In 1337 Barlaam the Calabrian, one of the representatives of Byzantine Humanism, attacked the spiritual practices of the Hesychast (from the Greek word *hēsychia*, meaning quiet) monks, who claimed that Christian asceticism and spirituality could lead to the vision of the "uncreated light" of God. Barlaam's position was upheld by several other theologians, including Akyndinus and Nicephorus Gregoras. After much debate, the church gave its support to the main spokesman of the monks, Gregory Palamas, who showed himself as one of the foremost theologians of medieval Byzantium (1296–1359). The councils of 1341, 1347, and 1351 adopted the theology of Palamas and, after 1347, the patriarchal throne was consistently occupied by his disciples. John Cantacuzenus, who, as emperor, presided over the council of 1351, gave his full support to the Hesychasts. His close friend, Nicholas Cabasilas, in his spiritual writings on the divine liturgy and the sacraments, defined the universal Christian significance of Palamite theology. The influence of the religious zealots, who triumphed in Constantinople, outlasted the empire itself and contributed to the perpetuation of Orthodox spirituality under the Turkish rule. It also spread to the Slavic countries, especially Bulgaria and Russia. The monastic revival in northern Russia during the last half of the 14th century, associated with the name of St. Sergius of Radonezh, as well as the contemporaneous revival of iconography (*e.g.*, the work of the famous painter Andrey Rublev), would be unthinkable without constant contacts with Mt. Athos, the centre of Hesychasm and with the spiritual and intellectual life of Byzantium.

Pierre Vals—*Paris Match*



Orthodox monk meditating in a chapel on Mount Athos.

Along with the Hesychast revival, a significant "opening to the West" was taking place among some Byzantine ecclesiastics. The brothers Prochorus and Demetrius Cydones, under the sponsorship of Cantacuzenus, for example, were systematically translating the works of Latin theologians into Greek. Thus, major writings of Augustine, Anselm of Canterbury, and Thomas Aquinas were made accessible to the East for the first time. Most of the Latin-minded Greek theologians eventually supported the union policy of the emperors, but there were some—like Gennadius Scholarius, the first patriarch under the Turkish occupation—who reconciled their love for Western thought with total faithfulness to the Orthodox Church.

ORTHODOXY UNDER THE OTTOMANS (1453–1821)

The Christian ghetto. According to Muslim belief, Christians, as well as Jews, were considered as "people of the Book"; *i.e.*, their religion was seen as not entirely false, but incomplete. Accordingly, provided that Christians submitted to the dominion of the caliphate and the Muslim political administration and paid appropriate taxes, they deserved consideration and freedom of worship. Any Christian mission or proselytism among the Muslims, however, was considered a capital crime. In fact, Christians were formally reduced to a ghetto existence: they were the *Rūm millet*, or the "Roman nation" conquered by Islām but enjoying a certain internal autonomy.

Conditions of Christians under Muslim rule

In January 1454 the Sultan allowed the election of a new patriarch, who was to become *millet-bachi*, the head of the entire Christian *millet*, or in Greek the "ethnarch," with the right to administer, to tax, and to exercise justice

over all the Christians of the Turkish empire. Thus, under the new system, the patriarch of Constantinople saw his formal rights and jurisdiction extended both geographically and substantially: on the one hand, through the privileges granted to him by the sultan, he could practically ignore his colleagues, the other Orthodox patriarchs, and, on the other hand, his power ceased to be purely canonical and spiritual but became political as well. To the enslaved Greeks, he appeared not only as the successor of the Byzantine patriarchs but also as the heir of the emperors. For the Ottomans, he was the official and strictly controlled administrator of the *Rūm millet*. In order to symbolize these new powers, the patriarch adopted an external attire reminiscent of that of the emperors: mitre in form of a crown, long hair, eagles as insignia of authority, and other imperial accoutrements.

Consequences of the *millet* system

The new system had many significant consequences. Most important, it permitted the church to survive as an institution; indeed, the prestige of the church was actually increased because, for Christians, the church was now the only source of education and it alone offered possibilities of social promotion. Moreover, through the legal restrictions placed on mission, the new arrangement created the practical identification of church membership with ethnic origin. And finally, since the entire Christian *millet* was ruled by the patriarch of Constantinople and his Greek staff, it guaranteed to the Phanariots, the Greek aristocracy of the Phanar (now called Fener, the area of Istanbul where the patriarchate was, and still is, located), a monopoly in episcopal elections. Thus, Greek bishops progressively came to occupy all the hierarchical positions. The ancient patriarchates of the Middle East were practically governed by the Phanar. The Serbian and Bulgarian churches came to the same fate: the last remnants of their autonomy were formally suppressed in 1766 and 1767, respectively, by the Phanariot patriarch Samuel Hantcherli. This Greek control, exercised through the support of the hated Turks, was resented more and more by the Balkan Slavs and Romanians as the Turkish regime became more despotic, taxes grew heavier, and modern nationalisms began to develop.

It is necessary, however, to credit the Phanariots with a quite genuine devotion to the cause of learning and education, which they alone were able to provide inside the oppressed Christian ghetto. The advantages they obtained from the Porte (the Turkish government) for building schools and for developing Greek letters in the Romanian principalities of Moldavia and Walachia that were entrusted to their rule came to play a substantial role in the rebirth of Greece.

Relations with the West. The Union of Florence became fully inoperative as soon as the Turks occupied Constantinople (1453). In 1484 a council of bishops condemned it officially. Neither the sultan nor the majority of the Orthodox Greeks were favourable to the continuation of political ties with Western Christendom. The Byzantine cultural revival of the Palaeologan period was the first to experience adverse effects from the occupation. Intellectual dialogue with the West became impossible. Through liturgical worship and the traditional spirituality of the monasteries, the Orthodox faith was preserved in the former Byzantine world. Some self-educated men developed a remarkable ability to develop the Orthodox tradition through writings and publications, but they were isolated exceptions. Probably the most remarkable among them was St. Nicodemus of the Holy Mountain, the Hagiorite (1748–1809), who published the famous *Philocalia*, an anthology of spiritual writings, and also translated and adapted Western spiritual writings (*e.g.*, those of the Jesuit founder, Ignatius of Loyola) into modern Greek.

East–West contacts through education and ecumenical correspondence

The only way for Orthodox Greeks, Slavs, or Romanians to acquire an education higher than the elementary level was to go to the West. Several of them were able to do so, but, in the process, became detached from their own theological and spiritual tradition.

The West, in spite of much ignorance and prejudice, had a constant interest in the Eastern Church. At times there was a genuine and respectful curiosity; in other instances, political and proselytistic (conversion) concerns prevailed. Thus, in 1573–81, a lengthy correspondence was initiated by the Lutheran scholars from Tübingen (in Germany), including Philipp Melanchthon. However interesting as a historical event, this correspondence, which includes the *Answers* of Patriarch Jeremias II (patriarch 1572–95), shows how little mutual understanding was possible at that time between the Reformers and traditional Eastern Christianity.

Relations with the West, especially after the 17th century, were often vitiated in the East by the incredible corruption of the Turkish government, which constantly fostered diplomatic intrigues. An outstanding example of such manipulation was the *kharāj*, an important tax required by the Porte at each patriarchal election. Western diplomats were often ready to provide the amount needed in order to secure the election of candidates favourable to their causes. The French and Austrian ambassadors, for example, supported candidates who would favour the establishment of Roman Catholic influence in the Christian ghetto, while the British and Dutch envoys supported patriarchs who were open to Protestant ideas. Thus, a gifted and Western-educated patriarch, Cyril Lucaris, was elected and deposed five times between 1620 and 1638. His stormy reign was marked by the publication in Geneva of a *Confession of Faith* (1629), which was, to the great amazement of all contemporaries, purely Calvinistic (*i.e.*, it contained Reformed Protestant views). The episode ended in tragedy. Cyril was strangled by Turkish soldiers at the instigation of the pro-French and pro-Austrian party. Six successive Orthodox councils condemned the *Confession:* Constantinople, 1638; Kiev, 1640; Jassy, 1642; Constantinople, 1672; Jerusalem, 1672; and Constantinople, 1691. In order to refute its positions, the metropolitan of Kiev, Peter Mogila, published his own *Orthodox Confession of Faith* (1640), which was followed, in 1672, by the *Confession* of the patriarch of Jerusalem, Dosítheos Notaras. Both, especially Peter Mogila, were under strong Latin influence.

These episodes were followed, in the 18th century, by a strong anti-Western reaction. In 1755 the Synod of Constantinople decreed that all Westerners—Latin or Protestant—had invalid sacraments and were only to be admitted into the Orthodox Church through Baptism. This practice of the Greek Church fell into disuse only in the 20th century.

THE CHURCH OF RUSSIA (1448–1800)

The "third Rome." *Origin of the Muscovite patriarchate.* At the Council of Florence, the Greek "metropolitan of Kiev and all Russia." Isidore, was one of the major architects of the Union. Having signed the decree, he returned to Moscow in 1441 as a Roman cardinal but was rejected by both church and state, arrested, and then allowed to escape to Lithuania. In 1448, after much hesitation, the Russians received a new primate, Jonas, elected by their own bishops. Their church became "autocephalous"; *i.e.*, administratively independent under a "metropolitan of all Russia," residing in Moscow. In territories controlled by Poland, Rome (in 1458) appointed another "metropolitan of Kiev and all Russia." The tendencies toward separation from Moscow that had existed in the Ukraine since the Mongol invasion and that were supported by the kings of Poland thus received official sanction. In 1470, however, this metropolitan broke the union with the Latins and re-entered—nominally—the jurisdiction of Constantinople, by then under Turkish control.

Independence of the Moscow metropolitanate

After this, the fate of the two churches "of all Russia" became quite distinct. The metropolitanate of Kiev developed under the control of Roman Catholic Poland. Hard pressed by the Polish kings, the majority of its bishops, against the will of the majority of their flock, eventually accepted union with Rome at Brest-Litovsk (1596). In 1620, however, an Orthodox hierarchy was reestablished, and a Romanian nobleman, Peter Mogila, was elected metropolitan of Kiev (1632). He created the first Orthodox theological school of the modern period.

the famous Academy of Kiev. Modelled after the Latin seminaries of Poland, with instruction given in Latin, this school served as the theological training centre for almost the entire Russian high clergy in the 17th and 18th centuries. In 1686 the Ukraine was finally reunited with Muscovy, and the metropolitanate of Kiev was attached to the patriarchate of Moscow, with approval given by Constantinople.

Muscovite Russia, meanwhile, had acquired the consciousness of being the last bulwark of true Orthodoxy. In 1472 Grand Prince Ivan III (reigned 1462–1505) married Sophia, the niece of the last Byzantine emperor. The Muscovite sovereign began to use more and more of the Byzantine imperial ceremonial, and he assumed the double-headed eagle as his state emblem. In 1510 the monk Philotheus of Pskov addressed Basil III as "tsar," (or emperor), saying: "Two Romes have fallen, but the third stands, and a fourth there will not be." The meaning of the sentence was that the first Rome was heretical, the second—Byzantium—was under Turkish control, and the third was Moscow. Ivan IV, the Terrible, was crowned emperor, according to the Byzantine ceremonial, by the metropolitan of Moscow, Makary, on January 16, 1547. In 1551 he solemnly presided in Moscow over a great council of Russian bishops, the Stoglav ("Council of 100 Chapters"), in which various issues of discipline and liturgy were settled and numerous Russian saints were canonized. These obvious efforts to live up to the title of the "third Rome" lacked one final sanction: the head of the Russian Church was lacking the title of "patriarch." The "tsars" of Bulgaria and Serbia did not hesitate in the past to bestow the title on their own primates, but the Russians wanted an unquestionable authentication and waited for proper opportunity. It occurred in 1589 when the patriarch of Constantinople, Jeremias II, was on a fund-raising tour of Russia. He could not resist the pressure of his hosts and established the metropolitan Job as "patriarch of Moscow and all Russia." Confirmed later by the other Eastern patriarchs, the new patriarchate obtained the fifth place in the honorific order of the Oriental sees, after the patriarchs of Constantinople, Alexandria, Antioch, and Jerusalem.

The "third Rome" ideology

Relations between patriarch and tsar. After the 16th century, the Russian tsars always considered themselves as successors of the Byzantine emperors and the political protectors and financial supporters of Orthodoxy throughout the Balkans and the Middle East. The patriarch of Moscow, however, never pretended to occupy formally the first place among the patriarchs. Within the Muscovite Empire, many traditions of medieval Byzantium were faithfully kept. A flourishing monastic movement spread the practice of Christian asceticism in the northern forests, which were both colonized and Christianized by the monks. St. Sergius of Radonezh (*c.* 1314–92) was the spiritual father of this monastic revival. His contemporary, St. Stephen of Perm, missionary to the Zyryan tribes, continued the tradition of SS. Cyril and Methodius, the "apostles to the Slavs" in the 9th century, in translating the Scripture and the liturgy into the vernacular. He was followed by numerous other missionaries who promoted Orthodox Christianity throughout Asia and even established themselves on Kodiak Island off the coast of Alaska (1794). The development of church architecture, iconography, and literature also added to the prestige of the "third Rome."

Russian monastic and missionary activities

The Muscovite Empire, however, was quite different from Byzantium both in its political system and in its cultural self-understanding. The Byzantine "symphony" (harmonious relationship) between the emperor and the patriarch was never really applied in Russia. The secular goals of the Muscovite state and the will of the monarch always superseded canonical or religious considerations, which were still binding on the medieval emperors of Byzantium. Muscovite political ideology was always influenced more by the beginnings of western European secularism and by Asiatic despotism than by Roman or Byzantine law. Though strong patriarchs of Constantinople were generally able to oppose open violations of dogma and canon law by the emperors, their Russian successors were quite powerless; a single metropolitan of Moscow, St. Philip (metropolitan 1566–68), who dared to condemn the excesses of Ivan IV, was deposed and murdered.

A crisis of the "third Rome" ideology occurred in the middle of the 17th century. Nikon (reigned 1652–58), a strong patriarch, decided to restore the power and prestige of the church by declaring that the patriarchal office was superior to that of the tsar. He forced the tsar Alexis Romanov to repent for the crime of his predecessor against St. Philip and to swear obedience to the church. Simultaneously, Nikon attempted to settle a perennial issue of Russian church life: the problem of the liturgical books. Originally translated from the Greek, the books suffered many corruptions through the centuries and contained numerous mistakes. In addition, the different historical developments in Russia and in the Middle East had led to differences between the liturgical practices of the Russians and the Greeks. Nikon's solution was to order the exact compliance of all the Russian practices with the contemporary Greek equivalents. His liturgical reform led to a major schism in the church. The Russian masses had taken seriously the idea that Moscow was the last refuge of Orthodoxy. They wondered why Russia had to accept the practices of the Greeks, who had betrayed Orthodoxy in Florence and had been justly punished by God, in their view, by becoming captives of the infidel Turks. The reformist decrees of the patriarch were rejected by millions of lower clergy and laity who constituted the Raskol, or schism of the "Old Believers." Nikon was ultimately deposed for his opposition to the tsar, but his liturgical reforms were confirmed by a great council of the church that met in the presence of two Eastern patriarchs (1666–67).

Schism in the Russian Church

The reforms of Peter the Great (reigned 1682–1725). The son of Tsar Alexis, Peter the Great, changed the historical fate of Russia by radically turning away from the Byzantine heritage and reforming the state according to the model of Protestant Europe. Humiliated by his father's temporary submission to Patriarch Nikon, Peter prevented new patriarchal elections after the death of Patriarch Adrian in 1700. After a long vacancy of the see, he abolished the patriarchate altogether (1721) and transformed the central administration of the church into a department of the state, which adopted the title of "Holy Governing Synod." An imperial high commissioner (*Oberprokuror*) was to be present at all meetings and, in fact, to act as the administrator of church affairs. Peter also issued a lengthy *Spiritual Regulation* (*Dukhovny Reglament*) that served as bylaws for all religious activities in Russia. Weakened by the schism of the "Old Believers," the church found no spokesman to defend its rights and passively accepted the reforms.

With the actions of Peter, the Church of Russia entered a new period of its history that lasted until 1917. The immediate consequences were not all negative. Peter's ecclesiastical advisers were Ukrainian prelates, graduates of the Kievan academy, who introduced in Russia a Western system of theological education; the most famous among them was Peter's friend, Feofan Prokopovich, archbishop of Pskov. Throughout the 18th century, the Russian Church also continued its missionary work in Asia and produced several spiritual writers and saints: St. Mitrofan of Voronezh (died 1703), St. Tikhon of Zadonsk (died 1783)—an admirer of the German Lutheran Johann Arndt and of German Pietism—as well as other eminent prelates and scholars such as Platon Levshin, metropolitan of Moscow (died 1803). All attempts at challenging the power of the tsar over the church, however, always met with failure. The metropolitan of Rostov, Arseny Matsiyevich, who opposed the secularization of church property by the empress Catherine the Great, was deposed and died in prison (1772). The atmosphere of secularistic officialdom that prevailed in Russia was not favourable for a revival of monasticism, but such a revival did take place through the efforts of a young Kievan scholar, Paissy Velichkovsky (1722–94), who became the abbot of the monastery of Neamts in Romania. His Slavonic edition of the *Philocalia* con-

tributed to the revival of Hesychast traditions in Russia in the 19th century.

THE ORTHODOX CHURCHES IN THE 19TH CENTURY

Autocephalies in the Balkans. The ideas of the French Revolution, the nationalistic movements, and the ever-living memory of past Christian empires led to the gradual disintegration of Turkish domination in the Balkans. According to a pattern existing since the late Middle Ages, the birth of national states was followed by the establishment of independent, "autocephalous" Orthodox churches. Thus the collapse of the Ottoman rule was accompanied by the rapid shrinking of the actual power exercised by the patriarch of Constantinople. Paradoxically, the Greeks, for whom—more than anyone—the patriarchate represented a hope for the future, were the first to organize an independent church in their new state.

The establishment of independent nationalistic churches

In Greece. In 1821 the Greek revolution against the Turks was officially proclaimed by the metropolitan of Old Patras, Germanos. The patriarchate, being the official Turkish-sponsored organ for the administration of the Christians, issued statements condemning and even anathematizing the revolutionaries. These statements, however, failed to convince anyone, least of all the Turkish government, who on Easter Day in 1821 had the ecumenical (Constantinopolitan) patriarch Gregory V hanged from the main gate of the patriarchal residence as a public example. Numerous other Greek clergy were executed in the provinces. After this tragedy, the official loyalty of the patriarchate was, of course, doubly secured. Unable either to communicate with the patriarchate or to recognize its excommunications, the bishops of liberated Greece gathered in Návplion and established themselves as the synod of an autocephalous church (1833). The ecclesiastical regime adopted in Greece was modelled after that of Russia: a collective state body, the Holy Synod, was to govern the church under strict government control. In 1850 the patriarchate was forced to recognize what was by then a *fait accompli*, and granted a charter of autocephaly (*tómos*) to the new Church of Greece.

In Serbia. The independence of Serbia led, in 1832, to the recognition of Serbian ecclesiastical autonomy. In 1879 the Serbian Church was recognized by Constantinople as autocephalous under the primacy of the metropolitan of Belgrade. This church, however, covered only the territory of what was called "old Serbia." The small state of Montenegro, always independent from the Turks, had its own metropolitan in Cetinje. This prelate, who was also the civil and military leader of the nation, was consecrated either in Austria, or, as in the case of the famous bishop-poet Pyotr II Negosh, in St. Petersburg (1833).

In the Austro-Hungarian empire, two autocephalous churches, with jurisdiction over Serbs, Romanians, and other Slavs, were in existence during the second half of the century. These were the patriarchate of Sremski-Karlovci (Karlowitz), established in 1848, which governed all the Orthodox in the Kingdom of Hungary; and the metropolitanate of Czernowitz (now Chernovtsy) in Bukovina, which, after 1873, also exercised jurisdiction over two Serbian dioceses (Zara and Kotor) in Dalmatia. The Serbian dioceses of Bosnia and Herzegovina, acquired by Austria in 1878, remained autonomous but were never completely independent from Constantinople.

In Romania. The creation of an independent Romania, after centuries of foreign control by Bulgarians, Turks, Greek-Phanariots, and, more recently, Russians, led in 1865 to the self-proclamation of the Romanian Church as autocephalous, even against the violent protests of the Phanar. As in Greece, the new church was under the strict control of the pro-Western government of Prince Alexandru Cuza. Finally, as in the Greek case, Constantinople recognized the Romanian autocephaly under the metropolitan of Bucharest (1885). The Romanians of Transylvania, still in Austria–Hungary, remained under the autocephalous metropolitan of Sibiu and others under the church of Czernowitz.

In Bulgaria. The re-establishment of the Church of Bulgaria eventually was secured, but not without tragedy and even a schism; this happened mainly because the issue of re-establishing the autocephalous church arose at a time when both Greek and Bulgarian populations lived side by side in Macedonia, Thrace, and Constantinople itself, though still within the framework of the Ottoman imperial system. After the Turkish conquest, and especially in the 17th and 18th centuries, the Bulgarians were

governed by Greek bishops and were often prevented from worshipping in Slavonic. This enforced policy of Hellenization was rejected in the 19th century when Bulgarians began to claim not only a native clergy but also equal representation on the higher echelons of the Christian *millet; i.e.*, the offices of the patriarchate. These claims were met with firm resistance by the Greeks. The alternative was a national Bulgarian Church, which was created by a sultan's firman (decree) in 1870. The new church was to be governed by its own Bulgarian exarch, who resided in Constantinople itself and governed all the Bulgarians who recognized him. The new situation was uncanonical, because it sanctioned the existence of two separate ecclesiastical structures on the same territory. Ecumenical Patriarch Anthimus VI convened a synod in Constantinople, which also included the Greek patriarchs of Alexandria and Jerusalem (1872). The council condemned "phyletism"—the national or ethnic principle in church organization—and excommunicated the Bulgarians, who were certainly not alone guilty of "phyletism." This schism lasted until 1945, when a reconciliation took place with full recognition of Bulgarian autocephaly within the limits of the Bulgarian state.

The problem of the national or ethnic principle

After their liberation from the Turkish yoke, the Balkan churches freely developed both their national indentities and their religious life. Theological faculties, generally following German models, were created in Athens, Belgrade (in Yugoslavia), Sofia (in Bulgaria), and Bucharest (in Romania). The Romanian Church introduced the full cycle of the liturgical offices in vernacular Romanian. But these positive developments were often marred by nationalistic rivalries. In condemning "phyletism," the synod of Constantinople (1872) had, in fact, defined a basic problem of modern Orthodoxy.

The church in imperial Russia. *The Spiritual Regulation* of Peter the Great remained in force until the very end of the Russian Empire (1917). Many Russian churchmen consistently complained against the submission of the church to the state, but there was little they could do except to lay plans for future reforms. This they did not fail to do, and in the 20th century the necessary changes were rapidly enacted. Though Peter himself and his first successors tended to deal personally and directly with church affairs, the tsars of the 19th century delegated much authority to the *Oberprokurors*, who received a cabinet rank in the government and were the real heads of the entire administration of the church. One of the most debilitating aspects of the regime was the legal division of Russian society by a rigid caste system. The clergy was one of the castes with its own school system, and there was little possibility for its children to choose another career.

In spite of these obvious defects, the church kept its self-awareness, and among the episcopate such eminent figures as Philaret of Moscow (1782–1867) promoted education, theological research, biblical translations, and missionary work. In each of its 67 dioceses, the Russian Church created a seminary for the training of priests and teachers. In addition, four theological academies, or graduate schools, were established in major cities (Moscow, 1769; St. Petersburg, 1809; Kiev, 1819; Kazan, 1842). They provided a generally excellent theological training for both Russians and foreigners. The rigid caste system and the strictly professional character of these schools, however, were serious obstacles to their seriously influencing society at large. It was, rather, through the monasteries and their spirituality that the church began to reach the intellectual class. More influential than the rigid discipline of the large monastic communities, the prophetic ministry of the "elders" (*startsy*), who acted as living examples of the standards of the spiritual life or as advisers and confessors, attracted large masses of the common people, and also intellectuals. St. Seraphim of Sarov (1759–1833), for example, lived according to the standards of the ancient Hesychast tradition that had been revived in the Russian forests. The *startsy* of Optino —Leonid (1768–1841), Makarius (1788–1860), and Ambrose (1812–91)—were visited not only by thousands of ordinary Christians but also by the writers Nikolay Gogol, Leo Tolstoy, and Fyodor Dostoyevsky. The latter was inspired by the *startsy* when he described in his novels monastic figures such as Zossima in *The Brothers Karamazov*. From the ranks of an emerging group of Orthodox lay intellectuals, the production of a living theology—if less scholarly than in the academies—was taking shape. The great influence of a lay theologian like Aleksey Khomyakov (1804–60), who belonged to the Slavophile (pro-Slavic) circle before it acquired a political flavour, eventually helped in the conversion to Orthodoxy at the end of the century of such leading Marxists as Sergey Bulgakov (1871–1944) and Nikolay Berdyayev (1874–1948).

Significance of Russian monasticism

Missionary expansion also continued, with the theological Academy of Kazan specializing in missions to Islām. By the year 1903, the liturgy was celebrated in more than 20 languages in the region of Kazan. An Orthodox missionary society coordinated these missionary efforts. Nikolay Kasatkin (1836–1913), canonized as a saint in 1970, founded an indigenous church in Japan. A married priest, Ivan Veniaminov, was sent to Alaska in 1822 in order to continue the work of the first mission. His work among the Aleuts, Eskimos, and Tlingit Indians is still continuing today. Under the name of Innocent, Veniaminov was the first Orthodox bishop to reside on American soil (1840).

Disproportionately larger and richer than its sister churches of the Balkans and the Middle East, the Church of Russia included, in 1914, more than 50,000 priests, 21,330 monks, and 73,299 nuns. It supported thousands of schools and missions. It cooperated with the Russian government in exercising great influence in Mid-Eastern affairs. Thus, with Russian help, an Arab (Meletios Doumani) rather than a Greek was elected for the first time as patriarch of Antioch (1899). With the successive partitions of Poland and the reunions with Russia of Belorussian and Ukrainian territories, many Eastern Catholic descendants from those who had joined the Roman communion in Brest-Litovsk (1596) returned to Orthodoxy.

The condition of the Russian Church on the eve of World War I

After 1905, Tsar Nicholas II gave his approval for the establishment of a preconciliar commission charged with the preparation of an all-Russian Church Council. The avowed goal of the planned assembly was to re-establish the church's independence, lost since Peter the Great, and eventually to restore the patriarchate. This assembly, however, was fated to meet only after the fall of the empire.

THE ORTHODOX CHURCH SINCE WORLD WAR I

The almost complete disappearance of Christianity in Asia Minor, the regrouping of the Orthodox churches in the Balkans, the tragedy of the Russian Revolution, and the Orthodox diaspora in the West radically changed the entire structure of the Orthodox world.

The Russian Revolution and the Soviet period. The Church of Russia was less unprepared than generally believed to face the revolutionary turmoil. Projects of necessary reforms had been prepared since 1905, and most clergy did not feel particularly attached to the fallen regime that had deprived the church of its freedom for several centuries. During the rule of the provisional government, in August 1917 a council representing the entire church met in Moscow, including 265 members of the clergy and 299 laymen. The democratic composition and program of the council had been planned by the Pre-Conciliar Commission. It adopted a new constitution of the church that provided for the re-establishment of the patriarchate, the election of bishops by the dioceses, and the representation of laymen on all levels of church administration. It was only in the midst of the new revolutionary turmoil, however, that Tikhon, metropolitan of Moscow, was elected patriarch (October 31, 1917—six days after the Bolshevik take-over). The bloody events into which the country was plunged did not allow all of the reforms to be carried out, but new bishops were elected in several dioceses by the people.

The Bolshevik government, because of its Marxist ideology, considered all religion as the "opium of the

The effects of the Russian Revolution on the church

people." On January 20, 1918, it published a decree depriving the church of all legal rights, including that of owning property. The stipulations of the decree were difficult to enforce immediately, and the church remained a powerful social force for several years. The patriarch replied to the decree by excommunicating the "open or disguised enemies of Christ," without naming the government specifically. He also made pronouncements on political issues that he considered of moral importance: in March 1918 he condemned the peace of Brest-Litovsk that brought an unsatisfactory armistice between Russia and the Central Powers, and in October he addressed an "admonition" to Lenin, calling on him to proclaim an amnesty. Tikhon was careful, however, not to appear as a counter-revolutionary and in September 1919 called the faithful to refrain from supporting the Whites (anti-Communists) and to obey those decrees of the Soviet government that were not contrary to their Christian conscience.

The independence of the church suffered greatly after 1922. In February of that year, the government decreed the confiscation of all valuable objects preserved in the churches. The patriarch would have agreed to that measure if he had had the means to check on the government contention that all confiscated church property would be used to help the starving population on the Volga. The government refused all guarantees but supported a group of clergy who were ready to cooperate with it and to overthrow the patriarch. While Tikhon was under house arrest, this group took over his office and soon claimed the allegiance of a sizable proportion of bishops and clergy. This became known as the schism of the "Renovated" or "Living" Church, and it broke the internal unity and resistance of the church. Numerous bishops and clergy faithful to the patriarch were tried and executed, including the young and progressive metropolitan Benjamin of Petrograd. The "Renovated" Church soon broke the universal discipline of Orthodoxy by admitting married priests to the episcopate and by permitting widowed priests to remarry.

Upon his release, Tikhon condemned the schismatics and many clergy returned to his obedience. But he also published a declaration affirming that he "was not the enemy of the Soviet government" and dropped any opposition to the authorities, setting a pattern that is still continued. Tikhon's attitude of conformism did not bring immediate results. His designated successors (after he died in 1925) were all arrested. In 1927 the "substitute *locum tenens*" (holder of the position) of the patriarchate, Metropolitan Sergius, pledged loyalty to the Soviet government. Nevertheless, under the rule of Joseph Stalin in the late 1920s and 1930s, the church suffered a bloody persecution that claimed thousands of victims. By 1939 only three or four Orthodox bishops and 100 churches could officially function: the church was practically suppressed.

Post-World War II developments in the Soviet Union

A spectacular reversal of Stalin's policies occurred, however, during World War II. Sergius was elected patriarch in 1943 and the "Renovated" schism was ended. Under Sergius' successor, Patriarch Alexis (1945–70), the church was able to open 25,000 churches and the number of priests reached 33,000. But a new anti-religious move was initiated by Prime Minister Nikita Khrushchev in 1959–64, reducing the number of open churches to less than 10,000.

With the election of Patriarch Pimen (1971), which followed the death of Alexis, the future of the church in the Soviet Union is still uncertain. In spite of 50 years of antireligious propaganda, the church still commands the loyalty of millions, yet, in order to survive, its leaders must show total cooperation with the government.

The Balkans and eastern Europe. In bringing about the fall of the Turkish, Austrian, and Russian empires, World War I provoked significant changes in the structures of the Orthodox Church. On the western borders of the Soviet Union, in the newly born republics of Finland, Estonia, Latvia, and Lithuania, the Orthodox minorities established themselves as autonomous churches. The first three joined the jurisdiction of Constantinople, and the Lithuanian diocese remained nominally under Moscow. In Poland, which now included several million Belorussians and Ukrainians, the ecumenical patriarch established an autocephalous church (1924) over the protests of Patriarch Tikhon. After World War II, the Estonian, Latvian, and Lithuanian autonomies were again suppressed, and in Poland the Orthodox Church was first reintegrated to the jurisdiction of Moscow and later was declared autocephalous again (1948).

In the Balkans, changes were even more significant. The five groups of Serbian dioceses (Montenegro, patriarchate of Karlovci, Dalmatia, Bosnia-Herzegovina, Old Serbia) were united (1920–22) under one Serbian patriarch, residing in Belgrade, the capital of the new Yugoslavia. Similarly, the Romanian dioceses of Moldavia-Walachia, Transylvania, Bukovina, and Bessarabia formed the new patriarchate of Romania (1925), the largest autocephalous church in the Balkans. Finally, in 1937, after some tension and a temporary schism, the patriarchate of Constantinople recognized the autocephaly of the Church of Albania.

Relations between church and state in the Balkans

After World War II, Communist regimes were established in the Balkan states. There were no attempts, however, at liquidating the churches entirely, similar to the persecutions that took place in Russia in the 1920s and 1930s. In both Yugoslavia and Bulgaria, church and state were legally separated. In Romania, paradoxically, the Orthodox Church remained legally linked to the Communist state. With its solid record of resistance to the Germans, the Serbian Church was able to preserve more independence from the government than its sister churches of Bulgaria and Romania. Generally speaking, however, all the Balkan churches adopted an attitude of loyalty to the new regime, according to the pattern given by the patriarchate of Moscow. At that price, they could keep some theological schools, some publications, and the possibility to worship. This is also the case of the Orthodox minority in Czechoslovakia, which was united and organized into an autocephalous church by the patriarchate of Moscow in 1951. Only in Albania did a Communist government announce the total liquidation of organized religion, following the Cultural Revolution of 1966–68.

Among the national Orthodox churches, the Church of Greece is the only one that preserved the legal status it acquired in the 19th century as the national state church. As such, it was supported by the successive political regimes of Greece. It could also develop an impressive internal mission. The Brotherhood Zoe ("Life"), organized according to the pattern of Western religious orders, was quite successful in creating a large system of church schools, in sponsoring various Christian organizations of professional men and women, and in publishing religious literature, yet did not always succeed in closing the gap between a conservative church and the Western-oriented intellectuals.

Conditions of the Eastern patriarchates

The Orthodox Church in the Middle East. As a result of the Greco–Turkish War, the entire Greek population of Asia Minor was transferred to Greece (1922); the Orthodox under the immediate jurisdiction of the ecumenical patriarchate of Constantinople were thus reduced to the Greek population of Istanbul and its vicinity. This population, rapidly shrinking in recent years, is now reduced to a few thousand. Still recognized as holding an honorary primacy among the Orthodox churches, the ecumenical patriarchate also exercises jurisdiction over several dioceses of the "diaspora" and, by consent of the Greek government, over the Greek islands. The impressive personality of Patriarch Athenagoras I (1948–72), who was succeeded by Demetrios, contributed to its prestige on the pan-Orthodox and ecumenical levels. The patriarchate convened pan-Orthodox conferences in Rhodes, Belgrade, and Geneva and has been coordinating preparations for a "Great Council" of the Orthodox Church scheduled for the 1970s.

Together with the ecumenical patriarchate, the ancient sees of Alexandria, Antioch, and Jerusalem are remnants of the Byzantine imperial past, but under the present conditions they still possess many opportunities

of development: Alexandria, as the centre of emerging African communities (see below *The Orthodox diaspora and missions*); Antioch, as the largest Arab Christian group, with dioceses in Syria, Lebanon, and Iraq; and Jerusalem, as the main custodian of the Christian holy places in that city.

The two ancient churches of Cyprus and Georgia, with their quite peculiar history, continue to play important roles among the Orthodox sister churches. Autocephalous since 431, the Church of Cyprus survived the successive occupations, and often oppressions, by the Arabs, the Crusaders, the Venetians, the Turks, and the English. Following the pattern of all areas where Islām was predominant, the archbishop is traditionally seen as the ethnarch of the Greek Christian Cypriots. Archbishop Makarios also became the first president of the independent Republic of Cyprus in 1960. The Church of Georgia, isolated in the Caucasus in a country that became part of the Russian Empire in 1801, is the witness of one of the most ancient Christian traditions. It received autocephaly from its mother Church of Antioch as early as the 6th century and developed a literary and artistic civilization in its own language. Its head bears the traditional title of "Catholicos-Patriarch." When the Russians annexed the country in 1801, they suppressed Georgia's autocephaly and the church was governed by a Russian "exarch" until 1917 when the Georgians re-established their ecclesiastical independence. Fiercely persecuted during the 1920s, the Georgian Church survives to the present day as an autocephalous patriarchate.

Orthodoxy in the United States. The first Orthodox communities in what is today the continental United States were established in Alaska and on the West Coast, as the extreme end of the Russian missionary expansion through Siberia (see above *The church in imperial Russia*). Russian monks settled on Kodiak Island in 1794. Among them was St. Herman (died 1837, canonized 1970), an ascetic and a defender of the natives' rights against their exploitation by ruthless Russian traders. After the sale of Alaska to the United States, a separate diocese "of the Aleutian Islands and Alaska" was created by the Holy Synod (1870). After the transfer of the diocesan centre to San Francisco and its renaming as the diocese "of the Aleutian Islands and North America" (1900), the original church establishment exercised its jurisdiction on the entire North American continent. In the 1880s, it accepted back into Orthodoxy hundreds of "Uniate" parishes of immigrants from Galicia and Carpatho-Russia, particularly numerous in the northern industrial states and in Canada. It also served the needs of immigrants from Serbia, Greece, Syria, Albania, and other countries. Some Greek and Romanian communities, however, invited priests directly from the mother country without official contact with the American bishop. In 1905 the American archbishop Tikhon (future patriarch of Moscow) presented to the Russian synod the project of an autonomous, or autocephalous, church of America, whose structure would reflect the ethnic pluralism of its membership. He also foresaw the inevitable Americanization of his flock and encouraged the translation of the liturgy into English.

Organization and canonical status of American Orthodox churches

These projects, however, were hampered by the tragedies that befell the Russian Church following the Russian Revolution. The administrative system of the Russian Church collapsed. The non-Russian groups of immigrants sought and obtained their affiliation with mother churches abroad. In 1921 a "Greek Archdiocese of North and South America" was established by the ecumenical patriarch Meletios IV Metaxakis. Further divisions within each national group occurred repeatedly, and several independent jurisdictions added to the confusion.

A reaction against this chaotic pluralism manifested itself in the 1950s. More cooperation between the jurisdictions and a more systematic theological education contributed to an increased desire for unity. A standing conference of bishops was established in 1960. In 1970, the patriarch of Moscow, reviving Tikhon's project of 1905, formally proclaimed its diocese in America (which had been in conflict with Moscow since 1931 on the issue of "loyalty" to the Soviets) as the autocephalous Orthodox Church in America, totally independent from administrative connections abroad. The ecumenical patriarchate of Constantinople, however, protested this move, turned down a request for autonomy presented by the Greek archdiocese (the largest single Orthodox body in the U.S.), and reiterated its opposition to the use of English in the liturgy (1970). This latest crisis of American Orthodoxy involves the very understanding of the Orthodox presence in the Western world, centring on the question of the utility of preserving the ethnic ties of the past.

The Orthodox diaspora and missions. Since World War I, millions of east Europeans were dispersed in various areas where Orthodox communities had never existed before. The Russian Revolution provoked a massive political emigration, predominantly to western Europe and particularly France. It included eminent churchmen, theologians, and Christian intellectuals, such as Bulgakov, Berdyayev, and V.V. Zenkovsky, who were able not only to establish in Paris a theological school of great repute but also to contribute significantly to the ecumenical movement. In 1922 Patriarch Tikhon appointed Metropolitan Evlogy to head the émigré churches, with residence in Paris. The authority of the metropolitan was challenged, however, by a group of bishops who had left their sees in Russia, retreating with the White armies, and who had found refuge in Sremski-Karlovci as guests of the Serbian Church. Despite several attempts at reconciliation, the "Synod" of Karlovci, proclaiming its firm attachment to the principle of tsarist monarchy, refused to recognize any measure taken by the re-established patriarchate of Moscow. This group transferred its headquarters to New York and is also known as the "Russian Orthodox Church outside of Russia." It has no canonical relation with the official Orthodox patriarchates and churches. A "Ukrainian Orthodox Church in exile" finds itself in a similarly irregular canonical situation. Other émigré groups found refuge under the canonical auspices of the ecumenical patriarchate.

Theological and missionary activities after World War I

After World War II, a very numerous Greek emigration took place to western Europe, Australia, New Zealand, and Africa. In East Africa, without much initial effort on their part, these Greek-speaking emigrants have attracted a sizable number of black Christians, who have discovered in the Orthodox liturgy and sacramental worship a form of Christianity more acceptable to them than the more dogmatic institutions of Western Christianity. Also, in their eyes, Orthodoxy has the advantage of having no connection with the colonial regimes of the past. Orthodox communities, with an ever increasing number of native clergy, are spreading in Uganda, Kenya, and Tanzania. Less professionally planned than the former Russian missions in Alaska and Japan, these young churches constitute an interesting development in African Christianity.

Ecumenical involvement. Between the two world wars, many Orthodox churchmen of the ecumenical patriarchate of Constantinople, of Greece, of the Balkan churches, and of the Russian emigration took part in the ecumenical movement. After World War II, however, the churches of the Communist-dominated countries failed to join the newly created World Council of Churches (1948): only Constantinople and Greece did so. The situation changed drastically in 1961, when the patriarchate of Moscow applied for membership and was soon followed by other autocephalous churches. Before and after 1961, the Orthodox consistently declared that their membership did not imply any relativistic understanding of the Christian truth, but that they were ready to discuss with all Christians the best way of restoring the lost unity of Christendom, as well as problems of common Christian action and witness in the modern world.

During the reign of Pope John XXIII, when Roman Catholicism became actively involved in ecumenism, the Orthodox—after some hesitation—contributed to the new atmosphere. The spectacular meetings in the 1960s

between Patriarch Athenagoras and the Pope in Jerusalem, Istanbul, and Rome, the symbolic lifting of ancient anathemas, and other gestures were signs of rapprochement, although they are sometimes mistakenly interpreted as if they were ending the Schism itself. In the Orthodox view, full unity can be restored only in the fullness of truth witnessed by the entire church and sanctioned in sacramental communion.

BIBLIOGRAPHY. The best special account of the church in Byzantium until 1261 is found in G. EVERY, *The Byzantine Patriarchate*, 2nd ed. rev. (1962); general information about the entire history of the Eastern Church is given in A. SCHMEMANN, *The Historical Road of Eastern Orthodoxy* (1963; orig. pub. in Russian, 1954). Of special interest for 19th and 20th century history of Orthodoxy are J. MEYENDORFF, *L'Église orthodoxe: hier et aujourd'hui* (1960; Eng. trans., *The Orthodox Church: Its Past and Its Role in the World Today*, 1962); and T. WARE, *The Orthodox Church* (1963). S.A. RUNCIMAN, *The Great Church in Captivity: A Study of the Patriarchate of Constantinople from the Eve of the Turkish Conquest to the Greek War of Independence* (1968), is an excitingly written critical evaluation of the Greek struggle for survival in the Ottoman Empire. CHARLES A. FRAZEE, *The Orthodox Church and Independent Greece, 1821–1852* (1969), uses contemporary diplomatic archives to describe the role of the Greek Church in an event that also involved all major European powers. The best general account of Russian medieval Christianity is by G. FEDOTOV, *The Russian Religious Mind*, 2 vol. (1946–66); on contemporary problems and events, see S. BOLSHAKOFF, *The Foreign Missions of the Russian Orthodox Church* (1943); and particularly, N. STRUVE, *Les Chrétiens en U.R.S.S.*, 2nd rev. ed. (1964; Eng. trans., *Christians in Contemporary Russia*, 1966).

(J.M.)

Eastern Rite Churches

Eastern rite churches, consisting of the Byzantine, Alexandrian, Antiochene, Chaldean, and Armenian rites, are Eastern Christian churches that trace their origins to various ancient national or ethnic Christian groups in the East but are in union with the Western Catholic Church under the jurisdiction of the papacy at Rome.

Nature and significance. The Eastern rite churches include the heterogeneous groupings of Eastern Catholics in communion with the Roman Catholic Church. Eastern Catholics, in contrast to Western, or Latin, Catholics, who have a history continuous from the 1st century AD, trace their origins largely to the failure of the ecclesiastical authorities at the Council of Ferrara–Florence in 1439 to unite Christians of the East and West. Stimulated by this unsuccessful beginning, however, and encouraged also by the later missionary activities of monastic orders, such as the Jesuits, Dominicans, Franciscans, and Capuchins, the proponents of the goal of the eventual reunion of Eastern and Western Christians began to achieve some elements of success. The Brest-Litovsk Union of 1596—under which all but two Ukrainian Orthodox bishops submitted to the demand of their Polish Catholic king that they accept the primacy of the pope—in a substantial way signalled the effective advent of Eastern rite churches. Other smaller groups had united with Rome in previous centuries, but the Ukrainians who were united with Rome at this time were the largest branch of Eastern Catholics to move in that direction. Prior to this event, Eastern Catholics were limited to Italo-Albanians in southern Italy and Sicily, a large number of Maronites (Lebanese Christians of the Syro-Antiochene rite) who became associated with Rome in the 12th century, and some Armenians in the Syria–Lebanon region who also trace their relationship with Rome to the 12th century. A number of Nestorians (followers of the 5th-century patriarch of Constantinople, Nestorius, who was declared a heretic) were united with Rome in 1551, Ruthenians (an east central European people) in 1595, Romanians of Transylvania in 1698, and Melkites (Syrian Christians of the Byzantine rite) in 1724. Political factors also played a role during the reunion process; Eastern Christians were, and are, much influenced by nationalistic loyalities in their respective regions. As these various groups of Eastern Catholics grew in number, Rome encouraged and established ecclesiastical hierarchies.

Significance of the Brest-Litovsk Union

To understand more fully the hierarchies of Eastern Catholics, the larger context of Eastern Christianity must be reviewed. Eastern Catholic churches correspond in kind to the more numerous Byzantine Orthodox churches and the Eastern independent, or Oriental, churches; *i.e.*, those that do not accept the decrees of the ecumenical Council of Chalcedon (451). Within this fuller context, Eastern Catholics as a group are the smallest segment within Eastern Christianity. Furthermore, from the viewpoint of the Byzantine and non-Chalcedonian traditions, Eastern Catholics may be looked upon with suspicion, primarily because of the latinizing influence found in their ranks. Hence the majority of Byzantine Orthodox and Eastern independent churches characterize Eastern Catholics as "uniate" churches. The expression uniate is taken from the Slavic *uniya*, a term coined by the opponents of the Brest-Litovsk Union. "Uniatism" implies hybridism, or the tendency for latinization, and hence a betrayal of one's ancient and nationalistic tradition. Eastern rite churches would prefer to be considered as united churches rather than uniate, with its negative implications.

Eastern rite churches make manifest the pluralistic composition of the Roman Catholic tradition. Permission for the various Eastern rites is a concession from Roman Catholic canon law, for a rite indicates more than liturgy; it points to an entire life style and discipline of a church tradition. Eastern Catholic rites—in contradistinction to Western Catholic rites—permit a married clergy and the immediate admission of baptized infants to the sacraments of communion (the Lord's Supper) and confirmation. In the "Decrees on the Catholic Churches of the Eastern Rite" adopted by the second Vatican Council (1962–65), the Roman pontiff reaffirmed the pledge of his predecessors to preserve the rites of the Eastern churches. "All of the Eastern Rite members should know and be convinced," states the decree, "that they can and should always preserve their legitimate liturgical rite and their established way of life, and that these may not be altered except to obtain for themselves an organic improvement." At present, there exist five distinct Eastern rite traditions: the Alexandrian, Antiochene, Armenian, Chaldean, and Byzantine.

The Byzantine rite. By far the most significant Eastern rite is the Byzantine. It affects the most persons, is the most widely distributed, and has had an impact upon the four other rites. From the original Byzantine rite, 13 canonical rites were derived: Albanian (dispersed; *i.e.*, no longer indigenous to the land of its origin), Belorussian (dispersed, but with a bishop in London), Bulgarian, Greek, Hungarian, Italo-Albanian, Melkite, Romanian (suppressed by the government in 1948), Russian (dispersed), Ruthenian, Slovak (suppressed by the government in 1950, re-established in 1968), Ukrainian, and Yugoslav. Several of the dispersed or suppressed rites have memberships in other countries, especially in the United States. Originally the Byzantine rite represented the Church of Constantinople and was Greek, but as Constantinople extended its political and ecclesiastical influence, the rite was translated into the vernacular of the diverse peoples it embraced. Liturgically, the Byzantine rite is based upon the liturgies of St. Basil, a 4th-century theologian and monastic leader, and St. John Chrysostom, a 4th-century scriptural interpreter and patriarch of Constantinople, as well as on the Presanctified Liturgy (in which bread and wine consecrated on the previous Sunday is used in communion), which legend attributes to Pope St. Gregory the Great (reigned 590–604). The Liturgy of St. Basil is celebrated ten times a year, the Liturgy of the Presanctified during Lent, and the Liturgy of St. Chrysostom during the greater part of the year. The authorship of these liturgies extends back to the temple ritual tradition of the Jews and the accumulative contributions of the early Church Fathers. In effect, the liturgies of Basil and Chrysostom represent a culmination of a process of accumulation and accretion rather than exact authorship. The liturgies generally are divided into three parts: the prayers of preparation, liturgy of the catechumens, and the liturgy of the faithful.

Distribution of the Byzantine rite

The Byzantine rite embraces a wide group of peoples. The Syrian Christians are known as Melkites (imperialists; Syrian *malka*, "king" or "emperor"). Melkites today are found mainly in the patriarchates of Alexandria, Antioch, and Jerusalem. (A patriarchate comprises all dioceses of a particular rite in a certain territory and is presided over by a patriarch.) Since the time of the Catholic Melkite patriarch Cyril VI (1724–59), there has been an uninterrupted line of Catholic Melkite patriarchs. Residing at Damascus (Syria) or Cairo (Egypt), the patriarch assumes the title "Patriarch of Antioch and of all the East, of Alexandria and of Jerusalem." The Melkites have been divided between Catholic and Orthodox Melkites, but union was briefly achieved under Patriarch Dorotheos I, who accepted the decrees of the Council of Ferrara–Florence in the 16th century. Under the rule of Maximos III Mazlūm (1833–55), progress and reform began and then continued in the 20th century under the ecumenical leadership and foresight of Maximos IV Sa'igh, elected patriarch in 1947 and made a cardinal in 1965.

Among the Catholics of the Byzantine rite, the Ukrainians and Ruthenians are among the most numerous migrants to North America. The Rev. Ivan Valansky in 1886 opened the doors of the first Catholic church of Byzantine rite in the United States at Shenandoah, Pennsylvania. Originally from the region west and southwest of Russia, many of these Eastern Catholics left their homeland to avoid being pressed into Orthodox churches. In 1965 their archbishop Josef Slipyj was named a cardinal. Romanian Catholics of the Byzantine rite, also once numerous, experienced similar pressures in 1948 when the government encouraged incorporation into the Orthodox Church of Romania. Though the number of Catholics of Byzantine rite found today among Greeks, Bulgarians, Russians, Italo-Albanians, Georgians, Finns, Estonians, Latvians, Hungarians, Yugoslavians, and Belorussians has dwindled, their widespread existence reveals the extensive influence of the Byzantine rite. Over 2,000,000 Catholics of the Byzantine rite are scattered throughout the non-Communist world. In the 1940s over 5,600,000 Byzantine-rite Catholics lived in countries with Communist governments; the statistics are unavailable for their present numbers.

The Alexandrian rite. Eastern Catholics of the Alexandrian rite are found in North Africa among Egyptians and Ethiopians. Numerically a minority among Coptic and Ethiopian Orthodox Christians, these Catholics identify with the same heritage of apostolic beginnings associated with the Evangelist St. Mark, who, according to legend, travelled in the 1st century AD to Alexandria, then second in importance only to Rome.

Egyptian Catholics. The Catholic Coptic patriarch in Egypt is called significantly the "Patriarch of Alexandria and of All the Preaching of St. Mark." The history of Eastern Catholics in this region, however, has been turbulent. In 6th-century Egypt, two lines of patriarchs were established, one representing the majority of Coptic Christians who were non-Chalcedonian and the other representing the minority in communion with Rome. The

Reunion of Coptic Christians with Rome

Council of Ferrara–Florence led to premature expectations of reunion under the Coptic patriarch John XI, but it never materialized. The 17th century brought renewed gestures for reunion through the efforts of representative Capuchins and Franciscans, but with little results until the 18th century, when a Coptic Orthodox bishop, Amba Athanasius, became a Catholic. In the meantime, Raphael Tukhi, another convert studying in Rome, prepared liturgical books in Coptic and enhanced the beginnings of a Coptic Catholic Church of the Alexandrian rite that began to take shape in the 19th century. In 1895 Rome elevated a Coptic Catholic priest, George MaCaire, who took the name Cyril Makarios, as vicar apostolic to the whole diocese of Egypt, thus giving further recognition to the small number of Eastern Catholics in the land. Further growth was seen in the 20th century; Amba Mark II Khuzam was patriarch until 1958; and his successor, Amba Stephen Sidaruss, was made cardinal in 1965. The Coptic liturgy is derived from the Greek liturgy of Alexandria. Today, Catholic Copts enjoy civic recognition; their strength is found among the least privileged class of Egyptians. They now number about 95,000, with a patriarchate at Alexandria and three other dioceses.

Ethiopian Catholics. The Ethiopian Catholics have never had a strong foothold among the Ethiopian populace, whose Christian roots date from the middle of the 4th century. Early attempts to establish a Catholic Church in Ethiopia followed from the activities of Portuguese explorers in the 16th century, primarily those of a physician named Bermudes. Later, Pope Julius III in 1555 appointed a Jesuit, João Nunes Barreto, as "patriarch of Ethiopia" and sent him and his clerical court to Ethiopia. He died (1561) before reaching Ethiopia. In the 17th century, Pedro (or Pero) Páez, another Jesuit, had more success through his influence upon the autocratic ruler Malak Sagad III (Susenyos), who summarily ordered obedience to Rome and in 1622 installed Afonso Mendes as patriarch. This resulted in a period of bloodshed and chaos among the Christians in Ethiopia. When Sagad was succeeded on the throne by his son Fasilidas, the latter was faithful to the Ethiopian Orthodox Church, and thus the process of forced obedience was halted; in 1636 Mendes was expelled from the country. Against this background, the Ethiopian government banned Catholic priests from the country for some 200 years. Renewed and more discrete measures were begun by Lazarists and Capuchins in the 19th century. In the early 1970s there were administrative centres of Ethiopian Catholics at Addis Ababa (the metropolitan see), Asmara, and Adigrat; seminaries at Asmara and Adigrat; and preseminaries at Keren (in Eritrea), Hebo, and Atat. The greatest response to the Catholic Ethiopians (now numbering over 76,000) is found among the pagan Galla tribe. In 1950 an Ethiopian was appointed by Rome to be titular bishop of Suzusa and given the title "Apostolic Administrator for Catholics of the Ethiopian Rite." The Egyptians and Ethiopians employ their own Coptic and Ge'ez languages, respectively, in their Alexandrian liturgies.

The Antiochene rite. *Maronites.* The largest single group of Eastern Catholics in the Middle East and throughout the world in the early 1970s was the Maronite Church, which adheres to the Antiochene rite. With 600,000 in Lebanon and about 350,000 or more abroad, the Maronites, like their Phoenician ancestral fathers, maintained a spirit of trade and adventure that has established communities around the world. They have about 50 parishes in the United States and sizable groups in Uruguay, Argentina, Brazil, and even Australia and South Africa. There are no non-Catholic Maronites; their patriarch is called "Maronite Patriarch of Antioch and All the Orient." While maintaining local autonomy over their church, Maronites have been in association with Rome since the 12th century. The Maronite patriarch Jeremias II al-Amshiti participated at the Lateran Council in 1215. Maronites have retained their ancient Syriac liturgy and have maintained a deep sense of their religious and social identity in spite of Muslim domination, pressures for latinization, Turkish rule, and influences of a French protectorate in the first half of the 20th century. No doubt this testifies to the spirit of independence nurtured by their isolation in mountain dwellings. Maronites also derive great strength from an uninterrupted history of monastic rule. With a patriarchate at Bkerke (Lebanon), the Maronite rite also has two archdioceses (Aleppo, Syria; and Beirut, Lebanon), eight dioceses, an apostolic administration (governed by Rome), and an apostolic exarchy (an ecclesiastical territory under authority delegated by the pope) in the United States.

Phoenician origins

Syrian Catholics. Unlike the Maronites, the Syrian Catholics emerged from no very unified background. The Syrians were divided after the Council of Chalcedon (451) between Melkites and Jacobites (those not accepting the decrees of Chalcedon). Early efforts in the 13th and 14th centuries by Dominicans and Franciscans to bridge the division in favour of Rome were not successful. Communication between the Jacobite patriarch Naamat-Allah and Pope Gregory XIII in 1583 opened the

Ancient divisions among Syrian Christians

way for future contacts with Rome. By 1656 a Jacobite, Andrew Akhijan, was converted to Catholicism and in 1667 was acknowledged by Pope Clement IX to be the successor to the Jacobite throne at Mardin. Thus, the Catholic patriarchate was initiated among the Syrians. The Catholic succession has continued, and in more recent times Ignatius Gabriel Tappouni (died 1968) was raised to the cardinalate in 1936, the first Syrian to be appointed to this position. Seeking to maintain continuity with the past and encouraged by Rome, Syrian Catholics have traced the Antiochene liturgical rite to the ancient Liturgy of St. James, using the same original Edessene dialect of Syriac. The purity of the language, however, has not healed the checkered history that the Syrian Catholics have known in their relations with the Jacobite Syrians. Within the patriarchate there are about 79,000 members, and approximately 10,000 live elsewhere.

The Malankars. The Jacobites living in the region of Malankar, or Malabar, in southwestern India, like the Syrian Jacobites, reacted to the latinization forced on them in the 16th century by Portuguese traders who did not appreciate fully the Chaldean (or Syro-Oriental) rite practiced by Malabar Christians. In the mid-17th century, under the leadership of an archdeacon, Thomas Parampil, these Indian Catholics turned from the Chaldean rite and followed the Jacobite Syrians of Antioch. The complicated history of the Jacobites of Malabar has been one of the particular tragedies of Indian Christian history. In the 20th century, Ghiverghis Panikerveetil, a priest and educator, created a new monastic community called "Of the Imitation of Christ." In 1925 he was consecrated bishop and took the name of Mar (Lord) Ivanios. He was commissioned by his synod to explore with Rome whether the past history of schism initiated by Parampil could be corrected. Rome subsequently welcomed the bishops along with their adopted Antiochene rite into communion with Rome. At first, only Mar Ivanios and Mar Teothilos responded favourably to the invitation and were received in 1930. These Malankara Catholics, as they are called, distinguish themselves from Chaldean- and Latin-rite Catholics in Malabar, and their growing number (about 162,000) is causing concern among the larger number of Jacobites in South India.

The Chaldean rite. *Chaldeans.* The Chaldean rite is East Syrian, in contrast to the Antiochene rite, which is West Syrian. Both share a common Syriac origin, however, and liturgically are related to the early Jerusalem-Antioch liturgy. Originally, the Christians of this rite were from Mesopotamia and Chaldea, descendants of the ancient Babylonians, later spreading throughout Asia, including India. The name Chaldean was first used at the Council of Ferrara–Florence by Pope Eugenius IV in 1445 when former Nestorians of Cyprus were reconciled with Rome, after having been reconverted to Roman Catholicism en masse in the previous century. In the 16th century, following his profession of faith to Rome, the superior of the Rabbān Hormizd monastery near al-Qūsh (Turkey), John Sulaka, was appointed (1553) by Pope Julius III to be the patriarch to Catholic Nestorians. He was assassinated two years later, and contacts with Rome became weaker. During this period the term Chaldean came into common use to distinguish the followers of Rome from the other Nestorians of the East. Both groups have their roots in the Syrian Church of the East, which was in existence before the birth of Nestorius. The successors of Sulaka (later reverting to Nestorianism) took on the name "Simeon"—Sulaka had called himself Simeon VIII—and the title "Patriarch-Catholicos of Babylon of the Chaldeans." Other Chaldean Catholics continued their relationship with Rome, and under the leadership of the metropolitan of Diyarbakir (Turkey), Joseph, who became a Catholic in 1672, the line of Catholic Chaldean patriarchs was re-established. The Edessene dialect of the Syriac language is used in the liturgy with the Scripture lessons in the vernacular. With its patriarchal archdiocese in Baghdad (Iraq), the Chaldean Rite Church has eight other archdioceses and six dioceses. Approximately 235,000 Chaldeans are under the jurisdiction of the patriarchate.

Origins of the Chaldean rite

Syro-Malabar Catholics. The Chaldean rite was carried by Syrian Christians to the Malabar coast of India, where the Malabar Christians have long considered themselves Christians of St. Thomas, direct descendants of that Apostle's missionary efforts. The Chaldean rite can be traced back to 6th-century contacts with missionaries from Mesopotamia. Their liturgical language was Syriac and their bishops were Chaldeans ("Babylonians"). The Malabarese (Syro-Indians) came to the attention of Rome as a result of conflicts that erupted under Portuguese political control from the 15th to the 17th centuries. The Portuguese sought latinization and control of the Malabarese; the ensuing spirit of discontent culminated in the schism (1653) led by the Malankar leader Thomas Parampil. Through the efforts of Carmelite friars under the apostolic vicar Giuseppe Sebastiani, sent by Pope Alexander VII in 1656 to quell the discontent, the majority of the Malabarese resumed their allegiance to Rome, apparently because Sebastiani had consecrated Alexander Parampil, a cousin of Thomas, as bishop. Upon Alexander's death, however, a Carmelite of the Latin rite was chosen to succeed him. Only recently has indigenous Indian leadership been developed among the Malabarese. Pope Leo XIII appointed three Indian bishops in 1896, and in 1923 Pope Pius XI re-established a Syro-Indian hierarchy, with the archdiocesan seat at Ekrakulam. In 1956 another archdiocese was established at Changanācher. There are, in addition, five suffragan sees and four apostolic exarchies (ecclesiastical jurisdictions with bishops directly under the pope). In the 1970s the vernacular, Malayalam, was taking on increased importance, replacing Syriac, within the liturgical life of the Malabarese. Approximately 1,800,000 persons adhere to the Syro-Malabar Church.

The Armenian rite. Armenians trace their Christian history to the missionary activities of the apostles St. Bartholomew and St. Thaddaeus, but their actual history as a "Christian nation" dates to the beginning of the 4th century when Christianity became the prevailing religion in Armenia under the leadership of Gregory the Parthian, surnamed by the Armenians Lowsavorich' (the Illuminator), who converted their king Tiridates (Trdat) III, and with him the nation, to the Christian faith. Armenians assert that they are the first Christian nation—a distinction that has cost them much hardship and suffering due to persecutions even into the 20th century.

The first Christian nation

The Armenian Catholic Church—under the jurisdiction of Rome rather than under the Armenian Apostolic Orthodox patriarchs of Echmiadzin (Armenian Soviet Socialist Republic) or Cilicia (Lebanon)—has the smallest number of followers. As early as the 12th century there were Armenian Catholics among the Armenians who fled from Muslim oppressors and established the Kingdom of Cilicia in Turkey. This came to an end in 1375, but Armenian monks known as the Friars of Unity laid the groundwork for the future Catholic Armenian Church under Dominican influence. Their goal was realized with the election of the Armenian bishop of Aleppo (Syria) Abraham Ardzivian—who took the name Peter—as catholicos of Sis (Kozan) in 1740 under Pope Benedict XIV. Because of rivalries and numerous difficulties under the Turks, the Catholic see was moved from Sis to Kuraym to Bzummār and, finally, to Beirut (the last three in Lebanon), where it is located today. The head of Armenian Catholics is called "Patriarch of the Catholic Armenians and Catholicos of Cilicia" and has always taken the name of Peter. The jurisdiction of the Armenian Catholic patriarchs includes Syria, Lebanon, Egypt, and Iraq, as well as Turkey. Other Armenian Catholics under the jurisdiction of Rome are in France, Greece, and Romania. The most illustrious patriarch has been Gregory Peter XV Agagianian (died 1971), elected in 1937 and made a cardinal in 1945. Due to the press of duties as the head of the Congregation for the Propagation of the Faith, for the Roman Catholic Church, he resigned as patriarch in 1962, and his successor became Ignatius Peter XVI Batanian. The Mekhitarists, an order of Armenian Catholic monks, have centres in Venice and in Vienna. The monks have performed noteworthy service

Persecution of Armenian Christians

in the preservation of ancient Armenian literature and in the field of publications. The liturgy continues to be practiced in the classical Armenian, a testimony to the endurance of Armenian Christians, who in 1965 marked the 50th anniversary of their most recent persecution under the Turks (approximately 1,500,000 Armenians, including Armenian Apostolic Orthodox, Armenian Catholics, and Armenian Protestants, were killed because they would not forfeit their faith). Approximately 60,000 Armenian Catholics are under the jurisdiction of the patriarchate, and 40,000 outside.

The Eastern rite churches today. The majority of Eastern rite churches find themselves today as did their forefathers, from the 7th century onward, within an Islāmic environment, though there also exist Marxist and Hindu contexts for Indian Christians and the complex forces of secularism that confront all the rites. Furthermore, Eastern Catholics, except for the Maronites, as well as Protestants, are a "Christian minority" among Christians of the independent churches not in union with Constantinople. It is this minority status that presents the greatest challenge to Eastern Catholics as they seek to find a creative religious witness in their world. Eastern Catholics generally have an outstanding reputation among other Christians and Muslims, despite their small numbers, for establishing an orderly community of followers. Accused by many non-Eastern Catholics of being too organized and latinized by Rome, they are also held in suspicion by Muslims as foreign agents of the West. Thus, the conditions for Eastern Catholics today is not easy. The most distinctive contribution of Eastern Catholics, especially within Islāmic areas, is made through their educational institutions, which look toward a new era of dialogue and coexistence with their Muslim neighbours.

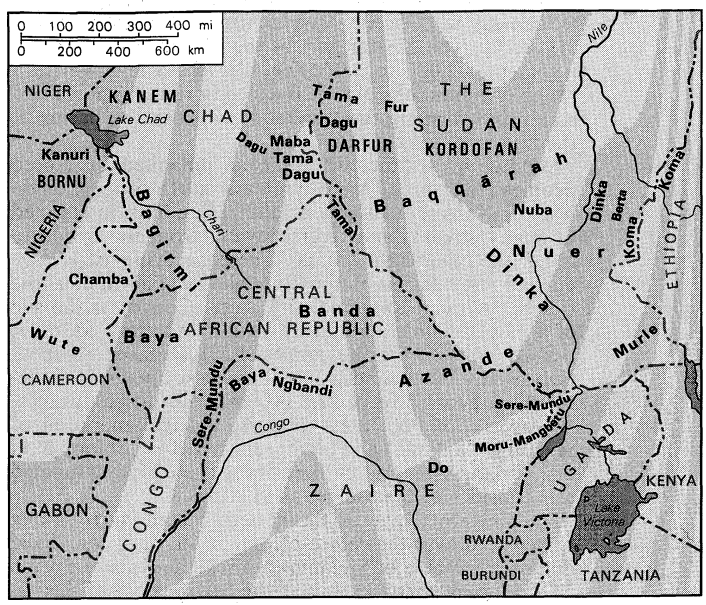
Eastern Sudan, Cultures of the

The name Sudan (Country of the Blacks) was given by medieval Arab writers to the savanna belt that extends across the continent of Africa from Cape Verde on the Atlantic to the rise of the highlands of Ethiopia. Topographically, this Sudanic belt is a plateau averaging somewhat less than 1,500 feet (450 metres) in altitude, with a length of over 3,000 miles (4,800 kilometres) and an average width of about 650 miles (1,000 kilometres). This belt of open country, with its clearly marked dry season of intense heat and its wet season of growth, is bounded along most of its southern fringe by thick forests and along its northern edge by desert. The area from around Lake Chad eastward, traditionally designated as the eastern Sudan, is now shared between the republics of The Sudan, Zaire (Congo [Kinshasa]), Chad, Cameroon, Nigeria, and the Central African Republic. The societies within eastern Sudan portray diverse linguistic, ethnic, social, cultural, and religious characteristics.



Distribution of the peoples of the eastern Sudan.

PEOPLES AND LANGUAGES

Because of the great cultural diversity, it is difficult to classify the types of cultures found among the various peoples in the eastern Sudan. The selection of cultures that follows merely suggests some rather prominent cultural patterns, illustrative of the wide range present.

The cattle-herding Baqqārah

Bedouin Arabs invading southward from Arabia and North Africa reached the area of Lake Chad as early as the 16th century; gradually they intermarried extensively with the Negroid inhabitants, so that many tribes came to exhibit Negroid characteristics. Toward the end of the 18th century, the Baqqārah (nomadic cattlemen), who claim Arab descent, moved eastward to the central regions of what is now the Democratic Republic of The Sudan. This part of the savanna belt is flat and tree covered and suitable to an economy of nomadic cattle husbandry. The majority of the peoples living there have taken not only to raising cattle but also to cultivating millet, sorghum, cotton, and other traditional crops. All are Muslim. Some of the major Baqqārah tribes are the Humr, who number about 55,000, and the Messiria, Hawazma, and Rizeigat.

In the Nuba Hills, a rugged, almost mountainous area in a region traditionally known as Kordofan and now a province of the Democratic Republic of The Sudan, there live a Negro people called the Nuba, who, because of the terrain, have tended to be isolated from the peoples migrating about them in the Nile Valley and other areas of the eastern Sudan. Numbering about 500,000, the Nuba are subdivided into over 50 different ethnic groups with a multiplicity of languages. Despite their ethnic and linguistic diversity, there exits what has been called a "Nuba culture" based upon some affinities such as clan structure and the regulation of intertribal conflicts. Very little is known about the ancient history of the Nuba tribes, but there are oral traditions that they migrated from the west. The country of the Nuba is well watered, densely wooded, and rich in vegetation. The Otoro is the largest tribe (about 40,000 people), inhabiting eight hills in the eastern part of Nuba country.

Between Kordofan and Lake Chad, along the northern fringes of the eastern Sudan, there are a number of Negro peoples who were among the first sub-Saharan inhabitants to be strongly influenced by the Arabian commerce and culture penetrating from the north (from about the 11th century onward). Situated on the African frontier of the

trans-Saharan caravan routes, these peoples were in a position to develop more diversified cultures and elaborate economies and social structures. Representative of these populations are the groups residing in Darfur, the Republic of The Sudan's westernmost province—the largest resident group being the Fur, after whom the province is named, who occupy the centre and number about 1,300,000. The greater part of the country of the Fur is a plateau—2,000 to 3,000 feet above sea level—with a range of mountains of volcanic origin running north and south and forming the watershed between the basins of the Nile and Lake Chad.

Another important cultural zone inhabited by Negro peoples is the broad band lying just north of the Congolese rain forest, in an area of undulating hills, intersected by many streams and rivers flowing from the divide to either the Nile or the Congo. The zone, lying astride the current boundaries of the Republic of The Sudan, the Central African Republic, and Zaire (Congo), is the site of typical Sudanic agriculture—with sorghum and millet usually constituting the staples. Representative of these peoples are the Azande, one of the best known Sudanic-speaking peoples of central Africa, who probably number about 750,000; they comprise an agglomeration of invading Sudanic and indigenous tribes differing in origin, language, and culture but thoroughly assimilated and considering themselves all as Azande.

The western fringe of the eastern Sudan, surrounding Lake Chad, was the centre of one of the most long-lived and most notable of Sudanic empires, the Kanem-Bornu. The ruling dynasty, known as the Sef, was established as early as the 8th century in Kanem (now a province of Chad) and removed later to Bornu (now a province of Nigeria) and lasted until 1846—making it perhaps the longest reigning dynasty in world history. The empire flourished from the 11th century on, when it developed as the Sudanese terminus of the important trans-Saharan trade route running to Libya; most of the peoples of the empire became Muslims at that time. Today the dominant ethnic group in the area is that of the Kanuri of Bornu, a tall Negro people who number about 1,250,000 and inhabit open savanna country. Their current economy is based on millet agriculture, but they remain a commercial people with a well-developed internal and external trade in various crafts, cowhides, and other goods.

Major language groups

The major language groups in the eastern Sudan are Congo-Kordofanian, to which the Azande and Nuba languages belong, and Nilo-Saharan, to which the languages of the Kanuri and Fur belong; the term Sudanic languages is applied to these and other languages spoken by peoples from Ethiopia to Nigeria. The Baqqārah tribes are entirely Arabized, and most of the Fur, too, now speak Arabic. Even among the Nuba, Arabic is becoming the lingua franca.

SOCIAL ORGANIZATION

Political and territorial organization. Broadly speaking, the societies of the eastern Sudan exhibit two types of political organization: the hierarchical systems of the Azande, Kanuri, and Fur; and the segmentary systems of the Humr Baqqārah and Otoro. Zandeland, for example, is divided into a number of autonomous chiefdoms. The structure of authority within each chiefdom is pyramidical, with chiefs at the apex of the hierarchy (previously kings), followed by sub-chiefs, deputies, and finally homestead heads. The homestead is the basic political, social, and economic unit. Absolute authority lies with the aristocratic Avungara clan, and commoners can only reach the positions of deputy or homestead head. Local groupings, in which descent is reckoned in the male line, are not associated with clans or sections of clans; they are political and administrative units. Clans have little corporate life, and genealogical links between clansmen are seldom known.

The Kanuri also have a hierarchical administrative and political structure. The household or compound is the basic political unit; a number of households join to form wards, hamlets, villages, and districts. At the head of this hierarchy is the *shehu*, who is the formal head of the government and the religious leader of the state. With the exceptions of the *shehu* and heads of households, heads of wards, hamlets, and districts are appointed. As among the Azande, members of agnatic descent groups (descent groups traced through the male line) are dispersed, and political units do not coincide with kinship groupings.

A similar political and administrative structure of the centralized type also existed among the Fur. There was a sultan at the head of the state, which was divided into four regions in turn divided into districts, subdistricts, and villages. Each village had a council of elders who decided minor cultivation disputes and enforced their decisions by advice and warning. The rights of the village were vested in its inhabitants jointly. Ultimate authority lay with the sultan, who could depose officials beneath him when their power became a threat to his dominance.

In contrast, the Humr Baqqārah have a political system based on a segmentary lineage organization. The tribe is divided into two sections, each of which is divided into a further five sections, each comprising major lineages, camps, and extended families. All these groups have potential leaders. The significant residential and herding unit is the camp, the composition of which changes with the seasons. Within each tribe, and at every level, there is a process of splitting, migration, and resettling that results in a continuous change of alliance among groups and individuals. Blood feuds occur between segments and are settled by payment of blood money. Power among the Humr Baqqārah stems from wealth and strength of personality.

Political organization of the Otoro

The Otoro political system consists of a number of territorial segments that do not coincide with kinship groupings. Clan members are scattered in different localities; the basic political unit is the hill community, whose members share a tract of land and a common code of morality. Feuding between hill communities has been constant, but members of the same hill community must not kill one another. The Otoro have recognized tribal boundaries defined by periodically renewed intertribal treaties. Because of the continual raids and wars between segments, a chieftainship, with the power to use force to maintain peace, has been established.

Family and kinship patterns. In all five societies descent is reckoned in the male line, but the significance of agnatic ties among kin groups differs from one society to another. Among the Azande there are 188 exogamous clans that function primarily as political and administrative units. Clan members are expected to join together to celebrate births, marriages, and funerals. The Azande recognize obligations to the kin of both parents, but greater importance attaches to the paternal connection. Until he is married an Azande has not achieved a man's full status. Marriage is a series of events, each of which is marked by the transfer of goods from one group of kin to the other. Wives of a dead man are inherited by his sons or brothers. Polygyny is also practiced and is regarded as a means of extending affinal relationships and acquiring support. Although divorce is now common, a broken marriage was considered a shameful thing because it destroyed the network of relationships.

As among the Azande, Kanuri descent groups are based upon the individual's relations to the kin of his parents, with emphasis on the patrilineal line. There are two types of relationship that are significant in kinship, economic, and political spheres: discipline–respect relationships (modelled on the father–son relationships) and shame–avoidance relationships demanding subdued and self-controlled behaviour (*e.g.*, a junior must not speak until he is spoken to by his senior, nor can they eat together from the same bowl). Kanuri practice cousin marriage with virilocal residence (*i.e.*, residence with or near the husband's parents), and one in two marriages is polygynous. A person depends on his kinsmen, friends, and political and economic patrons for help over his marriage. Divorce is easy, and the rate is high: 80–90 percent.

The Fur also reckon descent patrilineally, but residence is customarily uxorilocal (with or near the wife's parents). If a husband disagrees with his affines, however, he may take his wife to live with his own group. Cousin

marriage, sororate (customary marriage with a deceased wife's sister), levirate (customary marriage to an elder brother's widow), and polygyny are practiced.

Lineage organization of the Humr Baqqārah

Among the Humr Baqqārah, members of the smallest lineage (*surra*), together with their dependents, form a single camp. The organization of a *surra* depends on the number of cattle and the distribution of their ownership among its members. Each *surra* has a leader who is wealthy but who has no administrative functions unless he is already a member of the local government. Whereas members of a camp form the basic unit of cooperation over herding, the household is the main unit of cooperation in agriculture, although some activities connected with agriculture involve a wider group. Preferred marriage within the *surra* is with a parallel cousin. Many first marriages, contracted to conform to the expectation of elders, end in divorce, but in subsequent marriages people are free to choose their marriage partners.

Among the Otoro there are 35 patrilineal clans of various size. With the exception of the Chungur clan, which is the traditional holder of the hereditary chieftainship, all clans are socially of equal order. Clan members intermarry with each other, although clan exogamy was the rule in the past. In the economic and religious spheres the clan does not exercise influence, but it does impose upon its members the collective duty of blood feud in the case of homicide between clans. Patrilineal descent is important in determining the social identity of a person, inheritance, and rights and duties concerning marriage and bridewealth (gifts from the groom and his kinsmen to the father of the bride and his kinsmen). Though the Otoro are patrilineal, matrilineal ties are also important. Polygyny and leviratic marriages are practiced, and bridewealth payments establish wider contact between social groups. Divorce is negotiated and settled by the families concerned. The marriage is dissolved by the total refund of the bridewealth to the former husband.

Social stratification. All the groups have some form of class distinction. The Azande's Avongara clan recognizes rigid distinctions between chiefs and commoners, and generally among the Azande there are distinctions between conquering and conquered groups and slaves. Political, economic, and social status depend on birth, but the politically superior group, the Avongara, must maintain their position by organized political and military means.

Kanuri society is also hierarchical, the Shehu being the highest political and religious authority and being most prominent in trade and other economic activities. There are also slaves. The introduction of western-type education and native governments produced new classes with non-traditional premises and aspirations.

The highest political office among the Fur has been that of the sultan, who has been surrounded by a body of councillors dependent on royal patronage. Locally, there has been a descending hierarchy of hereditary fief stewards, village heads, and, lastly, heads of households. Ironworkers have been a despised class not allowed to intermarry with ordinary Fur. Among the Humr Baqqārah, the main distinction is between persons of Arab descent (who hold the positions of power) and non-Arabs. In other respects, a person's wealth and personality determine his successful bid for leadership.

Traditionally, among the Otoro there were no political offices, but only a special hereditary ritual office—that of "chief of the Path," who acted as intermediary in peace negotiations between conflicting parties. Today, however, there are chiefs selected by the local government from among persons of local wealth and importance. In addition there are age-grades; membership in each grade (there are five grades) lasts three years, after which all the members are promoted together to the next higher grade. Promotion is marked with festivities, and members of each age-grade live separately. This system marks the development of a person from an ordinary youth to that of a "big man." Girls also form age-grade groups.

Socialization and education. In all five societies under comparison, there are ritual and ceremonial practices marking the stages in the life cycle of the individual—birth, circumcision, puberty, marriage, and death. There is little formal education among the Azande, Otoro, Humr Baqqārah, and Fur.

Circumcision distinguishes boyhood from manhood. It is a recent introduction among the Azande, having spread from the south despite being opposed by the Avongara. Among the Kanuri, no mention of the newly born baby is made, and even its sex is unknown outside the household except for very close friends of the family. Among the Otoro, an individual achieves higher status as he is promoted from one age-grade to another. There is also an association of cicatrization (scarring) with a test of manhood: killing an enemy entitles a person to have a small pattern of scars on his back. Similar patterns are also made on the upper arms of successful hunters. Men take part in wrestling and fighting as part of their training for manhood. Among the Azande and Nuba, there are very few schools at elementary level established by missions. Education has made little headway among the Humr Baqqārah because it comes into conflict with their way of life—people are reluctant to send their children to schools because livestock and cattle herding will suffer. There are a few Qur'ānic schools among the Fur, in which elementary Arabic, arithmetic, and the Qur'ān are taught. The Kanuri also have Qur'ānic schools and are the most advanced in terms of formal education. They also have an advanced system of government and administration, which came into operation during the colonial period at the beginning of the 20th century.

Qur'ānic schools of the Fur and Kanuri

ECONOMIC ORGANIZATION

Settlement patterns. The five societies selected for comparison exhibit three different patterns of settlement. The Otoro and Azanda live in scattered groups. Otoro homesteads are scattered irregularly over hilltops and valleys, a number of homesteads constituting a village, villages combining to form hill communities, a number of which make up the tribe. Similarly, the Azande live in family groups in scattered homesteads separated by strips of bush. Among the Otoro and the Azande, the homesteads are the basic social and economic unit. In contrast, the Kanuri and Fur have more compact settlements. The Kanuri settlements, composed of walled compounds, vary in size from Maiduguri, the capital, with over 100,000 people, down to small hamlets of three to four households. The Fur live in homesteads, a number of which constitute a village. The third type of settlement pattern is that of the Humr Baqqārah, who live in tent camps. Their nomadic existence does not permit the formation of permanent settlements.

Production and technology. The economy of most of the peoples of eastern Sudan is dependent on cultivation, with animal husbandry, and sometimes hunting and fishing, providing an important supplement to agriculture. A wide variety of crops, including grain, sesame, vegetables, sorghum, maize, groundnuts, and cotton, are grown, the latter two sometimes as cash crops. Among the Humr Baqqārah cultivation is a subsidiary occupation. They move in a regular seasonal cycle according to the availability of water and grass. In winter, or at the end of the rains, they move south, and in spring, or during the rains, they move north. Some cultivation of millet and, in recent years, of cotton as a cash crop, is undertaken. Throughout their territory the Humr Baqqārah have communal grazing rights, whereas cultivable plots of land are owned individually and handed down from father to son.

The technology of these societies is simple: among the Otoro the making of bedsteads, mat weaving, and pottery are undertaken. The Azande, on the other hand, are prominent as craftsmen and artists. Their superior material culture, particularly their knives, spears, and shields, was one of the factors by which they dominated their neighbours and brought about the spread of their culture. Basketmaking, net weaving, pottery, smelting, metalworking, and ivory and wood carving are also undertaken. Among the Kanuri weaving, metalworking, dyeing, tanning, smithing, and other occupations are organized under headmen in each settlement. Each occupation

Prominence of Azande arts and crafts

comes under an overall headman who lives in the capital city. There are ironworkers in every Fur village; other Fur crafts include tanning and weaving of cloth and basketry. The Humr Baqqārah produce leather goods and basketry to meet their own needs.

Property and exchange systems. Land among the Otoro, Azande, Kanuri, and Fur is the principal economic asset. Among the Otoro land can be acquired through inheritance, purchase, lease, and by clearing and cultivating new areas. The Otoro and the rest of the Nuba tribes convert nearly their whole agricultural surplus into livestock. Although livestock are used for clan sacrifices, they are not sold for money, and neither are they slaughtered for meat. Among the Nuba tribes, however, people use livestock for certain standardized payments such as bridewealth or gifts to kin relations. Iron, because of its rarity and its use in weapons and tools, became the standard medium of exchange. Handicraft products are paid for in grain, sesame, hoes, spears, goats, axheads, and, nowadays, in money.

Whereas livestock is a secondary source of wealth to the Otoro, cattle are the primary source of wealth, prestige, and political position for the Humr Baqqārah. Cattle were once the medium of exchange, but during the 20th century cash has become significant.

Before the introduction of cotton and money, wealth among the Azande was primarily in the form of perishable agricultural produce, and it was customary to destroy the property of a man after his death. Only chiefs were able to accumulate wealth, since they received tribute and prisoners of war as perquisites. There was little exchange between households, although iron tools and spears were used in bridewealth payments.

Among the Fur, property consists of houses, domestic articles, rolls of cloth, and cattle kept mainly for resale. Rights over land are held jointly by descent groups and are vested in a titleholder. There are organized marketplaces in which the medium of exchange has been, and still is, money. Previously, cloth may have served as a medium of exchange. Agricultural products are exchanged for tools and utensils, cloth, and other commodities. Labour is exchanged for beer.

The Kanuri have organized marketplaces in which agricultural produce and craft products are sold. Money is thus the medium of exchange and constitutes the main form of wealth among the Kanuri. Land is an important economic asset, but nowadays wealth and prestige lie in success in trade, in politics, in the civil service, and in the acquisition of Western educaton.

RELIGIOUS PRACTICES

The Humr Baqqārah, Fur, and Kanuri peoples adhere to Islāmic beliefs and practices, Islām having come to them through Arab influence. Traditional local practices, however, coexist with Islāmic beliefs. Among the Fur, for example, the splashing of sanctuaries with a flour and water paste is carried out to ensure fertility. There are also rain cults thought to have been introduced from farther west. Sacrifices are made at shrines and at ancestral tombs when the rains are likely to fall. The office of rainmaker is hereditary.

Witchcraft of the Otoro and Azande

The Otoro and Azande have their own local beliefs and practices, which are significant as a means of social control, and Islām and Christianity have very little influence. Among the Otoro there is a widespread belief in oracles and witchcraft as a means of punishing offenders and establishing justice. Charms bought from Arab or West African charm sellers, diviners, grain priests, and rainmakers are used to find and punish evildoers. Leprosy, imagined to be caused by supernatural powers, is believed to be connected with offenses such as sexual intercourse in forbidden kinship degrees and homicide. Witchcraft, a magic at the disposal of any individual, is effective only if directed against a person guilty of a crime.

Among the Azande the power of witchcraft is inherited. Diviners, oracles, vengeance magic, and the use of leeches are means of counteracting it. The Avongara clan may not be accused of witchcraft because the chief and his oracle are considered infallible.

DEVELOPMENTS IN THE 20TH CENTURY

The influence of European contact and of self-government on the societies of the eastern Sudan has varied. Innovations introduced among the Humr Baqqārah have included cotton cultivation, use of cash, wage labour, and improvements in breeding. With the introduction of local government, the traditional power structure was altered, but the traditional agnatic groupings remain as units of administration. The economic and social importance of cattle has not changed.

Although the traditional economic organization of the Kanuri persists, more people are seeking individual advancement in trade, administration, and politics and by means of Western education. The household, however, remains the economic and social unit, and the superior–subordinate relations within it have continued as a basis for maintaining the traditional society and its values. The traditional power structure of the Kanuri overlaps with their modern political organization based on the emergence of political parties.

The Otoro have experienced a number of changes introduced by Europeans and Arabs. Larger tracts of land are being worked, new crops have been introduced, modern chieftainship has been instituted, and a new system of law and order has been introduced. The younger generation of Nuba who work outside their homeland bring back new habits and interests, and the authority of the older generation is thus weakened. Nevertheless, the Nuba still retain their social structure and identity.

Since the incorporation of Darfur into The Sudan at the turn of this century, a new administration has been introduced. The independence of the Fur and other tribes has been modified by the formation of regional local governments, each with its own judicial and financial powers. The basic tribal local government, however, is still founded on the rule of hereditary or traditional headmanship of a tribe or on sultanates.

Attempted resettlement of the Azande

The most noticeable social and economic changes have occurred among the Azande, who since the 1920s have been constantly settled and resettled. In 1945 a resettlement scheme was introduced based upon the manufacture of cloth, cooking oil, and soap from cotton grown by the Azande. It was at first successful, but eventually proved unacceptable to the Azande themselves since it was not sufficiently in accord with their value system. Sporadic revolt in the area has also delayed development.

BIBLIOGRAPHY. E.E. EVANS-PRITCHARD, *Witchcraft, Oracles and Magic Among the Azande* (1937, reprinted 1958) and *The Azande: History and Political Institutions* (1971), are the best authoritative accounts; while CONRAD C. REINING, *The Zande Scheme* (1966), deals with recent changes among the Azande due to resettlement. P.T.W. BAXTER and AUDREY BUTT, *The Azande, and Related Peoples of the Anglo-Egyptian Sudan and Belgian Congo* (1953), offers a general ethnographic account. S.F. NADEL, *The Nuba* (1947), remains the only anthropological study of the Nuba tribes. A.J. ARKELL, "The History of Darfur, 1200–1700 A.D.," *Sudan Notes and Records*, 32:37–70, 207–238 (1951) and 33:129–155, 244–275 (1952); A.C. BEATON, "The Fur," *ibid.*, 29:1–39 (1948); and G.D. LAMPEN, "History of Darfur," *ibid.*, 31:177–209 (1950), are useful historical accounts. H.G. BALFOUR-PAUL, "A Prehistoric Cult Still Practised in Muslim Darfur," *Jl. R. Anthrop. Inst.*, 86:77–86 (1956); and A.C. BEATON and R.C. COOKE, "Bari and Fur Rain Cults and Ceremonies," *Sudan Notes and Records*, 22:181–203 (1939), are of ethnographic interest. FREDRIK BARTH, "Economic Spheres in Darfur," in RAYMOND FIRTH (ed.), *Themes in Economic Anthropology* (1967), is a recent account that gives an interesting analysis of aspects of economic organization among the Fur. IAN G. CUNNISON, *Baggara Arabs* (1966), is the best anthropological study of lineage organization and politics among the Baqqārah. C.G. and B.Z. SELIGMAN, *Pagan Tribes of the Nilotic Sudan* (1932); and H.A. MACMICHAEL, *A History of the Arabs in The Sudan and Some Account of the People Who Preceded Them and of the Tribes Inhabiting Dárfūr*, 2 vol. (1922, reprinted 1967), and *The Tribes of Northern and Central Kordofán* (1912, reprinted 1967), are classics that provide further ethnographic and historical data. J.D. TOTHILL (ed.), *Agriculture in The Sudan* (1948), remains the only detailed authority on agriculture in The Sudan. RONALD COHEN, *The Kanuri of Bornu* (1967), is a recent anthropological study of the Kanuri; and S.J. HOGBEN and A.H.M. KIRK-GREENE, *The Emirates of North-*

ern Nigeria (1966), offers a well-documented historical study. C.K. MEEK, *The Northern Tribes of Nigeria*, 2 vol. (1925, reprinted 1969), provides comprehensive data on the cultures of northern Nigeria. A.H.M. KIRK-GREENE, "The Linguistic Statistics of Northern Nigeria: A Tentative Presentation," *African Language Review*, 6:75–101 (1967), provides recent statistics on the languages and population of northern Nigeria. JOSEPH H. GREENBERG, *The Languages of Africa* (1963); and A.N. TUCKER, *The Eastern Sudanic Languages* (1940), provide detailed linguistic classifications and data on the eastern Sudan. Important travel books are HEINRICH BARTH, *Travels and Discoveries in North and Central Africa, . . . 1849–55*, 5 vol. (1857–58; reprinted in 3 vol., 1965); M.O. AL-TUNUSI, *Voyage au Darfour* (1845); IGNAZ PALLME, *Reitebeschreibung von Kordofan* (1843; Eng. trans., *Travels in Kordofan*, 1844); DIXON DENHAM, HUGH CLAPPERTON, and WALTER OUDNEY, *Narrative of Travels and Discoveries in Northern and Central Africa, in the Years 1822, 1823*, and *1824* (1826); H.R. PALMER, *Sudanese Memoirs*, 3 vol. (1928); WILHELM JUNKER, *Reisen in Afrika 1875–1886*, 3 vol. (1889–91; Eng. trans., *Travels in Africa During the Years 1875–1886*, 3 vol., 1890–92); JOHN and KATE H. PETHERICK, *Travels in Central Africa, and Explorations of the Western Nile Tributaries*, 2 vol. (1869); and GUSTAV NACHTIGAL, *Sahārā und Sûdân*, 3 vol. (1879–89).

(A.Al-Sh.)

Eastern Woodlands Indians

At the time of the European discovery of North America, the area stretching from Lake Superior to the Atlantic coast was occupied by many different Indian groups speaking languages that belong to three distinct language families: Iroquoian, Algonkian, and Siouan. The major speakers of northern Iroquoian languages include the Iroquois confederacy (Mohawk, Oneida, Onondaga, Cayuga, Seneca, and, later, Tuscarora), the Huron confederacy, Tionontati (Petun or Tobacco Nation), Wyandot (a group of Hurons and Tionontati), Neutral, Wenrohronon, Erie, Susquehanna (Conestoga), and Laurentian Iroquois. The major speakers of Algonkian languages include the Passamaquoddy, Malecite, Abnaki, Penobscot, Pennacook, Massachuset, Nauset, Wampanoag, Narraganset, Niantic, Pequot, Mohegan, Nipmuc, Pocomtuc, Mahican, Wappinger, Montauk, Delaware (Lenni Lenape), Powhatan, Ojibwa (Chippewa), Menominee, Sauk (Sac), Kickapoo, Miami, and Illinois. The Winnebago, who also lived in the eastern woodlands, spoke a Siouan language.

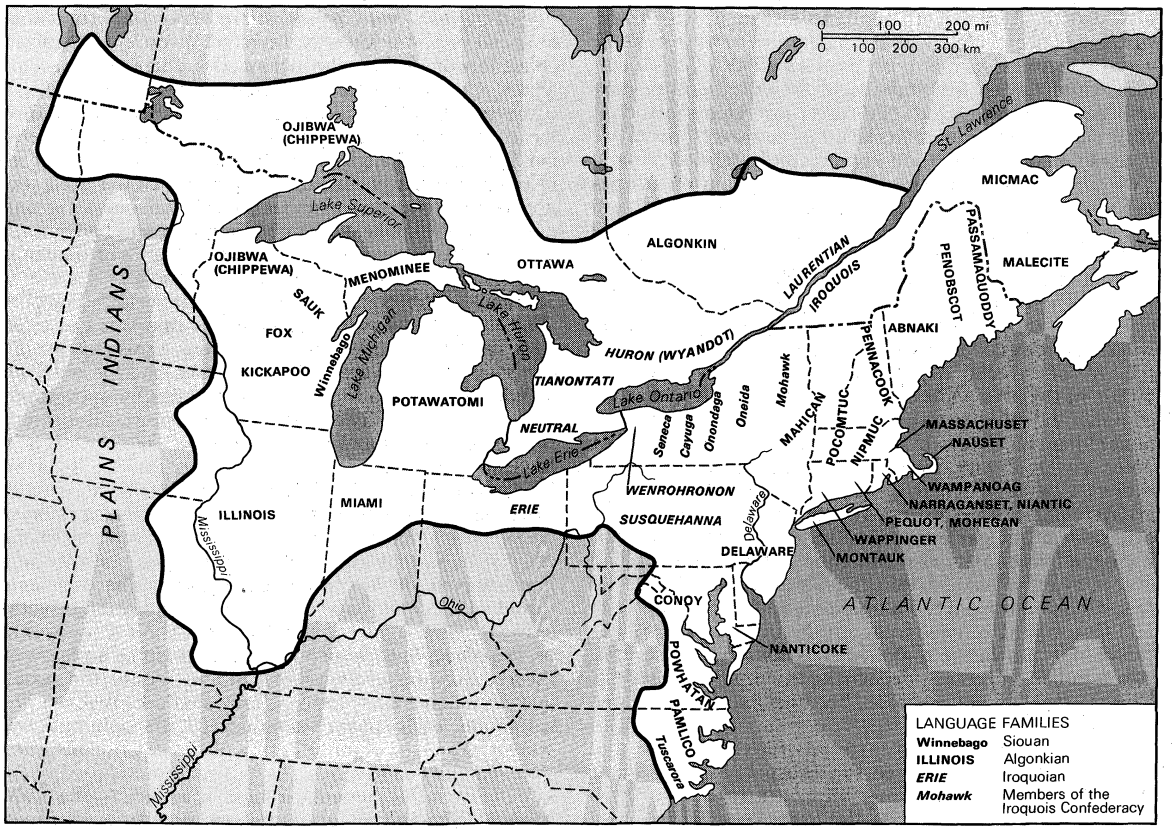
Forest resources

Although the area generally was a wooded one, it was in the open spaces in the forests that many of the best natural resources were to be found. In consequence, the heaviest population concentrations were near or along the seacoast, lakes, ponds, marshes, creeks, and rivers. There animals could be hunted, fish caught, birds taken, leaves, seeds, and roots of wild plants gathered, shellfish collected, and crops grown. Certain areas were favoured with resources not found elsewhere in the region. In certain parts of the upper Great Lakes area, wild rice (*Zizania aquatica*) grew in abundance, and the Menominee especially depended on it. Buffalo (bison) roamed the plains–prairie area, and such groups as the Sauk, Fox, Illinois, and Miami, who lived near the prairie, hunted them. On the Atlantic Coast, shellfish were plentiful and played an important part in the diet.

TRADITIONAL CULTURE PATTERNS

Economic systems. *Food production and consumption.* Except in the northern part of the upper Great Lakes area and the northern part of the Eastern Seaboard—areas that do not have a growing season long enough for corn (maize) to mature—some agriculture was practiced. The three principal plants cultivated were corn, beans, and squash, plants the Iroquois termed the three sisters because they were to be found like sisters together in the fields. Generally, it was the women who cultivated the fields, planting the seed, weeding, and harvesting the crops. Men, however, usually aided in clearing the land preparatory to planting. The type of agriculture practiced is often termed horticulture, as domesticated draft animals were not used. The implements used in planting were the hoe and the digging stick (dibble stick), a wooden stick pointed at one end that was used to make a hole in the ground into which the seeds could be dropped and then covered.

Adapted from *International Journal of American Linguistics* (1953)



Distribution of Eastern Woodlands Indians.

Of all the groups in the area, the Iroquoian tribes were probably the most dependent on agriculture, but even they did not rely wholly on it. The population of the area was never great enough to have exhausted the supply of wild plants and animals, and as a result the Indians living there did not have to expend the time and effort necessary for intensive agriculture. They also could avoid a dull and monotonous, though balanced, diet confined to corn, beans, and squash and could enjoy a rich and varied diet merely by travelling to the proper places at the proper times of the year to collect food. Leaves of wild plants were gathered in the spring and cooked as greens. Later in the year, berries and other seeds were gathered. Fish were caught in the spring, summer, and fall—different species being plentiful at different times of the year. Birds were taken, and in certain areas the spring roosting places of pigeon provided virtually unlimited amounts of squab. In early spring, the maple trees were tapped for their sap. Fall was the best time for hunting, and numbers of families went into the forests at this season of the year to hunt. The seasonal round of activities was, then, a varied one and one that, contrary to common opinion, afforded a great deal of leisure time, for the Indians did not wander aimlessly around, barely avoiding starvation by collecting what few eatable foods were available. They relied, instead, on their knowledge of the country to provide them with a diverse diet and diverse experiences in obtaining it.

Some cooking was accomplished by roasting over the fire or baking in the ashes, but the most popular method was boiling. The typical meal included soup cooked in a pottery or bark vessel. Dishes, however, were made not of pottery but of bark or of carved wood, as were the spoons used in eating. Each individual had his own bowl and spoon, and so an invitation to a feast was likely to include the invitation to "Come, and bring your bowl and spoon." Corn was generally prepared by pounding it with a wooden pestle in a wooden mortar hollowed out of a tree trunk. Before pounding, the corn was usually soaked in ashes to make removal of the hull easier. Occasionally, however, the corn was ground between two flat stones.

Housing, transportation, and weapons. As the land provided the Indian with food, so also it provided him with other necessities of life. The culture of 19th-century white American farmers has been labelled a "wood culture," and the earlier Indian cultures of the area may also be so characterized: the forest provided the Indian with many of the raw materials that he used to make his houses (as well as the food implements described above).

Wigwams and longhouses

Two types of houses were built: the wigwam by the upper Great Lakes and Eastern Seaboard Algonkians and the longhouse by the Iroquoians. The wigwam was made by driving a number of pointed poles into the ground to make a circular or oval floor plan. These poles were tied together with strips of bark and reinforced with other poles tied horizontally to make a dome-shaped framework that was covered with bark, reeds, or woven mats, the type of covering depending on the availability of materials in the area. A fire in the centre provided heat for cooking and for warmth. Although the Iroquoian longhouse, like the wigwam, was made of a framework of poles covered with bark sheets, it was arbor-shaped rather than dome-shaped, having straight sides and an arched roof. After European contact, the roof shape often was of the gable type. Rather than being circular or oval, the longhouse was rectangular in floor plan and had a door at either end. A longhouse was approximately 20 feet wide and ranged from less than 50 feet to more than 200 feet in length, depending on the number of families living in it. Down the middle of the house were the fires, two families on either side sharing the fire in the middle. The average longhouse probably had five fires and ten families.

The forest also provided materials for the dugouts and bark canoes commonly used for transport in this area of many lakes and streams, the birchbark of the northern portions of the area making the best canoes. The forest also provided materials for the frames of the snowshoes, which made travel in the winter easier and which were essential in the north (a man on snowshoes could outrun a moose or other large animal in the snow and take him with an ease that was not possible in more clement seasons). The bows and arrows and the spears used in hunting and warring were also made of wood provided by the forest. Points for the arrows and spears were chipped from flint or other suitable stone, as were the knives and other sharp-edged implements.

Clothing. Animals of the forest provided the skins from which the women made clothing. The basic item of men's dress was the breechclout, a strip of skin drawn between the legs and held in place by looping it over a belt at the waist. For protection from the cold or while travelling in the forest, leggings (basically, two tubes of skin also attached to the waist belt) were added. A cape or robe of skin or fur was also worn in cold weather. The basic item of women's dress was a skirt, to which might be added leggings tied at the knee and a cape or robe. Both men and women wore moccasins, the soft-soled and heelless shoe adapted, among other things, for use with the snowshoe. The clothing of both sexes might be decorated with painting, porcupine-quill embroidery, shells, or shell beads. For special occasions, such as feasts and war expeditions, the body might also be decorated with paint and jewelry. (The face might also be tattooed.) Long hair was admired and might be greased to give added lustre. A number of men plucked out some hair and cut the remainder to form roaches or other distinctive styles.

Social organization. The relatively small numbers of Indians who lived in the area and their particular manner of obtaining the essentials of life—food, clothing, and shelter—did not require an elaborate social organization to coordinate their activities. Rather, it was a way of life that tended to foster individual self-reliance. Division of labour was simple: women took care of the children, did the cooking and other household tasks, made the clothing and basketry containers, and did much of the agricultural work; and the men hunted, fished, traded, warred, and made the houses and the implements that they used. Beyond this division of labour by sex, there was little specialization.

Bands, tribes, and confederations. An important unit of social organization was the band, a loosely organized collection of people who occupied a particular tract of land and who recognized a common identity, including a name for themselves. A number of names now known locally as Indian tribal names were band names. Several bands comprised a tribe, which, like the band, was loosely organized and which in many parts of the area was not so much a political unit as a cultural one—a group of people who spoke a common language and had similar customs. (It is the names of tribes rather than of bands that are listed at the beginning of this article.)

Leaders and councils

Although chieftainships often were inherited, personal ability was the basis for the influence that was exercised by a chief (sometimes termed sachem, especially in the eastern part of this area). The man who had the requisite abilities was chosen to succeed. Particularly important to a chief was his ability to persuade. As one result, oratory was highly valued and developed into a fine art; even in English, the power of Indian oratory is evident. Typically, the councils of the Indians involved the making of speeches, but the intent of this oratory was not to impress others with mere rhetoric but to find a solution to the issue at hand that all could agree to. If unanimity was not achieved, no action could be taken. The dissidents would either continue to express their opposition or withdraw; in either case, the effectiveness of the group would be weakened. Speech making, then, served as a means of ascertaining the diversity of opinion within the group and the manner in which consensus could be reached, for commonly each speaker summarized the opinions previously expressed before offering his own. Councils often were lengthy affairs.

Councils (including some religious councils—the Indians typically did not draw a sharp distinction between sacred and secular affairs) normally opened with the

smoking of a pipe. In the Midwest, this practice was elaborated into the calumet ceremony used to greet foreigners and on other occasions. It is from this custom that the phrase "smoke the peace pipe" is derived.

League of the Iroquois

The most elaborate and powerful political organization developed in this area was that of the League of the Iroquois, but even this league rested on the political principles to be found elsewhere. Unanimity was required (the failure to achieve this unanimity being one of the reasons for the Iroquois defeat at the hands of the Revolutionists during the Revolutionary War), and oratory was highly regarded. Tradition has it that the league was formed as a result of the efforts of Dekanawida and Hiawatha probably sometime in the 15th or 16th century. The intent of the league was to establish peace among the five tribes of the Iroquois (the sixth member of the league, the Tuscarora, was to join it in the early part of the 18th century); and thus one of the most important parts of the constitution of the league established the price for murder: ten strings of wampum (shell beads) for the life of a man and 20 strings of wampum for the life of a woman, to be paid to the kinsmen of the murdered person. (If a man murdered another man, the total paid by the relatives of the murderer was 20 strings of wampum—ten for the murdered man's life and ten for the murderer's life, which had been forfeited by the act of murder; the total for murder of a woman by a man was 30 strings of wampum, and so on.) Before the establishment of the league, tribes might go to war if the compensation was not considered just, a common custom in the area. (Witchcraft, not murder, was the most serious crime among Indians and evoked capital punishment.) The fixing of the price prevented war from occurring between members of the league, although not between members of the league and other tribes.

If the League of the Iroquois was a league of peace to its members, it was not to other Indian groups. In the 17th century, beaver had become scarce in Iroquois territory. They began a series of wars with their neighbours, defeating and dispersing the Hurons and Tionontati in 1649–50 (a number of Hurons and Tionontati were to join forces to become the Wyandot), the Neutrals in 1651, the Erie in 1656, and the Susquehanna in 1675. Earlier, about 1638, the Wenrohronons had joined the Hurons in consequence of Iroquois attacks on them. The Iroquois then took on still more distant Indian peoples.

The founding of the League of the Iroquois has been dated variously from about 1460 to about 1600, but, regardless of whether the date is pre- or post-Columbian, it seems likely that its strength and effectiveness increased as a consequence of European influence on the continent. Somewhat similarly, loose confederacies of various Indian bands were established along the Eastern Seaboard after European contact, in part to counter the force of the whites. Later, diverse groups of Indians living in the upper Great Lakes area banded together in a like manner, under the leadership of particularly influential chiefs, in order to affect events in that region.

Warfare

It seems likely that warfare among Indians increased in the years following European settlement and the establishment of trading posts. War parties were, typically, groups of men gotten together for the purpose of raiding for loot or for captives. For example, if compensation for murder had not been agreed on, a war party might be raised to avenge the murder and might include the taking of a captive to replace the murdered person. Before setting out, there might be a ceremony in which the men would boast of previous exploits, both to gain recruits and to rouse feelings to the proper pitch.

Among the Iroquoian, captives taken during war might be killed or brought back to the village, where they were either tortured to death or adopted into the tribe. If the captive was taken to compensate for a previous murder, he was often given to the family of the murdered person, and that family decided whether the captive was to be tortured to death or adopted as a member of the family. If the decision was for torture, members of the community tried to excel each other in the invention of tortures. The captive tried to accept these tortures without crying out—a practice that has contributed to the white stereotype of the stoic Indian. A captive who was killed might be scalped. Scalping may have been introduced by the Europeans, but the evidence is not conclusive. It may have been merely an elaboration of the old Indian custom to take a piece of hair or clothing of the killed person as a trophy of the event.

Clans. An important kind of social group in the area, particularly in the more southerly parts, where agriculture was relatively more important and population density higher, was the clan (sometimes now termed sib). The division of a tribe into clans served both to divide the community into smaller cooperating units and to provide a means of uniting it with others. Members of the same clan had certain obligations toward one another, regardless of tribal or community affiliations. They were expected to provide hospitality to visitors of the same clan, for example. Loyalty to clan often overshadowed that to the nuclear family, but the marriage tie among Indians often was a relatively unstable one and frequently was marked by little or no ceremony. In contrast, clan affiliation continued for life. On occasion, clan membership was as important as tribal, band, or village membership.

Names and relationships

Clans often have names that refer to an animal. The Seneca clans, for example, are Turtle, Bear, Beaver, Wolf, Snipe, Hawk, Deer, and Heron. The animal, or totem (a word adopted into English from the Algonkian word meaning "kinsmen"), had a special relationship to the clan. Members of a clan considered themselves to be related, whether an actual genealogical relationship could be traced or not. Partly because of this view, the members of a clan were not permitted to marry within the clan (that is, clans were exogamous).

Among the Iroquoians and the Delawares, a child automatically belonged to the clan of his mother (that is, the clans were matrilineal). Among the Winnebago and many other upper Great Lakes (Central) Algonkians, a child belonged to the clan of his father (that is, the clans were patrilineal—such patrilineal clans sometimes being termed gentes; singular, gens). Thus, for example, an Iroquois child of a father who belonged to the Wolf clan and a mother who belonged to the Turtle clan was a member of the Turtle clan, the clan of his mother. Further, he could not marry (without being accused of committing incest) a girl who also belonged to the Turtle clan. And if he married a girl, say, of the Bear clan, she did not become a member of the Turtle clan but remained a member of her own clan, the Bear clan, because clan membership was for life. (In a few instances, an individual might be adopted into another clan, but this had nothing to do with marriage.) In tribes that had clans, everyone in the tribe belonged to a clan; and, if a captive or other person was adopted into the tribe, he was also adopted into a clan of that tribe.

Commonly in this area, each clan owned a number of names, and a newborn child was given one of the clan's names that was not currently in use (that is, a name belonging to someone then deceased or a name that had been given up for a new name by someone still living). Certain names carried special responsibilities, such as those belonging to the 50 chiefs of the Iroquois League. When a chief died, the women of his clan decided on a successor, who was a member of the same clan. If the successor was approved by the other chiefs, he was given the name of the deceased chief in the condolence ceremony, in which the chief was "raised up" and resuscitated by giving his name to his successor.

Among many upper Great Lakes tribes, the clan owned a bundle of sacred objects, with which there was associated a ritual that was performed periodically by members of the clan. At least in recent times, the Iroquois had no comparable clan ceremonies; rather, a significant part of their ritual life centred on ceremonies in recognition of foods as they matured. These rituals included the maple, strawberry, bean, green corn, and harvest festivals, as well as the midwinter ceremony.

In some groups, such as the Winnebago and the Iroquois, the clans were grouped into two sides or moieties

("halves"), which had reciprocal obligations. Among the Iroquois, for example, members of a moiety buried the dead of the opposite moiety. Traditionally, the moieties were exogamous, and thus, in a sense, they provided wives for each other.

Medicine societies. Also often important in Indian religion are the medicine societies, so termed because one of their important functions was curing and because their membership consisted of individuals who had undergone such cures. The most famous medicine society among the upper Great Lakes Indians was the Mide Society (Midewiwin, or Grand Medicine Society), a society that held elaborate annual or semi-annual meetings during which various magical feats were performed. Of the various Iroquois medicine societies, the False Face Society is most familiar to whites because the carved wooden masks worn by members of this society during their rituals often are to be found exhibited in museums and pictured in books on Indian art.

Belief systems. Not all curing was performed by members of medicine societies. Certain individuals (often termed medicine men or shamans in anthropological literatures or powwows in the literature on New England Indians) had the power to cure, a power that was often indicated in a vision or dream. Dreams were especially important, because, generally among the people of this area, dreams indicated not only the causes of illness and an individual's power to cure but also the means of maintaining good fortune in various aspects of life. So much attention was paid to dreams that, among some Indians, a mother customarily asked her children in the morning if they had dreamed, for dreams were to be cultivated and attended to. Dreams could also influence the decisions of councils; as some early writers said, "The dream is the God of the country." Although the vision had some importance and although boys in the various tribes might seek a vision experience (particularly about the time of puberty), the vision quest (and the concomitant acquisition of a guardian spirit) was not as important in the area as a whole as it was among the Plains Indians.

Dreams and visions

The reliance on dreams, on the other hand, should not be interpreted as meaning that these Indians lived in a fantasy world. In these societies in which great emphasis was placed on self-reliance and on individual competence, attention to the content of dreams provided a means of understanding oneself and of bringing to consciousness knowledge stored in the unconscious, including knowledge as to where one's greatest abilities lay; for dreams and visions might indicate whether one had special ability in warfare, hunting, and the like.

Indians, moreover, did not lack real knowledge of herbal medicine. Indeed, it was the reputed success of their medicine that added credibility to the value of bottles of "Indian oil" and other medicines sold by the touring "Indian shows" put on by whites. Certain other practices, such as the sweat baths taken in small structures built for the purpose, also were beneficial in the treatment of others. The Indian practice of soliciting the aid of medicine societies and shamans to cure illnesses not cured by "natural" means is not unlike the modern-day treatment of psychosomatic illnesses.

More difficult for a member of Western civilization to comprehend is the "spirit world" of the Indian, for it appears to the outsider as if the Indian world was populated by a number of spirits, including spirits of such natural objects as the sun, the moon, thunder, and the trees. Some anthropologists have interpreted these beliefs as meaning that the Indians believed in pure supernatural power—that is, a force in the universe that, like electricity, could attach itself to certain persons and things. The Algonkian word *manito*, the Siouan word *wakan*, and the Iroquoian word *orenda* have been interpreted as referring to such supernatural power. There is some recent evidence, however, suggesting that this difference between Western and Indian thought rests on a different classification of the animate and inanimate worlds. The Indians classed as animate such things as the sun and the moon. And even those things that they regarded as inanimate they treated as "beings"—to be feasted as human beings are, to be called by kinship terms as human beings are, and in general to be paid attention to. Their exploits, like those of human beings, are reported in tales and myths.

COLONIAL HERITAGE

When the whites arrived on the North American continent, they brought manufactured goods that the Indians wanted and new diseases that they did not. Certain of the new diseases proved particularly virulent among Indians because they did not have the immunity that the whites had developed through centuries of exposure. At one time or another, all the Indian tribes were decimated by epidemics. In one notable instance, an epidemic swept over New England, killing many Indians in 1616–17, just a few years before the Pilgrims landed at Plymouth, a catastrophe that the Pilgrims saw as a sign of God's favour. (One reason that the Indian Squanto was so friendly to the Pilgrims was that he had been taken as a captive to Europe, spent some time in England, and had returned after the epidemic.)

Trade

The extensive trade that developed between the Indians and the Europeans (French, English, and Dutch) rested on the European desire for furs, particularly for beaver fur (beaver fur makes a fine felt, and beaver hats were the rage in Europe), and on the Indian desire for European-manufactured objects, particularly guns, kettles, needles, fishhooks, other metallic objects, and beads.

The Europeans soon discovered the Indians' desire for wampum (tubular beads made of shell) and thus established "wampum factories" in New Jersey and on Long Island. The Indians used wampum for jewelry and for gifts or signs to mark significant occasions. Important messages, for instance, were accompanied by strings of wampum; the making of treaties involved the exchange of wampum belts to confirm the sincerity of the parties and to serve as reminders of the agreement. They also were used on other political and religious occasions and kept as reminders of the occasions. Because it was valuable, wampum became a medium of exchange not only between Indians and white traders but also among the colonists. Because the coinage in common use in the colonies was already various, including Spanish, Portuguese, French, and Dutch coins as well as English ones, the adoption of wampum as another medium of exchange was an easy matter. Wampum, however, was not used as money before European contact.

Indian resistance to the settlers

The initial European settlement clung to the Atlantic coast—the sea providing the lifeline to the European homeland that the colonists needed—and thus the Eastern Seaboard Indians were first affected by the newcomers' desire for land. They were ill equipped to counter the invasion. Not only were their numbers relatively small and made even smaller by the epidemics, but their political organization was not of the kind that easily led to unified action of numbers of men. Friction between Indians and colonists did occasionally erupt, however, as in the Pequot War (1637) and King Philip's War (1675–76). Such resistance could not be maintained long, and these eastern Indians, as other Indians after them, began to adopt European ways as a means of survival. Such adoption often involved the acceptance and practice of Christianity as well as other features of European life. Some missionaries were especially influential. John Eliot, for example, accomplished the monumental task of translating the Bible into Algonkian and publishing it. There remain in New England and on Long Island some few reservations on which the Indians still are to be found. Further south, however, the Delawares gradually sold their land in the 18th century and began to drift west, becoming involved in the affairs of the country there.

The Iroquois fared somewhat better than the coastal Algonkians. In the 17th century and in the 18th century, they lived too far inland for European settlement, and only parts of their eastern territory were settled by whites. Also, the Europeans wished to maintain their trading relations with them and, through them, with Indians living farther west. The Iroquois themselves took advantage of this situation, engaging in war and diplo-

macy to maintain their position of power in the Northeast. Their power was finally broken in the American Revolution when George Washington, aware of the alliance of a number of Iroquois with the British, sent a punitive expedition into what is now upstate New York. After the Revolution, a number of Iroquois moved to Canada, though many remained in New York state. With the exception of many Oneida who moved to Wisconsin, those who remained in New York successfully resisted 19th-century efforts to move them (along with other eastern Indians) west of the Mississippi, and a number of them still live on the six Iroquois reservations in the state.

Like the Indians farther east, those of the upper Great Lakes area were greatly affected by the fur trade. The French established a series of trading posts, and the English challenged them for control of the area. Indians from the east, such as the Delawares, Wyandots, Ottawas, and Shawnee, drifted into the area seeking furs and land. The result was a series of wars and skirmishes between the English and the French and the Indians. Among the Indians, there emerged a series of prophets who attempted to revitalize Indian society and a series of chiefs who attempted to unite the Indians for the purposes of war. Notable among these were the Delaware Prophet, the Ottawa Pontiac, the Miami Little Turtle, the Shawnee Tecumseh and his half brother, the Shawnee Prophet (Tenskwatawa), and the Sauk Keokuk and Black Hawk. The upper Great Lakes Indians responded to various pressures put on them by whites, and many of them moved west. They are now to be found on reservations and other settlements of the more western states, though some still live in the upper Great Lakes area.

If there is any single thread that runs through the complex history of Indian–white relations, it is probably that of ambivalence. The Indians had certain resources that the whites wanted, and the whites had certain items that the Indians wanted. At times, these interests could be pursued to the benefit of all involved, but too often the interests of the various groups were in conflict. Emotionally, too, the attitudes have often been those of ambivalence: the Indians both wanting acceptance by whites and wanting their own separate identity and the whites both wanting to be rid of the Indians and admiring them. This ambivalence is likely to continue, for their histories and cultures are now so entwined that it is impossible to separate them.

BIBLIOGRAPHY. Names, locations, and historical events are summarized in FREDERICK WEBB HODGE (ed.), *Handbook of American Indians, North of Mexico*, 2 vol. (1907–10); and JOHN R. SWANTON, *The Indian Tribes of North America* (1952). Indian cultures of the area are summarized in ROBERT E. and PAT RITZENTHALER, *The Woodland Indians of the Western Great Lakes* (1970); W. VERNON KINIETZ, *The Indians of the Western Great Lakes, 1615–1760* (1940); and in general surveys of North American Indians as CLARK WISSLER, *Indians of the United States*, rev. ed. (1966); RUTH M. UNDERHILL, *Red Man's America* (1953); and OLIVER LA FARGE, *A Pictorial History of the American Indian* (1956). Descriptions of particular cultures include: FRANK G. SPECK, *Penobscot Man: The Life History of a Forest Tribe in Maine* (1940); W.D. and R.S. WALLIS, *The Micmac Indians of Eastern Canada* (1955); ROGER WILLIAMS, *A Key into the Language of America* (1643, reprinted 1971), despite its formidable title a delightful book and the best description of a southern New England Indian people; ALDEN T. VAUGHAN, *New England Frontier: Puritans and Indians, 1620–1675* (1965); WILLIAM W. NEWCOMB, JR., *The Culture and Acculturation of the Delaware Indians* (1956); LEWIS H. MORGAN, *League of the Ho-de-no-sau-nee, or Iroquois* (1851, reprinted 1966); GEORGE T. HUNT, *The Wars of the Iroquois* (1940); ANTHONY F.C. GEARING, *The Face of the Fox* (1970). An extensive listing of books and articles on particular tribes is given in GEORGE PETER MURDOCK, *Ethnographic Bibliography of North America*, 3rd ed. (1960).

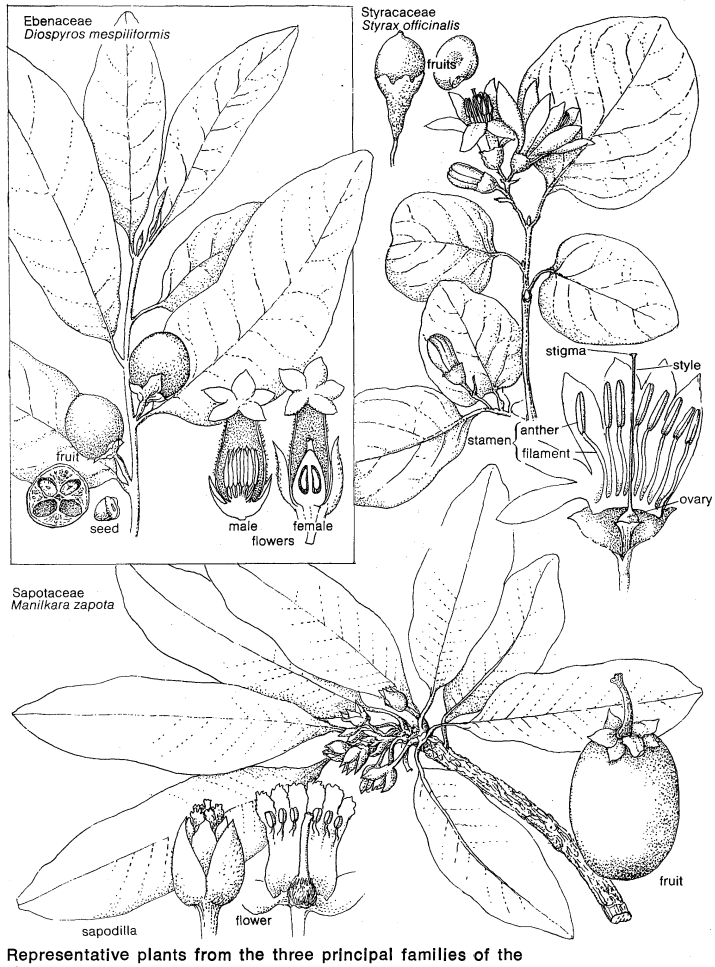
(E.To.)

Ebenales

The ebony order of flowering plants (Ebenales) consists essentially of woody trees or shrubs growing in the tropics. They have simple, smooth-margined leaves arranged alternately along the stems and bear radially symmetrical flowers that display diverse floral plans. The sepals and petals usually number four or five, and they are always fused. The male reproductive structures, or stamens, are variable in number and are arranged in one or more whorls. The female structure, or gynoecium, is superior —*i.e.*, positioned above the point of attachment of the sepals, petals, and stamens—and it is usually composed of many sections called carpels. The ovules, or seed precursors, are attached to a central axis in the ovary. Glandular, or secretory, cells are often present in the flowers.

Five families are included in the ebony order. Only three of these are of numerical or economic importance, however. They are the Ebenaceae, the Sapotaceae, and the Styracaceae.

Drawing by M. Pahl based on (*Diospyros* flowers) J. Hutchinson, *Families of Flowering Plants;* the Clarendon Press, Oxford



Representative plants from the three principal families of the ebony order.

GENERAL FEATURES

Distribution and abundance. The family Styracaceae contains about 150 species, which are grouped into ten genera; these plants grow mostly in hot climates. The most important genus, *Styrax*, contains about 100 species, of which one is found in the Mediterranean area (*Styrax officinalis*).

The family Ebenaceae contains only four to six genera, although it has a total of some 450 species. The genus *Diospyros* (persimmon and ebony) is the most important

one in the family both numerically (350 species) and economically. The present-day distribution of the family Ebenaceae is largely pantropical. One-third of the species are found in Asia (India, Indonesia, Indochina, and the Philippines); another third are in Africa and Madagascar; and, of the remaining third, one-half are in Central and South America and the other in Oceania (including Australia). There are, of course, a few species in subtropical climates, and four are found in warm temperate zones (North America and Asia). Ecologically, 85 percent of the tropical species grow in forests, with 60 percent in the evergreen forests. The zone of distribution of different species of the family Ebenaceae varies enormously; for example, *Diospyros virginiana* (persimmon) extends from Texas to Florida and northern Connecticut, but *D. mafiensis* is known only from a very small area in East Africa.

The four-continent distribution of Ebenaceae

The family Sapotaceae contains 63 to 126 genera, depending on the authority consulted, and more than 600 species, whose features contrast sharply depending on whether the species is found in the New World or the Old World. For example, no genus with a two-whorled calyx or with more stamens than petals is to be found in the Americas. Genera of plants with ovaries of three or fewer chambers occur very frequently in the Americas, but are exceptional in the Old World. The same contrast applies to the relative distribution of unisexual—separate male or female—flowers. In Africa the area from Guinea to the Congo Basin is richly endowed with species of the family Sapotaceae, particularly in Cameroon and Gabon. Madagascar has both pantropical and endemic (strictly native) genera. The island of Mauritius has an endemic genus (*Labourdonnaisia*). The genus *Northea* is found only in the Seychelles. The dry forests, savannas, and steppes that range from The Sudan to the Zambezi River are poor in Sapotaceae species, apart from a few endemics, of which *Butyrospermum parkii* is of economic importance—its oily seeds are pressed to obtain shea butter. New Caledonia is outstanding in the Australo-Papuan zone for the number of endemics of this family. Several regions of tropical America also have particular genera, in addition to genera with more extensive distributions.

Economic importance. *Family Styracaceae.* Economically, the best known representative of the family Styracaceae is the Malayan *Styrax benzoin*, a tall tree that is the source of the resin, benzoin. The resin forms in cavities caused by the destruction of tissues in the wood of stems and branches. *Styrax tonkinensis* is also a source of resin; deep incisions are made in the trunks, and the drops of resin that form in the cuts are collected about two months later. The resins contain vanillin, benzoic acid, and cinnamic acid. The Arab benzoin trade dates back before the Christian Era and provided incense to the Middle East and China. In the Western world it is used for perfumes and as a balsam and antiseptic. Several plants of the family Styracaceae are also used for ornamental purposes (*e.g., Halesia, Styrax*).

Ebony family. The family Ebenaceae is of economic importance especially for its timber, which is used in cabinets. The wood, which is denser than water and hence sinks, has a hard, fine grain and is difficult to work, but it takes a magnificent polish. The heartwood of a number of species of *Diospyros* is used to provide a variety of colours: green in *D. chloroxylon* from India; red in *D. rubra* from the Mascarene Islands; white in *D. chryophyllos*, also from the Mascarene Islands; and variegated from *D. hirsuta.* Finally, the black woods, the true ebonies, are obtained from *D. dendo* and *D. mespiliformis*, which grow in equatorial Africa; *D. crassiflora* in Gabon and Cameroon; *D. ebenum* in Ceylon; *D. melanoxylon* in India; *D. perrieri* and *D. haplostylis* in Madagascar; and *D. celebica* in the Celebes. There are also other species that produce true ebonies. The quality of the wood is related to chemical changes in the cell walls that occur with respect to the formation of gums. As a result of abusive and indiscriminate exploitation, natural stands of these trees have been considerably diminished.

Edible fruits

The fruits of some species of *Diospyros* are edible. The name itself signifies "celestial fruit" or "fruit of the gods." The best known of these is the kaki, or Japanese persimmon, *Diospyros kaki,* cultivated in Japan. About 800 varieties of this species have been developed, some of which have been acclimatized to the Mediterranean area. The fruits, large orange-red berries, are very astringent until fully ripe, at which time the tannin content is completely transformed into insoluble crystals. The juice is then sweet and palatable.

Although *D. kaki* has been cultivated in Japan for several centuries, it originated in China where it is also highly valued. The fruits of *D. virginiana*, the common persimmon of the United States, are used in jam making or dried like prunes. *D. ebenaster*, the black sapote, is a popular fruit, but little known outside Mexico. The dark colour of the flesh may make it unattractive to the uninitiated, yet it is considered to be equal in quality to the Japanese persimmon. *D. lotus*, a native of Central Asia and the Middle East, is grown in the Mediterranean area of western Europe as an ornamental tree. *D. mespiliformis* from Africa not only has edible fruit but its leaves, roots, and bark possess bactericidal properties. The bark of *D. multiflora* is used in the preparation of arrow poisons.

Family Sapotaceae. There are many species of the family Sapotaceae that are important as sources of timber, fruit, and gamboge (a resin). The heavy, hard, and long-lasting woods of some species of *Pouteria* (white balata) and *Manilkara* (red balata) are harvested in the Guianas and in Brazil, as is *Chrysophyllum prieurei*, also from the Guianas, and *Mastichodendron* species (ironwoods) from the Antilles. In Africa among the commercially important species are *Tieghemella heckelii* from the Ivory Coast and Gabon and *Autranella congolensis* of Central Africa. In tropical Asia several species of *Palaquium* are cut for timber, as is *Sideroxylon zwagei* in Indo-Malaya.

The fruits of some Sapotaceae species are edible. The sapodilla (fruit of *Manilkara zapota*, sometimes called *Nispero achras*) has been described as luscious, cool, agreeable, and fragrant. This plant, a native of southern Mexico, not only furnishes an excellent fruit but also a gum, known even to the early Aztecs, who chewed it. Now the milky latex is extracted from the trunk and from unripe fruit, boiled with aromatic ingredients, and made into chewing gum. This useful tree has been cultivated in many hot regions: West Bengal in India, the Hawaiian Islands, and parts of Africa. The sapote (*Calocarpum mammosum*) is another useful fruit from Central America. It is said that Cortés, the Spanish conqueror of Mexico, and his army were able to stay alive by eating this fruit during their march from Mexico to Honduras. It is also cultivated in the West Indies, South America, and the Philippines. In the West Indies the sapote is called marmalade plum; in Cuba, mamey colorado. The star apple (from *Chrysophyllum cainito*) is another fruit of Central America and the West Indies.

Other fruits of the family Sapotaceae with local popularity are the canistel (*Lucuma nervosa*), grown in Cuba and Florida; the abia (*Pouteria caimito*) in Peru; and the gambeya (*Synsepalum dulcificum*) in Africa.

Economically valuable oils from seeds

The seeds of many Sapotaceae species contain useful oils, and those of several species of *Madhuca* from India are used both locally in the production of mohwra and illipe butter and exported for the manufacture of edible fats. The oil cakes made of these seeds are rich in saponins (glucose-containing substances that produce soapy lathers) and toxic substances, which have to be eliminated before the cakes can be used as animal fodder. The *beurre de Karité* ("butter of Karité") of The Sudan and the Nile River area across to Senegal is extracted from the seeds of *Butyrospermum paradoxum* (now *Vitellaria paradoxa*), a variously shaped tree native to the savannas of the area. This oil is an important element in the nutrition of the native populations of those areas. In southern Morocco the seeds of *Argania spinosa* yield an oil totalling about 50 percent of the weight of the kernel. The oil, of strictly local use, is an important item in the diet of the tribes of the area.

Other species of the family Sapotaceae furnish latex for

commercial use. Gutta-percha, related to rubber but not elastic, is used to insulate submarine electric cables and in the manufacture of golf balls; the substance is found in several species of *Palaquium* from Malaysia (*e.g.*, *P. gutta* and *P. leiocarpum*). In tropical America *Manilkara bidentata* provides a latex known as balata gum, which goes into the manufacture of diving belts.

NATURAL HISTORY

Little is known about the biology of the family Ebenaceae. The aromatic flowers of many species open at night, and the petals fall the next morning. Parthenocarpy, the production of fruits without fertilization, has been observed in *Diospyros kaki*, from which seedless fruits have been obtained. The dormancy of the seeds in some species has been shown to result from the mechanical resistance of the seed coats.

Sapotaceae as keys to the ages of forests

Ecologically, the family Sapotaceae is represented most abundantly in damp forests, where they give an indication of the age of the forest by their quantity relative to other species. They are usually large-sized trees. Members of this family are also fairly numerous in the coastal thickets of tropical seas and along river banks. Although they are practically lacking in the arid zones, spiny representatives grow in semi-arid areas, and small trees less than ten feet high occur in thickets in New Caledonia.

Only the cultivated species have really been studied. It has been observed, however, that certain species (*e.g.*, *Butyrospermum paradoxum*) are a particular attraction to bees and that others are pollinated at night by bats.

FORM AND FUNCTION

Family Styracaceae. The family Styracaceae is composed of small trees or shrubs with alternately arranged leaves that lack stipules, small leaflike appendages at the bases of leafstalks. The leaves are characterized by a hairy covering of stellate (branched in starlike patterns) plant hairs or scales. They have five-parted flowers with a calyx that is often fused.

The corolla (collection of petals) is almost many petalled. The male reproductive complex is usually composed of two whorls of stamens (diplostemony) although single whorls sometimes occur. The gynoecium is located above the attachment point of the other flower parts or is partly enclosed by the bases of the sepals, petals, and stamens—its position is thus said to be superior or semi-inferior. It is composed of three to five segments called carpels, which form the same number of interior chambers, or locules. The partitions between the locules, however, are incompletely formed and exist only in the lower half of the ovary. One or more erect or pendulous ovules are present in each locule. The fruits are drupes (stony-seeded, nonsplitting fruits) or capsules, containing one or more seeds.

The ebony family. The family Ebenaceae consists of trees and shrubs with alternate (rarely opposite) simple, smooth-margined leaves that lack stipules. The plant hairs are generally formed of single cells but sometimes occur in tufts, or at times are branched into two parts. Glandular hairs also occur.

The solitary flowers occur in leaf axils (upper angles between leafstalks and stems) or form restricted, few-flowered inflorescences (clusters). They occasionally occur even on the trunk or older branches (cauliflory). They are radially symmetrical, and their parts occur in basic numbers of three to seven. The plants are dioecious—the male and female flowers occur on separate plants—but both flower sexes often have vestigial or sterile organs of the opposite sex in their structure. The stamens are generally attached either to the inner surface of the tubular structure formed by the joined lower portions of the petals (corolla tube) or at its base. They are either equal in number to the corolla lobes (petals) or two to four times as many (up to 120). In the female flowers the superior ovary is composed of two to eight carpels with as many locules or more, because of the formation of false septa, or walls. Each locule contains one or two ovules suspended from its summit. The fruit is usually a berry containing one to 16 seeds.

Family Sapotaceae. The family Sapotaceae consists mainly of large trees that are easily recognizable by the sticky latex throughout the plant. Their branched plant hairs also are distinctive, but the arms, or branches, of the hairs may not always be equal. The leathery leaves are simple and lack stipules; foliation is dense, particularly at ends of branches where the leaves form tufts.

Sapotaceous flowers may be solitary, grouped in axillary inflorescences, or cauliflorous. They are usually small, regular in shape, and bisexual. Each flower has a calyx of four to eight overlapping sepals in a single whorl. The corolla has as many parts as has the calyx, but the overlapping petals are always more or less fused. The stamens occur in two, three, or even more whorls; their arrangement is characteristic: attached, singly or in groups, opposite the petals. The superior ovary is composed of fused carpels with one to 30 locules, each containing one ovule attached along the central axis of the ovary.

The fruit is usually a hardened berry containing one to five seeds (rarely more), which are liberated after the fallen fruit rots on the ground. The seeds characteristically have a thick, smooth, and shiny seed coat and a large, dull, basal scar (hilum). The position, size, and shape of the hilum is often used to delimit groups within the family. The seeds contain a well-developed endosperm (nutrient tissue for the developing embryo) and are frequently rich in oil.

EVOLUTION AND CLASSIFICATION

Evolution. The order Ebenales is thought to have had its ancestry in the order Theales, especially the family Theaceae. The family Styracaceae is considered to be the most primitive within the order. *Styrax officinalis*, which grows today in the Mediterranean region, is known as a fossil from the Eocene Epoch (38,000,000 to 54,000,000 years ago) from areas where it is now lacking (*e.g.*, central Germany).

Fossil specimens

Fossil members of the genera *Diospyros* and *Royena* have been uncovered in strata of the Upper Cretaceous (about 65,000,000 years ago and earlier), and wood samples of the family Ebenaceae have been taken from Oligocene rock (26,000,000 to 38,000,000 years ago) in Hungary.

Members of the family Sapotaceae lived during the Upper Cretaceous, according to the fossil record, with representatives of the genus *Sideroxylon* in Europe as late as the Oligocene Epoch. The family is now pantropical, with one-third of its genera in Central and South America, one-third in Africa, and one-third in India and the Pacific.

Classification. *Annotated classification.*

ORDER EBENALES

Trees or shrubs. Leaves simple, entire (smooth-margined), alternate. Flowers radially symmetrical; sepals and petals of 4 or 5 fused segments each. Stamens variable in number, arranged in one or more whorls. Ovary superior (sepals, petals, and stamens arise at its base), composed of many carpels (ovule-bearing segments), and with axile placentation (ovules attach along the central axis).

Family Styracaceae

Small trees or shrubs. Leaves without stipules; stellate (star-shaped) hairs or scales present on leaves. Latex (milky fluid) absent. Flowers bisexual, occasionally polygamous (with bisexual and unisexual flowers present on the same plant). Stamens usually in two whorls, alternate with the petals. Ovary superior to inferior, composed of 3 to 5 carpels with 1 or more erect or pendulous ovules per locule (chamber) Fruit a drupe (stone-seeded fleshy fruit) or capsule. Ten genera and about 150 species distributed mostly in hot climates.

Family Symplocaceae

Trees and shrubs. Leaves simple, alternate, often leathery. Flowers bisexual, radially symmetrical, in racemes (clusters with a central axis and lower flowers maturing first). Sepals 5, fused, overlapping. Petals 5, fused, or in 2 series of 5 each, fused. Stamens 5, or in 2 or 3 whorls or more of 5 each, epipetalous (attached to inside of floral tube) or free of corolla (petals). Ovary inferior (surrounded by the basal portions of the sepals, petals, and stamens) or semi-inferior, of 2 to 5 carpels and locules. Ovules 2 to 4 per locule, anatropous (inverted and straight), pendulous, on axile placenta.

Fruit drupaceous, 1 seed in each locule of the stone. Two genera and about 500 species distributed in the tropics and subtropics except Africa.

Family Lissocarpaceae

With the characteristics of the family Ebenaceae except the ovary is inferior. One genus (*Lissocarpa*) and 2 species distributed in tropical South America.

Family Ebenaceae (ebony family)

Trees or shrubs. Leaves simple, entire, alternate, and without stipules. Latex absent. Flowers solitary or in few-flowered clusters, radially symmetrical, 3- to 7-parted, usually unisexual with separate sexes on different plants (dioecious), occasionally polygamous. Stamens inserted at the base of the corolla tube (hypogynous) or on the corolla tube (epipetalous), either equal in number to the corolla lobes or 2 to 4 times as many (up to 120). Ovary superior, of 2 to 8 carpels with the same number of locules as carpels or more through the formation of false septa. Ovules 1 or 2 per locule, anatropous, suspended from summit of locule. Fruit usually a berry containing 1 to 16 seeds. Four to 6 genera and about 450 species distributed largely within the tropics of both hemispheres with a few species in warm temperate zones.

Family Sapotaceae

Mostly large trees with sticky latex throughout and characteristic plant hairs bearing 2 branches (2-armed hairs). Leaves simple, usually entire and leathery, alternate, without stipules, usually in dense foliation particularly at branch ends where tufts of leaves occur. Flowers usually small, radially symmetrical, bisexual, rarely unisexual or polygamous, solitary or grouped in axillary clusters (in the upper angles between leaves and stem) or borne directly on the trunk or older branches (cauliflorous). Calyx of 4 to 8 overlapping sepals in a single whorl, fused at the base or completely free. Corolla parts as many as the sepals, the petals always more or less fused. Stamens in 2, 3, or more whorls, epipetalous, inserted singly or in groups opposite petals. Ovary superior, of fused carpels, with 1 to 30 locules and axile placentation. Ovules 1 per locule, anatropous, erect. Fruit a hardened berry with 1 to 5 seeds, rarely more. Genera number 63 to 126 depending on authority consulted, with more than 600 species mostly of damp tropical forests.

Critical appraisal. A considerable difference of opinion continues on the subdivision of the family Sapotaceae into tribes or subfamilies, as well as on the delimitation and position of its genera. One authority, for example, in his treatment of the order included 63 genera; another, 126. The lack of complete herbarium material complicates the task of placing the various taxonomic groups (genera and species) within such a homogeneous family. The characteristics available for separating genera and species are, according to some workers, a continuous network of smoothly intergrading features that do not permit easy separation into smaller groups. As a result, it is almost impossible to assess the evolutionary trends of the family.

Some authorities remove the family Styracaceae from the order Ebenales. The pollen is similar to that of the family Ebenaceae, however, but is also rather like that of the Cornaceae and Nyssaceae, both of which are families of the order Cornales.

Ebert, Friedrich

Friedrich Ebert, a leader of the German Social Democratic movement, became the first Social Democratic president of the German Republic. At heart a constitutionalist who wanted to establish parliamentary democracy but abhorred revolution, he was throughout his life attacked by conservatives of every shade as well as by radical leftists whom he did not scruple to suppress in bloody clashes that occurred during the early years of the republic.

Archiv fur Kunst und Geschichte, Berlin

Ebert, *c.* 1924.

Ebert was born on February 4, 1871, in Heidelberg, the son of a master tailor. He learned the saddler's trade and travelled through Germany as a journeyman saddler. He soon became a Social Democrat and trade unionist, representing so-called revisionist—gradualist, liberal—"trade-union" Socialism, without, however, displaying a deep interest in the ideological struggles of Marxism. His attention was always directed toward practical improvement in the living conditions of the German working class and, above all, its social and moral betterment.

Work with the Social Democratic party

In 1905 Ebert became secretary general of the German Social Democratic Party (SPD). The party had steadily increased in membership and electoral support and had accumulated physical assets and property. He updated party administration, introducing typewriters and filing systems that the party had lacked until that time due to its fear of house searches.

Ebert succeeded August Bebel as party chairman in 1913. Under his leadership, the Social Democratic movement gained increasing influence in German national politics. It was Ebert, in particular, who on August 3, 1914, prevailed upon German Social Democrats to support the war appropriations. The action of the German Social Democratic Party did not differ from that of the other Socialist parties of Europe, in which nationalist feelings remained stronger than internationalist convictions. To its own detriment, Ebert's party gave the "Fatherland" its unconditional support without requiring that Germany adopt a genuine peace policy. In consequence, it lacked the power to force the government to adopt a policy through which Germany might have escaped the crushing defeat that was to destroy the empire and also eventually Ebert's postwar policy.

Ebert could not hold the entire party to his course for long. In March 1917, a left-wing faction left the party to become the Independent Social Democratic Party of Germany (USPD), strenuously rejecting war appropriations and Germany's war policy. Another group split from the SPD to form the Communist Party of Germany

(KPD). The leftists who had withdrawn from the SPD sought a social revolution, while Friedrich Ebert and his party wanted to establish a German parliamentary democracy. Even in the midst of the war, the Catholic Centre Party, the Democratic Party (previously the Progressive Party), and the Social Democrats had formed the so-called Black–Red–Gold (Weimar) coalition, named after the colours of the flag of the liberal revolution of 1848.

With Ebert's active cooperation, a new government, headed by Prince Max of Baden and consisting of the three parties of the Black–Red–Gold coalition, was organized in October 1918 through a sweeping constitutional reform that in essential respects foreshadowed the Weimar Constitution. Thus, Germany would not have needed a revolution to achieve parliamentary democratic reform, and Ebert did everything he could to prevent such a revolution from occurring. "I hate the revolution like sin," he later said to Chancellor Max of Baden. But the revolution of November 1918 was not made by Germans to bring about the advent of the republic, democracy, or even Socialism. For nearly all Germans, the revolution had only one aim: peace. Rightly or wrongly, the German people believed that Emperor William II would not secure peace for Germany.

The revolution, winning its race with peace, came three days before the armistice. It triumphed in Berlin on November 9, and on the same day Prince Max of Baden, acting on his own authority, asked Friedrich Ebert to replace him as chancellor. Ebert, who still hoped to establish a regency for the Emperor, actually held office as chancellor for one day. On November 10 he yielded to the *fait accompli* of the revolution and set up an entirely Socialist government, with representatives from the SPD and USPD. Calling itself the Council of People's Representatives, the government derived its authority from the Workers and Soldiers Council, which claimed to speak for Germany and the German Republic but in truth had been elected rather arbitrarily by the factories and regiments of Berlin alone. Ebert was determined to place the power of the Council of People's Representatives and the Workers and Soldiers Council in the hands of a freely elected German parliament as soon as possible. He wished to see a liberal coalition government rather than a Socialist regime in power.

The elections of January 1919 gave the Black–Red–Gold coalition a majority of 85 percent. The republic's first government, under Ebert's fellow party member Philipp Scheidemann, was based on this tripartite coalition, and the new German constitution, the Weimar Constitution, so-called after the town in which it was drawn up, was the work of the coalition. By the votes of the three parties forming the coalition, Ebert was elected the first president of the republic.

Election to the presidency

Ebert and Hugo Preuss, a professor of constitutional law whom he had charged with the task of drafting the constitution, wished to alter the organic structure of the *Reich*. But the old German states (the *Länder*, or territories) successfully resisted the "unitary state" (*Einheitsstaat*) of Ebert and Preuss. Prussia in particular continued to exist as a state. The groups and forces that had until then been the pillars of the old Germany also remained intact, for the first years of the Weimar Republic were taken up by the bloody civil war which the government, under Ebert's presidency, waged against the leftist Socialists and Communists, who had been Ebert's former comrades. The republic exhausted itself in the civil war against Communism and lacked the strength to carry out the basic changes in the *Reich* that might have placed the republic on a lasting foundation. The workers did not want to make an armed defense of the democratic republic. So Ebert and his friend Gustav Noske, the defense minister, had recourse to volunteer groups, the *Freikorps*, which were principally composed of officers of the old army, and suppressed the Communist uprising out of hatred of Communism rather than love of the republic. The old officer corps formed the backbone of the Reichswehr, the republic's army. Together with the officer class and the old officialdom, the Junkers—the landed gentry east of the Elbe River—with their great estates and influence in social and political life, also survived the revolution.

With the elections to the republic's first parliament on June 6, 1920, the Black–Red–Gold coalition lost its majority and was never to regain it. The Social Democratic Party thereby lost its commanding position in the *Reich*, and the political constellation on which Ebert's leadership had been based dissolved. The electoral defeat was a direct result of the Treaty of Versailles. At that time many Germans, including Ebert, were convinced that the peace of Versailles aimed at the destruction of Germany. The resulting loss of confidence in the Black–Red–Gold coalition was the death blow of the Weimar Republic, although in fact the country's strength and stability had remained untouched.

Nevertheless, the first consequence of the Treaty of Versailles was a coup d'etat against the republic, the Kapp Putsch, by radical nationalists, a part of the Reichswehr, and the *Freikorps* which were to be disbanded under the provisions of the peace treaty. The coup of March 13, 1920, led by Wolfgang Kapp, a provincial bureaucrat who planned a restoration of the monarchy, collapsed after a few days, but Ebert's dream of a reconciliation between the army and the Social Democrats was shattered.

Soon thereafter, the government was confronted by a near-fatal crisis. When, in January 1923, Germany was declared in default of coal deliveries under the reparations provisions of the Treaty of Versailles, France, wishing to settle the reparations question decisively, occupied the Ruhr territory. Ebert, like nearly all Germans, supported national resistance and the general strike in the Ruhr, which was directed toward ending foreign military control. But Germany suffered as a result of the strike, in which eventually millions became idle. Inflation assumed staggering proportions, and the country experienced its most severe social and political crisis. Adolf Hitler nearly succeeded in seizing power in Bavaria. Chancellor Wilhelm Cuno, an independent, appointed on the eve of the Ruhr struggle as a man whom Ebert particularly trusted, was helpless in the face of the crisis. Gustav Stresemann, of the right of center People's Party, who succeeded Cuno, brought the crisis under control. Ebert initially appointed him only with hesitation and treated him with reserve but finally gave him his full support. He bitterly rebuked his own party when, protesting Stresemann's move to a more rightest position, it dropped out of the governing coalition and thus brought about the chancellor's resignation in November 1923. In point of fact, Ebert's party had thereby eliminated itself from active participation in German national politics for many years to come.

Last years

The unity of the *Reich* was preserved. Inflation was ended through monetary reform, and a means for resolving the reparations question was partially resolved in an American proposal providing for their reduction. The evacuation of the Ruhr district was in sight. Yet much of the German right persisted in its defamation of Friedrich Ebert. The judgment of a German court, which ruled that Ebert had committed high treason, at least in the legal sense, during the war by his support of a munition worker's strike, contributed to his early death. He died February 28, 1925, at the age of 54.

BIBLIOGRAPHY. Ebert's writings, speeches, and notes may be found in *Friedrich Ebert: Schriften, Aufzeichnungen, Reden*, with previously unpublished material from his estate, compiled by FRIEDRICH EBERT, JR., with a brief biography by PAUL KAMPFFMEYER, 2 vol. (1926); see also *Friedrich Ebert: Kämpfe und Ziele* (1927); PAUL LOEBE *et al.*, *Friedrich Ebert und seine Zeit* (1928); HERMANN MUELLER-FRANKEN, *Die November-Revolution Erinnerungen* (1928); and PHILIPP SCHEIDEMANN, *Memoiren eines Sozialdemokraten*, 2 vol. (1928; Eng. trans., *Memoirs of a Social Democrat*, 2 vol., 1929). There is no definitive biography of Ebert, but useful information may be found in MICHAEL FREUND, "Friedrich Ebert," *Die grossen Deutschen*, vol. 4 (1957); MAX PETERS, *Friedrich Ebert*, 2nd ed. (1954), in German; and CARL E. SCHORSKE, *German Social Democracy, 1905–1917* (1955).

(M.Fre.)

Echinodermata

The Echinodermata comprise a phylum of marine invertebrate animals whose extant representatives include sea lilies and feather stars (Crinoidea), starfishes or sea stars (Asteroidea), brittle stars or serpent stars (Ophiuroidea), sea urchins (Echinoidea), and sea cucumbers (Holothuroidea). Beginning with Lower Cambrian strata almost 570,000,000 years old, echinoderms have a rich fossil history and are well represented by many bizarre groups, most of which are now extinct.

Echinoderms have been known to man since ancient times; echinoids, for example, were used extensively by Greeks and Romans for medicinal purposes and as food. During the Middle Ages, fossil echinoids and parts of fossil crinoids were objects of superstition. In the early part of the 19th century, the Echinodermata (meaning spiny-skinned), recognized as a distinct group of animals, occasionally were associated with the coelenterates in a group known as the Radiata. Echinoderms now may be separated into 20 classes, based mainly on differences in skeletal structures. The number of extant species exceeds 6,000, and approximately 13,000 fossil species have been described.

GENERAL FEATURES

Structure. Echinoderms have a skeleton composed of numerous plates of mineral calcium carbonate (calcite). Part of the body cavity, or coelom, is a water-vascular system, consisting of fluid-filled vessels that are pushed out from the body surface as tentacles and are used in locomotion, feeding, respiration, and sensory perception. The conspicuous five-rayed, or pentamerous, symmetry of living echinoderms tends to obliterate their fundamental bilateral symmetry; *i.e.*, body of mirror-image halves.

Colour and size range

Diversity. Echinoderms exhibit various forms, sizes, and colours and especially brilliant colours such as reds, oranges, greens, and purples. Many tropical species are dark brown to black, but lighter colours are common among species not normally exposed to strong sunlight. Although most echinoderms are small in size, ranging to several centimetres (one inch is 2.54 cm) in diameter, some attain relatively large sizes; *e.g.*, some sea cucumbers (Holothuroidea) are as long as two metres, and some starfishes (Asteroidea) have a diameter of one metre (about 3.3 feet). Among the largest echinoderms were fossil crinoids (sea lilies), which attached to surfaces by holdfasts on stems exceeding 20 metres (66 feet) in length.

Distribution and abundance. Diverse echinoderm faunas consisting of many individuals and many species are found in all marine waters of the world except the Arctic, where few species occur. Asteroids (starfishes) and echinoids (sea urchins), including globular spiny urchins and flattened sand dollars, are commonly found along the seashore. Although many species are restricted to specific temperate regions, Arctic, Antarctic, and tropical forms often are widely distributed; numerous species associated with coral reefs, for example, range across the entire Indian and Pacific oceans. Many of the echinoderms of Antarctica are distributed around the continent; those with a floating (planktonic) immature, or larval, stage may be widely distributed, carried great distances by ocean currents. Some species, particularly in Antarctic and deep-sea regions, which have achieved a wide distribution without benefit of a floating larval stage, may have done so by migration of adults across the sea floor or, in the case of shallow-water species, by passive transport across oceans in seaweed.

IMPORTANCE

Role in nature. Echinoderms play an important role in the general ecology of the sea; they are, for example, efficient scavengers of decaying matter on the sea floor and they prey upon various organisms, thereby helping to regulate their numbers. On the other hand, they produce vast numbers of larvae that provide food for other planktonic organisms. By burrowing into rocks along a shore, echinoderms help to alter shorelines; in addition, they affect the structure of sea floor sediments. Echinoderm skeletons, which formed a large part of massive limestone beds, now are used by paleontologists to date them.

Representative extant echinoderms.
(Top left) An asteroid, *Astropecten*, showing typical five-rayed symmetry. (Top centre) A crinoid, the feather star *Notocrinus*. The long arms carrying pinnules and slender cirri are used for attachment to a substrate. (Top right) An ophiuroid, *Ophiomyxa flaccida*, has long slender arms and disc with mouth. (Bottom left) A holothurian, *Cucumaria*, has a soft body with numerous tube feet and ten tentacles around the mouth. (Bottom centre) An irregular echinoid, the sand dollar, *Meoma ventricosa*. (Bottom right) A regular echinoid, *Astropyga*, has long spines, test with five-rayed symmetry, and a soft anal cone central structure.

Relation to man. *Advantages.* Some of the larger species of tropical holothurians (sea cucumbers), known commercially as *trepang* or *bêche-de-mer*, are dried and used in soups, particularly in the Orient. Raw or cooked mature sex organs, or gonads, of sea urchins (Echinoidea) are regarded as a delicacy in parts of the world, including Europe, the Mediterranean region, and Chile. Some tropical holothurians produce a toxin, known as holothurin, which is lethal to many kinds of animals; Pacific island natives kill fish by poisoning waters with holothurian body tissues that release the toxin. Holothurin does not appear to affect man; in fact, the toxin, which reduces the rate of growth of certain types of tumours, may have medical significance. The easily obtained eggs and spermatozoa of echinoderms, particularly those of echinoids (sea urchins), have been used to conduct much research in developmental biology; indeed, echinoids have been collected in such large numbers that they have become rare or have disappeared altogether from the vicinity of several marine biological laboratories.

Holothurin toxin

Disadvantages. Some starfishes, which prey upon commercially usable mollusks such as oysters, have caused extensive destruction of oyster beds. Sea urchins along the California coast have prevented the regrowth of commercial species of seaweed by eating the young plants before they could become firmly established. The "crown-of-thorns" starfish, which feeds on living polyps of reef corals, has caused extensive short-term damage to coral reefs in some parts of the Pacific and Indian oceans.

NATURAL HISTORY

Reproduction and life cycle. *Types of reproduction.* In most species the sexes are separate; *i.e.*, there are males and females. Reproduction is usually sexual, involving fertilization of eggs by spermatozoa, though several species of holothurians (sea cucumbers), asteroids (starfishes), and ophiuroids (brittle stars) can also reproduce asexually by splitting in half and growing new parts.

In sexual reproduction, eggs and spermatozoa are shed into the water, where the eggs are fertilized. Spawning consists of the shedding of numerous eggs (up to several million) by females and spermatozoa by males. Most echinoderms spawn on an annual cycle, with the spawning period normally lasting one or two months during spring or summer; several species, however, are capable of spawning all year. Spawn-inducing factors are complex and may include external influences such as temperature, light, and salinity of the water; in the case of one Japanese feather star (Crinoidea), spawning is correlated with phases of the moon and takes place during early October, when the moon is in the first or last quarter. Many echinoderms aggregate before spawning, thus ensuring fertilization of eggs. Some also display a characteristic unusual behaviour during the spawning process; some asteroids and ophiuroids raise the centre of the body off the sea floor; holothurians may raise the front end of the body and wave it about.

Types of development. After an egg is fertilized, the development of the resulting embryo into a juvenile echinoderm may proceed in a variety of ways. Small eggs with little yolk material develop into free-swimming larvae that become part of the plankton, actively feed on small organisms for a period of time, then transform, or metamorphose, into juvenile echinoderms and settle to the bottom. Large eggs with greater amounts of yolk material may develop into a larval form that is planktonic but subsists upon its own yolk material, rather than feeding upon small organisms, before eventually transforming into a juvenile echinoderm. Methods of development involving an egg, planktonic larval stages, and a juvenile form are termed indirect. Large eggs with abundant quantities of yolk material may develop directly into juvenile echinoderms, without passing through a larval stage; this type of development is termed direct.

Direct and indirect development

In direct development, the young usually are reared by the female parent. Parental care or brood protection ranges from actual retention of young inside the body of the female until they are born as juveniles to care of the young on the outer surface of the body. Brood protection is best developed among Antarctic, Arctic, and deep-sea echinoderms, in which young may be held around the mouth or on the underside of the parent's body, as in some starfishes (Asteroidea) and sea cucumbers (Holothuroidea), or in special pouches on the upper surface of the body, as in some sea urchins (Echinoidea), sea cucumbers, and asteroids.

During indirect development, the fertilized egg divides many times to produce a hollow ball of cells (gastrula) pushed in at one end to form a primitive gut. Echinoderms resemble vertebrates and some other invertebrate groups in that the hole through which the gut opens to the outside (blastopore) marks the position of the future anus; the mouth is at the opposite end of the body from the blastopore. A pair of subdivided hollow pouches arise from the gut and develop into the body cavity (coelom) and water-vascular system.

The gastrula develops into a basic larval type called a dipleurula larva, characterized by bilateral symmetry; hence the name, which means little two sides. A single band of hairlike projections, or cilia, is found on each side of the body and in front of the mouth and anus. The characteristic larvae found among the living classes of echinoderms (*i.e.*, auricularia, bipinnaria, and pluteus larvae) are modifications of the basic dipleurula pattern.

Larval types

Because the ciliated band of the dipleurula larva of holothurians becomes sinuous and lobed, thus resembling a human ear, the larva is known as an auricularia larva. The dipleurula larva of asteroids develops into a bipinnaria larva, with two ciliated bands, which also may become sinuous and form lobes or arms; one band lies in front of the mouth, the other behind it and around the edge of the body. Echinoids and ophiuroids have complex advanced larvae closely similar in type. The larva, named pluteus, resembles an artist's easel turned upside down and has fragile arms formed by lobes of ciliated bands and supported by fragile rods of calcite, the skeletal material. The echinoid larva (echinopluteus) and the ophiuroid larva (ophiopluteus) usually have four pairs of arms but may have fewer or more. An extra unpaired arm on the plutei of sand dollars and cake urchins extends downward, presumably to help keep the larva up-

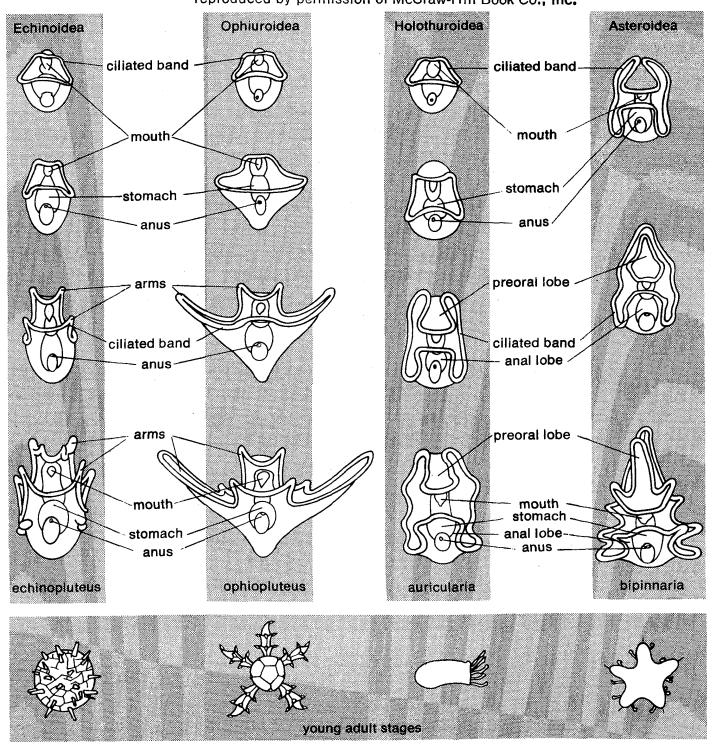

Figure 1: Development of echinoderms from similar early larval stages to diverse forms of young adults.

right. The crinoids (sea lilies), which apparently lack a dipleurula larval stage, have a barrel-shaped larva called a doliolaria larva. The doliolaria larva also occurs in other groups; in holothurians, for example, it is the developmental stage after the auricularia larva, which may not occur in some species. A doliolaria larva usually contains large quantities of yolk material and moves with the aid of several ciliated bands arranged in hoops around the body.

Although most larval stages are small, often less than one millimetre (0.04 inches) in length, some holothurian larvae 15 millimetres (0.6 inches) long have been described, and the length of bipinnaria larvae of some starfishes may exceed 25 millimetres (0.9 inches).

Metamorphosis

After a few days to several weeks as plankton, echinoderm larvae undergo a complex transformation, or metamorphosis, that results in the form known as the juvenile echinoderm. During metamorphosis, the fundamental bilateral symmetry is overshadowed by a radial symmetry dominated by formation of five water-vascular canals. Among holothurians, echinoids, and ophiuroids, the larvae metamorphose as they float, and the young sink to the sea floor; among crinoids and asteroids, however, the larvae attach to the sea floor prior to metamorphosis.

Longevity, growth, and regeneration. The average life span of echinoderms is about four years, and some species may live as long as eight or ten. The rate of growth may depend to a large extent upon factors such as type and abundance of available food and temperature of the surrounding water.

The ability to regenerate, or regrow, lost or destroyed parts is well developed in echinoderms, especially sea lilies (Crinoidea), starfishes (Asteroidea), and brittle stars (Ophiuroidea), which can regenerate new arms if existing ones are broken off. An example of echinoderm regeneration frustrated early attempts to keep starfishes from destroying oyster beds; when captured starfishes were chopped into pieces and thrown back into the sea, they actually increased in numbers. So long as a portion of a body, or disc, remained associated with an arm, new starfishes regenerated. Some sea cucumbers (Holothuroidea) can expel their internal organs (autoeviscerate) under certain conditions (*i.e.*, if attacked, if the environment is unfavourable, or on a seasonal basis); a new set of internal organs regenerates within several weeks. Sea urchins (Echinoidea) readily regenerate lost spines, pincerlike organs called pedicellariae, and small areas of the internal skeleton, or test.

Food and feeding habits. Echinoderms feed in a variety of ways. A distinct feeding rhythm frequently occurs, with many forms feeding only at night, others feeding continuously. Feeding habits range from active, selective predation to omnivorous scavenging or nonselective mud swallowing.

Range of habits

Crinoids feed exclusively on floating plankton, capturing the organisms in a network of mucus produced by soft appendages, called tube feet, contained in grooves on the tentacles, or arms. The arms are spread at right angles to the prevailing current, and small animals are passed to the mouth along the grooves by activity of the cilia and the tube feet.

Many asteroids are active predators on shellfishes and even upon other starfishes; other asteroids are mud swallowers. When feeding, some asteroid species extrude their stomach through the mouth onto the prey, which then is partially digested externally, after which the stomach is eventually retracted and digestion is completed inside the body. Most ophiuroids feed on small organisms, either floating or on the bottom, which are captured by the arms and tube feet and passed toward the mouth. Ophiuroids with arms branched in a complex manner may feed similarly to crinoids.

The more primitive, so-called regular, sea urchins (echinoids) are omnivorous or vegetarian browsers, either scraping algae and other small organisms from rocks with their hard teeth or eating seaweed; several deep-sea regular echinoids feed exclusively on plants carried into the sea from the land. The more advanced echinoids (irregular echinoids), which usually lack teeth, are burrowers and pass small organisms to the mouth with the aid of spines and tube feet. Several species of echinoid sand dollars sometimes feed on suspended organisms carried to them by ocean currents as they lie on the sea floor. Some holothurians (sea cucumbers) remain attached to a surface for indefinite periods of time, capturing plankton in a network of branching, sticky tentacles; others select food from the sea floor and push it into the mouth with their tentacles. A large number of holothurians feed by actively swallowing mud and sand, digesting the organic material, and egesting the waste in the form of characteristic castings, in a manner similar to that of earthworms.

Under artificial conditions, as in aquariums, echinoderms can survive apparent starvation for several weeks at a time. After a holothurian has autoeviscerated, it is unable to feed during the several weeks required for gut regeneration. Echinoderms may derive a significant amount of nourishment, at least for the outer cell layers of the body, from organic material dissolved in seawater.

Locomotion. Asteroids and echinoids, which use spines and tube feet in locomotion, may move forward with any area of the body and reverse direction without turning around. The feet may be used either as levers, by means of which the echinoderm steps along a surface, or as attachment mechanisms that pull the animal. Ophiuroids (brittle stars) tend to move by thrashing the arms in one of several possible methods, including a rowing motion in which strokes are taken by two pairs of extended arms; the fifth arm either is extended forward in the direction in which the animal is travelling or trails behind.

Holothurians (sea cucumbers) generally move with the mouth, or oral, end leading, movement being carried out by both the tube feet and contraction and expansion of the body; sluglike movement is common. Holothurians of the family Synaptidae are able to pull themselves across a surface using their sticky arms as anchors.

Stalked crinoids (sea lilies), so-called because they have stems, generally are firmly fixed to a surface by structures at the ends of the stalks called holdfasts. There is, however, evidence to imply that at least some fossil forms could release themselves to move to new attachment areas. The unstalked crinoids (feather stars) generally swim by thrashing their numerous arms up and down in a coordinated way; for example, in a ten-armed species, when arms 1, 3, 5, 7, and 9 are raised upward, arms 2, 4, 6, 8, and 10 are forcibly pushed downward; then the former groups of arms thrashes downward as the latter is raised. Feather stars that do not swim pull themselves across a surface using their arms.

Swimming

Swimming is known to occur in crinoids, ophiuroids, and holothurians. Some holothurians, formerly regarded as strictly bottom-living forms, are capable of efficient swimming; others, with gelatinous or flattened bodies and reduced calcareous skeletons, appear to spend most of their lives swimming in deep water.

Righting response. Among echinoderms a normal position may be with the mouth either facing a surface, as in asteroids, ophiuroids, and echinoids, or facing away from it, as in crinoids and holothurians. When overturned, echinoderms within a short time exhibit a righting response. Starfishes (asteroids) show this response most effectively, using the tube feet and the arms to perform a slow, graceful somersault that restores their normal position. Sea urchins (echinoids) can roll themselves over by concerted action of their tube feet and spines. The flat sand dollar can turn itself over only by burrowing into the sand until its position is vertical, then toppling over. In more agile groups such as holothurians, crinoids, and ophiuroids, righting is performed with relative ease.

Burrowing. Many echinoderms burrow in rock, soft sediments, or sand; crinoids, however, do not burrow because their feeding apparatus must be kept clear of sediment. Some urchins use the combined abrasive actions of their spines and teeth to burrow several inches into rock, usually in areas of severe wave and tidal action. The most characteristic burrowing echinoderms are the more advanced, or irregular, echinoids, which excavate soft sediments to various depths; most sand dollars burrow just below the surface, and some echinoids (spatangids)

may be found at depths of 38 centimetres (15 inches) or more. Holothurians use tentacles and contraction of the body wall in burrowing that generally is related to feeding. Several asteroid species bury themselves in sandy or muddy areas. The characteristic position of several ophiuroid groups involves burying the body into a surface and leaving only the tips of the arms projecting for food gathering.

Ecology. *Habitats.* Echinoderms are exclusively marine animals, with only a few species tolerating even brackish water; among the exceptions are a few tropical holothurians (sea cucumbers) that can withstand partial drying if stranded on a beach by a receding tide. Most echinoderms cannot tolerate marked changes in salinity, temperature, and light intensity and tend to move away from areas where these factors are not optimal. The behaviour of a large proportion of shallow-water species is regulated by light; *i.e.*, individuals remain concealed during the day and emerge from concealment at night for active feeding. Echinoderms are found in the warmest and coldest of the world's seas; those species that can tolerate a broad temperature range usually also have a broad geographic range. The horizontal or vertical distribution of many species is also governed by water temperature. The influence of pressure upon echinoderms has not yet been thoroughly investigated; pressure is of tremendous physiological importance to marine animals generally, however, and deep-sea dwelling echinoderms probably have special adaptations to their environment.

Influence of external factors

Echinoderms occupy a variety of habitats. Along a rocky shore, starfishes (asteroids) and sea urchins (echinoids) may cling to rocks beneath which sea cucumbers (holothurians) and brittle stars (ophiuroids) are concealed. Some sea urchins have special adaptations (*e.g.*, particularly strong skeletons and well-developed tube feet for attachment) for coping with surf pounding against rocks. In sandy areas starfishes, brittle stars, irregular sea urchins, and sea cucumbers may bury themselves or move on the surface. Large populations of all living groups of echinoderms occur in mud and ooze offshore. In some marine areas, echinoderms are the dominant organism; in the deepest ocean trenches, for example, holothurians may comprise more than 90 percent by weight of the living organisms.

Echinoderms frequently use other animals as homes; thousands of brittle stars, for example, may live in some tropical sponges. Sea cucumbers may attach themselves to the spines of sluggish Antarctic echinoids, and one sea cucumber attaches itself to the skin of a deep-sea fish. On the other hand, echinoderms are also hosts to a wide variety of organisms. Various crustaceans and barnacles, for example, cause the formation of galls, or tumourlike growths, in the skeletons of sea urchins, and crinoids are hosts of specialized parasitic worms. Commensal worms, which do no damage, are associated with most groups; an interesting case of commensalism is the association between various tropical sea cucumbers and the slender pearlfish, which often is found in the rectum of the holothurian, head protruding through its anus. Pinnotherid crabs may be found in the rectum of echinoids and holothurians in Peru and Chile, and highly modified parasitic gastropod mollusks are frequently found in the body cavities of holothurians. A conspicuous parasitic sponge grows on two species of Antarctic ophiuroids.

Predation and defense. Although echinoderm populations do not generally suffer from heavy predation by other animals, ophiuroids form a significant part of the diet of various kinds of fishes and some asteroids. In addition, echinoids (sea urchins) are frequently eaten by sharks, bony fishes, spider crabs, and gastropod mollusks; crows, herring gulls, and eider ducks may either peck their tests (internal skeletons) or drop them repeatedly until they break; and mammals, including the Arctic fox, sea otters, and man, also eat them in considerable numbers. Asteroids are eaten by other asteroids, mollusks, and crustaceans, and some holothurians are eaten by fishes and by man. Crinoids appear to have no consistent predators.

Echinoderms can protect themselves from predation in a variety of ways, most of which are passive. The presence of a firm skeleton often deters predators; echinoids, for example, have a formidable array of spines and, in some cases, highly poisonous stinging pincerlike organs (pedicellariae), both of which may cause intense pain and fever in man. Some asteroids use chemical secretions to stimulate violent escape responses in other animals, particularly predatory mollusks. Some holothurians secrete from the anus a sticky mass of white threads, which may entangle or distract predators; others produce the toxin holothurin, lethal to many would-be predators.

Passive defense mechanisms

Aggregation. Echinoderms tend to aggregate in large numbers and evidently also did so in the past; fossil beds consisting almost exclusively of immense numbers of one or a few species are known from as early as the Lower Cambrian. In present-day seas, ophiuroids may cover large areas of the sea floor; vast aggregations of echinoids are also common. Holothurians, crinoids, and some asteroids also often show a tendency to aggregate.

The phenomenon of aggregation is apparently a response to one or more environmental factors, chief of which is availability of food; *e.g.*, large numbers of ophiuroids and crinoids occupy areas in which strong currents carry large amounts of plankton. An ophiuroid raises some arms into the water to capture food, using other arms to hold on to other nearby ophiuroids; in this way, a large aggregation can maintain its position in an environment in which a single ophiuroid or a small clump of them would be swept away. As stated previously, aggregation also enhances possibilities for successful propagation of a species and possibly may increase chances for survival from predators. It has been postulated both that aggregation is a passive phenomenon resulting from interactions between individuals and the environment and also that it is a demonstration of true social behaviour, a result of interactions among individuals; the question of the cause of the phenomenon has not yet been resolved.

FORM AND FUNCTION

External features. *Symmetry and body form.* Many echinoderms of the Paleozoic Era (about 570,000,000–225,000,000 years ago) either lacked symmetry or had bodies whose halves were mirror images of each other (*i.e.*, were bilaterally symmetrical). Bilateral symmetry, which still occurs in all groups, is especially marked in the larval stages. A tendency toward radial symmetry (the arrangement of body parts as rays), which developed early in echinoderm evolution, eventually became superimposed upon the fundamental bilateral symmetry, often obliterating it. Radial symmetry, usually five-rayed (pentamerous), is conspicuous among all groups of living echinoderms. Although the reasons for the success of radial symmetry are not yet completely clear, it has been postulated that a pentamerous arrangement of skeletal parts strengthens an animal's skeleton more than would, for example, a three-rayed symmetry.

Pentamerous structure is evident in the arrangement of the tube feet, which usually radiate from the mouth to the tips of the arms in five bands. Many of the major organ systems, including the water-vascular system, muscles, hemal system (a complex arrangement of spaces), and parts of the nervous system are also pentamerous. The skeleton follows a pentamerous pattern, except in the case of the holothurians.

The four distinct growth patterns among the echinoderms provide the basis for separating the phylum into four subphyla. Among homalozoans, the pattern is asymmetrical. In crinozoans, bands of tube feet radiate from the mouth, cross the theca (*i.e.*, sheath or calyx), and extend onto the arms; in asterozoans the bands of tube feet radiate outward from the mouth onto the arms to produce a star shape; and in the armless echinozoans, the tube feet form five meridians on the spherical or cylindrical body.

Growth patterns

The crinoid (sea lily, feather star) mouth is centrally located on the theca, from which arise a variable number of arms resembling fern fronds. Although five is the primitive number of arms, they branch once or several times in most living forms to produce 10 to 200 arms.

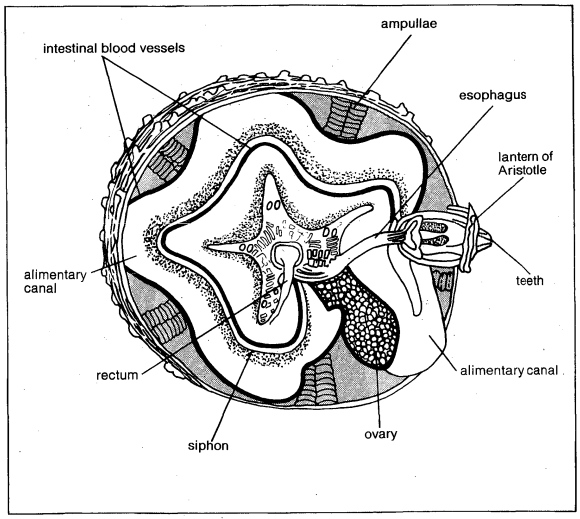

Figure 2: Sea urchin, split so that the oral half is removed, showing alimentary canal and other organs.
From T. Parker and W. Haswell, *A Textbook of Zoology;* St. Martin's Press, Inc., Macmillan & Co., Ltd.

Crinoids either are supported on a stem, or stalk, attached to the underside of the theca or lack stalks, as is the case with most living forms; unstalked crinoids attach themselves by means of slender appendages adapted for grasping (prehensile cirri).

Asteroids (starfishes) have a large central disc from which radiate five or more hollow arms containing parts of the major internal organ systems. The underside (oral surface) of the disc contains a centrally located mouth; the underside of each arm contains five or more bands of tube feet in special grooves called ambulacral furrows. The upper (aboral) surface of the disc has a centrally located anus (often absent) and the sieve plate (madreporite) of the water-vascular system (described below). Seven-armed starfish species are not unusual, and one Antarctic genus may have up to 50 arms.

Ophiuroids (brittle stars) have a small disc from which five arms radiate. The larger internal organs usually are confined to the disc. The centrally located mouth is on the underside of the disc as are the tube feet, which are not arranged in special grooves. Although most ophiuroids have five arms, a few have six or more, and in one group the five arms are branched.

In echinoids (sea urchins) the skeleton forms a rounded, or globular, test of solid plates; tube feet, which emerge through holes in the plates, form five conspicuous bands, or ambulacra. Spaces between bands of feet are termed interambulacra. Regular echinoids are roughly spherical in shape, with a centrally located mouth at the junction of the five bands containing tube feet (ambulacra); the anus is located on the side of the body opposite the mouth (aboral). Irregular urchins are elongated or flattened in shape, with the anus on the oral or aboral surface of the body. In regular and some irregular echinoids, the mouth is equipped with five teeth operated by a complex system of plates and muscles called Aristotle's lantern.

Holothurians (sea cucumbers) are elongated, with mouth and anus at opposite ends of the body. The spaces between the tube feet, which are arranged in five rows, or radii, are known as interradii. The tube feet may be more numerous on the underside of the body than elsewhere, scattered over radii and interradii, or absent. Most holothurians are soft-bodied because the skeleton is reduced and the skeletal units, called ossicles or spicules, are microscopic in size. Holothurians usually show bilateral symmetry outside, radial symmetry inside.

Skeleton. The skeleton is conspicuous in echinoderms, with the exception of the holothurians, forming an effective armour. Each skeletal unit (ossicle) usually consists of two phases, a living tissue (stroma) and a complex lattice (stereom) of mineral calcium carbonate, or calcite, which is derived from the stroma. In living echinoderms, certain properties of calcite are not evident in the stereom because of its latticed structure and the presence of soft stroma; in fossils, however, the stroma may be replaced by secondary calcite, and recognition of fragments of echinoderm skeletons in fossil strata is easier because no other animal group has the same type of skeleton.

Each ossicle is formed from granules which, after secretion from special lime-secreting cells, enlarge, branch, and fuse to build up a three-dimensional network of calcite. Parts of the skeleton enlarge as an animal grows, and resorption and regeneration of the skeleton may occur.

Variety of skeletal structures

Echinoderms have a variety of skeletal structures. In the echinoids, a hollow test (internal skeleton) consisting of ten columns of plates bears large and small spines and the pincerlike organs (pedicellariae) used in defense and to remove unwanted particles from the body. Pedicellariae, also found in the asteroids, are absent from crinoids, ophiuroids, and holothurians. The complex feeding apparatus of echinoids (Aristotle's lantern) consists of 40 ossicles held together by muscles and sutures.

Crinoids (sea lilies) have a hollow sheath (theca or calyx) composed of two or three whorls, each consisting of five skeletal plates; the stalk and the slender appendages (cirri) of unstalked forms consist of a series of drum-shaped ossicles. The asteroid (starfish) skeleton, composed of numerous smooth or spine-bearing ossicles of various shapes, is held together by muscles and ligaments, so that the entire body is flexible. The arms of asteroids are hollow, those of ophiuroids (brittle stars) solid, with the central axis of each arm consisting of elongated ossicles termed vertebrae. The microscopically sized ossicles of holothurians are highly variable in form, ranging from flat lattice plates with holes to exquisitely symmetrical wheels, and are usually numerous; one tropical species, for example, has more than 26,000,000 ossicles in its body wall. A ring of plates, called the calcareous ring, surrounds the tube leading from the mouth to the stomach (*i.e.*, the esophagus) of holothurians. Although located in a similar position to that of the echinoid Aristotle's lantern, the calcareous ring functions as a point of insertion for muscles, not as a feeding apparatus.

Internal features. *Water-vascular system.* The water-vascular system, which functions in the movement of tube feet, is a characteristic feature of echinoderms, and evidence of its existence has been found in even the oldest fossil forms. An internal hydraulic system of canals and reservoirs containing a watery fluid, the system consists of a sieve plate, or madreporite, and a ring vessel, or water-vascular ring, which are connected by a frequently calcified vessel called the stone canal. From the ring vessel, five radial water canals extend outward and give rise to branches that end in the tube feet, which are in contact with the sea. The ring vessel in ophiuroids, asteroids, and holothurians has bulbous cavities called Polian vesicles, which apparently serve to maintain pressure in the system and to hold reserve supplies of fluid; ophiuroids have four or more vesicles, asteroids five, holothurians from 1 to 50. Crinoids lack Polian vesicles, and echinoids have five structures known as either Polian vesicles or spongy bodies.

The madreporite, which is usually located externally, takes in water from outside the body; if internally located, as is the case in many holothurians, fluid is taken from the body cavity. The water or fluid passes from the madreporite to the ring vessel and along the radial canals to the tube feet. The tube feet are extended by contractions of localized muscle areas in the radial canals (ophiuroids) or by contractions of offshoots of the radial canals called ampullae (asteroids, echinoids, and holothurians); the contractions force fluid into the tube feet, which then extend.

The structure of the system varies from group to group; asteroids, for example, frequently have more than one madreporite. Radial canals may lie inward or outward from the skeleton. The tube feet may have well-developed suckers with great holding power, may taper to a point, or be adapted for respiration, feeding, burrow building, mucus production, or sensory perception.

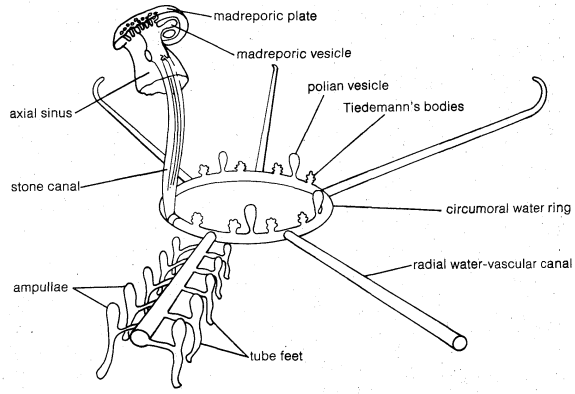

Figure 3: Water-vascular system of an asteroid.
From D. Nichols in R.A. Boolootian (ed.), *Physiology of Echinodermata* (1966); John Wiley & Sons, Inc.

Tube feet

The tube feet of crinoids, which are found in clumps of three on the arms and barblike structures (pinnules) projecting from them, spread a net of sticky mucus that traps small organisms. In ophiuroids, the tube feet are used to gain a hold on a surface and to pass food to the mouth. The numerous tube feet of asteroids are used in locomotion; asteroids with suckerlike tube feet may use them to exert a continuous pull on the valves of shellfish (*e.g.*, oysters, mussels) until muscles holding the valves tire and open slightly, allowing insertion of the asteroid's stomach. Tentacles around the mouth of holothurians are modified tube feet used to capture food; tentacles used to capture plankton are branched and sticky, those used to scoop mud and shovel it into the mouth have a simpler structure.

The tube feet of echinoids serve a variety of functions. The mouth of regular echinoids is surrounded by sensory tube feet, and tube feet further from the mouth are used in locomotion. On the upper side of the body near the anus, the tube feet have respiratory and sensory functions. The tube feet of irregular echinoids, which burrow, are modified in various ways for feeding, burrow construction, and sensory and respiratory functions.

Body wall and body cavity. The body wall (epidermis) contains hairlike projections (cilia) in most echinoderms except ophiuroids; the body wall of crinoids has relatively few. The cilia, capable of producing a waving motion, are used to carry food particles toward the mouth or to remove unwanted particles from the body. The epidermis also contains glandular and sensory cells. The epidermis of skeletal elements such as spines and pedicellariae, which project from the body surface, often is worn away. The extensive body cavity (coelom) is modified to form several specialized regions. Two important subdivisions of the coelom are called the perivisceral coelom and the water-vascular system. The perivisceral coelom is a large, fluid-filled cavity in which the major organs, particularly the digestive tube and sex organs (gonads), are suspended. The water-vascular system was described previously. Other regions of the coelom include the axial sinus (absent from adult holothurians and all echinoids), the madreporic vesicle, and the hyponeural sinus (often called the perihemal system).

Alimentary system and blood systems. The digestive canal consists of a tube, which is almost straight (asteroids and ophiuroids) or coiled in a clockwise direction (crinoids and holothurians). The tube may be divided into esophagus, stomach, intestine, and rectum. Specialized branches of the digestive tube provide enlargement of the digestive surface and may serve other functions; *e.g.*, digestive glands of asteroids, diverticula of echinoids and crinoids, siphons in echinoids, and respiratory trees in holothurians. The anus, absent in ophiuroids and a few asteroids, is present in other groups. The mouth is near the centre of the oral surface, at the point of convergence of the areas containing the tube feet.

The blood system is a complex system of spaces that are neither part of the coelom nor true vessels. A hemal ring and five radial hemal canals surround the esophagus and radial canals of the water-vascular system. A sixth hemal space arises from the hemal ring and enters the axial organ (described below). In addition, a complex network of hemal spaces is associated with the alimentary canal and gonads.

Axial organ. The axial organ, a complex and elongated mass of tissue found in all echinoderms except holothurians, represents the common junction of the perivisceral coelom, the water-vascular system, and the hemal system. Although its functions are not yet well understood, the axial organ plays a part in defense against invading organisms, can contract, is responsible for a circulation of fluids, and may have excretory and secretory activity.

Nervous system and sense organs. The echinoderm nervous system is complex. In all groups, a nerve plexus lies within and below the skin. In addition, the esophagus is surrounded by one to several nerve rings, from which run radial nerves often in parallel with branches of the water-vascular system. Ring and radial nerves coordinate righting activity.

Although echinoderms have few well-defined sense organs, they are sensitive to touch and to changes in light intensity, temperature, orientation, and the surrounding water. The tube feet, spines, pedicellariae, and skin respond to touch, and light-sensitive organs have been found in echinoids, holothurians, and asteroids.

Reproductive system. The masses of sex cells that comprise the gonads of crinoids fill special cavities in the arms or pinnules. Crinoids are the only echinoderms with gonads outside the main body cavity, probably because its volume is reduced. Asteroids typically have ten gonads, two in each arm, which are located near the arm base, appearing as a feathery tuft or a mass of tubules resembling a bunch of grapes. The numerous gonads of some species are arranged in rows along each arm. Ophiuroids have gonads attached to sacs that hang into the body cavity; the sacs, which open outside the body at the bases of the arms, may have one gonad or as many as 1,000 attached.

Number of gonads

Regular echinoids typically have five gonads attached to the interambulacra. A duct from each gonad opens to the exterior near the anus. Most irregular echinoids have four gonads, some have three or five, a few have two; the ducts are on the upper surface of the body. Holothurians differ from all other living echinoderms in having a single gonad, which consists of branching or unbranched tubules; the tubules open into a single duct, which opens to the exterior near the front end of the body. Since many early fossil echinoderms have a single genital opening, or gonopore, it is assumed that these forms also had only one gonad; the condition in holothurians thus is regarded as primitive.

PALEONTOLOGY AND EVOLUTION

Extinct echinoderms. The phylum Echinodermata was already well diversified by the Early Cambrian Period, so that a considerable amount of Precambrian evolution must have taken place. A possible early echinoderm, a Precambrian fossil from Australia with a superficial resemblance to an edrioasteroid (fossil class Edrioasteroidea) had triradial symmetry, from which pentamerous symmetry might have been derived. One problem in the study of echinoderm evolution has been the incomplete nature of the fossil record. Three of the 16 extinct classes of echinoderms now recognized were discovered after 1966, and the decade between 1960 and 1970 saw the discovery of several living fossils; *i.e.*, representatives of groups long thought to be extinct, most notably the somasteroid *Platasterias* and the oegophiuroid *Ophiocanops*. Such data have prompted reassessments and rearrangements of the classification of the phylum.

Relationships among early fossil classes of echinoderms are not clear. In their attachment to the sea floor, certain classes of the subphylum Crinozoa (*e.g.*, eocrinoids, cystoids, paracrinoids, blastoids, and crinoids) are interrelated, and the earliest stem form for these crinozoans probably resembled an eocrinoid. Classes of the fossil subphylum Homalozoa probably represent evolutionary

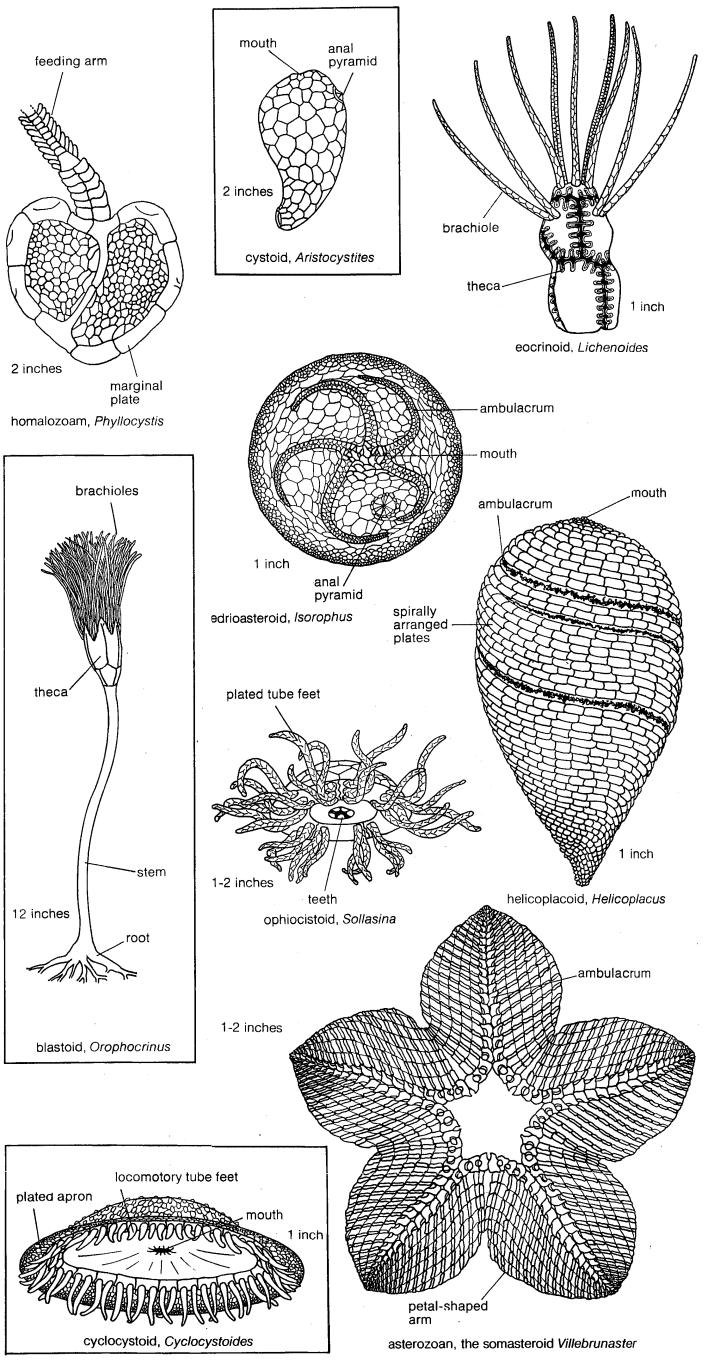

Figure 4: Representative extinct echinoderms. Approximate size is given for each.

Durham, *Yale Scientific Magazine*, vol. 39, no. 2 (1964); (eocrinoid, blastoid, ophiocistoid, cyclocystoid) D. Nichols in R.A. Boolootian (ed.), *Physiology of Echinodermata* (1966), John Wiley & Sons, Inc.; (edrioasteroid) R.V. Kesling and L. Mirtz, *Contributions from the Museum of Paleontology*, University of Michigan, vol. 15, no. 14 (1960); (helicoplacoid) J.W. Durham and K.E. Caster, "Helicoplacoidea: A New Class of Echinoderms," *Science*, vol. 140, pp. 820–822 (May 17, 1963), copyright 1963 by the American Association for the Advancement of Science; (asterozoan) W.K. Spencer, *Philosophical Transactions of the Royal Society*, B, vol. 235, p. 87 (1951).

end points. The extinct edrioasteroids (subphylum Echinozoa) are possibly related to the echinoids and holothurians; suggested relationships between edrioasteroids and asteroids have not yet been proved.

Conflicting views of relationships

Extant echinoderms. Relationships among the living classes of echinoderms involve two conflicting views. On one hand, many authorities believe that larval stages reflect the evolutionary history of these groups; thus, because echinoids and ophiuroids have pluteus larvae, they appear to form a natural group, holothurians and asteroids forming another. Recent biochemical studies of pigments and other complex substances found in echinoderms also indicate ophiuroid–echinoid and asteroid–holothurian relationships.

On the other hand, comparative anatomy and paleontology contradict these relationships; *i.e.*, early ophiuroids tend to approach asteroids (rather than echinoids) in skeletal structure, while early asteroids show some striking resemblances to crinoids (rather than holothurians) in arm structure. By these criteria, therefore, a crinoid-like ancestor could have given rise to an asteroid–ophiuroid line. Present-day echinoids and holothurians appear to have little in common apart from symmetry; the earliest echinoids with overlapping plates in the test, however, share several features with primitive holothurians, and other fossil groups in the subphylum Echinozoa have structures reminiscent of echinoids and holothurians.

Opponents of the use of larval stages as indicators of evolutionary affinities argue that larvae are unreliable criteria, not only because planktonic larval stages are not typical of echinoderms and are lacking altogether in some species but also because larvae themselves may undergo evolutionary changes. Since paleontological and anatomical evidence found thus far is persuasive, a classification based on adult forms rather than on early larval stages is preferable.

Relationships between echinoderms and other phyla have been studied for more than 100 years, but even with increased knowledge of anatomy and developmental biology the position of echinoderms within the animal kingdom is far from clear. A larval form (tornaria larva) of hemichordates, which resembles the dipleurula larva of echinoderms, has resulted in the conclusion that echinoderms are related to hemichordates and, by assumption, to all chordates. In addition, it has been proposed that some members of the extinct subphylum Homalozoa are chordates, ancestors of the urochordates, cephalochordates, and craniates, but also relatives of the echinoderms. Neither view has been established with certainty.

CLASSIFICATION

Distinguishing taxonomic features. The various subphyla within the Echinodermata are defined in terms of dominant growth patterns. Homalozoa are asymmetrical. Most Crinozoa are attached to the sea floor and have bands of tube feet radiating from the mouth and extending onto the arms. Asterozoa have bands of tube feet radiating from the mouth and extending onto the arms to produce a star shape (divergent growth pattern). Echinozoa lack arms and have tube feet circling the spherically shaped body (meridional growth pattern).

Below the subphylum level, criteria for classification vary, but the basis usually is the skeleton; subdivisions into classes and orders, for example, can be defined in terms of skeletal structure and the arrangement of its component parts.

Annotated classification. The echinoderms once were divided into two great groups, the Pelmatozoa and the Eleutherozoa, the names referring to living habits; *i.e.*, pelmatozoans attach to the sea floor for at least part of their life cycle, unattached eleutherozoans are capable of moving freely over the sea floor. It has been argued that such separation is unnatural because each group contains a mixture of subgroups bearing no relationship to the evolutionary history of the phylum; an alternative classification, presented below, has been established. The terms pelmatozoan and eleutherozoan are now used merely to describe the life habits of echinoderms. Some holothurians (subphylum Echinozoa), for example, have adopted a pelmatozoan habit, attaching themselves to rocks and feeding on plankton; others are eleutherozoan, moving about the sea floor while feeding.

The classification below is essentially that from the *Treatise on Invertebrate Paleontology* (see below *Bibliography*) but has been modified to accommodate recent discoveries. Totally extinct classes, marked with a dagger (†), are known only by fossils.

PHYLUM ECHINODERMATA (echinoderms)

Marine invertebrates worldwide in distribution; living adults with body pattern having structures present in 5s (pentam-

ous); skeleton composed of calcite; internal organs within a body cavity (coelom) that also includes a water-vascular system and tentacles; about 6,000 extant species, about 13,000 extinct species described.

†**Subphylum Homalozoa** (carpoids)

Fossils only (Cambrian to Middle Devonian) about 365,000,000–570,000,000 years ago; without radial symmetry; with fundamentally asymmetrical flattened body.

†*Class Stylophora*

With unique single feeding arm formerly misinterpreted as a stem.

†*Class Homostelea*

With no feeding arm, but with stem composed essentially of 2 series of plates.

†*Class Homoiostelea*

With a feeding arm and a complex stem composed in part of more than 2 series of plates.

†*Class Ctenocystoidea*

With no feeding arm and no stem, but with unique feeding apparatus consisting of a grill-like array of movable plates around mouth.

Subphylum Crinozoa

Fossil and living forms (Lower Cambrian to Recent); radially symmetrical; a partly meridional growth pattern tends to produce a cup-shaped theca (sheath); a partly radially divergent growth pattern produces arms or armlike organs (brachioles) that carry feeding extensions of the radial areas (ambulacra).

†*Class Eocrinoidea*

Lower Cambrian to Silurian about 430,000,000–570,000,000 years ago; body usually consisting of stem, theca, and feeding brachioles.

†*Class Cystoidea*

Lower Ordovician to Devonian about 395,000,000–500,000,000 years ago; with theca and brachioles, with or without stem; numerous plates of theca perforated by numerous thecal pores of a unique type, apparently unconnected with water-vascular system.

†*Class Paracrinoidea*

Middle Ordovician about 460,000,000 years ago; with stem, theca, and arms with barblike structures (pinnules); plates of theca with pore system of unique type.

†*Class Edrioblastoidea*

Middle Ordovician; with stem and theca; no arms or brachioles.

†*Class Parablastoidea*

Lower to Middle Ordovician about 460,000,000–500,000,000 years ago; resemble blastoids (see below, class Blastoidea), but differ in structure of ambulacra and in numbers of thecal plates.

†*Class Lepidocystoidea*

Lower Cambrian; theca and brachioles; no stem; theca covered with numerous overlapping plates.

†*Class Blastoidea*

Silurian to Permian about 280,000,000–430,000,000 years ago; stem, theca with 18–21 plates arranged in 4 rings; numerous feeding brachioles, distinctive infoldings of theca (hydrospires) well developed.

Class Crinoidea (sea lilies and feather stars)

Lower Ordovician to Recent; 700 living species; with, or secondarily without, stem; theca reduced to small cup carrying hollow, usually branching, feeding arms with numerous pinnules; includes fossil orders Inadunata, Flexibilia, and Camerata; living order Articulata; living representatives, stalked sea lilies and unstalked feather stars.

Subphylum Asterozoa

Fossil and living forms (Lower Ordovician to Recent); radially symmetrical with star-shaped body resulting from growth of arms in 1 plane along 5 divergent axes; mouth central, lying on same side of body as tube feet; tube feet, radial water vessels, and other structures restricted to mouth (oral) surface of body.

Class Stelleroidea

Features as subphylum above.

Subclass Somasteroidea. Fossil and living forms (Ordovician to Recent); body flattened; skeleton of arms featherlike (pinnate); transverse growth axes dominant; disc small, arms petal-like; no anus; no pincerlike organs (pedicellariae); 1 suspected living species, *Platasterias latiradiata* in Mexico; rare.

Subclass Asteroidea (starfishes or sea stars). Fossil and living forms (Ordovician to Recent); 1,800 living species; arms broad, hollow; pinnate structure of arms disrupted by dominant longitudinal growth axes; tube feet numerous, carried in deep open grooves roofed by discrete ambulacral ossicles (skeletal units); many groups with suctorial tube feet, pedicellariae, and anus; respiration by interradial gills on aboral surface of body; includes living orders Platyasterida, Paxillosida, Valvatida, Spinulosida, Forcipulatida, Euclasterida, and Zorocallida.

Subclass Ophiuroidea (brittle stars or serpent stars). Fossil and living forms (Ordovician to Recent); 2,000 living species; disc sharply distinct from long, slender arms; longitudinal growth axes dominant; no furrow for tube feet; ambulacral ossicles fused to form vertebrae of arms; no suctorial tube feet; no anus; no pedicellariae; respiration by interradial gills on oral surface of body; includes fossil order Stenurida, living orders Oegophiurida, Phrynophiurida, and Ophiurida.

Subphylum Echinozoa

Fossil and living forms (Lower Cambrian to Recent); radially symmetrical with fundamentally globoid body secondarily cylindrical or discoid; meridional growth patterns, thus projections from body (outspread arms or brachioles) totally absent; nervous, skeletal, muscular, and water-vascular system differentiated into meridional systems but underlying bilateral symmetry generally evident.

†*Class Cyclocystoidea*

Middle Ordovician to Middle Devonian about 375,000,000–460,000,000 years ago; small, disc-shaped; theca composed of numerous plates; ambulacral system with multiple branching.

†*Class Edrioasteroidea*

Lower Cambrian to Lower Carboniferous about 340,000,000–570,000,000 years ago; discoid to cylindrical; five well-developed straight or curved ambulacral food grooves radiate from a central mouth.

†*Class Helicoplacoidea*

Lower Cambrian; pear-shaped or spindle-shaped; spirally pleated contractile flexible internal skeleton (test); columns of plates arranged spirally.

†*Class Ophiocistioidea*

Lower Ordovician to Upper Silurian about 395,000,000–500,000,000 years ago; dome-shaped body partly or completely covered by well-developed test; 5 ambulacral tracts carry plated tube feet relatively enormous in size.

†*Class Camptostromatoidea*

Lower Cambrian; medusa-shaped; body wall plated by several kinds of ossicles; periphery of test with numerous plated arms; symmetry presumed to be radial.

Class Holothuroidea (sea cucumbers)

Fossil and living forms (Ordovician to Recent); 1,100 living species; cylindrical body, elongated orally–aborally, with mouth at or near one end, anus at or near the other; mouth surrounded by conspicuous ring of feeding tentacles; no spines or pedicellariae; single interradial gonad; skeleton usually reduced to form microscopic spicules; includes fossil order Arthrochirotida, living orders Dendrochirotida, Dactylochirotida, Aspidochirotida, Elasipodida, Molpadiida, and Apodida.

Class Echinoidea (sea urchins)

Fossil and living forms (Ordovician to Recent); 900 living species; globular, discoid, or oval in shape, with test of interlocking plates bearing movable spines and pedicellariae; mouth directed downward; anus present; 5 or fewer interradial gonads.

Subclass Perischoechinoidea. Fossil orders Bothriocidaroida, Echinocystoida and Palaechinoida; living order Cidaroida.

Subclass Euechinoidea. Living superorders Diadematacea, Echinacea, Gnathostomata, and Atelostomata. Gnathostomata, and Atelostomata comprise the irregular (more advanced) echinoids; all other groups include regular (more primitive) echinoids.

Critical appraisal. No classification satisfies the requirements of all students of a group. Although many paleontologists and zoologists agree with the higher classification presented here, some disagreement about important points persists. Even though the use of growth patterns as criteria for separating subphyla accommodates most major groups, some problems remain; while crinozoans, for example, are defined as possessing a theca and arms or brachioles, members of class Edrioblastoidea lack both arms and brachioles but have a well-developed theca.

As mentioned previously, several members of the subphylum Homalozoa sometimes are regarded as true chordates rather than echinoderms. Such a classification, how-

ever, would necessitate a reassessment of the entire phylum Echinodermata since the phylum then would not be unique in possessing a latticelike calcite skeleton and a water-vascular system.

In the subphylum Asterozoa, some authors prefer to accord class status to the subclasses. The subclass categories, however, serve to emphasize the close relationships between somasteroids and asteroids on the one hand and somasteroids, asteroids, and ophiuroids on the other. Within the class Asteroidea the orders Paxillosida and Valvatida are often combined into the order Phanerozonida. The recently defined orders Euclasterida and Zorocallida have separated several troublesome genera from the ill-defined order Forcipulatida.

The subphylum Echinozoa includes the classes Cyclocystoidea, Camptostromatoidea, and Helicoplacoidea; although none displays any trace of pentamerous symmetry, the cyclocystoids and camptostromatoids apparently are radially symmetrical. The extinct class Edrioasteroidea includes many members that apparently were permanently attached to the sea floor by a stem, thus differing from other echinozoans and approaching the crinozoans.

Although there is some agreement that the irregular urchins (sand dollars, cake urchins) have been derived from several sources (*i.e.*, are polyphyletic), polyphyly has not yet been proved, and it has been suggested that subdivision of the Echinoidea into two subclasses (Regularia and Irregularia) should be reintroduced.

Study of the higher classification of echinoderms is an active field; undoubtedly the classification will continue to be revised as new emphases and discoveries are developed.

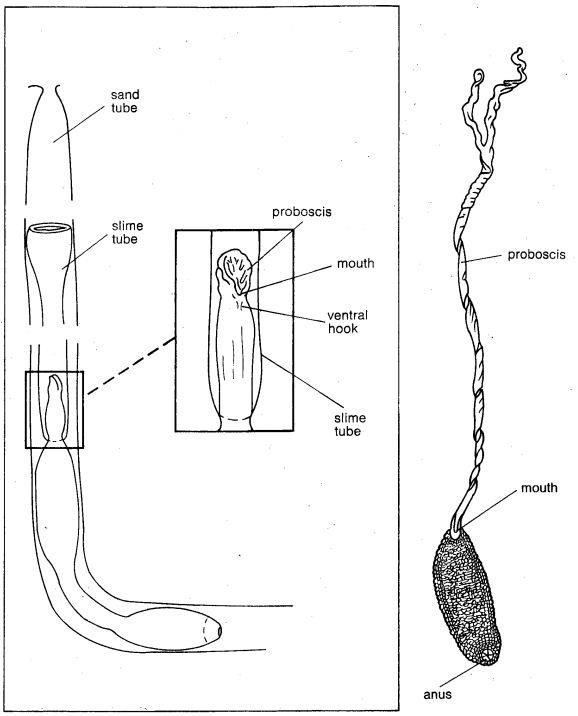
(D.L.P.)

Echiura

The phylum Echiura, also known as Echiuroidea or Echiurida, or the spoonworms, are sausage-shaped organisms with a flattened extension of the "head" that is curved along its lateral edges and sometimes shaped like a scoop or spoon to form a nonretractable anterior proboscis. Adult spoonworms vary from a few millimetres to 600 millimetres in length. In *Urechis* the proboscis is only a fraction of the length of the trunk; however, in *Ikeda* the proboscis may exceed 10 times the trunk length and measure more than one metre.

Apart from a few brackish-water species, echiurids are marine and occur in seabeds throughout the world. Although some species inhabit rock crevices, most live in burrows in the mud. A flow of water is maintained through the burrow by peristaltic contractions of the body. Some respiration probably takes place across the body wall, but the hind gut is often utilized as a respiratory organ by drawing water through the anus.

Life cycle. The sexes are separate and, apart from members of the family Bonelliidae, superficially alike. Ova or spermatozoa produced by an unpaired gonad and shed into the coelomic fluid contained in the body cavity are nourished there until maturation is complete. The mature gametes are taken up by ciliated funnels of the anterior nephridia, which lose their excretory function. Then the gametes pass into thin-wall nephridial sacs and are stored there until their expulsion into the sea where fertilization takes place. Spiral cleavage occurs in the zygote; a free-swimming trochophore larva develops and metamorphoses into a burrowing worm.



Echiurids.
(Left) *Urechis caupo.* (Right) *Bonellia viridis.*
From Paul A. Meglitsch, *Invertebrate Zoology*, copyright © 1967 by Oxford University Press, Inc.; reprinted by permission

Species of the family Bonelliidae are unusual in that the male (only one to six millimetres long) is parasitic within a modified nephridium (or uterus) of a female. A male develops when a larva comes in contact with a female's proboscis, which secretes a hormone that affects larval development. The larva passes to the esophagus and undergoes reduced metamorphosis to a sexually mature male; however, the proboscis and circulatory system fail to develop and only a reduced digestive system forms. Cilia cover the entire body (as with the larva), yet a system of gonoducts develops fully. The male remains within the egg-storage organ of the female, presumably to fertilize the eggs as they are shed into the water.

Form and function. The trunk of spoonworms is sac-like, with a body wall composed of three muscle layers. Anteriorly is a muscular but noncontractile, tactile proboscis, which is highly mobile and capable of great extension in some species. The mouth is situated at the base of the proboscis. Typically, there is a pair of setae on the ventral surface behind the mouth and one or two circles of setae around the posteriorly located anus. The body cavity is filled with coelomic fluid containing two types of cells; in some species, one type of cell contains a respiratory pigment similar to hemoglobin. The alimentary canal is coiled and associated along much of its length with a siphon, or collateral intestine, whose function is obscure. A pair of anal vesicles with an excretory function arises from the end of the intestine. Single to numerous nephridia are attached to the ventral body wall. Most species have a closed vascular system comprising dorsal, ventral, and neurointestinal blood vessels. The nerve cord is ventral. The gonads arise from a mesentary above the nerve cord or from others near the cloaca. They are diffuse, and eggs or spermatozoa are shed into the coelomic fluid.

Feeding

Feeding methods vary according to the size of the proboscis. Species with a long proboscis reach out and pick up detritus around the burrow entrance; the material collected becomes attached to strings of mucous and is transferred to the mouth. In species with a short proboscis, a mucous tube is secreted and forms a lining to the burrow. Food particles drawn into the burrow with the flow of water for respiration become fixed to the mucous tube. When this is filled, the tube and its contents are swallowed.

Classification and phylogeny. *Distinguishing taxonomic features.* Although the form of the proboscis and the number of setae present on the body are important, the most significant features are internal and include musculature, vascular system, and number of nephridia. Spoonworms were earlier linked with the peanutworms (see SIPUNCULA), then Adam Sedgewick assigned them to the phylum Annelida. They were not widely accepted as Annelida; and, after W.W. Newby (1940) studied the embryology and development of *Urechis caupo*, they became established as a separate phylum.

Annotated classification. The following classification from A.C. Stephen and S.J. Edmonds (1972) incorporates earlier views.

PHYLUM ECHIURA (spoonworms)

Unsegmented, coelomate, bilaterally symmetrical marine invertebrates; muscular, saclike, or subcylindrical body with nonretractable muscular proboscis; mouth situated anteriorly near base of proboscis, anus posterior at extremity of body; setae often present, number one or two on ventral surface, occasionally one or two rings form around anus; one, two, or many nephridia in body cavity; pair of anal vesicles arise from cloaca; about 130 species described.

Order Echiuroinea

Longitudinal musculature of body lies between a circular outer layer and an oblique inner layer of muscle; vascular system present; posterior intestine not specialized as respiratory organ; not more than 20 pairs of nephridia.

Family Bonelliidae

Sexually dimorphic; female with saclike trunk, proboscis often bifid; nephridia one or two; ventral setae two or absent, anal setae absent; anal vesicles usually branched; male small, degenerate, parasitic in or on female.

Family Echiuridae

Sexes alike; proboscis never bifid; nephridia paired; one pair ventral setae, anal setae usually absent; anal vesicles mainly saclike.

Order Xenopneusta

Longitudinal musculature of body wall between circular outer layer and oblique inner layer of muscles; vascular system absent; posterior intestine modified as respiratory organ; nephridia, two or three pairs; one family, Urechidae.

Order Heteromyota

Longitudinal musculature of body wall outside both circular and oblique muscle layers; nephridia unpaired, numerous (up to 400); one family, Ikedaidae.

Critical appraisal. The affinities of the spoonworms are obscure. Although they share a few features with the Annelida (*i.e.*, spiral cleavage in embryo, trochophore larva, signs of segmentation in nervous system during early development, setae in all but degenerate bonellid males), the evidence is too slender to suggest a close affinity. The peanutworms (phylum Sipuncula), with which the spoonworms were once united, are bilaterally symmetrical, coelomate, unsegmented worms, but the two groups have few other characters in common. Fossil spoonworms have been recorded from the Cretaceous.

(R.W.S.)

Eckehart, Meister

The greatest German speculative mystic, Meister Eckehart was the founder of the school of "Rhineland Mystics" and the ancestor of German Protestantism, Romanticism, Idealism, and Existentialism. He was essentially a preacher, and his most significant works are transcripts from sermons he delivered in medieval German. Some of his bold expressions about the soul's union with God were condemned by the Inquisition. Although his philosophy amalgamates Greek, Neoplatonic, Arabic, and Scholastic elements, it is unique. His doctrine, sometimes abstruse, always arises from one simple personal mystical experience to which he gives a number of names. By doing so, he was also an innovator of the German language, contributing many abstract terms. The National Socialist movement in Germany in the 1930s made him one of its intellectual pioneers, by blatantly falsifying his teaching. Today there is a great interest in Eckehart among some Marxist theorists and Zen Buddhists.

Johannes Eckehart (or Eckhart) was born about 1260 at Hochheim, Thuringia. He entered the Dominican Order when he was 15 and studied in Cologne, perhaps under the Scholastic philosopher Albert the Great. The intellectual background there was influenced by the great Dominican theologian Thomas Aquinas, who had just died. In his mid-30s, Eckehart was nominated vicar (the main Dominican official) of Thuringia. Before and after this assignment he taught theology at Saint-Jacques' priory in Paris. It was also in Paris that he received his master's degree (1302) so that always after he was called Meister Eckehart.

German works

He wrote four works in German (usually called "treatises"). At about the age of 40 he wrote the *Talks of Instruction*, on self-denial, the nobility of will and intellect, and the obedience to God. At the same period, he faced the Franciscans in some famous disputations on theological issues. In 1303, he became provincial (leader) of the Dominicans in Saxony and, three years later, vicar of Bohemia. His main activity, especially from 1314, was preaching to the contemplative nuns established throughout the Rhine valley. He resided in Strassburg as a prior.

The best attested German work of this middle part of his life is the *Book of Divine Consolation* dedicated to the Queen of Hungary. The other two treatises were *The Nobleman* and *On Detachment.* The teachings of the mature Eckehart describe four stages of the union between the soul and God: dissimilarity, similarity, identity, breakthrough. At the outset, God is all, the creature is nothing; at the ultimate stage, "the soul is above God." The driving power of this process is detachment (*Gelassenheit* or *Abgeschiedenheit*).

1. Dissimilarity: "All creatures are pure nothingness. I do not say they are small or petty: they are pure nothingness." Whereas God inherently possesses being, creatures do not possess being but receive it derivatively. Outside God, there is pure nothingness. "The being (of things) is God." The "noble man" moves among things in detachment, knowing that they are nothing in themselves and yet aware that they are full of God—their being.

2. Similarity: Man thus detached from the singular (individual things) and attached to the universal (Being) discovers himself to be an image of God. Divine resemblance, an assimilation, then emerges: the Son, image of the Father, engenders himself within the detached soul. As an image, "thou must be in Him and for Him, and not in thee and for thee."

3. Identity: Eckehart's numerous statements on identity between God and the soul can be easily misunderstood. He never has substantial identity in mind, but God's operation and man's becoming are considered as one. God is no longer outside man, but he is perfectly interiorized. Hence such statements: "The being and the nature of God are mine; Jesus enters the castle of the soul; the spark in the soul is beyond time and space; the soul's light is uncreated and cannot be created, it takes possession of God with no mediation; the core of the soul and the core of God are one."

4. Breakthrough: To Meister Eckehart, identity with God is still not enough; to abandon all things without abandoning God is still not abandoning anything. Man must live "without why." He must seek nothing, not even God. Such a thought leads man into the desert, anterior to God. For Meister Eckehart, God exists as "God" only

when the creature invokes him. Eckehart calls "Godhead" the origin of all things that is beyond God (God conceived as Creator). "God and the Godhead are as distinct as heaven and earth." The soul is no longer the Son. The soul is now the Father: it engenders God as a divine person. "If I were not, God would not be God." Detachment thus reaches its conclusion in the breakthrough beyond God. If properly understood, this idea is genuinely Christian: it retraces, for the believer, the way of the Cross of Christ.

These teachings are to be found in his Latin works too. But the Latin *Sermons, Commentaries on the Bible,* and *Fragments* are more Scholastic and do not reveal the originality of his thought. Nevertheless, Eckehart enjoyed much respect even among scholars. In his 60th year he was called to a professorship at Cologne. Heinrich von Virneburg—a Franciscan, unfavorable to Dominicans, anyway—was the archbishop there, and it was before his court that the now immensely popular Meister Eckehart was first formally charged with heresy. To a list of errors, he replied by publishing a Latin *Defense* and then asked to be transferred to the pope's court in Avignon. When ordered to justify a new series of propositions drawn from his writings, he declared: "I may err but I am not a heretic, for the first has to do with the mind and the second with the will!" Before judges who had no comparable mystical experience of their own, Eckehart referred to his inner certainty: "What I have taught is the naked truth." The bull of Pope John XXII, dated March 27, 1329, condemns 28 propositions extracted from the two lists. Since it speaks of Meister Eckehart as already dead, it is inferred that Eckehart died some time before, perhaps in 1327 or 1328. It also says that Eckehart had retracted the errors as charged.

Heresy charge

Eclipse, Occultation, and Transit

Eclipse, occultation, and transit are related astronomical events in which three celestial bodies are aligned; the body passing between the other two obscures some or all of the light of one of these as seen from the other. The difference in terminology is related to the relative sizes of the obscuring and obscured bodies.

The word eclipse comes from the Greek *ekleipsis* "abandonment." The Sun is eclipsed when the Moon comes between it and the Earth; the Moon is eclipsed when it moves into the shadow of the Earth cast by the Sun. Eclipses of natural or artificial satellites of a planet occur as the satellites move into the planet's shadow. The two component stars of an eclipsing binary star move around each other in such a way that their orbital plane passes through or very near the Earth, and each star periodically eclipses the other as seen from the Earth.

When the apparent size of the eclipsed body is much smaller than that of the eclipsing body, the phenomenon is known as an occultation. Examples are the disappearance of a star, nebula, or planet behind the Moon, or the vanishing of a natural satellite or space probe behind some body of the solar system.

A transit occurs when, as viewed from the Earth, a relatively small body passes across the disk of a larger body, usually the Sun or a planet, eclipsing only a very small area: Mercury and Venus periodically transit the Sun, and a satellite may transit its planet.

PHENOMENA OBSERVED DURING ECLIPSES

Lunar eclipse phenomena. The Moon may, when full, enter the shadow of the Earth. The motion of the Moon around the Earth is from west to east relative to the Sun, so that, for an observer facing south, the shadowing of the Moon begins at its left edge (if the Moon were north of the observer, as, for example, in parts of the Southern Hemisphere, the opposite would be true). If the eclipse is a total one and circumstances are favourable, the Moon will pass through the umbra, or darkest part of the shadow, in about two hours (see Figure 1). During this time, the Moon is usually not quite dark. A part of the sunlight, especially the redder light, penetrates the Earth's atmosphere, is refracted into the shadow cone, and reaches the Moon. Meteorological conditions on Earth strongly affect the amount and colour of light that can penetrate the atmosphere. Generally, the totally eclipsed Moon is clearly visible and has a reddish-brown, coppery colour, but the brightness varies strongly from one eclipse to another.

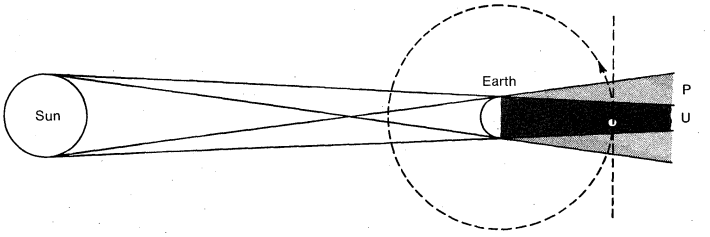

Figure 1: *Eclipse of the Moon.*
The moon revolving in its orbit around the Earth passes through the shadow of the Earth. U (umbra) is the total shadow, P (penumbra) the partial shadow.

After the Moon leaves the umbra, it must still pass through the penumbra of the shadow. When the border between umbra and penumbra is visible on the Moon, the border is seen to be part of a circle, the projection of the circumference of the Earth. This is a direct proof of the spherical shape of the Earth. Because of the Earth's atmosphere, the edge of the umbra is rather diffuse, and the times of contact between the Moon and the umbra cannot be observed accurately. The progress of a lunar eclipse can be adequately followed with the naked eye, field glasses, or a small telescope.

During the eclipse the surface of the Moon cools, at a rate dependent on the constitution of the lunar soil, which is not everywhere the same. Many spots on the Moon sometimes remain brighter than their surroundings during totality—particularly in their output of infrared radiation—possibly because their heat conductivity is less, but the cause is not fully understood.

Cooling of the Moon during eclipses

An eclipse of the Moon can be seen under similar conditions at all places on the Earth where the Moon is above the horizon.

Solar eclipse phenomena. Totality at any particular solar eclipse can only be seen from a relatively narrow belt on Earth. The various phases observable at a total solar eclipse are illustrated in Figure 2A. "First contact" designates the moment when the disk of the Moon, invisible against the bright sky background, just touches the disk of the Sun. The partial phase of the eclipse then begins, as a small indentation in the western rim of the Sun becomes noticeable. The dark disk of the Moon now gradually moves across the Sun's disk, and the bright area of the Sun is reduced to a crescent. The sunlight, shining through gaps in foliage and other small openings, is then seen to form little crescents of light that are images of the light source, the Sun. Toward the beginning of totality, the direct light from the Sun diminishes very quickly and the colour changes. The sky becomes dark but, along the horizon, the Earth's atmosphere still appears bright because the umbra of the Moon's shadow on the Earth extends over a rather narrow region. The scattered light coming in from a distance beyond this region produces weird effects. Men, animals, and birds re-

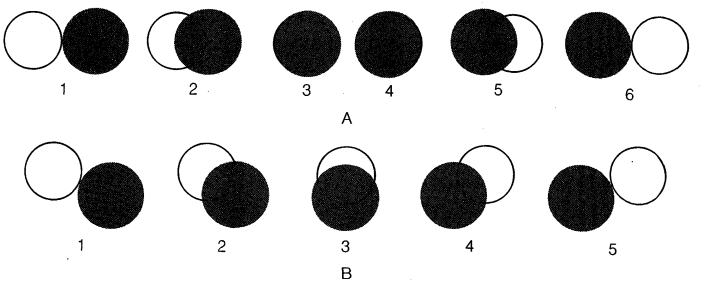

Figure 2: *Successive phases of a solar eclipse.* The dark disk of the Moon gradually moves across the disk of the Sun from west (right) to east (left). (A) Total eclipse: (1) first contact; (2) partial phase; (3) second contact, beginning of totality; (4) third contact, end of totality; (5) partial phase; (6) fourth contact. (B) Partial eclipse: (1) first contact; (3) maximum phase; (5) last contact.

act with fear; birds may go to roost as they do at sunset.

As the tiny, narrow crescent of sunlight disappears, little bright specks remain where depressions in the Moon's edge, the limb, are last to obscure the Sun's limb. These specks are known as Baily's beads, after the 18th-century English astronomer Francis Baily, who first drew attention to them. The beads vanish at the moment of second contact, when totality sets in. This is the climax of the eclipse. The reddish prominences and chromosphere of the Sun, around the Moon's limb, can now be seen. The brighter planets and stars become visible in the sky. The white corona extends out from the Sun to a distance of more than a sun's diameter, at which point it fades into invisibility. The temperature in the path of totality falls by some degrees. The light of totality is considerably brighter than that of the Full Moon, but it is quite different (see below).

The moment of third contact approaches, at which time many of the phenomena of second contact appear again in reverse order. Suddenly the first Baily's bead appears, now on the other side of the Moon. More beads of light follow, the Sun's crescent grows again, the corona disappears, and daylight brightens. The thin crescent of the Sun gradually widens, and about one and a quarter hours later the eclipse ends with fourth contact, when the last encroachment made by the Moon on the Sun's rim disappears.

During the partial phase, both before and after totality, it is necessary to protect the eyes against injury by the intense brilliance of the Sun. It should be viewed directly only through strong filters, a dark smoked glass, or a heavily fogged photographic plate or film.

Shadow bands

When totality is imminent and only a small crescent of the Sun remains, the so-called shadow bands can often be seen on plain light-coloured surfaces, such as open floors and walls. These are striations of light and shade, moving and undulating, several centimetres (or inches) wide. Their velocity and direction depend on air currents at various heights, as they are caused by refraction of sunlight by small inhomogeneities in the Earth's atmosphere. A similar phenomenon is the projection of water waves on the bottom of a sunlit swimming pool or bath.

THE GEOMETRY OF ECLIPSES, OCCULTATIONS, AND TRANSITS

Eclipses of the Sun. An eclipse of the Sun takes place when the Moon comes between the Earth and the Sun so that the Moon's shadow sweeps over the face of the Earth (see Figure 3). This shadow consists of two parts: the umbra, or total shadow, a cone into which no direct sunlight penetrates; and the penumbra, or half shadow, which is reached by light from only a part of the Sun's disk.

To an observer within the umbra, the Sun's disk appears completely covered by the disk of the Moon; such an eclipse is called total. To an observer within the penumbra, the Moon's disk appears projected against the Sun's disk so as to overlap it partly; the eclipse is then called partial for that observer. The umbra cone is narrow at the distance of the Earth, and a total eclipse is observable only within the narrow strip of land or sea over which the umbra passes. A partial eclipse may be seen from places within the large area covered by the penumbra. Sometimes the Earth intercepts the penumbra of the Moon but is missed by its umbra; only a partial eclipse of the Sun is then observed anywhere on the Earth.

By a remarkable coincidence, the sizes and distances of the Sun and Moon are such that they appear as very nearly the same angular size (about 0.5°) at the Earth, but their apparent sizes depend on their distances from the Earth. The Earth revolves around the Sun in an elliptical orbit, so that the distance of the Sun changes slightly during a year, with a correspondingly small change in the apparent size, the angular diameter, of the solar disk. In a similar way, the apparent size of the Moon's disk changes somewhat during the month because the Moon's orbit is also elliptical. When the Sun is nearest to the Earth and the Moon is at its greatest distance, the apparent disk of the Moon is smaller than that of the Sun. If an eclipse occurs at this time, the Moon's disk passing over the Sun's disk cannot cover it completely but will leave the rim of the Sun visible all around it. Such an eclipse is said to be annular. Total and annular eclipses are called central.

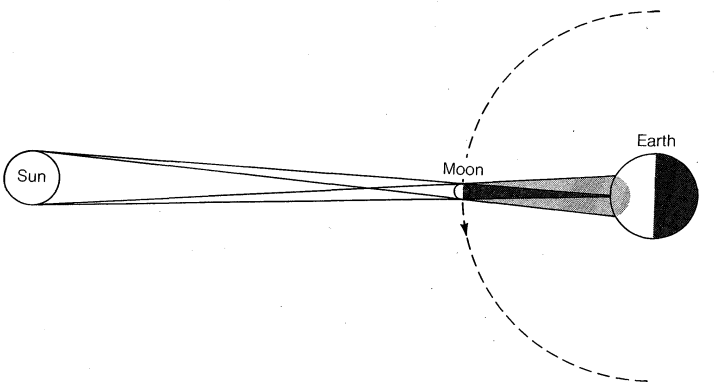

Figure 3: *Eclipse of the Sun.* The shadow of the Moon sweeps over the surface of the Earth. In the darkly shaded region (umbra) the eclipse is total; in the lightly shaded region (penumbra) the eclipse is partial. The shaded region on the opposite side of the Earth indicates the darkness of night. (Dimensions of bodies and distances are not to scale.)

In a partial eclipse (Figure 2B), the centre of the Moon's disk does not pass across the centre of the Sun. After the first contact, the visible crescent of the Sun decreases in width until the centres of the two disks reach their closest approach. This is the moment of maximum phase, and the extent is measured by the ratio between the smallest width of the crescent and the diameter of the Sun. After maximum phase, the crescent of the Sun widens again until the Moon passes out of the Sun's disk at the last contact.

Eclipses of the Moon. When the Moon moves through the shadow of the Earth (see Figure 1) it loses its bright direct illumination by the Sun, although its disk still remains faintly visible. As the shadow of the Earth is directed away from the Sun, a lunar eclipse can occur only at the time of Full Moon—that is, when the Moon is on the side of the Earth opposite to that of the Sun. A lunar eclipse appears much the same at all points of the Earth from which it can be seen. When the Moon enters the penumbra, a penumbral eclipse occurs. The dimming of the Moon's illumination by the penumbra is so slight as to be scarcely noticeable, and penumbral eclipses are rarely watched. After a part of the Moon's surface is in the umbra and thus darkened, the Moon is said to be in partial eclipse. After about an hour, when the whole disk of the Moon is within the umbra, the eclipse becomes total. If the Moon's path leads through the centre of the umbra, the total eclipse lasts about an hour and three-quarters.

Penumbral eclipse

Eclipses, occultations, and transits of satellites. These phenomena are conveniently illustrated by the four larg-

est satellites of Jupiter, whose eclipses provide a frequently occurring and fascinating spectacle to the telescopic observer. The three innermost moons (Io, Europa, and Ganymede) disappear into the shadow of Jupiter at each revolution, though the fourth (Callisto) is not eclipsed every time. Because of the sizeable dimensions of these bodies, some minutes elapse between first contact with the shadow and totality. The orbits of these satellites lie nearly in the same plane as Jupiter's orbit around the Sun, and, at practically every revolution of each satellite, the following four eclipse phenomena take place: (1) eclipse of the satellite when it passes through Jupiter's shadow; (2) occultation of the satellite when it disappears behind the planet, as seen from the Earth; (3) transit of the satellite across the disk of Jupiter; (4) transit of the shadow of the satellite across the planet's disk.

Figure 4 illustrates these phenomena; it shows Jupiter

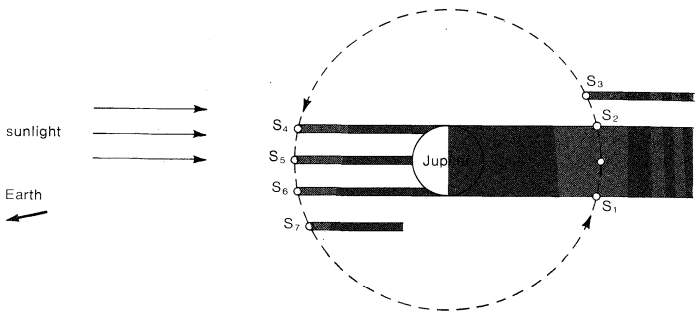

Figure 4: *Eclipses of the satellites of Jupiter.* S_1–S_7 mark successive positions of one of these satellites as it revolves in its orbit around Jupiter.

and the orbit of one of its satellites, the direction of the sunlight illuminating the system, and the direction toward the Earth, from where the observation is made. When the satellite arrives at the point S_1 of its orbit, it enters Jupiter's shadow (eclipse) and vanishes. At S_2 it comes out of the shadow, but, to the terrestrial observer, it is now hidden behind the planet (occultation) until at S_3 it reappears at the limb. When the satellite reaches the position S_4, its shadow falls on Jupiter causing a small dark spot on its surface. Seen from the Earth, the satellite is to the left of Jupiter approaching Jupiter's limb, at the time that its shadow spot passes across the planet's disk (transit of shadow). At S_5 the satellite starts to pass in front of the planet (transit of satellite), following its shadow spot. Both Jupiter and the satellite must have their illuminated sides facing the Earth. They differ little in total surface brightness; near the limb the satellite is somewhat brighter than the planet's surface on which it appears projected, but near the middle of the disk it is hardly distinguishable. At S_6 the shadow leaves the planet, and at S_7 the satellite emerges at the limb.

Proof of finite speed of light

Historically, the eclipses of Jupiter's satellites are important, for they provided one of the earliest proofs of the finite speed of light. It is possible to calculate with considerable precision the times of disappearance and reappearance of a satellite undergoing eclipse. The Danish astronomer Ole Rømer in 1675 noticed discrepancies between the observed and calculated times of such eclipses, which he correctly explained as being due to the difference in the travel time of light when the Earth is nearest to Jupiter or farther away from it.

A related phenomenon is the occultation of a space probe by a planet. During the beginning and the end of such an occultation, signals sent out by the spacecraft and received on Earth have penetrated the planet's atmosphere and can yield information about atmospheric density and composition.

THE FREQUENCY OF SOLAR AND LUNAR ECLIPSES

A solar eclipse, especially a total one, can be seen from only a limited part of the Earth, while the eclipsed Moon can be seen at the time of the eclipse wherever the Moon is above the horizon.

In most calendar years there are two lunar eclipses; in some years one or three or none occur. Solar eclipses occur two to five times a year, five being exceptional; there were five in 1935 and will be again in 2206. The average number of total solar eclipses in a century is 66 for the Earth as a whole.

Numbers of solar eclipses predicted to take place during the 20th to 25th centuries are:

1901–2000:	228	eclipses,	of which	145	are	central
2001–2100:	224	"	"	144	"	"
2101–2200:	235	"	"	151	"	"
2201–2300:	248	"	"	156	"	"
2301–2400:	248	"	"	160	"	"
2401–2500:	237	"	"	153	"	"

Any point on Earth may, on the average, experience no more than one total solar eclipse in three to four centuries. The situation is quite different for lunar eclipses. An observer remaining at the same place (and granted cloudless skies) can see 19 or 20 lunar eclipses in 18 years: three or four total eclipses and six or seven partial eclipses may be visible from beginning to end, and five total eclipses and four or five partial eclipses at least partially visible. All these numbers can be worked out from the geometry of the eclipses. A total lunar eclipse can last as long as an hour and three-quarters, but for a solar total eclipse maximum duration of totality is only 7½ minutes. This difference results from the fact that the Moon is much smaller in cross-section than the extension of the Earth's shadow but can be only a little greater in apparent size than the Sun.

Cycles of eclipses. The eclipses of the Sun and Moon occur at New Moon and Full Moon, respectively, so that one basic time period involved in the occurrence of eclipses is the synodic month; *i.e.*, the time of one revolution of the Moon around the Earth with respect to the Sun.

A solar eclipse does not occur at every New Moon, because the Moon's orbit plane is inclined to the ecliptic, the plane of the orbit of the Earth around the Sun. The angle between the planes is about 5°; thus the Moon can pass well above or below the Sun. The line of intersection of the planes is called the line of the nodes, being the two points where the Moon's orbit intersects the ecliptic plane. The ascending node is the point where the Moon crosses the ecliptic from south to north, and the descending node that where it goes from north to south. The nodes move along the orbit from west to east, going completely around the ecliptic in about 19 years. The Moon's revolution from one node to the same node again (called the draconic month, 27.212220 days) takes somewhat less time than a revolution from Full Moon to Full Moon (the synodic month, 29.530589 days). For an eclipse to occur, the Moon has to be near one of the nodes of its orbit. The draconic month, therefore, is the other basic period of eclipses.

The saros period

Resonance between these two periods produces what is called the saros period, after which time Moon and Sun return very nearly to the same relative positions. The saros was known to the ancient Babylonians (see below *Use of eclipses for astronomical purposes: In ancient astronomy*). It comprises 223 lunations (the time period from New Moon to New Moon)—that is, 6,585.321124 days, or 241.9986 draconic months. This is nearly a whole number, so that the Full Moon is in almost the same position (*e.g.*, very near a node) at the beginning and end of a saros, a lapse of time equalling 18 years and 10⅓ days or 11⅓ days if five leap years fall within the period. Thus, there is usually a close resemblance between any eclipse and the one taking place 18 years and 11 days earlier or later. Since the date differs by only about 11 days in the calendar year, the latitudes on Earth of the two eclipses will be about the same, and so will the relative apparent sizes of Sun and Moon. The saros period also comprises 238.992 anomalistic months, again nearly a whole number. In one anomalistic month, the Moon describes its orbit from perigee to perigee, in which point it is nearest to the Earth. So the Moon's distance from the Earth is the same after a whole number of anomalistic months and very nearly the same after one

saros. The saros period is, therefore, extremely useful for the prediction of both solar and lunar eclipses.

Because of the extra one-third day in the saros, the eclipse recurs each time approximately 120° farther west on the surface of the Earth. After three saroses, or 54 years and about a month (a period known to the ancient Greeks as *exeligmos*), the longitude is repeated.

There is a regular shift on Earth to the north or to the south of successive eclipse tracks from one saros to the next. The eclipses occurring when the Moon is near its ascending node shift to the south, those happening when it is near its descending node shift to the north. A saros series of eclipses begins its life at one pole of the Earth and ends it at the other. Every saros series lasts about 1,300 years and comprises 73 eclipses. About 42 of these series overlap at any time.

The inex period

Two consecutive saros series are separated by the inex period, 29 years minus 20 days—that is, 358 synodic months—after which time the New Moon has come from one node to the opposite node. The lifetime of an inex group is about 23,000 years, 70 groups coexisting, each comprising 780 eclipses. All other cycles in eclipses are combinations of the saros and the inex.

Prediction and calculation of solar and lunar eclipses. The problem may be divided into two parts. The first is to find out when an eclipse will occur, the other to determine when and where it will be visible.

For this purpose it is convenient first to consider the Earth as fixed and to suppose the observer looking out from its centre. To this observer, O in Figure 5, the Sun

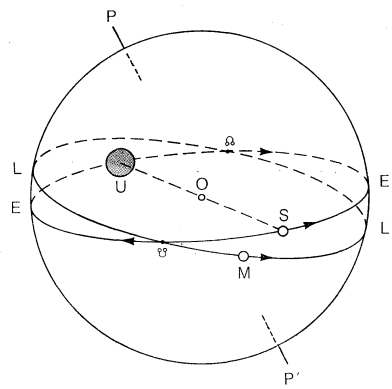

Figure 5: Apparent motions of the Sun and the Moon on the celestial sphere (see text).

and Moon appear projected on the celestial sphere. While this sphere appears to him to rotate daily, as measured by the positions of the stars, around the line PP′ (the Earth's axis of rotation), the Sun's disk, S, appears to travel slowly along the great circle EE′ (the ecliptic), making a complete revolution in one year. At the same time the Moon's disk, M, revolves along the circle LL′ once during a lunar month. The angular diameters of the two disks S and M are each about 0.5° but vary slightly.

Every month the Moon's disk revolving along LL′ will overtake the more slowly moving Sun once, at the moment of New Moon. Usually the Moon's disk will pass above or below the Sun's disk. Overlapping of the two results in an eclipse of the Sun; which can happen only when the New Moon occurs at a moment when the Sun is near the points ☊ or ☋; these signs denote the ascending and descending nodes of the Moon's orbit.

The crosscut of the umbra, the shadow cone of the Earth, at the distance of the Moon (as shown in Figure 5), may be projected like a disk U onto the celestial sphere. It subtends an angle of about 1.4°; its centre will always be opposite to the Sun's disk and will travel along EE′. An eclipse of the Moon takes place whenever the Moon's disk overlaps the shadow disk; this happens only when the shadow disk is near one of the nodes or the Sun is near the opposite node. The passage of the Sun through the lunar nodes is therefore the critical time for both solar and lunar eclipses. The Moon's orbit plane, represented by the circle LL′, is not fixed, and its nodes move slowly along the ecliptic in the direction indicated by the arrow, making a complete revolution in about 19 years. The interval between two successive passages of the Sun through one of the nodes is termed an "eclipse year," and, since the Moon's node moves so as to meet the advancing Sun, this interval is about 18.6 days less than a tropical (or ordinary) year.

The eclipse year

In Figure 6 the region of the ascending node as seen

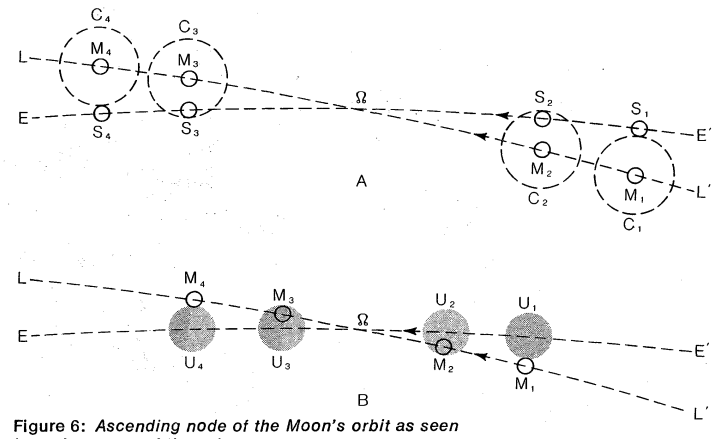

Figure 6: *Ascending node of the Moon's orbit as seen from the centre of the sphere.* Conditions necessary for (A) a solar eclipse and (B) a lunar eclipse (see text).

from the centre of the sphere is much enlarged. Here the node is kept fixed and the apparent motions of the Sun and the Moon are shown relative to the node. To the imaginary observer at the centre of the Earth, the Sun's disk will travel along the circle EE′, the Moon's disk along LL′. The Sun is so distant compared with the size of the Earth that, from all places on the Earth's surface, the Sun is seen nearly in the same position as from the centre. But the Moon is relatively near and its projected position on the celestial sphere is different for various observing stations on the Earth; it may be displaced as much as 1° from the position in which it is seen from the centre of the Earth. If the radius of the Moon's disk is enlarged by 1°, a circle, C, is obtained that encloses all possible positions of the Moon's disk seen from anywhere on the Earth. Conversely, if any circle of the Moon's size is drawn inside this "Moon circle," C, there is a place on the Earth from which the Moon is seen in that position.

Accordingly, there will be an eclipse of the Sun somewhere on the Earth whenever the Moon overtakes the Sun in such a position that the Moon circle, C, passes over the Sun's disk; when the latter is entirely covered by the Moon circle, the eclipse will be central (total or annular). From Figure 6A it is evident that a solar eclipse will take place if a New Moon occurs while the Sun moves from S_1 to S_4. This period is called the eclipse season; it starts 19 days before the Sun passes a node and ends 19 days after. Since there is a New Moon every month, at least one solar eclipse, and sometimes two, occurs during every eclipse season—of which there must be two in each calendar year. A fifth solar eclipse during a calendar year is possible because part of a third eclipse season may occur in the beginning of January or the end of December. When the New Moon falls within 11 days of the node passage (between S_2 and S_3), the eclipse will be central.

The eclipse season

Figure 6B illustrates the condition necessary for a lunar eclipse. If a Full Moon occurs within 13 days of a node passage of the Sun (when the shadow disk, U, passes the ascending node), the Moon will be eclipsed. Most eclipse seasons, but not all, will thus also contain a lunar eclipse. When three eclipse seasons fall in a calendar year, there may be three lunar eclipses in that year, as will next happen in 1982. Eclipses of the Sun are evidently more frequent than those of the Moon, but the former are visible only from a very limited region of the Earth, the latter from a whole hemisphere.

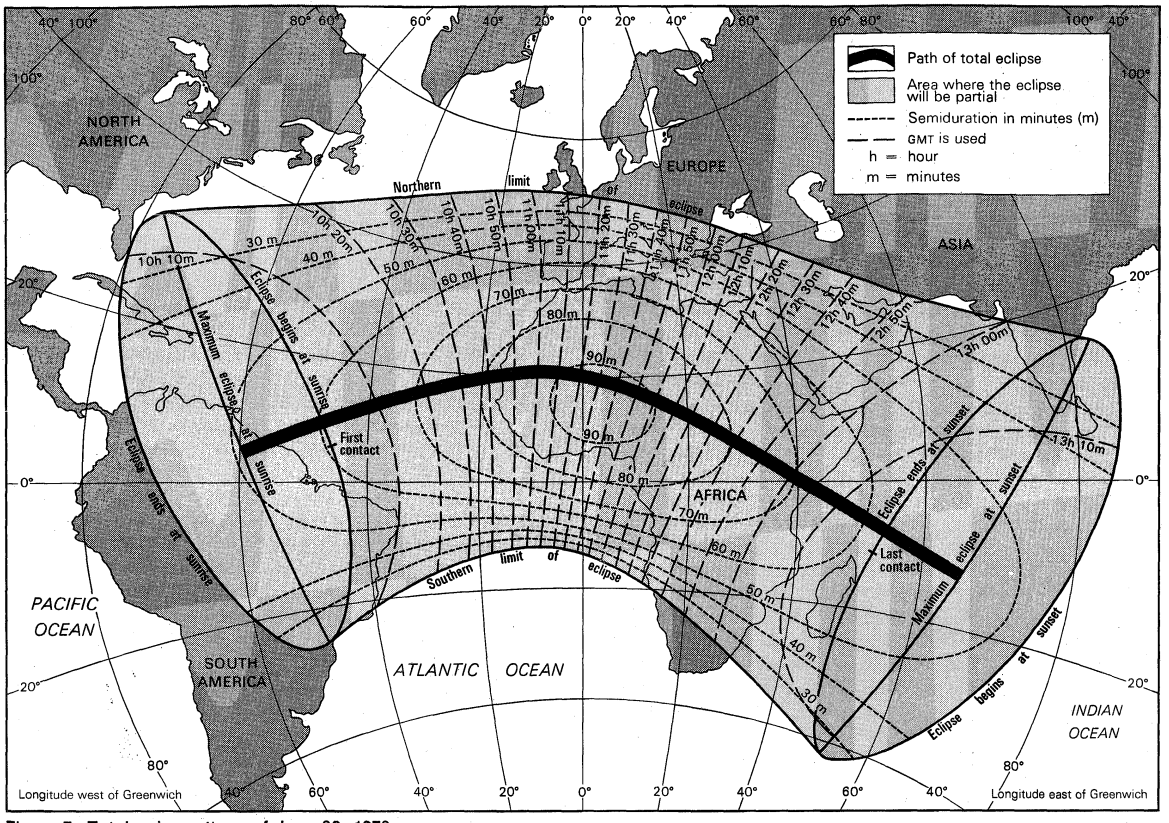

Figure 7: Total solar eclipse of June 30, 1973.
By courtesy of the U.S. Naval Observatory

During a solar eclipse the shadow cones (umbra and penumbra) of the Moon sweep across the face of the Earth (Figure 3), while at the same time the Earth is rotating on its axis. Figure 7 illustrates the circumstances of the total solar eclipse of June 30, 1973. The heavy black line marks the path along which the umbra travels from South America across the Atlantic Ocean—and Africa—into the Indian Ocean. Within the area of this lane, the eclipse is total. The wide surrounding region bounded by the full line is that covered by the penumbra, where the eclipse is partial. Within the area at its extreme left, the Sun is already in partial eclipse when it rises; within the area at the right, the Sun sets during the partial eclipse.

The astronomical ephemerides, or tables, published for each year give such maps for the more important eclipses as well as data for accurate calculation of the times of contact at any observing station. Calculations are made some years ahead in ephemeris time (ET), which is defined by the orbital motion of the earth and the planets. At the time of the eclipse, the correction is made to universal time (UT), which is defined by the rotation of the Earth and is not rigorously uniform.

It is possible with the aid of modern tables to predict solar eclipses several years ahead with an accuracy of a few seconds. For predictions of longer range, the main uncertainty is that of the Moon's motion. Eclipses can, of course, be "predicted backward" as well as forward, and the calculation of ancient eclipses has been of value in historical research (see below).

ECLIPSE RESEARCH ACTIVITIES

Solar research. During a solar eclipse, the Moon acts as a screen outside Earth's atmosphere. As seen from Earth, the Moon's dark projection on the Sun crosses the Sun at about 350 kilometres (220 miles) per second. For a few seconds, the bright, ordinarily visible disk of the Sun, called the photosphere, is eclipsed, while the chromosphere, the Sun's lower atmosphere, remains visible at the Sun's edge. In this brief time light emitted from the chromosphere can be studied and its decrease in intensity with height above the photosphere can be measured. Discrimination between layers within the chromosphere is possible to some extent. An instrument, the coronagraph, has been developed to obscure the brilliant photosphere artificially at times outside of eclipses, but the study of thin layers of the solar chromosphere and corona is still best done during an eclipse.

Study of solar chromosphere

The first photograph of a solar eclipse was taken in 1851, and the first of scientific importance by the British scientist and inventor Warren de la Rue and the Italian astronomer Angelo Secchi in 1860.

Spectroscopic observations. The ordinary spectrum of the Sun contains a brilliant many-coloured background—the continuum. This radiation emanates chiefly from the lower layers of the solar atmosphere. Cooler atoms higher up, however, selectively absorb the radiations, so that the solar spectrum consists of the bright rainbow background with many narrow gaps—dark lines —where the light has been absorbed.

Spectroscopy was first applied to the eclipsed Sun in 1868, when the path of totality passed over India and Malaya and the spectrum of bright lines originating in the solar prominences was observed. One of these lines was supposed by the British astronomer Joseph Norman Lockyer to be emitted by an unknown chemical element, which he called helium (from Greek *hēlios*, "sun"); helium was not identified on Earth until 1895. During the same eclipse, the French astronomer P.-J.-C. Janssen was inspired to find a means of observing the solar prominences without an eclipse, in which he succeeded the next day.

At the moment of totality, when the Moon obliterates the last trace of the bright photosphere, with its dark-line spectrum, the light from the upper tenuous layers of the atmosphere (which is usually lost in the much brighter photospheric light) flashes into view with the characteristic bright-line spectrum of a luminous gas. This spectrum, first observed in 1870, disappears within four to five seconds, as the Moon moves across the Sun. Because of its evanescent character, it has been called the flash spectrum. A second flash occurs at the end of totality.

Analysis of flash spectra has led to some surprising results. The spectrum matches the dark-line spectrum only roughly. The lines of the neutral metals are of comparable strength in the two spectra, but those of the ionized metals (*i.e.*, those made up of atoms that have lost one or more electrons) are markedly enhanced in the flash spectrum. The difference is attributed, in part, to lower pressures in the upper layers, but high temperature appears to contribute to the increased excitation. This is especially true for the flash lines of ionized helium, which do not appear at all in the ordinary dark-line spectrum. These require excitation temperatures of at least 25,000° K (about 45,000° F) for their production, whereas the temperature required to produce the observed quality and quantity of bright emission from the surface is only 6,000° K (about 10,800° F).

Other observations. Extending upward from the chromosphere, and closely related to it, are the so-called prominences, one of the striking features of a total eclipse, which project outward into space, sometimes as far as several hundred thousand miles. They appear as rose-coloured patches of flame, projecting well beyond the limb of the Moon, and consist of long interlacing filaments of incandescent gas.

Solar corona

During totality can be seen one of the most beautiful of natural phenomena, the solar corona, which shines like finely etched white frost against the deep blue of the eclipse-darkened sky. The form of the corona presented at different eclipses is almost infinitely variable. On occasion, usually when sunspots are near a minimum, long streamers extend four or five solar diameters away from the Sun. At other times, especially close to sunspot maximum, the corona is more nearly circular, but with jagged, petal-like extensions. The corona is faint, 500,000 times or so less brilliant than the Sun itself. Consequently the sky glare surrounding the Sun ordinarily hides the coronal details, and, before the development of the coronagraph, it was believed to be impossible to record the corona except during an eclipse.

Also interesting are observations of the radio emission of the Sun during a solar eclipse. When the Moon crosses different parts of the Sun, inhomogeneities in the generation of solar radio waves can be localized.

For geodetic purposes, measuring the Earth, the exact timing of the moments of the contacts of Moon and Sun are important, because these depend on the site of observation and so on the shape of the Earth.

The Sun's ultraviolet radiation and X-radiation helps to create and influences the ionosphere, a region in Earth's upper air where many atoms are ionized. The ionosphere changes during an eclipse as the ionizing radiation is cut off.

So that observations of the ionosphere made during an eclipse can be interpreted correctly, it is necessary to predict the times and phases of the eclipse as it reaches the high layers of Earth's atmosphere, where they may be substantially different from times and phases on the surface.

In addition to light and other electromagnetic radiation, the Sun continually emits charged particles or corpuscles; these particles form what is called the solar wind. This radiation is also screened from Earth during an eclipse of the Sun. Because the velocity of the particles is much less than that of light, and because of the movement of the Earth–Moon system around the Sun, the corpuscular eclipse should come some hours before the optical eclipse and over a different place on the surface of the Earth. No certain evidence of a corpuscular eclipse has been found, probably because observations of the solar wind are difficult and can be made only outside the atmosphere.

Observation from rockets

Since about 1960, rockets have been sent high into Earth's atmosphere to gather data during eclipses. Their trajectories are chosen to lie largely in the region from which the chromosphere and inner corona are visible, while the photosphere is eclipsed, and they gather data on X-rays and ultraviolet emission that cannot penetrate Earth's lower air.

The search for comets in the vicinity of the Sun during total eclipses has been rewarded on a few occasions.

Tests of relativity during solar eclipse. One of the predictions of the general theory of relativity, as presented by Einstein in 1915, is the deflection of light rays by a gravitational field, for example that of the Sun. According to this theory the deflection, which causes the image of a star to appear slightly too far from the Sun's image, amounts to 1.75 seconds of arc (a small fraction of a degree) at the limb of the Sun and decreases in proportion to the apparent distance from the centre of the solar disk of the star whose light is deflected. This is twice the amount given by the older Newtonian dynamics if light is assumed to have inertial properties. If light does not have such properties, as is generally accepted now, the Newtonian deflection is zero. To test the theory, extremely precise measurements are needed, of as many stars as possible around the Sun, and preferably close to it. The brightness of the corona prevents stars closer to the Sun than one solar diameter from being observed. During totality the sky around the Sun is photographed with long-focus cameras to give the largest possible scale. Then the equipment is left in place, and about half a year later the same region of the sky with the same stars in it can be photographed again, now during the night and without the disturbing gravity field of the Sun. Comparison of the two sets of photographs shows the amount of gravitational displacement of starlight by the Sun and serves as a test of theory. Results of a number of eclipse observations made since 1918 have verified Einstein's prediction, though the deduced values are somewhat uncertain as a consequence of the very small displacement.

Favourable conditions for observing solar eclipses. The most important conditions for observation of a solar eclipse are the duration of totality, the weather, and the position of the eclipse site.

When all circumstances are as favourable as possible, the duration of totality can be as long as seven minutes and 40 seconds. Among the determining factors are the excess of the apparent diameter of the Moon over that of the Sun, the relative velocities of the Sun and Moon across the sky as seen from the Earth, and the position of the intersection of the shadow cone with the surface of the Earth. To permit the longest observations, this intersection, the zone of totality, should be as close as possible to the Moon, so that the zone will be larger, and should fall at the region on Earth where Earth's rotational speed is at a maximum, so that an observer will remain longer in the moving shadow. Both these conditions are best met when the zone of totality falls near the Equator. In spite of all care, however, clouds at the moment of the eclipse can ruin everything. Clouds form more readily than usual because of the drop in temperature within the shadow, and the chances of good weather are increased when the eclipse takes place in desert regions or in dry weather conditions.

Likely weather conditions and accessibility of the site are considered important in choosing a site for an eclipse expedition. The expected scattering of light in the atmosphere and the quality of seeing (atmospheric steadiness) are also taken into account, so that, in spite of transportation difficulties, a site in the mountains may be preferred. A less turbulent atmosphere is also to be found over water, so that a coastal site from which the eclipsed Sun can be observed over the sea is often chosen. Sometimes observations are planned from a site near the limit of the zone of totality, where the Moon's edge can be seen apparently moving grazingly through the chromosphere.

Since 1963 the use of specially equipped aircraft as observation platforms above the clouds has made possible great increases in the observation time. Flying in the direction of the motion of the Moon's shadow, the aircraft can remain within the umbra for a long time, and this extends the effective duration of totality. Supersonic aircraft moving at about 1,200 miles (1,930 kilometres) per hour could keep pace with the shadow so that totality would be prolonged to an hour or more for observers on board.

Lunar research. Lunar eclipses can yield information about the cooling of the Moon's soil when the Sun's radi-

ation is suddenly removed and, therefore, about the soil's conductivity of heat and its structure. Infrared and radio-wavelength radiation from the Moon decline in intensity more slowly than does visible light emission during an eclipse because they are emitted from below the surface, and measurements indicate how far the different kinds of radiation penetrate into the lunar soil. Infrared observations show that at many "bright spots" the soil retains its heat much longer than in surrounding areas. Because of the absence of a lunar atmosphere the solid surface is exposed to the full intensity of ultraviolet and corpuscular radiation from the Sun, which, in some rock materials, may give rise to fluorescence. Observations during lunar eclipses have given positive results for this phenomenon with the appearance of abnormal bright regions in the obscured parts of the Moon.

Lunar "bright spots"

TRANSITS OF MERCURY AND VENUS

At the time of inferior conjunction (*i.e.*, when moving between the Earth and the Sun) the planet Mercury, seen from the Earth, usually passes north or south of the Sun because of the inclination of its orbit. But if the conjunction occurs when Mercury is very near one of the nodes of its orbit, the planet crosses the disk of the Sun as a small black circular spot, visible only with a telescope. Since the Earth passes Mercury's nodes on May 7 and November 9, transits can occur only near those dates. The shortest possible interval between two successive transits is seven years.

Transits of Venus can be seen without a telescope if the eyes are properly protected. When the transit is central it takes about eight hours. The phenomenon is rare and can happen only within a day of two of the dates when the Earth passes the nodes of Venus' orbit—that is, on June 7 and December 8. The transits come in pairs, with an interval of eight years between members of a pair; between the pairs, more than 100 years elapse.

Transits of Venus are helpful in finding the parallax and from it the distance of the Sun, as first pointed out by the British astronomer Edmond Halley in 1679. Parallax is the apparent difference in direction of an object when observed from different positions. The transits of June 1761 and 1769 and those of December in 1874 and 1882 were, therefore, extensively observed. The next pair of transits of Venus will occur on June 8, 2004 and June 6, 2012. It is not likely that so much trouble will be taken to observe them, since other, more accurate methods of determining the solar parallax have now been developed.

One kind of observation for determining parallax consists in fixing the times of the contacts of the disks of the planet and the Sun from different points on the Earth. The observers at past transits became aware of a few remarkable phenomena. When Venus was partially overlapping the disk of the Sun, the part of the limb of the planet that extended beyond the Sun was seen to be surrounded with a radiant aureole, which observers of the transit in 1761 ascribed to the presence of an atmosphere on Venus. A second phenomenon was seen just after second and before third contact (see Figure 1), when Venus just touched the Sun's limb on the inside; this consisted in the development of a little dark connection—the so-called black drop—between Venus and the limb. Because of the black drop, the times of contact could not be sharply defined. Presumed causes of the black drop are diffraction, atmospheric agitation, and also, perhaps, instrumental and physiological factors.

The black drop

The amount of sunlight intercepted during a transit depends on the diameter of the planet, and measuring this amount of sunlight may be one of the most accurate ways of determining the planet's diameter.

Other modern investigations possible during transits pertain to the screening of solar particles from Earth by the inner planets when they are close to conjunction. These electrically charged particles, forming part of the solar wind, have a velocity far less than that of light and are not only screened by the planet's disk but also by any magnetic field the planet may have, so that their influence on the Earth's magnetic field need not coincide with the time of the optical occultation.

OCCULTATIONS BY THE SUN AND MOON

The occultation of the Crab Nebula by the solar corona, the extensive outer atmosphere of the Sun, takes place each year in June. The Crab Nebula is a radio source (Taurus A), and, when the occultation occurs, its pattern of radio emission is observed to broaden significantly. The broadening is attributed to scattering of radio-frequency radiation by the density irregularities in the extended corona. The nearest approach of Sun and Crab Nebula is at about five solar radii; the scattering is brought into evidence up to 60 solar radii.

The Moon sometimes occults a planet but very often occults a star. As a consequence of the inclination of the Moon's orbit with respect to the ecliptic (the Sun's apparent annual path) and the movement of the nodes of the Moon's orbit, all the stars in a belt of 10° around the ecliptic are occulted at some time during a period of about nine years. Among these stars are the bright stars Aldebaran, Regulus, Spica, and Antares and the star clusters Pleiades, Hyades, and Praesepe, and the Crab Nebula.

Since the Moon always moves eastward, an occulted star disappears at the Moon's eastern limb and reappears at the western. These phenomena can be best observed at the dark limb of the Moon.

Efforts have been made to determine the apparent diameter of stars by accurately estimating the time they take to disappear behind the Moon; with modern optics and electronic devices this would not be impossible in some cases. But there are complications of two kinds: first, many stars are close binaries (doubles); and, second, the decline of the light of the occulted star shows an optical phenomenon called a diffraction pattern. But, for the purpose of yielding basic data on the perturbations (disturbances) in the Moon's orbit and on irregularities in the rotation of the Earth, the exact times of star occultations are still of value.

The disappearance or reappearance of Jupiter takes more than one minute, but the time for a minor planet is under one second, and that for even a giant star like Aldebaran or Antares is less still, by a factor of ten. Other stars disappear nearly instantaneously, indicating that the Moon has no sensible permanent atmosphere.

Occultation of the Crab Nebula by the Moon has attracted much interest because of the possibility it affords of finding out whether the nebula's X-ray emission comes from a small source like a star or from a more extended source like a cloud of gas. Observations on July 7, 1964, indicated that the X-ray source in the central region of the nebula had a width of about 1′ of arc, which is roughly one light-year at the distance of the Crab Nebula—that is, a relatively extended source.

Lunar occultation of the Crab Nebula

The Crab Nebula can also be observed as a radio source during an occultation by the Moon. Because the radio waves are subject to refraction by electrons, an estimate of the density of the lunar atmosphere can be made. The density has proved to be below the possibility of measurement; the upper limit of density obtained by this method is very much lower than that determined by optical means.

ECLIPSING BINARY STARS

When, in a binary system (a double star whose components are in orbit around a common centre), one component comes between the other and the Earth, an eclipse occurs and the amount of light received from both stars together is reduced; a total eclipse gives the greatest reduction, and the light is reduced to a minimum. Two eclipses take place during each revolution. The first star shown to have light that varied through eclipses in this way was Algol (Beta Persei). Its variability was discovered in 1667 by the Italian astronomer Geminiano Montanari, but the explanation as eclipsing variable was not proposed until a century later by the English astronomer John Goodricke. At present, about 3,000 eclipsing binaries are known.

The many possible sizes of the two stars, both in relation to each other and to the size and tilt of their orbits, combined with the eccentricity (deviation from the circu-

lar) of the orbits, lead to a large variety of ways in which the light of the system changes during a revolution: the so-called light curve.

If the orbits of the two stars are not circular, then the motion in the orbits is not uniform but is most rapid near periastron (stars closest together) and least rapid near apastron (stars farthest apart). Therefore, the eclipses may not be equally spaced in time, as they are in the case of circular orbits. Study of the spacing and durations of the light minima will yield both the eccentricity and the orientation of the orbits.

A steady change in the spacing of the minima as well as in their relative duration means that the line of apsides (major axis of the relative orbit) is rotating; the most rapid such rotation known is that of the eclipsing binary GL Carinae (see also STAR).

If the two stars are unequal in size, they may wholly overlap for some time. When the star of higher surface brightness is behind, the resulting eclipse is darker than that resulting when the brighter star cuts off the light of the dimmer one. Limb darkening, the tendency for a star to appear less brilliant near the edge of its apparent disk, also influences the shape of the light curves, and the amount of limb darkening present may be determined from those curves.

Spectroscopic studies of the light of a double star allow determination of the ratio of the masses of the components to each other. The sum of the masses, however, can only be determined if the inclination of the orbit is known. In the case of an eclipsing binary, the plane of the orbit is known to be directed to the Earth. Therefore, eclipsing binaries can be made to reveal complete information about their masses; this is one reason why they are so energetically studied.

A rapidly rotating star bulges at its equator. Also, many double stars are so close together that they distort each other tidally; in the case of very close pairs, this distortion has caused them to turn always the same sides toward each other. If such stars are eclipsing binaries, the amount of distortion can, in some cases, be determined from the light curve. For some stars the ratio of the long axis of the star to the short has been found to be as great as 5:3.

The star Zeta Aurigae

There are a few star systems like Algol, notably Zeta Aurigae, in which the difference in the sizes of the components is so great that the crossing of the smaller, brighter star before the disk of the supergiant companion should really be called a transit rather than an eclipse. This particular star has the remarkably long orbital period of 972 days and consists of an orange supergiant having a diameter of almost 300,000,000 kilometres (186,000,000 miles, about equal to the diameter of Earth's orbit) and a much smaller, brighter star, only three times larger than the Sun. The secondary minimum lasts for 38 days, and a very sensitive photometer must be employed to detect the extremely slight fading of light when the smaller star is shining through the extended, tenuous atmosphere of the large one (see also STAR).

ECLIPSES IN HISTORY

In ancient times eclipses were regarded as portents; hence it is not surprising that many eclipses are mentioned in history and in literature, in addition to those recorded in astronomical writings.

The value of these records may be classified as follows: (1) literary and historical, depending on the interest that they aroused and their connection with historical events; (2) chronological, insofar as they make it possible to verify chronological systems resting on other evidence and to supply dates for events connected with the eclipses; (3) astronomical, including the determination by ancient astronomers of the periods and motions of the Sun and Moon and by modern astronomers of the mean rate of change of those motions.

Literary and historical references. *Chinese.* In the *Shu Ching* ("Classic of History") it is stated that Hsi and Ho (semidivine figures sent by the legendary emperor Yao to the four corners of the Earth to keep the Sun on its course and to prevent eclipses) had neglected the duties of their office and had abandoned themselves to drink in their own cities. The king, Chung K'ang, placed the Marquess of Yin in command of an army with instructions to punish them. The Marquess issued a florid address to his troops in which he referred to Hsi and Ho as having neither heard nor known anything on a recent occasion when "the Sun and Moon did not meet harmoniously in Fang." This phrase is taken by Chinese scholars, ancient and modern, to mean an eclipse. It would therefore appear that a military expedition was sent to punish Hsi and Ho for failing to observe or to prevent an eclipse. There are good reasons for believing that this part of the *Shu Ching* is a literary restoration dating from the 4th century AD, but enough is found in a quotation in the *Tso Chuan* ("Commentary of Tso," compiled between 430 and 250 BC) and in statements in the *Bamboo Annals* to prove that the reference is to an authentic eclipse, though its relation to the supposed offense of Hsi and Ho is doubtful. Attempts have been made to identify this eclipse, but the necessary data are wanting. The accepted Chinese chronology places the accession of Chung K'ang in 2159 BC. The *Bamboo Annals*, whose chronology is probably nearer to the truth, place it in 1952 BC. The *Shih Ching*, or "Classic of Poetry," contains a lamentation caused by an eclipse of the Moon followed by an eclipse of the Sun. The dates are clearly defined and are found to agree with events in 734 BC. The earliest eclipses that have been definitely identified are (for the Moon) that of 1361 BC and (for the Sun) that of 1217 BC, both derived from inscriptions on ancient oracle bones. The eclipses recorded in the *Ch'un Ch'iu*, "Spring and Autumn" annals, possess chronological and astronomical rather than literary interest. Some evidence for a total eclipse of the Sun in 1375 BC has been found in the form of a clay tablet record excavated at ancient Ugarit (now in Syria).

Assyrian. The Assyrian eponym canon, which preserves the names of the annual magistrates who gave their names to the years, records under the year that corresponds to 763–762 BC: "Insurrection in the city of Ashur. In the month Sivan the sun was eclipsed." The reference must be to the eclipse of the Sun on June 15, 763 BC. A reference to the same eclipse has been found in the Bible: " 'And on that day,' says the Lord God, 'I will make the sun go down at noon, and darken the earth in broad daylight' " (Amos 8:9).

The Homeric references

Greek. Homer, in the *Odyssey*, twice makes the unrecognized Odysseus predict that Odysseus will return "as the old moon wanes, and the new appears"; that is, at New Moon, when alone an eclipse of the Sun is possible. On the day when Odysseus was to become known and slay his wife's suitors, the seer Theoclymenus notes among other portents of gloom that "the sun has perished out of heaven, and an evil mist has spread over all." This was interpreted by Plutarch and Eustathius as a total eclipse of the Sun. Some modern scholars have regarded it as merely a vision of the seer. An identification with the solar eclipse of April 16, 1178 BC, which was total in or near Ithaca, has been suggested. But it is not improbable that this story belongs to legend rather than to history.

In a fragment of a lost poem by Archilochus occur the words:

> Nothing there is beyond hope, nothing that can be sworn impossible, nothing wonderful, since Zeus, father of the Olympians, made night from mid-day, hiding the light of the shining sun, and sore fear came upon men.

This phenomenon has been identified as the total eclipse of the Sun on April 6, 648 BC.

Small fragments survive of other poetic descriptions of eclipses, and the ninth paean of Pindar, addressed to the Thebans, takes an eclipse of the Sun as its theme, as follows:

> Beam of the sun! O thou that seest afar, what wilt thou be devising? O mother of mine eyes! O star supreme, reft from us in the daytime! Why has thou perplexed the power of man and the way of wisdom, by rushing forth on a darksome track?

Pindar then proceeds to speculate on the meaning of the

eclipse as a portent. The poem probably refers to the solar eclipse of April 30, 463 BC, which was nearly total at Thebes.

The most famous of ancient eclipses was a total eclipse of the Sun that happened, according to Herodotus, during a battle between the Lydians and the Medes. The portent induced them to conclude peace. Herodotus further says that Thales of Miletus predicted this eclipse to the Ionians for the very year in which it happened. Babylonians were certainly predicting eclipses at about that time by means of the saros (see above). But, as that cycle gives eclipses for every year, the statement about Thales must, if true, mean that he predicted that an eclipse of that particular year would attain a great magnitude and that it would take place in Asia Minor. Such a prediction can be made by the saros without any mathematical computation. The eclipse was certainly that of May 28, 585 BC, and must have been predicted by means of the eclipse of May 18, 603 BC. Several ancient writers have recorded 585 BC or some neighbouring year as the date of the eclipse.

The historian Thucydides comments on the frequency of eclipses during the Peloponnesian War. The most interesting of these were the solar eclipse of August 3, 431 BC, when "the sun assumed the shape of a crescent and became full again, and during the eclipse some stars became visible" (a statement that agrees well with modern computation), and the lunar eclipse of August 27, 413 BC. That date had been selected by the Athenian commanders Nicias and Demosthenes for the departure of their armies from Syracuse. All preparations were ready, but the signal had not been given when the Moon was eclipsed. The soldiers and sailors clamoured against departure, and Nicias, in obedience to the soothsayers, resolved to remain thrice nine days. This delay enabled the Syracusans to capture or destroy the whole of the Athenian fleet and army.

Eclipses in Thucydides

August 15, 310 BC, is the date of a total eclipse of the Sun said to have been seen by the commander Agathocles and his men the day after he had sailed from Syracuse on his way to Africa. Modern computations of the eclipse track render it probable that he sailed to the north of Sicily.

In Plutarch's dialogue concerning the features of the Moon's disk, one of the characters, called Lucius, deduces from the phases of the Moon and the phenomena of eclipses a similarity between the Earth and the Moon and illustrates his argument by means of a recent eclipse of the Sun, "which, beginning just after noon, showed us plainly many stars in all parts of the heavens, and produced a chill in the temperature like that of twilight." This eclipse has been identified with that of March 20, AD 71. Further on, Lucius refers to a brightness that appears round the Moon's rim in total eclipses of the Sun. There are numerous other references to eclipses in Greek literature.

Roman. A large number of eclipses was recorded in Roman history. One that has attracted the attention of students of astronomy and of the Roman calendar alike is stated by Cicero to have occurred in what may have been the 350th year from the foundation of Rome. He also says that it was described by the poet Quintus Ennius: "On the Nones of June the sun was covered by the moon and night." This would appear to have been the solar eclipse of June 21, 400 BC, which reached a total or almost total phase at Rome a few minutes after sunset. It seems to show that in that year the calendar month of June began 16 days later than it did after the Julian reform. The eclipse of the Moon on June 21–22, 168 BC, has attracted much attention. The Romans were at that time at war with Macedonia, and Polybius says that this eclipse was interpreted as an omen of the eclipse of a king and thus encouraged the Romans and discouraged the Macedonians.

Use of eclipses for chronological purposes. No one system of dating has been continuously in use since ancient times. Formerly, dates were frequently expressed in terms of a king's reign; years were also named after officials of whom lists have been preserved (eponym canons, see above). In these cases it is important to be able to equate certain specific years thus defined with years before the Christian Era (BC). This can be done whenever the date of an eclipse or other identifiable and calculable astronomical phenomenon is given in an ancient record.

Chinese chronology can be confirmed accurately by eclipses from the Shang dynasty (*c.* 1766–*c.*1122 BC) onward. The chronology of Ptolemy's canon list of kings, which gives the Babylonian series from 747 to 539 BC, the Persian series from 538 to 324 BC, the Alexandrian series from 323 to 30 BC, and the Roman series from 30 BC onward, is confirmed throughout by eclipses. The eclipse of 763 BC, recorded in the eponym canon, makes it possible to carry the chronology back with certainty through the period covered by that canon to 893 BC. Assyrian, Babylonian, and Persian records provide a reliable chronology for the countries with which Assyria, Babylon, and Persia came into contact, but there is no check from eclipses on Greek or Egyptian historical chronology before the Persian period. Identifiable eclipses recorded under named Roman consuls extend back to 217 BC. The dated solar eclipse of Ennius, the lunar eclipse seen at Pydna in Macedonia on June 21–22, 168 BC, and an eclipse of 190 BC can be used to determine the position of Roman calendar months in the natural year; and occasionally eclipses help to fix the precise dates of a series of events, such as those connected with the Athenian disaster at Syracuse.

Use of eclipses for astronomical purposes. *In ancient astronomy.* At least from the time of King Nabonassar (747 BC), a dated canon of astronomical observations was preserved at Babylon and included all eclipses. This rendered it possible to determine accurately the intervals between eclipses and must have facilitated the discovery of the 18-year cycle (more exactly the cycle of 6,585⅓ days that the 10th-century Greek lexicographer Suidas named the saros) and its multiple, the 54-year cycle of 19,756 days (see above). It has been seen that Thales probably used such a cycle. In a Babylonian observation tablet of 568 BC, mention is made of failure to observe a predicted eclipse of the Moon, which is found by computation to have been real but invisible at Babylon. It was doubtless predicted by cycle. Tables based on the saros go back to the 4th century BC. Lunar eclipses give more accurately than any other observation the actual time when Sun and Moon are in opposition. From an early date the Babylonian astronomers must have deduced from them not only the mean interval between two conjunctions (closest apparent approaches) of Sun and Moon but also the principal inequality (change of speed) in the motion of the Moon and the similar inequality in the motion of the Earth (or, as according to their geocentric theory they conceived it, of the Sun). They were able to define the periods of these inequalities (the cause of which lies in the ellipticities of the orbits), which astronomers call the anomalistic month and year.

Babylonian record of observations

In the same way, since eclipses happen only when the Sun and Moon are at the intersections of their orbital planes called nodes, and since the path of the shadow in a lunar eclipse depends on the position of the centre of the Sun in relation to the node, the Babylonians were also able to determine the position and motion of the nodes. By assuming, as is approximately true, that the saros of 6,585⅓ days contained an exact number: (1) of synodic months, or revolutions of the Moon measured from the Sun, (2) of anomalistic months, or revolutions of the Moon measured from its apogee or perigee (*i.e.*, from its farthest distance from and closest approach to the Earth), and (3) of draconic months, or revolutions of the Moon measured from its node, astronomers, perhaps as early as the 6th century BC, computed the relative motions of the Sun and Moon, the lunar perigee and apogee, and the nodes. About 500 BC the Chaldean astronomer Nabu-rimmani, apparently from a more accurate study of eclipse observations, obtained improved values that: for the motion of the Moon relative to the Sun were 10″ of arc per annum too small; for the Moon's perigee motion 20″ of arc per annum too great; and for the motion of its

node 5″ of arc too small. Still more accurate values were obtained by Kidinnu about 383 BC, from whom they passed to the Greek astronomer Hipparchus. In the system of Nabu-rimmani the distance of the Moon from its node was used for the prediction of the magnitude of lunar eclipses.

In modern astronomy. Ancient eclipses are of the highest value for the determination of "secular accelerations"—*i.e.*, for the determination of the progressive, as distinct from the periodic, changes in celestial motions. In 1693 the British astronomer Edmond Halley asserted his belief that the Moon's motion was subject to acceleration but did not specify the amount. In 1749 the British astronomer Richard Dunthorne demonstrated from a comparison of the recorded with the computed times of eclipses distributed over 2,000 years that such an acceleration existed and assigned to it the value of 10″ of arc a century. By this is meant that the effect of the acceleration is to produce an advance of 10″ of arc in the Moon's longitude in the course of a century. The French mathematician and astronomer P.-S. Laplace showed in 1787 that such an acceleration should be the gravitational effect of the secular diminution in the eccentricity of the Earth's orbit; but, according to J.C. Adams in 1853, the acceleration due to this cause amounted to 6″ of arc only in a century. The residue must be explained by other causes, mainly tidal friction.

FOTHERINGHAM, "A Solution of Ancient Eclipses of the Sun," *Mon. Not. R. Astr. Soc.*, 81:104–126 (1920), computation of the accelerations of the Moon and Sun in 11 eclipses between 1062 BC and AD 364, with quotations from ancient records; F. BOLL, "Finsternisse," *Pauly-Wissowa, Real-Encyclopaedie*, 6:2329–2364 (1909); O. NEUGEBAUER, "The History of Ancient Astronomy: Problems and Methods," *J. Near Eastern Studies*, 4:1–38 (1945); J. NEEDHAM, *Science and Civilisation in China*, vol. 3 (1959), discussion of eclipses, placed in the context of Chinese astronomy, with extensive references to original literature; A. PANNEKOEK, *De groei van ons wereldbeeld* (1951; Eng. trans., *A History of Astronomy*, 1961), critical consideration of astronomical knowledge of the peoples in the ancient world and the place of astronomy in their cultures; SIR B. LOVELL (ed.), *Astronomy*, 2 vol. (1970), discourses in the physical sciences from 1851 to 1939, many of which are devoted to solar eclipses; *Explanatory Supplement to the Astronomical Ephemeris and the American Ephemeris and Nautical Almanac* (HMSO, 1961), a full presentation of all data for the calculation of astronomical phenomena.

(J.H.)

Ecology

Long unfamiliar to the public, and relegated to a second-class status by many in the world of science, ecology emerged in the 1960s as one of the most popular and most important aspects of biology. It has become painfully evident that the most pressing problems in the affairs of men—expanding populations, food scarcities, environmental pollution, and all the attendant sociological and political problems—are to a great degree ecological.

The word ecology was coined by a German zoologist, Ernst Haeckel, who applied the term *oekologie* to the "relation of the animal both to its organic as well as its inorganic environment." The word comes from the Greek *oikos*, meaning "household, home, or place to live." Thus ecology deals with the organism and its environment. The word environment includes both other organisms and physical surroundings. It involves relationships between individuals within a population and between individuals of different populations. These interactions between individuals, between populations, and between organisms and their environment form ecological systems, or ecosystems. Ecology has been defined variously as "the study of the interrelationships of organisms with their environment and each other," as "the economy of nature," and as "the biology of ecosystems."

HISTORICAL BACKGROUND

Ecology had no firm beginnings. It evolved from the natural history of the Greeks, particularly Theophrastus, a friend and associate of Aristotle. He first described the interrelationships between organisms and between organisms and their nonliving environment. Later foundations for modern ecology were laid in the early work of plant and animal physiologists.

Chronological sequence. In the early and mid-1900s two groups of botanists, one in Europe and the other in America, studied plant communities from two different points of view. The European botanists concerned themselves with the study of the composition, structure, and distribution of plant communities. The American botanists studied the development of plant communities, or succession. Both plant and animal ecology developed separately until American biologists emphasized the interrelation of both plant and animal communities as a biotic whole.

During the same period interest in population dynamics developed. The study of population dynamics received special impetus in the early 19th century, after a British economist, Thomas Malthus, called attention to the conflict between expanding populations and the capability of the earth to supply food. R. Pearl (1920), A.J. Lotka (1925), and V. Volterra (1926) developed mathematical foundations for the study of populations, and these studies led to experiments on the interaction of predators and prey, competitive relationships between species, and the regulation of populations. Investigations of the influence of behaviour on populations was stimulated by the recognition in 1920 of territoriality in nesting birds. Concepts of instinctive and aggressive behaviour were developed by K. Lorenz and N. Tinbergen, and the role of social behaviour in the regulation of populations was explored by V.C. Wynne-Edwards.

While some ecologists were studying the dynamics of communities and populations, others were concerned with energy-budgets. In 1920, August Thienemann, a German freshwater biologist, introduced the concept of trophic, or feeding, levels, by which the energy of food is transferred through a series of organisms, from green plants (the producers) up to several levels of animals (the consumers). An English animal ecologist, C.E. Elton (1927), further developed this approach with the concept of ecological niches and pyramids of numbers. Two American freshwater biologists, E. Birge and C. Juday, in the 1930s, in measuring the energy budgets of lakes, developed the idea of primary production, *i.e.*, the rate at which food energy is generated, or fixed, by photosynthesis. Modern ecology came of age in 1942 with the development, by R.L. Lindeman of the United States, of the trophic-dynamic concept of ecology, which details the flow of energy through the ecosystem. Quantified field studies of energy flow through ecosystems were further developed by Eugene and Howard Odum of the United

States; similar early work on the cycling of nutrients was done by J.D. Ovington of England and Australia.

The study of both energy flow and nutrient cycling was stimulated by the development of new techniques—radioisotopes, microcalorimetry, computer science, and applied mathematics—that enabled ecologists to label, trace, and measure the movement of particular nutrients and energy through the ecosystems. These modern methods encouraged a new stage in the development of ecology—systems ecology, which is concerned with the structure and function of ecosystems.

Conceptual development. Until recent years ecology lacked a strong conceptual base. Modern ecology, however, is now focused on the concept of the ecosystem, a functional unit consisting of interacting organisms and all aspects of the environment in any specific area. It contains both the nonliving (abiotic) and living (biotic) components through which nutrients are cycled and energy flows. To accomplish this cycling and flow, ecosystems must possess a number of structured interrelationships between soil, water, and nutrients, on the one hand, and producers, consumers, and decomposers on the other. Ecosystems function by maintaining a flow of energy and a cycling of materials through a series of steps of eating and being eaten, of utilization and conversion, called the food chain. Ecosystems tend toward maturity, or stability, and in doing so they pass from a less complex to a more complex state. This directional change is called succession. Whenever an ecosystem is used, and that exploitation is maintained—as when a pond is kept clear of encroaching plants or a woodland is grazed by domestic cattle—the maturity of the ecosystem is effectively postponed. The major functional unit of the ecosystem is the population. It occupies a certain functional niche, related to its role in energy flow and nutrient cycling. Both the environment and the amount of energy fixation in any given ecosystem are limited. When a population reaches the limits imposed by the ecosystem, its numbers must stabilize or, failing this, decline from disease, starvation, strife, low reproduction, or other behavioural and physiological reactions. Changes and fluctuations in the environment represent selective pressure upon the population to which it must adjust. The ecosystem has historical aspects: the present is related to the past and the future to the present. Thus the ecosystem is the one concept that unifies plant and animal ecology, population dynamics, behaviour, and evolution.

The unifying concept of ecology

SCOPE

Of necessity, ecology is a multidisciplinary science. It involves plant and animal biology, taxonomy, physiology, genetics, behaviour, meteorology, pedology, geology, sociology, anthropology, physics, chemistry, mathematics, and electronics. Often it is difficult to draw a sharp line between ecology and any of these, for all impinge on it. The same situation exists also within ecology. In understanding the interactions between the organism and the environment or between organisms, it is often difficult to separate behaviour from population dynamics, behaviour from physiology, adaptation from evolution and genetics, animal ecology from plant ecology.

Ecology developed along two lines: the study of plants and the study of animals. Plant ecology focuses on the relationships of plants to other plants and their environment. The approach is largely descriptive of the vegetational and floristic composition of an area and usually ignores the influence of animals on the plants. Animal ecology concerns the study of population dynamics, distribution, behaviour, and the interrelationships of animals and their environment. Because animals depend upon plants for food and shelter, animal ecology cannot be fully understood without a considerable background of plant ecology. This is particularly true in applied areas of ecology—wildlife and range management.

Both plant and animal ecology may be approached as the study of the interrelations of an individual organism with its environment, called autecology, or as the study of groups of organisms, called synecology.

Autecology, in many ways the classical study of ecology, is experimental and inductive. Because it is usually concerned with the relationship of an organism to one or more variables such as humidity, light, salinity, or nutrient levels, it is easily quantified and lends itself to experimental design both in the field and the laboratory. It has borrowed techniques from chemistry, physics, and physiology. Autecology has contributed at least two important concepts: the constancy of interaction between an organism and its environment, and the genetic adaptability of local populations to local environmental conditions.

Autecology and synecology

Synecology, on the other hand, is philosophical and deductive. It is largely descriptive and not easily quantified and contains a bewildering array of terminology. Only recently, since the advent of the electronic and atomic ages, has synecology developed the tools to study complex systems and enter an experimental phase. Important concepts developed by synecology are those concerned with nutrient cycling, energy budgets, and ecosystem development. Synecology has strong ties with pedology, geology, meteorology, and cultural anthropology.

Synecology may be subdivided according to environmental types, as terrestrial or aquatic. Terrestrial ecology, which may be further subdivided into forest, grassland, arctic, and desert ecology, concerns such aspects of terrestrial ecosystems as microclimate, soil chemistry, soil fauna, hydrologic cycles, ecogenetics, and productivity. Terrestrial ecosystems are more influenced by organisms and subject to much wider environmental fluctuations than are aquatic ecosystems. Aquatic ecosystems are affected more by the condition of the water and resist such environmental variables as temperature. Because the physical environment is so important in controlling aquatic ecosystems, considerable attention is paid to the chemical and physical characteristics of the ecosystem, such as the currents and the chemical composition of the water. By convention, aquatic ecology, called limnology, is limited to freshwater stream ecology and lake ecology. The former concerns life in flowing waters; the latter, life in relatively still water. Marine ecology deals with life in the open sea and in estuaries.

Other ecological approaches concern specialized areas. The study of the geographic distribution of plants and animals is ecological plant and animal geography. The study of population growth, mortality, natality, competition, and predator–prey relations is population ecology. The study of the genetics and ecology of local races and distinct species is ecological genetics. The study of the behavioral responses of animals to their environment, and of social interactions as they affect population dynamics, is behavioural ecology. Investigations of interactions between the physical environment and the organism fall under ecoclimatology and physiological ecology. The study of groups of organisms is community ecology (although it is difficult to separate it from studies of bioenergetics, biogeochemical cycles, and trophic-dynamic aspects of the community or ecosystem ecology). That part of ecosystem ecology concerned with the analysis and understanding of the structure and function of ecosystems by the use of applied mathematics, mathematical models, and computer programs is systems ecology. Systems ecology, concentrating on input and output analysis, has stimulated the rapid development of applied ecology, concerned with the application of ecological principles to the management of natural resources, agricultural production, and problems of environmental pollution.

Systems ecology

METHODOLOGY AND RESEARCH

Because ecologists work with living systems possessing numerous variables, the techniques used by physicists and chemists, mathematicians and engineers, require modification; they are not easily applied nor are the results as precise as those obtained in other sciences. It is relatively simple, for example, for a physicist to measure gain and loss of heat from metals or other inanimate objects, which possess certain constants of conductivity, expansion, surface features, and the like. To determine the heat exchange between an animal and its environment, how-

ever, a physiological ecologist is confronted with an array of almost unquantifiable variables and has the formidable task of both gathering the numerous data and analyzing them. Ecological measurements probably never will be as precise or as subject to the same ease of analysis as measurements in physics, chemistry, or certain quantifiable areas of biology.

In spite of these problems, various aspects of the environment can be determined by physical and chemical means, ranging from simple chemical identifications and physical measurements to the use of sophisticated mechanical apparatus. The development of biostatistics and proper experimental design, and the improvements in methods of sampling, permit a quantified statistical approach to the study of ecology. Because of the extreme difficulties of controlling environmental variables in the field, studies involving the use of experimental design are largely confined to the laboratory and to controlled field experiments designed to test the effects of only one variable or several variables. The use of statistical procedures, and the application of computer science to mathematical models based on data obtained from the field, are providing new insights into population interactions and ecosystem function. Mathematical programming is becoming increasingly important in applied ecology, especially in the management of natural resources and agricultural problems having an ecological basis.

Controlled environmental chambers enable experimenters to maintain plants and animals under known conditions of light, temperature, humidity, and daylength so that the effects of each variable (or combination of variables) on the organism can be studied. Biotelemetry and other electronic tracking equipment, products of the space age, permit the rapid and nondestructive sampling of plant and animal populations. Such tools enable ecologists to follow from a distance the movements and behaviour of a free-ranging animal by radio signals beamed from a sender attached to the organism. Radioisotopes are used for tracing the pathways of nutrients through ecosystems, for determining the time and extent of transfer of energy and nutrients through the different components of the ecosystem, and for the determination of food chains. The use of laboratory microcosms—aquatic and soil micro-ecosystems, consisting of biotic and nonbiotic material from natural ecosystems, held under conditions similar to those found in the field—are useful in determining rates of nutrient cycling, ecosystem development, and other functional aspects of ecosystems. Microcosms enable the ecologist to duplicate experiments and to perform experimental manipulation on them.

APPLICATIONS

Man, the dominant organism on earth, has stood apart from the interaction of living things; yet, as he is discovering, he is inextricably tied to his environment. The air he breathes, the water he drinks, the food he consumes, and the products he uses and throws away bind him to the functions of local and global ecosystems.

Man-influenced ecosystems

Agriculture, forestry, wildlife, and fisheries all represent some aspect of man's modification and exploitation of natural ecosystems. To achieve maximum food production, man has eliminated stable, complex ecosystems and replaced them with fragile, simplified single-species ecosystems, or monocultures, in which energy flow is funneled into crops. He has shortened food chains by selecting and breeding domestic stock that produces meat, milk, or wool by converting forage grasses directly into products useful to man. Successful agriculture depends upon the ecological adaptation of crop plants and domestic animals to environmental conditions and upon the genetic capability of plants to respond to cultural practices and fertilization. Fertilization alters the rate and amount of nutrients entering into ecosystems, and in some instances has undesirable side effects, as when excess phosphates stimulate algal blooms in ponds and lakes. Simplified ecosystems also attract pest species, both plant and animal, requiring costly control methods. Overgrazing of rangelands and mismanagement of crop fields result in wind and water erosion that carries topsoil to rivers and lakes and impoverishes agricultural lands.

Management of forests involves the manipulation of natural stands of trees by means of cutting practices and controlled burning to maintain the forest in a stage of development that favours those species most economically desirable. Management and exploitation of the fish populations for sustained yields requires a thorough knowledge of fish biology and of the essential physical and biological aspects of the environments. Failure to give careful consideration to these points, especially to the dynamics of populations, threatens to extinguish certain oceanic species, thus destroying the fishing industry and removing an important source of protein for man.

Environmental pollution represents a short-circuiting of the biogeochemical cycles, the chemical, or nutrient, cycles in nature. More materials are being poured into the global ecosystem, or biosphere, than can be recycled naturally. As these materials accumulate in the biosphere they have adverse, if not lethal, effects on various organisms. Too much sulfur dioxide in the atmosphere, for example, can kill and injure plants and animals; too much nitrogen and phosphorus in water can cause oxygen-depleting algal blooms that suffocate fish and other aquatic organisms.

Unnatural substances also enter biogeochemical cycles. Chlorinated hydrocarbon pesticides, such as DDT, are circulated by atmospheric and oceanic currents to all parts of the earth, where they are taken up, transferred through, and concentrated in several trophic levels. In strong enough doses they threaten the survival of organisms, such as predatory birds, by impairing metabolism and reproduction. Nuclear contaminants often follow, and become taken up in, normal metabolic cycles, thus presenting a health hazard.

Other man-induced changes in the ecosystem can create equally severe public health problems. In certain tropical regions, for example, the replacement of simple age-old irrigation practices with large-scale dam projects and warm, slow-moving water in miles of irrigation ditches has created ideal living conditions for snails that serve as secondary hosts for parasitic disease organisms. Atmospheric pollutants are responsible for a distinct rise in cases of chronic bronchitis; of nasal, pharyngeal, and optic irritations; and of lung cancer. The health and physical well being of man and the continued existence of his own environment depends on how he applies the principles of ecology toward the solution of many urgent environmental problems.

SOCIETIES AND PUBLICATIONS

Ecology is represented by a number of societies and journals throughout the world. The Ecological Society of America, founded in 1915, publishes two quarterly journals, *Ecology* and *Ecological Monographs*, and a quarterly *Bulletin*. The British Ecological Society, founded in 1913, publishes three journals: the *Journal of Ecology* (devoted to plants), the *Journal of Animal Ecology*, and the *Journal of Applied Ecology*. The Ecological Society of Australia, founded in 1960, publishes an annual *Proceedings of the Ecological Society of Australia*. The Ecological Society of Japan, founded in 1954, sponsors the *Japanese Journal of Ecology*. There are other important journals, with international boards of editors, published for ecologists by major publishing houses. One is *Oikos*, published by Munksgaard International for ecologists in Denmark, Finland, Iceland, and Scandanavia, although the papers it presents are of worldwide interest. *Oecologica*, published by Springer-Verlag, in Germany, in cooperation with the International Association for Ecology (Intecol), contains papers dealing with all aspects of ecology, including theoretical and behavioural ecology and epidemology. The *Journal of Experimental Marine Biology*, published by North Hollands Publishing Company, contains papers on all aspects of marine ecology, experimental work with ecosystems, and general ecological problems. *Limnology* and *Oceanography*, published bv the American Society of Limnology and Oceanography,

present papers on freshwater and marine ecology. Excellent papers on ecology can also be found in the *Journal of Wildlife Management*, published by the Wildlife Society.

BIBLIOGRAPHY. W.C. ALLEE *et al.*, *Principles of Animal Ecology* (1949), a somewhat dated but still important source book in animal ecology, with an excellent early history of ecology; H.G. ANDREWARTHA, *Introduction to the Study of Animal Populations* (1961), a concise summary of an important and controversial earlier text, *The Distribution and Abundance of Animals* by Andrewartha and L.C. BIRCH (1954); PETER FARB, *Ecology* (1963), an enjoyable introduction to ecology, heavily illustrated with outstanding photographs; E.B. FORD, *Ecological Genetics* (1964), a basic reference on adaptation and adjustments of wild populations to their environment; E.J. KORMONDY, *Concepts of Ecology* (1969), a short, interesting introduction to major concepts of ecology, and (ed.), *Readings in Ecology* (1965), a collection of annotated research papers that illustrate many important concepts of ecology, and ed. with R.S. LEISNER, *Ecology* (1971), a collection of essays; G.K. REID, *Ecology of Inland Waters and Estuaries* (1961), a good summary of ecological principles as applied to fresh water and estuarine ecosystems; P. SHEPARD and D. MCKINLEY (eds.), *The Subversive Science: Essays Toward an Ecology of Man* (1969), a collection of thoughtful and provocative papers written by contemporary students of the ecology of human populations; R.L. SMITH, *Ecology and Field Biology* (1966), a comprehensive survey of all aspects of ecology; T.R.E. SOUTHWOOD, *Ecological Methods* (1966), an advanced book on the study of populations, with emphasis on insects and quantitative analysis; G.M. VANDYNE (ed.), *The Ecosystem Concept in Resource Management* (1969), a technical review of the application of ecological theory to forest range, watershed, and wildlife management; K.E. WATT, *Ecology and Resource Management* (1968), a highly technical but important text relating mathematical models and computer programming to resource management; C.B. WILLIAMS, *Patterns in the Balance of Nature and Related Problems in Quantitative Ecology* (1964), an advanced treatise. See also the *Annual Review of Ecology and Systematics.*

(R.L.Sm.)

Econometrics

Econometrics, in the literal meaning of the term, is concerned with measurement in economics. But this is too broad to be descriptive of the subject as it is now studied and practiced, for the fact is that most of economics is concerned with measurement, and many economists are practicing statisticians. The difference is that econometrics seeks to determine and use relationships suggested by general economic analysis but put into mathematical form. It may, for example, seek to determine the relationship between food prices and the sales of food over a period of time (given other relevant variables) and to express that relationship in an equation that can be depicted as a demand curve, as that concept is understood in formal economic analysis. Or the econometrician may examine the relationship between costs and output in a given industry. He may try to find out what sort of mathematical relationship generally prevails between costs and output. Students of business cycles, to take another example, have attempted to discover whether cyclical fluctuations generated from systems of economic equations will throw light on the underlying mechanism of economic cycles. Econometric relationships are not precise: they are intended to demonstrate how actual economic processes evolve in time, but they are estimated as approximate statistical relationships in recognition of their basic probabilistic nature.

Studies of consumption data

The statistical analysis of demand. Many of the earliest studies in econometrics were attempts to quantify the relationship between the prices of a commodity and the amounts of it sold. In theory, the quantity demanded by individual consumers of particular goods and services depends on their incomes and on the relative prices of items the consumers intend to buy. Theory suggests also that changes in prices and income should have fairly predictable effects on the quantities sold.

Econometricians who first applied themselves to analyzing demand used collections of market statistics, compiled over time, known as time series, and studied the relationship between changes in price and changes in demand. Others turned to family-budget statistics that showed how families at various income levels spend their money. These data were used to estimate relationships between income and expenditure. Some studies have combined time series and family budget statistics.

At the practical level, such studies are useful in analyzing price behaviour. They show which commodities are elastic in demand (*i.e.*, have sales relatively responsive to changes in their prices) and which are inelastic (have sales less responsive to price changes). Such information has been useful in determining farm-price-support policy, rate structures for regulated industries, tariff policy, foreign-exchange-rate policy, rationing regulations in wartime, and tax policies. It has also been useful to private business in making price, inventory, and production decisions.

The analysis of production and supply. Econometric analysis has been applied not only to consumer behaviour but also to the behaviour of producers. The approach involves the examination of so-called production functions, cost functions, and supply functions.

Production functions. The production function is a mathematical expression of the technical relationship between the output of a firm and its various inputs (or factors of production). The earliest statistical analyses of the production function were made in an effort to test the theory that labour and capital are reimbursed according to their marginal productivities—*i.e.*, the amounts added to production by the "last" man hired or the "last" unit of capital employed. Studies by the University of Chicago economist Paul Douglas and his collaborator Charles Cobb, using econometric techniques, gave support to the theory. Their studies used a theoretical relationship expressed by an equation:

Studies of labour and capital inputs

$$X = AL^{\alpha}K^{\beta},$$

in which X is total output, L is labour input measured in man-hours, and K is the stock of capital equipment. The values of X, L, and K can be obtained from statistical data for different firms or industries or for all manufacturing industries at different time periods. The values of A, α, and β are then estimated.

If the Cobb–Douglas production function corresponds to reality, labour's share of manufacturing output, according to the marginal productivity theory, will be α, and capital's share will be β. Thus, a comparison of the estimated value for α with the share actually going to labour in the form of wages will provide a test of the theory. Cobb and Douglas found that α ranged between two-thirds and three-fourths in many countries and time periods, while values for β were between one-third and one-fourth. This implied that the sum of α and β tended to be unity, or, to put it another way, that labour and capital divide the total output between them (see DISTRIBUTION, THEORY OF).

More recent work on the production function has been based on a generalized form of the Cobb–Douglas equation, with the implication that the wage rate, adjusted for price changes, is related to labour productivity.

Cost and supply functions. Econometric work in the field of cost functions was originally undertaken to test the theory that marginal cost—the addition to total cost resulting from an increment in output—first declines as production expands but ultimately begins to rise. Econometric studies, however, have indicated that marginal cost often remains more or less constant. Such studies have been made for single plants, for firms, and for whole industries.

Marginal cost curves

Work in estimating supply functions has been confined for the most part to agriculture. Here the problem is to distinguish the effects of exogenous factors, such as temperature, rainfall, and pestilence, from those of endogenous factors, such as changes in prices and inputs. Time is an important element in agricultural supply functions. In tree crops such as cocoa, tea, and coffee, time lags between changes in market price and ensuing changes in production have often been estimated at more than two or three years. Field crops are estimated to have lags of one or two years.

The distribution of income and wealth. One of the well-known empirical regularities of statistical economics, observed in many societies over many generations, is that a small proportion of the population receives most of the income. Attempts have been made to describe this statistical regularity in mathematical terms. These attempts began with the work of an Italian economist and sociologist, Vilfredo Pareto. Efforts have also been made to explain why the distribution of income is so consistent, through the development of a probability process showing how incomes of different sizes are generated and how individuals move from one income class to another with the passage of time. No convincing probability process has yet been established to justify one particular distribution function to the exclusion of all others, but the analysis has enriched the understanding of the methods by which types of distribution functions come into being. This approach has also been applied to the distribution of wealth, the relative size of firms, and other economic phenomena. Distributional measures are frequently important in analyzing the effect of income inequality on aggregate demand.

Studies of the entire economy

Macro-econometric models. *Types of models.* After the mid-1930s the development of national income accounting and of macro-economic theory opened the way for macro-economic model building. This involved attempts to describe an entire economy in mathematical and statistical terms. The first models were those of the Dutch economist Jan Tinbergen in studies of The Netherlands and the United States. These contained equations describing input and output for the economy as a whole (aggregate-production functions), equations describing the share of the factors of production in the distribution of output, and import–export equations. In order to provide a mathematically complete system, equations were added for determining price levels, wage rates, interest rates, and other variables.

A model developed by L.R. Klein and A.S. Goldberger in the United States after World War II was the forerunner of a large family of macro-econometric models. It was constructed on an annual basis and has been elaborated upon in a form known as the Michigan model. A later generation of models was based on quarterly data to permit analysis of short-term movements of the economy and better estimation of the lags between different variables. The Wharton-Econometric Forecasting Unit model at the University of Pennsylvania and the model of the Office of Business Economics (OBE) of the U.S. Department of Commerce differ from the Michigan model in their more detailed lag structures (incorporating delayed time relationships among variables), many separate price equations for various economic sectors, and more monetary equations. The Wharton model, in addition, is divided into manufacturing and nonmanufacturing sectors. Both the Wharton and the OBE models have undergone considerable development and improvement.

A model at the Brookings Institution in Washington, D.C., is distinctive in being a quarterly system with eight separate production sectors. Each sector has its own set of equations for the price level, the wage rate, output, employment, and capital stock. This makes it a large system containing more than 300 simultaneous equations. It is also unique in having a set of equations that describe relations between industries. Work has been done on the Brookings model to enlarge its monetary sector, provide a complete balance-of-payments sector, and expand the set of interindustry equations. The methods developed for the Brookings model to combine interindustry relationships, known as input–output relationships, have been extended to the construction of a larger version of the Wharton model, which has equations for 50 input–output sectors together with more than 100 macro-economic equations.

A model jointly constructed by the U.S. Federal Reserve Board, the Massachusetts Institute of Technology, and the University of Pennsylvania, called the FRB–MIT–PENN model, is specially designed to handle the entire monetary sector. It has a large number of financial equations with a detailed lag structure and enough other equations to show the main directions of monetary influence on the economy.

Similar models have been developed in a number of advanced industrial countries, including Japan, Canada, Great Britain, The Netherlands, and Belgium. Many models have been constructed for developing economies as well, including those of Mexico, Israel, Brazil, and India.

The uses of models. A major purpose in the development of macro models has been improved economic forecasting and the analysis of public policy. They have also been applied to the analysis of economic fluctuations and economic growth.

The impact of the computer

The construction and use of models has, of course, been greatly aided by the electronic computer. In the earliest studies, all calculations had to be done laboriously by mechanical means. This limited the choice of methods to the simplest; it also restricted the size of the systems built and limited their applications. Modern computers enable econometric researchers to be much more experimental in testing ideas; they also enable them to deal with many nonlinear processes and to follow up a wide range of practical applications. Systems can now be solved in seconds. It is possible to consider the response of a whole set of dependent variables to dynamic patterns of change in a set of independent variables. The changes can be introduced with a great deal of flexibility, and the econometrician can make many forecasts, varying them according to different assumptions about alternative events. He can study policy alternatives in a much more complex fashion than in former days, when he was restricted to measuring a single change in one dependent variable resulting from a policy change expressed in a single independent variable.

At any point of time, historical values can be inserted into the equations of an econometric system. Values for the exogenous variables, representing policy commitments or the judgments of the forecaster, can also be inserted into the equations. The system can then be solved for values of the dependent variables—for example, gross national product in the coming year or components of gross national product. Many of the econometric models in the United States, Canada, Japan, The Netherlands, Great Britain, and other countries are regularly used in this way.

The growth of computer technology has also made it easier to study the dynamic behaviour of large systems of equations. It has been found that these systems generate movements that closely conform to historical economic fluctuations. Dynamic analysis by econometric models has thus thrown much light on the underlying mechanism of economic cycles.

BIBLIOGRAPHY. A first-generation general work on modern econometric methodology is TRYGVE HAAVELMO, *The Probability Approach in Econometrics*, supplement to *Econometrica*, vol. 12 (1944). Second-generation general books on methodology are *Studies in Econometric Method*, ed. by W.C. HOOD and TJALLING C. KOOPMANS (1953); and HENRI THEIL, *Economic Forecasts and Policy*, 2nd ed. (1961). These two books also contain some applied studies of substantive interest and are in the form of collections rather than pure systematic development of the subject. LAWRENCE R. KLEIN, *An Introduction to Econometrics* (1962), presents much of the second-generation material at an elementary level, with many examples based on modern micro-econometric studies and the earlier classics. A third generation of general textbooks that systematically develop the whole econometric methodology begins with J. JOHNSTON, *Econometric Methods* (1963); and continues with ARTHUR S. GOLDBERGER, *Econometric Theory* (1964); EDMOND MALINVAUD, *Statistical Methods in Econometrics* (1966); PHOEBUS J. DHRYMES, *Econometrics* (1970); and HENRI THEIL, *Principles of Econometrics* (1971). Three major macro-econometric model studies are described in LAWRENCE R. KLEIN and ARTHUR S. GOLDBERGER, *An Econometric Model of the United States, 1929–1952* (1955); J.S. DUESENBERRY *et al.* (eds.), *The Brookings Quarterly Econometric Model of the United States* (1965); and M.K. EVANS and LAWRENCE R. KLEIN, *The Wharton Econometric Forecasting Model* (1968). These studies deal with the construction, analysis, and application of macro models and are not primarily methodological.

(L.R.K.)

Economic Development

National income per capita is the conventional criterion of economic development and underdevelopment. This criterion may be applied to the level or to the rate of growth of per capita income. The "underdeveloped" countries are usually defined as those with a much lower level of per capita income than the "developed" countries. The income per capita definition of underdevelopment is based on the selection of an arbitrary level of per capita income (for example, $500 a year); the countries with per capita income below this level are put in the underdeveloped category.

It is necessary to consider some of the statistical and conceptual difficulties of using the conventional definition of underdevelopment before analyzing the causes of underdevelopment. The statistical difficulties are well-known. To begin with, there are the awkward borderline cases. Even if analysis is confined to the underdeveloped countries in Asia, Africa, and Latin America, there are rich oil countries, such as Kuwait or Venezuela, that have per capita incomes well above the demarcation line of $500 but that are otherwise underdeveloped in their general economic characteristics. Second, there are a number of technical difficulties that make the per capita incomes of many underdeveloped countries (expressed in terms of an international currency, such as the U.S. dollar) a very crude measure of their per capita real income. These difficulties include the defectiveness of the basic national income and population statistics, the inappropriateness of the official exchange rates at which the national incomes in terms of the respective domestic currencies are converted into the common denominator of the U.S. dollar, and the problems of estimating the value of the noncash components of real incomes in the underdeveloped countries. Finally, there are conceptual problems in interpreting the meaning of the international differences in the per capita income levels, discussed below.

Difficulties of measurement

The theoretical background

MEANINGS OF UNDERDEVELOPMENT

Material poverty and subjective discontent. When people talk about the problem of poverty of the underdeveloped countries, they seem to have in mind not one problem but two distinct problems, implying two different interpretations of the low per capita incomes of these countries. There are those who are concerned with the underdeveloped countries on humanitarian grounds; that is, with the problem of helping the people of these countries to attain certain minimum material standards of living in terms of such factors as food, clothing, shelter, and nutrition. For them, low per capita income is the measure of the problem of poverty in a material sense: the aim of economic development is to improve the material standards of living by raising the absolute level of per capita incomes. There are others who are concerned with the underdeveloped countries from the standpoint of international relations and in terms of reducing international tensions. They tend to see the low per capita incomes of the underdeveloped countries in relative terms; that is, in relation to the high per capita incomes of the developed countries. For them, even if an underdeveloped country is able to improve its material standards of living through a rise in the level of its per capita income, it may still be faced with the more intractable subjective problem of discontent created by the widening gap in the relative income levels between itself and the rich underdeveloped countries and the developed countries.

The interpretation of a low per capita income level as an index of poverty in a material sense may be accepted with two qualifications. First, the level of material living depends not on per capita income as such but on per capita consumption. The two may differ considerably when a large proportion of the national income is diverted from consumption to other purposes; for example, through a policy of forced saving. Second, the poverty of a country is more faithfully reflected by the representative standard of living among the great mass of its people. This may be well below the simple arithmetic average of per capita income or consumption when national income is unequally distributed and there is a wide gap in the standard of living between the rich and the poor.

The widening gap in incomes. More complicated issues are raised by the attempt to interpret the low per capita income level or, more specifically, the widening gap in the per capita incomes between the developed and the underdeveloped countries as an index of the subjective problem of discontent of the latter group of countries. To begin with, it should be noted that the "widening gap" may refer (1) to the gap in the rates of growth in per capita incomes and (2) to the gap in the levels of per capita incomes in a process of growth.

Broadly speaking, the growth rate in the total gross domestic product (GDP) of the underdeveloped countries has not lagged behind that of the developed countries. What has pulled down the rate of growth of their per capita product is not their slower rate of growth in output but their faster population growth. Thus, during the period 1960–67 the growth rate of the GDP of the underdeveloped countries was 5 percent, but their population growth was 2.5 percent, giving them a growth rate in per capita product of 2.5 percent. The growth rate of the GDP of the developed countries, on the other hand, was 4.8 percent, but their population growth was 1.2 percent, giving them a higher growth rate in per capita product of 3.6 percent. One of the fears behind the notion of the widening gap is that the underdeveloped countries will be held down by the vicious circle of low income, low savings, and economic stagnation. The available evidence casts considerable doubts on this theory. The savings rate of the underdeveloped countries has risen much higher than was thought possible in the 1950s, when the target saving rate was put at 10–12 percent of the GDP. During the period 1960–67 the gross saving rate among the Asian, African, and Latin American underdeveloped countries ranged between 11 and 16 percent of their GDP (excluding the special group of south European underdeveloped countries where both the saving ratio and the growth rate were higher). Further, among the Asian, African, and Latin American underdeveloped countries there does not seem to be an inevitable connection between a low level of per capita income as such and a slower rate of economic growth. During the period 1960–66, for example, very high rates of growth in total product of 5–7 percent or above have been attained by the relatively poor underdeveloped countries, such as South Korea, Thailand, the Philippines, Pakistan, and Nigeria, with per capita incomes between $100 and $200. On the other hand, rates of growth below 3 percent have been recorded for the relatively rich underdeveloped countries, such as Argentina and Uruguay, with per capita incomes above $500. This suggests that, given the appropriate economic policies, including population-control policies, there need not be any immutable reason why the growth rates of the underdeveloped countries should always lag behind those of the developed countries. There is, however, a further and arithmetically more intractable aspect of the widening gap. This arises simply from the operation of the arithmetic of growth on the large initial gap between the income levels of the developed and the underdeveloped countries. As an example, an underdeveloped country with a per capita income of $100 and a developed country with a per capita income of $1,000 may be considered. The initial gap in their incomes is $900. Let the incomes in both countries grow at 5 percent. After one year, the income of the underdeveloped country is $105, and the income of the developed country is $1,050. The gap has widened to $945. The income of the underdeveloped country would have to grow by 50 percent to maintain the same absolute gap of $900.

Effect of population growth

The crucial question is how far this sort of arithmetic can be related to the complex phenomenon of the subjective problem of the discontent of the underdeveloped countries with their economic status relative to that of the developed countries. First, the underdeveloped coun-

tries' sense of dissatisfaction and grievance arises not only from measurable differences in national incomes but also from the less easily measurable factors, such as their reaction against the colonial past and their complex drives to raise their national prestige and achieve equality in the broadest sense with the developed countries. Thus, it is not uncommon to find their governments using a considerable proportion of their resources in prestige projects, ranging from steel mills, hydroelectric dams, universities, and defense expenditure to international athletics. These symbols of modernization may contribute a nationally shared satisfaction and pride but may or may not contribute to an increase in the measurable national income. Second, it is possible to argue that in many cases the internal gap in incomes within individual underdeveloped countries may be a more potent source of the subjective level of discontent than the international gap in income. Faster economic growth may help to reduce the internal economic disparities in a less painful way, but it must be remembered that faster economic growth also tends to introduce greater disruption and the need for making bigger readjustments in previous ways of life and may thus increase the subjective sense of frustration and discontent. Finally, it is difficult to establish that the subjective problem of discontent will bear a simple and direct relationship to the size of the international gap in incomes. Some of the apparently most discontented countries are to be found in Latin America, where the per capita incomes are generally higher than in Asia and Africa. A skeptic can turn the whole approach to a *reductio ad absurdum* by pointing out that even the developed countries with their high and rising levels of per capita income have not been able to solve the subjective problem of discontent and frustration among various sections of their population.

Toward a workable criterion

Two conclusions may be drawn from the above points. First, the subjective problem of discontent in the underdeveloped countries is a genuine and important problem in international relations. But economic policy acting on measurable economic magnitudes can play only a small part in the solution of what essentially is a problem in international politics. Second, for the narrower purpose of economic policy there is no choice but to fall back on the interpretation of the low per capita incomes of the underdeveloped countries as an index of their poverty in a material sense. This can be defended by explicitly adopting the humanitarian value judgment that the underdeveloped countries ought to give priority to improving the material standards of living of the mass of their people. But, even if this value judgment is not accepted, the conventional measure of economic development in terms of a rise in per capita income still retains its usefulness. The governments of the underdeveloped countries may wish to pursue other, nonmaterial goals, but they would be able to make clearer decisions if they knew the economic cost of their decisions. The most significant measure of this economic cost can be expressed in terms of the foregone opportunity to raise the level of per capita income.

A SURVEY OF DEVELOPMENT THEORIES

The hypothesis of underdevelopment. If the underdeveloped countries are merely low-income countries, why call them underdeveloped? The use of the term underdeveloped in fact rests on a general hypothesis on which the whole subject matter of development economics is based. According to this hypothesis, the existing differences in the per capita income levels between the developed and the underdeveloped countries cannot be accounted for purely in terms of differences in natural conditions beyond the control of man and society: that is to say, the underdeveloped countries are underdeveloped because, in some way or another, they have not yet succeeded in making full use of their potential for economic growth. This potential may arise from the underdevelopment of their natural resources, of their human resources, or from the "technological gap." More generally, it may arise from the underdevelopment of economic organization and institutions, including the network of the market system and the administrative machinery of the government. The general presumption is that the development of this organizational framework would enable an underdeveloped country to make a fuller use not only of its domestic resources but also of its external economic opportunities, in the form of international trade, foreign investment, and technological and organizational innovations.

Growth economics and development economics. The task of development economics is to study how the underdeveloped countries may be enabled to make a fuller use of their potential opportunities for economic development. This may be contrasted with another branch of study, called growth economics, which is concerned with the study of the long-run, or steady-state, equilibrium growth paths of the economically developed countries, which have long overcome the problem of initiating economic development.

Growth theory assumes the existence of a fully developed modern capitalist economy with a sufficient supply of entrepreneurs responding to a well-articulated system of economic incentives to drive the growth mechanism. Typically, it concentrates on macroeconomic relations, particularly the ratio of savings to total output and the aggregate capital–output ratio (that is, the number of units of additional capital required to produce an additional unit of output). Mathematically, this can be expressed (the Harrod–Domar growth equation) as follows: the growth in total output (g) will be equal to the savings ratio (s) divided by the capital–output ratio (k); *i.e.*, $g = \frac{s}{k}$. Thus, suppose that 12 percent of total output is saved annually and that three units of capital are required to produce an additional unit of output: then the rate of growth in output is $\frac{12}{3}\% = 4\%$ per annum. This result is obtained from the basic assumption that whatever is saved will be automatically invested and converted into an increase in output on the basis of a given capital–output ratio. Since a given proportion of this increase in output will be saved and invested on the same basis, a continuous process of growth is maintained.

Misapplication of growth theory

Growth theory, particularly the Harrod–Domar growth equation, has been frequently applied or misapplied to the economic planning of an underdeveloped country. The planner starts from a desired target rate of growth of perhaps 4 percent. Assuming a fixed overall capital–output ratio of, say, 3, it is then asserted that the underdeveloped country will be able to achieve this target rate of growth if it can increase its savings to $3 \times 4\% = 12\%$ of its total output. The weakness of this type of exercise arises from the assumption of a fixed overall capital–output ratio, which assumes away all the vital problems affecting the underdeveloped country's capacity to absorb capital and invest its saving in a productive manner. These problems include the central problem of the efficient allocation of available savings among alternative investment opportunities and the associated organizational and institutional problems of encouraging the growth of a sufficient supply of entrepreneurs; the provision of appropriate economic incentives through a market system that correctly reflects the relative scarcities of products and factors of production; and the building up of an organizational framework that can effectively implement investment decisions in both the private and the public sectors. Such problems, affecting the underdeveloped country's absorptive capacity for capital and other inputs, constitute the core of development economics. Development economics is needed precisely because the assumptions of growth economics, based as they are on the existence of a fully developed and well-functioning modern capitalist economy, do not apply.

A "new orthodoxy" in development economics. The underdeveloped countries, even excluding those in southern Europe, still remain a very mixed collection of countries. They differ widely in area, population density, and natural resources. They are also at different stages in the development of market and financial institutions and of an effective administrative framework. These differences

Reasons for the change in theoretical models

are sufficient to warn against wide-sweeping generalizations about the causes of underdevelopment and all-embracing theoretical models of economic development. But when development economics first came into prominence in the 1950s, there were powerful intellectual and political forces propelling the subject toward such general theoretical models of development and underdevelopment. First, many writers who popularized the subject were frankly motivated by a desire to persuade the developed countries to give more economic aid to the underdeveloped countries, on grounds ranging from humanitarian considerations to considerations of cold war strategy. Second, there was the reaction of the newly independent underdeveloped countries against their past "colonial economic pattern," which they identified with free trade and primary production for the export market. These countries were eager to accept general theories of economic development that provided a rationalization for their deep-seated desire for rapid industrialization. Third, there was a parallel reaction, at the academic level, against older economic theory, with its emphasis on the problem of the efficient allocation of scarce resources and a striving after new and "dynamic" approaches to economic development.

All these combined to produce a crop of theoretical approaches that soon developed into a "new orthodoxy" with its characteristic emphasis on "crash" programs of investment in both material and human capital, on domestic industrialization, and on government economic planning as the standard ingredients of development policy. These theories still continue to have a considerable influence on the conventional wisdom in development economics, although in retrospect most of them have turned out to be partial theories. A broad survey of these theories, under three main heads, is given below. It brings out their interrelationships and is particularly relevant to the debate over whether the underdeveloped countries should seek economic development through domestic industrialization or through international trade. The limitations of these new theories—and how they have led to a gradual revival of a more pragmatic approach to development problems which falls back increasingly on the older economic theory of efficient allocation of resources—are then traced.

The missing-component approach. First, there are the theories that regard the shortage of some strategic input (such as the supply of savings, foreign exchange, or technical skills) as the main cause of underdevelopment. Once this missing component was supplied—say, by external economic aid—it was believed that economic development would follow in a predictable manner based on fixed quantitative relationships between input and output. The overall capital–output ratio, mentioned above, is the most well-known of these fixed technical coefficients. But similar fixed coefficients have been assumed between the foreign-exchange requirements and total output and between the input of skilled manpower and output.

Savings. Given the broad relationship between capital accumulation and economic development, it was plausible to argue in the 1950s that the underdeveloped countries were held back mainly by a shortage in the supply of capital. These countries were then saving only about 5–7 percent of their total product, and the raising of the saving ratio to 10–12 percent was frequently regarded as the central problem of economic development. But the saving ratios in the underdeveloped countries have been rising in recent decades until they have reached or passed this target level, and the saving-shortage theory has thus become less plausible. During the same period it has increasingly come to be recognized that there is much wastage of capital resources in the underdeveloped countries for various reasons, such as wrong choice of investment projects, inefficient implementation and management of these projects, and inappropriate pricing and costing of output. These faults are particularly noticeable in public-sector investment projects and are one of the reasons why the Pearson Commission Report of the International Bank for Reconstruction and Development

Aid and growth

(1969) finds that "the correlation between the amounts of aid received in the past decades and the growth performance is very weak." But even in the private sector there has been a considerable distortion in the direction of investment induced by policies designed to encourage import substitution. Thus, in most underdeveloped countries, a considerable part of private expansion investment, both foreign and domestic, has been diverted into the expansion of the manufacturing sector, catering to the domestic market through various inducements, including tariff protection, tax holidays, cheap loans, and generous foreign-exchange allocations granting the opportunity to import capital goods cheaply at overvalued exchange rates. As a consequence, there has developed a very considerable amount of excess capacity in the manufacturing sector of the underdeveloped countries pursuing import-substitution policies.

Foreign exchange. Since many of these manufacturing industries are high-cost industries with no reasonable prospects of becoming internationally competitive, their situation may be taken as evidence of the underdeveloped countries' inability to absorb capital. But it has frequently been argued that their lack of economic viability is caused primarily by a shortage of foreign exchange to buy essential industrial inputs. There is thus a second version of the missing-component approach, according to which the underdeveloped countries are held back because they are unable to expand their export receipts sufficiently to pay for the technologically irreducible minimum imports of capital goods and other industrial inputs required to sustain a reasonable rate of economic growth. This concept of technologically determined foreign-exchange requirements may now be examined.

The import-substitution approach to economic growth defines "industrialization" rather narrowly as the expansion of the modern manufacturing sector based on capital-intensive technology. Capital is therefore identified with durable capital equipment in the form of complex machinery and other inputs that the underdeveloped countries are not able to produce domestically. Thus, foreign-exchange requirements are calculated on the basis of the fixed technical input–output coefficients of the manufacturing sector.

The expanded view of industrialization

But an entirely different perspective on capital and foreign-exchange requirements is arrived at if a broader view of industrialization, more relevant to economic development, is adopted. For this purpose, industrialization may be regarded as the application of modern science, technology, and management to the task of raising the productivity of resources, not only in the manufacturing sector but in the economy as a whole, including the agricultural sector. If the aim of economic development is to increase the total national output, the concept of capital cannot be restricted to durable capital goods and complex forms of machinery. In the setting of the underdeveloped countries there are other forms of capital that are likely to contribute more to an increase in total output. The underdeveloped countries are characterized (1) by a large share of agriculture in their total output; (2) by the inadequacy of their social-overhead capital, particularly transport, communications, and irrigation; and (3) by the relatively large share of "nonreproducible" capital or natural resources in their total stock of productive equipment. In this setting, it must be expected that investment will improve the productivity of the inherited natural resources by the construction of a more adequate system of social-overhead capital, particularly transport and irrigation. This type of capital formation consists largely of construction work that has to be performed on the spot, as contrasted with the importation of machinery in prefabricated form. In particular, it requires large quantities of two types of inputs that the underdeveloped countries can advantageously produce at home. First, it requires various building materials, such as brick, cement, and tiles, that because of their weight, bulk, and heavy transport costs offer a natural advantage to local production. Second, and even more important, construction work requires the employment of a large number of workers engaged in the production of future

output instead of present output; and these workers must be supported by a subsistence fund of consumers' goods to maintain them during the waiting period before their work yields a return in the form of an increased quantity of consumable products. It can thus be seen why the older classical notion of capital as a subsistence fund is likely to be more important for the underdeveloped countries than the modern concept of capital as durable capital goods. The modern concept of capital is a reflection of the setting in the advanced countries in which agriculture forms only a small proportion of the total output and in which reproducible, or man-made, capital forms the bulk of productive equipment.

Weaknesses of the foreign-exchange-shortage theory

If this analysis is correct, the foreign-exchange-shortage theory as a species of the missing component suffers from two serious weaknesses. First, by emphasizing too narrow a concept of industrialization and capital, it distracts attention from the considerable potentialities of economic development open to the underdeveloped countries; namely, by import substitution in the production of the simpler tools and construction materials that they are likely to require in large quantities in the construction of their social overhead capital and by improving the productivity of the agricultural sector, which is the chief supplier of capital as subsistence fund. Second, if a large number of the manufacturing industries suffering from excess capacity have no reasonable prospects of increasing their efficiency and reducing their costs to become internationally competitive, then it is a waste of foreign-exchange resources to keep them running at their full technical capacity. Even if there were enough foreign exchange available to do so, it would be more economic to scrap these industries and divert the foreign exchange saved in this way to more productive uses, both in the domestic manufacturing sector and in the agricultural and export sectors.

Education. The third version of the missing-component approach regards the underdeveloped countries as being held back mainly by a lack of education and skills. If education and skill are defined as everything that is required to raise the productivity of the people in the underdeveloped countries by improving their skills, enterprise, initiative, adaptability, and attitudes, this proposition is true but is an empty tautology. This aspect of the missing-component approach, however, is formulated in terms of specific skills and educational qualifications that can be supplied by crash programs in formal education through massive expansion of schools, universities, and technical-training centres. The usual method of manpower planning thus starts from a target rate of expansion in output and tries to estimate the numbers of various types of skilled personnel that would be required to sustain this target rate of economic growth on the basis of fixed technical coefficients between inputs of skill and national output.

This approach was plausible enough in many underdeveloped countries immediately after their political independence, when there were obvious gaps in various branches of the administrative and technical services created by the departure of the nationals of the former colonial powers. It was then obviously important for the underdeveloped countries to train their own nationals as quickly as possible to fill these gaps. But most underdeveloped countries have already passed through this initial phase. In the meantime, as the result of programs in education expansion, their schools and colleges are annually producing large numbers of fresh graduates at much faster rates than their general rate of economic growth. This creates a growing problem of educated unemployment, which is one of the most potent causes of the subjective problem of discontent in the underdeveloped countries. An important factor behind the rapid educational expansion has been the expectation that students would obtain well-paid white-collar jobs at salary levels many times the prevailing per capita income of their countries. Thus, the underdeveloped countries' inability to create jobs to absorb their growing armies of graduates is an explosive element in what has come to be called the revolution of rising expectations.

There is a parallelism between the narrow concept of industrialization as the expansion of the manufacturing sector and the narrow concept of education as the academic and technical qualifications that can be supplied by the expansion of the formal educational system. If a broader concept of education, relevant for economic development, is needed, it is necessary to seek it in the pervasive educational influence of the economic environment as a whole on the learning process of the people of the underdeveloped countries. This is a complex process that depends, among other less easily analyzable things, on the system of economic incentives and signals that can mold the economic behaviour of the people of the underdeveloped countries and affect their ability to make rational economic decisions and their willingness to introduce or adapt to economic changes. Unfortunately, the economic environment in many underdeveloped countries is dominated by a network of government controls that tend not to be conducive to such ends. Indigenous entrepreneurs often find it more rewarding to devote their energy and ingenuity to the task of procuring the necessary government import licenses and other permits and exploiting the loopholes in government regulations than to the problem of raising the efficiency and productivity of resources.

Surplus resources and disguised unemployment. Next to be considered are theories that emphasize the surplus resources of the underdeveloped countries as the principal means of promoting economic development. There are two contrasting theories. The first concentrates on the countries with relatively abundant natural resources and low population densities and argues that a considerable amount of both surplus land and surplus labour may still exist in these countries because of inadequate marketing facilities and lack of transport and communications. Economic development is pictured as a process whereby these underutilized resources of the subsistence sector are drawn into cash production for the export market. International trade is regarded as the chief market outlet, or vent, for the surplus resources. This theory will be considered later. For the moment, it is useful to concentrate on the second theory, which is concerned with the thickly populated countries and the possibility of using their surplus labour as the chief means of promoting economic development. According to this theory, because of heavy population pressure on land, the marginal product of labour (that is, the extra output derived from the employment of an extra unit of labour) is reduced to zero or to a very low level. But the people in the subsistence sector are able to enjoy a certain customary minimum level of real income because the extended-family system of the rural society shares the total output of the family farm among its members. A considerable proportion of labour in the traditional agricultural sector thus contributes little or nothing to total output and is really in a state of disguised unemployment. This labour may therefore be drawn into other uses without any cost to society.

The concept of disguised unemployment

It is necessary to clear up a number of preliminary points about the concept of disguised unemployment before considering its applications. First, it is highly questionable whether the marginal product of labour is actually zero even in densely populated countries, such as India or Pakistan. Even in these countries, with existing agricultural methods, all available labour is needed in the peak seasons, such as harvest. The most important part of disguised unemployment is thus what may be better described as seasonal unemployment during the off-seasons. The magnitude of this seasonal unemployment, however, depends not so much on the population density on land as on the number of crops cultivated on the same piece of land through the year. There is thus little seasonal unemployment in countries such as Taiwan or South Korea, which have much higher population densities than India, because improved irrigation facilities enable them to grow a succession of crops on the same land throughout the year. But there may be considerable seasonal unemployment even in sparsely populated countries growing only one crop a year.

The main weakness in the proposal to use disguised unemployment for the construction of major social-overhead-capital projects arises from an inadequate consideration of the problem of providing the subsistence fund to maintain the workers during the waiting period before these projects yield consumable output. This may be managed somehow for small-scale local-community projects when the workers are maintained *in situ* by their relatives. But when it is proposed to move a large number of surplus workers away from their home villages for major construction projects taking a considerable time to complete, the problem of raising a sufficient amount of subsistence fund to maintain the labour becomes formidable. The only practicable way of raising such a subsistence fund is to encourage voluntary saving and the expansion of a marketable surplus of food that can be purchased with the savings to maintain the workers. The mere existence of disguised unemployment does not in any way ease this problem.

Critical minimum-effort theories. Third are those theories based on the proposition that the underdeveloped countries are firmly held down to their low per capita incomes by a series of interlocking vicious circles. Thus, a gradual or step-by-step effort to raise incomes would be of no avail: only "a big push" exceeding a certain critical minimum effort would give sufficient power to lift the underdeveloped countries out of their low-income equilibrium trap.

The population trap

One version of this theory holds that any gradual increase in total income would be swallowed up by an increase in population without raising the per capita income. Thus, a critical minimum effort is necessary to raise the rate of growth in total income above the maximum possible rate of growth in population, so that per capita incomes can be raised to generate a margin of savings above the minimum subsistence level, thus providing a means of escape from the low-level equilibrium trap. But this theory, as originally expounded, has been overtaken by events. Total national incomes in the underdeveloped countries have been rising at the average of 5 percent, compared with a population growth of 2.5 percent, giving them an average rise in per capita income of 2.5 percent per annum during most of the postwar period. In countries where the level of per capita income has remained constant, such as Argentina or Indonesia, the main cause seems to have been internal political instability rather than simple population pressure. This theory nevertheless serves a useful purpose in emphasizing the burden of population growth to the underdeveloped countries. The drawback of a rapidly increasing population is not only that it depresses the per capita level of income and consumption: it also requires a much larger amount of savings to equip the rapidly growing number of workers with the same amount of capital per head. But this may be more usefully interpreted as an argument for controlling population growth than as an argument for a critical minimum effort in increasing output.

A more elaborate and influential argument for a critical minimum effort is based on the need to overcome the smallness in the size of the domestic market resulting from the low incomes and purchasing power of the consumers in the underdeveloped countries. It is argued that this prevents the underdeveloped countries from taking advantage of the economies of large-scale production and the economies generated by a complementary group of industries. Thus, a single modern factory may fail because of the smallness of the market outlet for its output. What is needed is the simultaneous setting up of a group of factories producing consumer goods, so that among them they provide a sufficient volume of additional employment and purchasing power to provide a sufficiently large market for each other's products. The output of the consumers' goods produced by each factory should be expanded in a balanced way so that the supply matches the increased demand for the product generated by the expansion in incomes. The more ambitious versions of the theory then extend this framework to include balanced-growth relationships between consumer-goods industries and capital-goods industries and balanced-growth relationships between the whole of the manufacturing sector and the construction of new social-overhead capital. The labour supply for the new industries is assumed to be freely available from the disguised unemployment from agriculture. What is required is a big push in the form of a massive injection of external capital resources to finance the balanced-growth program of investment.

Objections to the big-push and balanced-growth approaches

Two main objections may be laid against the big-push and balanced-growth versions of the critical minimum-effort argument.

First, even if it is assumed that the raw labour from agriculture can be trained in sufficient numbers, it is still necessary to solve the problem of finding an army of entrepreneurs and managers to run a whole flock of brand-new industries. Further, there is the crucial problem of coordinating a comprehensive balanced-growth program. Planning, in the sense of drawing up on paper a formally consistent set of projects, is only the beginning. The really difficult part lies in the implementation of the various projects according to a planned timetable and keeping the plans in each sector in line with the rest. The greater the interdependence among the different components of the program, the greater is the likelihood that the delay or failure in one part of the program will throw the whole plan out of gear. The balanced-growth program is supposed to be carried out in a setting of a mixed economy (that is, an economy with substantial public and private sectors) with the government agencies taking a leading part. But the complex task of coordination required by the balanced-growth approach is well beyond the administrative capabilities of most of the underdeveloped countries. Further, the drive to make the investment programs as large as possible frequently strains the available resources and pushes the government continually to a position of having to take "crisis" measures, usually in the form of a sudden tightening of controls, particularly foreign-exchange controls. This adds to the uncertainties that inhibit private investment. In most underdeveloped countries the diseconomies generated by faulty coordination of investment plans and the shortage of competent entrepreneurs and managers would in practice outweigh the theoretical advantages claimed for a large-scale, integrated balanced-growth program.

Second, the balanced-growth approach is implicitly based on an autarkic policy of matching the expansion of domestic production to the expansion of the domestic market. It leaves out the balancing of demand and supply through exports and imports. Such an autarkic approach may be plausible for a very large underdeveloped country, such as India, although even there it has been a major factor responsible for slow economic growth. But the majority of the underdeveloped countries are very small countries. Out of some 90 of them, 72 have fewer than 15,000,000 population and 51 have fewer than 5,000,000 population. For the smaller countries, balanced growth within their national economy makes little economic sense. The economies of large-scale production must be sought in specialization for the export market.

INDUSTRIALIZATION VERSUS TRADE

The central issue of development policy may now be considered; that is, the relative importance of domestic industrialization and international trade as the principal factor in growth for the underdeveloped countries. The case for domestic industrialization, which underlies much of the new orthodoxy in development economics, is made up of negative arguments against international trade combined with positive arguments for the expansion of manufacturing as the leading sector in economic development.

Antitrade arguments

There are three main antitrade arguments. First, it is maintained that the pattern of international trade of the 19th century, in which foreign investment in mines and plantations led to an expansion of primary exports from the underdeveloped countries, did not adequately transmit the benefits of export expansion to the indigenous

people. The mines and plantations are said to be enclaves of foreign capital and economic organization creating a dualism between the modern export sector and the traditional sector of the rest of the country. Second, it is argued that the world-market demand for primary products is subject to violent fluctuations; thus, the underdeveloped countries, which specialize in a few primary products, are vulnerable to short-run fluctuations in their export receipts and need to insulate themselves against these fluctuations by encouraging domestic industries. Third, it is argued that, because of low-income elasticity of demand for primary products (*i.e.*, because less is spent on them as national incomes rise) and the substitution of synthetic materials for natural raw materials, there is a declining long-run trend in the world-market demand for primary products. Thus, export expansion in these products no longer offers an "engine of growth" to the underdeveloped countries.

The argument for industrialization

The positive argument for industrialization is based on the assumption that capital-intensive modern technology in manufacturing would raise labour productivity above its low level in the traditional-handicraft and the agricultural sectors. Because of this, it is argued, the modern manufacturing sector would be able to earn a high rate of profits; the re-investment of these profits provides the mainspring of economic development, which draws the surplus labour from agriculture. The existence of disguised unemployment in the agricultural sector means that a virtually unlimited supply of labour is available to the manufacturing sector at a constant wage rate, enabling the manufacturing sector to continue earning a high rate of profit for further investment.

The underdeveloped countries undoubtedly suffered the traumatic experience of a drastic fall in their export receipts during the Great Depression of the 1930s. The question arises of how far a delayed response to this experience is relevant in the postwar period; for international trade since World War II has been generally buoyant, and a second great depression has been avoided by the full-employment policies pursued in the advanced countries. The only notable recession in the postwar period has been the decline in raw-material prices from the exceptionally high levels they reached during the Korean War boom. As to whether the export earnings of the underdeveloped countries producing primary products are really more unstable than those of the developed countries in the postwar period, systematic empirical studies by a number of economists have cast considerable doubts on this once widely accepted proposition. Further, there is a greater recognition of the fact that fluctuations in export earnings depend on both the fluctuations in prices determined by the world-market factors and the fluctuations in quantities determined by the domestic factors in the underdeveloped countries. These include harvest fluctuations, political instability, and government marketing policies affecting the supply of exports. This leads to a general assumption underlying much of the argument for domestic industrialization and increasing national self-sufficiency. While the underdeveloped countries cannot control the world-market factor governing their international trade, they have an effective control over the internal factors governing their domestic economic activities. This is questionable on a closer analysis. The internal economic organization in many underdeveloped countries is extremely "brittle" and subject to frequent breakdowns and speculative instability of prices in the face of unforeseen changes, such as a bad harvest threatening famine conditions in a particular locality. The reasons for this arise from poor transport and communications, inadequate inventories of goods, lack of confidence aggravated by domestic inflation, and a generally underdeveloped market system. Thus, it is possible to argue that the underdeveloped countries' vulnerability to internal shocks can be reduced by freer international trade offering an elastic world-market supply of goods on which it can rely in its frequent emergencies. To take advantage of this, the underdeveloped countries would have to use a larger part of their export earnings to build up their foreign-exchange reserves instead of committing their foreign-exchange receipts up to the hilt in imported machinery and durable capital goods. This is another point confirming the significance of the classical notion of capital as circulating capital as contrasted with the modern concept of capital as fixed capital.

Factors affecting export performance

World-market demand. Global projections about future trends in the world-market demand for primary products based on broad secular factors are somewhat speculative and open to disagreement. The fact that the income elasticity of demand for these products is likely to be low because people demand proportionately less of food and basic consumer goods as their income rises can be countered by the broad factors working in the opposite direction, including the growth in world population and the worldwide depletion of natural resources. From the point of view of an underdeveloped country seeking to expand its exports, however, the more directly relevant consideration is not the size of aggregate world-market demand for primary products but its own share in the total market in a particular product. This depends on the relative costs and prices at which it can sell its exports compared with the rival sources of supply; that is to say, on the price elasticity of demand rather than the income elasticity of demand. A country's competitiveness in the export market is determined by two main factors: first, by the economic factors determining its comparative costs; and second, by the economic factors affecting the degree of its domestic inflation and the overvaluation of its currency at fixed exchange rates. Here again, detailed case by case studies of the underdeveloped countries' scope for increasing their exports have cast considerable doubts on the older pessimism about the unfavourable world-market-demand factors inhibiting their ability to expand exports. Depending on random factors, some countries may find it difficult to expand exports because they are already producing a large share of the total world supply or because the world-market demand for these particular products is stagnant. But, in the buoyant postwar conditions of international trade, this still leaves a wide range for expanding exports that do not suffer from these handicaps. Appropriate policies, such as the control of inflation and correction of the overvalued currency, combined with a diversion of capital and entrepreneurial resources from domestic industrialization to export expansion, can still do much to increase the foreign-exchange earnings of an underdeveloped country. Further, it should be remembered that the tendency to substitute synthetic for natural raw materials is not merely a matter of autonomous technical innovations; it is determined by the relative cost and availability of rival products. A country such as Malaysia has thus been able to maintain its exports of natural rubber in the face of competition by synthetic rubber by appropriate policies of research and investment that have increased the yield of natural rubber. Export expansion would still seem to provide an engine of growth for those countries that make appropriate efforts to increase the competitiveness of their exports.

Promotion of manufacturing industry as a source of growth

Development of domestic industry. The positive case for the expansion of the manufacturing sector to supply the domestic market may now be considered. It is based on the general assumption that by adopting modern capital-intensive technology, the manufacturing sector would raise the productivity of labour and become the leading sector, drawing in the disguised unemployment from the traditional agricultural sector. This familiar two-sector growth model is a formalization of the historical experience of countries such as England and Japan, which have successfully passed through the development process. How far it can be applied to the underdeveloped countries of the post-World War II period is a matter of some conjecture. In writings on the subject, the main emphasis is placed on the availability of an unlimited supply of labour at a constant wage to the manufacturing sector, enabling the latter to continue earning high profits for re-investment. But this distracts attention from the fact that the labour supply can play merely a passive role in the process. The dynamic mainspring of the development process has to be found in the ability of the manufactur-

ing sector to raise labour productivity and earn high profits. The crucial question, therefore, is how far the adoption of modern capital-intensive technology, by itself, would enable the manufacturing sector in the underdeveloped countries to raise productivity and economic efficiency. This returns to the fundamental problem of the underdeveloped countries' capacity to absorb capital and modern technology. As has been shown, most underdeveloped countries have tried to expand their domestic manufacturing sector and to substitute for imports by a variety of policies granting protection and subsidies. Yet a large proportion of the manufacturing industries have remained economically inefficient in the sense that they cannot withstand free competition with the imported goods. Another way of describing the situation is that these industries would make no profit or show losses if their outputs and inputs were valued at world-market prices. Yet within the closed-economy (that is, isolated from the world market) situation of many underdeveloped countries, these manufacturing industries seem to enjoy high profits in terms of the local currency, frequently in spite of a substantial excess capacity. These profits seem to arise not from a genuine increase in productivity through the adoption of modern technology but from the artificial economic distortions created by government policies. On the one hand, high protection, quantitative import controls, and domestic inflation combine to create a captured market yielding easy profits for the manufacturing industries. On the other hand, these industries enjoy subsidies in the form of low-interest loans, tax concessions, and a liberal allowance of foreign exchange, enabling them to import capital goods cheaply at overvalued exchange rates. The real economic resources that have gone into the expansion of the modern manufacturing sector in the underdeveloped countries thus seem to have been obtained not so much from a self-generating process of increase in productivity creating an expanding stream of re-investable resources but from the transfer of resources from other sectors, particularly from the export and the domestic agricultural sector.

Detrimental effects of import-substitution policies

As noted above, one of the arguments used against the 19th-century pattern of the expansion of primary exports was that foreign investment in the mines and plantations introduced an economic dualism between the export sector and the traditional sector. In many ways, the import-substitution policies pursued by the underdeveloped countries have aggravated this dualism between the manufacturing sector in big, modern cities and the traditional sector in the countryside. The diversion of limited capital funds in the form of cheap loans to the big economic units in the manufacturing sector means a greater scarcity of capital and higher rates of interest for the peasants and small economic units in the traditional sector. The diversion of limited government funds to the construction of large-scale public utilities catering to the needs of the urban manufacturing sector means that the rural districts are deprived even of the elementary public services. On top of all this, the wage level in the organized labour market in the manufacturing sector is very much higher than that in the unorganized labour market of the traditional sector. This is for a variety of reasons, ranging from trade-union pressures to the organizational need to retain an experienced labour force on a regular basis. This wage gap attracts an increasing flood of migrant labour from the countryside to towns. But, given the capital-intensive technology of the modern manufacturing sector, its employment-creating capacity is very limited. There is thus a dangerous process that transforms the disguised unemployment of the agricultural sector into the open unemployment of the shantytowns. The growing economic disparity created by domestic industrialization policies that discriminate in favour of big economic units in the urban manufacturing sector and against the peasants and small-scale economic units in the rest of the country is a powerful factor adding to the problem of subjective discontent and tensions in the underdeveloped countries.

One way out of these difficulties is to orient the manufacturing industries to the export market rather than to the domestic market. Some of the smaller Asian countries—notably Korea, Taiwan, Hong Kong, and Singapore—have successfully taken this escape route by exporting a variety of labour-intensive manufactured goods. They have been helped in this by an abundant supply of labour that is industrious, disciplined, and adaptable. Abundance of suitable raw materials may also provide a basis for the export of semimanufactured and processed products. The expansion of manufactured goods can be encouraged by the use of subsidies instead of tariff protection. But fundamentally it requires the drastic weeding out of inefficient manufacturing industries, retaining only those that have genuine prospects of becoming competitive in the world market.

The postwar record

LESSONS OF POSTWAR EXPERIENCE

The economic performance of the underdeveloped countries during the postwar period may now be examined. Broadly speaking, the GDP of the underdeveloped countries as a group grew at an average rate of 5 percent per annum during most of the postwar period. Out of a group of 54 countries, approximately half exceeded the 5 percent growth rate, and approximately half fell short of it during the period 1955–65. Looking more closely at the individual differences in economic performance during the period 1960–66, there were 18 high-growth countries (growth rate of 6 percent or higher), 21 medium-growth countries (growth rates between 4 and 6 percent), and 15 low-growth countries (growth rates less than 4 percent). These differences in economic performance are to some extent due to fortuitous causes, such as differences in the endowment of resources, which are not related to the development effort. But the figures also indicate several important lessons in development policy.

Agriculture. The first of these is the close connection between the rate of growth in the output of the agricultural sector and the general rate of economic development. The high rates of economic growth are associated with rapid expansion of agricultural output and low rates of economic growth with the slow growth of agriculture. This is to be expected, since agriculture forms a large part of the total domestic product and of the exports of the underdeveloped countries. What is more interesting is that the expansion of agricultural output has by no means been confined to those countries with an abundant supply of unused land to be brought under cultivation. Taiwan and South Korea, with some of the highest population densities in the world, have been able to expand their agricultural output rapidly by a vigorous pursuit of appropriate policies. These include the provision of adequate irrigation facilities, enabling a succession of crops to be grown on the same piece of land throughout the year; the use of high-yielding seeds and fertilizers, which raise the yields per acre in a dramatic fashion; and improvements in credit and marketing facilities and a general improvement in the economic organization of the agricultural sector.

Agricultural and capital formation

As has been shown, the importance of agricultural expansion for economic development derives from the vital role that the increase of the subsistence fund plays in the capital formation of the underdeveloped countries. This is particularly important in relation to social-overhead capital. It frequently develops that large-scale social-overhead projects such as multipurpose hydroelectric dams and superhighways are underutilized because of the lack of smaller projects, such as irrigation ditches or feeder roads. It is in the construction of this network of small-scale projects filling in the gaps in social-overhead capital that the increase in agricultural output as a source of capital formation is likely to play its most important role. Furthermore, agricultural development, by raising the incomes of the mass of the people in the countryside, has two important functions. First, it increases the size of the domestic market for the manufacturing sector, thus contributing significantly to balanced growth. Second, it reduces internal economic disparities between the urban centres and the rural districts.

Exports. A second conclusion to be drawn is the close connection between export expansion and economic development. The high-growth countries have been characterized by rapid expansion in exports. Here again it is important to note that export expansion has not been confined to those countries fortunate in their natural resources, such as the oil-exporting countries. Some of the underdeveloped countries have been able to expand their exports in spite of limitations in natural resources by initiating economic policies that shift resources from inefficient domestic manufacturing industries to export production. Nor has export expansion from the underdeveloped countries been confined to primary products. There has been a considerable expansion of exports of labour-intensive manufactured goods and semiprocessed goods.

Effects of trade barriers

It is in this context that the removal of trade barriers that developed countries have erected against underdeveloped countries can be seen as a more important way of helping these countries than simply increasing economic aid. Trade barriers are many. They include restrictions on temperate-zone agricultural products and sugar; restrictions on the simpler labour-intensive manufactured goods (which can be produced more cheaply by the underdeveloped countries); and tariff escalation, or higher rates of duties on processed products as compared with raw materials, which discourages the growth of processing industries in the underdeveloped countries. The removal of these trade barriers can help those underdeveloped countries that have already shown their capacity to take advantage of the available external economic opportunities, whereas a considerable part of aid flows into those underdeveloped countries that have not shown their capacity to absorb capital.

The conventional explanation of the connection between export expansion and economic development is that the foreign-exchange receipts from exports enable the underdeveloped countries to purchase their requirements of capital goods from abroad. This may be accepted without accepting the assumption of a fixed relationship between the foreign-exchange requirements and output. But in order to analyze the longer run impact of export expansion on an underdeveloped country, it is not sufficient to concentrate only on foreign-exchange receipts. Some of the countries that have obtained "windfall" receipts through the discovery of oil and other mineral products may or may not achieve a sustained rate of economic growth, depending on how productively they can invest their resources. From a longer run point of view, the increasing capacity of an underdeveloped country to adapt its resources and internal economic organization to the pressures of world-market demand and international competition may thus turn out to be a more important connecting link between export expansion and economic development. It is important in this connection to stress the educative effect of freer international trade in keeping an underdeveloped country open to the new ideas, new wants, and new techniques of production and methods of organization from abroad. This needs to be stressed all the more when the existing manufacturing sector of the underdeveloped countries—fostered by heavy protection—has failed in its function as a leading sector in transmitting a dynamic stimulus to the traditional sector of the economy.

Population. The third lesson to be learned is the need to control the rapid population growth of the underdeveloped countries. The average rate of population growth of the underdeveloped countries is 2.5 percent per year, but there are some countries where population growth is 3 percent or more. If the aim of economic development is to raise the level of per capita incomes, it is obvious that this can be achieved both by increasing the rate of growth of total output and by reducing the rate of growth of population. Development economists of the 1950s tended to neglect population-control policies. They were partly seduced by theories of dramatically raising total output through crash investment programs and partly by the belief that population growth could be controlled slowly, through gradual changes in social attitudes and values. But it is now increasingly recognized that changes in social values and attitudes are equally necessary in development programs aimed at increasing total output. More importantly, there have been great technical advances in methods of birth control that lend themselves to mass dissemination in the underdeveloped countries at very low cost. Furthermore, it must not be imagined that the benefits of birth-control policies are to be reaped only in the long run. As soon as some births are prevented, the relative increase in population in the working-age groups and the decline in the number of children immediately starts to release resources for increasing consumption and saving. Taking realistic rates of return on the investment of capital in the underdeveloped countries, a given amount of resources devoted to retarding population growth would be capable of contributing many times more to a rise in per capita incomes than the same amount of resources devoted to increasing total output.

Immediate advantages of population control

Growth potential. The fourth and the most general lesson to be learned is the importance of improving the absorptive capacity of the underdeveloped countries, not only for capital but also for all their opportunities for economic growth, including international trade, foreign investment, and technical innovation. This is their basic problem if one accepts the hypothesis that they are underdeveloped because they have not as yet succeeded in making effective use of their potential economic opportunities. The central element in this problem is one of the efficient allocation of the available resources. But efficient allocation of resources is not merely a matter of the formal optimum conditions of economic theory. It requires the building up of an effective institutional and organizational framework to carry out the allocation of resources. In the private sector this requires the development of a well-articulated market system that embraces the markets for final products and the markets for the factors of production. The vent for surplus theory explains how the exchange economy spreads by bringing the underutilized land and labour of the subsistence economy into export production. But at a later stage there is a need to concentrate not only on the spread but also on the intensification of the exchange economy through the growth of more specialized markets. In the public sector the development of the organizational framework requires improvements in the administrative machinery of the government, especially in its fiscal machinery.

Long-range planning of resource allocation

In the setting of the underdeveloped countries, one is concerned not only with the once for all problem of efficient allocation of resources but also with improving the capacity of these countries to make a more effective use of their resources over a period of time. That is to say, one is concerned not only with the static problem of the efficient allocation of given resources with the given organizational framework but also with dynamic problems of improving the capability of this framework. From this point of view, there is no conflict, as some people would like to maintain, between the static, or the short-run, considerations and the dynamic, or longer run, considerations. The two sets of requirements move in the same direction.

The problem of the efficient allocation of investable funds in the underdeveloped countries may be taken as an example. Static rules would require the underdeveloped countries to have higher rates of interest to reflect their greater capital scarcity. But many underdeveloped countries, under the influence of dynamic theories of economic development, have used a variety of direct and indirect controls to divert large sums of capital to the manufacturing sector in the form of loans at interest rates well below the level required to equate the demand and supply of capital funds. This has resulted not only in a wasteful use of scarce capital resources but also in a retardation of the development of a domestic capital market. Instead of developing a unified capital market for the whole country, this aggravates the financial dualism characterized by low rates of interest in the modern sector and high rates in the traditional sector. The policy

of keeping the official rate of interest below the equilibrium rate of interest also results in an excess demand for loans, leading to domestic inflation and pressure on the balance of payments and to a discouragement of the growth of domestic savings. Few private individuals are prepared to buy government securities when they frequently carry rates of interest below the rate of depreciation in the value of money. Through the pursuit of "cheap money" policies that contradict the real facts of capital scarcity, the governments of underdeveloped countries have failed to make use of the opportunity of building up a domestic capital market based on an expanding volume of transactions in government securities.

DEVELOPMENT IN A BROADER PERSPECTIVE

Modern economic development started in Great Britain, which in the 1780s accounted for a little over 1 percent of the total world population at that time. Since then, economic development has spread in widening circles to other parts of the world, spurred on by a series of technological innovations, particularly in the form of improvements in transport and communications. In the early decades of the 19th century, the circle of the developed countries was limited to western Europe. By the late 19th century, the circle had widened to include North America, Australia and New Zealand, and Japan. By the early 1970s about 34 percent of the total world population belonged to the developed countries, which among them have 87.5 percent of the total world gross national product. What are the prospects of the present-day underdeveloped countries of Asia, Latin America, and Africa joining this circle of economic development?

On the negative side there are a number of factors that have added to their difficulties. First, the level of per capita product in the present-day underdeveloped countries is much lower than in the developed countries in their preindustrialization phase (with the exception of Japan). Second, the present-day underdeveloped countries have large population bases and are handicapped by much faster rates of population growth. Third, they have generally a much weaker social and political framework to cope with the more explosive forces of discontent engendered by their reaction against their colonial past and by their present internal economic disparities.

Factors favouring economic development

On the positive side, the present-day underdeveloped countries can draw upon a greater store of scientific and technical knowledge from the advanced countries. The potential opportunities to exploit the "technological gap" are not confined to manufacturing. Modern science and technology can make immense contributions to agriculture, as illustrated by the Green Revolution created by the introduction of improved seeds and fertilizers in some Asian and Latin American countries. Modern methods of birth control can make a decisive contribution in the race for raising per capita incomes. In addition, as the circle of the developed countries widens, they are bound to exert an increasing upward pull on the underdeveloped countries.

The economic growth of the advanced countries has generally resulted in an expanding demand for the products and sometimes for direct labour services from the underdeveloped countries. But there are also the stronger localized pulls, such as the pull of the United States economy on Mexico and the pull of western Europe on the underdeveloped countries of southern Europe. The spectacular economic growth of Japan since World War II may also exert a similar pull on neighbouring countries in East Asia.

In conclusion, views as to whether underdeveloped countries are helped or hindered by being latecomers depend to a great extent on how the basic goal of economic development is defined. If the goal of development is to improve the material standards of living of the mass of the people in the underdeveloped countries, then there would seem to be some grounds for qualified optimism. Provided the underdeveloped countries are prepared to pursue appropriate economic policies, including population policies, there do not appear to be insuperable difficulties in achieving the goal of economic development in a narrower sense. But, if one views the goal of economic development in a wider sense of closing the widening gap in income levels, the prospects are less bright. The arithmetic of growth, operating on the initial differences in income, is bound to make it exceedingly difficult (though not impossible) for a presently underdeveloped country to make "a big leap" to overtake the leaders in economic development. But, as has been suggested, this second interpretation of the meaning of economic development virtually turns it into a problem in international power politics. Development economics has still a long way to go before it can begin to approach this problem.

BIBLIOGRAPHY. The statistics of national incomes and rates of growth are taken from the PEARSON COMMISSION REPORT, *Partners in Progress* (1969); and G.M. MEIER, *Leading Issues in Economic Development* (1970). The discussion of conceptual problems of national income measurement is based on S. KUZNETS, *Modern Economic Growth: Rate, Structure and Spread* (1966) and on H. MYINT, *The Economics of the Developing Countries*, 3rd ed. (1967). For a good exposition of growth economics, see R.M. SOLOW, *Growth Theory* (1970); and JOHN HICKS, *Capital and Growth* (1965). See also H. MYINT, "Economic Theory and Development Policy," *Economica*, n.s., 34:117–130 (1967), reprinted in his *Economic Theory and the Underdeveloped Countries* (1971). See R. PREBISCH, *Towards a New Trade Policy for Development* (1964), for an influential exposition of the role of foreign exchange; and MEIER, *op cit.*, for a documentation of the close relationship between economic growth and the expansion of agricultural and export production. Economic development in the broader perspective is discussed in the last three chapters of KUZNETS, *op. cit.*

(H.My.)

Economic Forecasting

To forecast is to foresee, to prophesy, to predict. Economic forecasting, therefore, is the prediction of any of the elements of economic activity. Such forecasts may be made in great detail or may be very general. In any case, they describe the expected future behaviour of all or part of the economy.

Obviously, everyone forecasts all the time; the decision to accept a new job, for example, involves the assumption (in effect, a forecast) that the employer will remain solvent and able to pay his employees. The decision to buy a new car or house involves an assumption (on the part of both buyer and seller) that future payments can and will be made according to the terms of the contract. The distinction between everyday forecasting and economic forecasting is simply that an economic forecast is more formal and explicit and usually involves the application of organized theory and carefully developed statistical techniques.

The importance of theory

Formal economic forecasting is usually based on a specific theory as to how the economy works. Some theories are complicated, and their application requires an elaborate tracing of cause and effect. Others are relatively simple, ascribing most developments in the economy to one or two basic factors. Many economists, for example, believe that changes in the supply of money determine the rate of growth of general business activity. Others assign a central role to investment in new facilities—housing, industrial plants, highways, and so forth. In the United States, where consumers account for such a large share of economic activity, some economists believe that consumer decisions to invest or save provide the principal clues to the future course of the entire economy. Obviously the theory that a forecaster applies is of critical importance to the forecasting process; it dictates his line of investigation, the statistics he will regard as most important, and many of the techniques he will apply.

Judgment in forecasting

Although economic theory may determine the general outline of a forecast, judgment also often plays an important role. A forecaster may decide that the circumstances of the moment are unique, and that a forecast produced by the usual statistical methods should be modified to take account of special current circumstances. This is particularly necessary when some event outside the usual run of economic activity inevitably has an economic effect. For example, forecasts of 1970 economic

activity in the United States were more accurate when the analyst correctly foresaw that Congress would reduce taxes, that gradual troop withdrawals from Vietnam would continue, and that the tight money policy of the Federal Reserve banks would be eased in early 1970. None of these conclusions followed from purely economic analysis; they all required judgment as to future decisions. Similarly, an economist may decide to adjust an economic forecast that was made by traditional methods to take account of other unique conditions; he may, for example, decide that consumers will alter their spending patterns because of special circumstances such as fear of future inflation or of threatened shortages.

Although judgment may be based on experience and understanding, it may also be no more than unconscious bias. Forecasts based on judgment cannot be subjected to the kind of rigorous checks applied to forecasts developed by the use of more objective techniques. Consequently, the most accurate and useful forecasts are likely to be those founded on essentially economic considerations and standard statistical techniques. Though they can then be modified by the application of judgment, the resulting changes should be stated explicitly enough so that anyone wishing to use a forecast will know where, and how, it has been affected by the forecaster's own judgment, or bias.

Economic forecasting is probably as old as organized economic activity, but modern forecasting got its impetus from the Great Depression of the 1930s. The effort to understand and correct the worldwide economic disaster led to the development of a vastly greater supply of statistics and also of the techniques needed to analyze them. After World War II, many governments committed themselves to maintaining a high level of employment. Most governments of the industrialized Western countries were prepared to intervene more often and more directly in economic affairs than previously. Business organizations manifested more concern with anticipating the future. Many trade associations now provide forecasts of future trends for their members, and a number of highly successful consulting firms have been formed to provide additional forecasting help for governments and businesses.

TYPES OF FORECASTING

Forecasting the GNP and its elements. Perhaps the forecasts most familiar to the public are those of gross national product and its elements. Gross national product, or GNP (see NATIONAL INCOME ACCOUNTING), is the total value of the goods and services produced in a nation. It is, therefore, a convenient and comprehensive measure for assessing changes in general economic welfare. A forecast of the GNP also provides a useful framework for more detailed forecasts of specific industries. Almost all developed nations maintain sets of national income accounts and make forecasts as well.

The gross national product can be regarded as being composed of three major components: spending by government, private investment spending, and spending by consumers. Net exports (that is, exports minus imports) are also counted in the GNP but their magnitude is usually small. (For the nations that depend more heavily on foreign trade, net exports are of course more important.)

Forecasting government spending

Government spending is usually the easiest part of the GNP to forecast. Government expenditures can be determined with a fair degree of accuracy for well over a year in advance by studying existing budgets and appropriations, modified to take account of new political or economic developments. Most such adjustments are relatively minor for any forecast that runs only a year or two into the future; new government programs usually have only a small effect on expenditures in the short run. An obvious exception to this is a major change in the military situation, which can drastically alter spending plans.

It is important to note that government spending, as counted in the GNP, is not the same as total budgeted expenditures. Spending gets into the GNP only when money is paid for goods—military equipment, buildings, and so on—or services, which principally means the wages and salaries of government employees. These kinds of expenditures account for only part of the government budget; the remainder represents money transferred to bondholders, other private citizens (particular people receiving pensions), and state and local governments. These funds affect the GNP only when they are finally spent by the recipients.

Forecasting private investment

Private investment poses far more difficult forecasting problems because it reflects many thousands of individual and corporate decisions that are not recorded publicly (as government budgets are) and that can be, and often are, changed very substantially. Private investment is the most erratic of the major categories of the GNP—the most subject to "boom and bust" cycles. A good forecast of investment spending is therefore essential to an accurate appraisal of the overall economic situation.

Capital investment by business (spending for new plants and equipment) is particularly important. The incomes generated in the process of manufacturing new equipment and building new plants play a major role in increasing consumer spending during periods of expansion. But when investment slumps, employment and incomes generally also suffer, slowing the entire economy. Business investment has thus been studied with great care, and a wide variety of methods to guide forecasters has been developed, including econometric models, surveys of business investment plans, regular reports on commitments for investment, and fundamental studies of the condition of the nation's stock of capital goods (see below *Forecasting Techniques*).

Business also invests in inventory—that is, goods in the process of production and finished goods not yet sold to the final consumer. Most of the time, inventories increase roughly in line with the trend of sales. If sales fall short of expectations, however, inventories tend to become excessive. Business then moves to reduce stocks by cutting back production. Such cutbacks can aggravate economic recessions; as production is reduced because of disappointing sales, incomes are thereby reduced and sales fall further, inventories must be cut even more, and so on in a downward spiral. Consequently, correct forecasts of inventory investment are both essential to good economic forecasting and also particularly difficult. Surveys of business plans to build or reduce inventory have been helpful; econometric methods have also been applied; but inventory investment remains one of the weak links in the forecasting process.

New home construction accounts for a relatively small share of the GNP, but it is important to the forecaster because home construction is a relatively volatile industry. Homebuilding activity responds quickly to changes in the availability of mortgage money from the principal mortgage lending institutions, and thus forecasters follow closely the flow of savings to these institutions and also the level of commitments that have been made to finance future construction. Information on the number of building permits issued is also helpful, as are statistics on the volume of new construction contracts.

Forecasting consumer spending

Economists used to believe that forecasting consumer spending was fairly simple; as a rule of thumb, consumers could be counted on to spend 94–95 percent of their current income and save the rest. Thus an analyst could calculate the amount of personal income generated by government spending, private investment, and past consumer spending, adjust for tax payments, and arrive at a good estimate of consumer spending. This method still works well in determining the average rate of spending over an extended period of time. But in rich countries consumers as a group are quite free to vary their spending patterns in the short run; they may at any particular time spend more than usual because they anticipate shortages or because they believe that their incomes will rise further; or they may cut back their spending if they fear that a recession is about to develop. Such variations from normal spending patterns have their main effect on durable goods such as automobiles and household appliances; spending is far more stable for nondurables (food, clothing, and the like) and for services.

Because consumers account for such a large proportion of all economic activity, a shift of just one or two percent between spending and saving can make the difference between rapid growth or recession for the entire economy. Economists now use surveys of consumer attitudes in attempting to read the mood of the public; surveys of intentions to buy durable goods such as automobiles and appliances have also been helpful.

Forecasting for an industry or firm. General economic conditions set the tone for all parts of the economy. Good forecasting for an industry or firm begins, therefore, with a good analysis of the overall economy. Within this framework, the analyst must then take account of the particular factors that are most important to his own industry. In some cases, the sales of an industry may correlate fairly directly with one or more of the elements of the national income and product accounts—lumber sales with home construction, for example, or sales of nondurable consumer goods with consumer income and total consumer spending. Forecasting for industries that produce basic materials usually requires a series of projections for specific markets. A steel forecast might be based on the outlook for such major steel markets as automobiles, construction, and metal containers. The basic forecast would then be adjusted for expected shifts in exports and imports of steel and for changes in inventories of steel or steel-using products. Such inventory changes are usually the result of actual or threatened strikes.

Forecasting is most difficult for companies that produce durable goods such as automobiles, industrial equipment, and appliances and for companies that supply the basic materials for these industries. This is because sales of such goods are subject to extreme variation. Annual sales of automobiles in the United States have increased by as much as 38 percent in one year and declined by as much as 26 percent in another. Consequently, the durable goods industries in general and automobile companies in particular have developed especially complex and sophisticated forecasting techniques. In addition to careful analysis of income trends (based on a general economic forecast) automobile companies support a number of studies of consumer attitudes and surveys of intentions to purchase automobiles.

Forecasting for an individual firm obviously begins with a forecast for the industry or industries in which it is involved. Beyond this, the analyst must determine the degree to which the company's share of each market may vary during the forecast period. Such variations can result from the introduction of a new product, the improvement of an existing product, the opening, closing, or expansion of plants, the activities of competitors, a change in sales effort, or a variety of other factors. Information required to make such assessments may come in part from the company's own investment and marketing plans. Information on the activity and sales prospects of competitors is frequently collected from the firm's own salesmen. An increasing number of companies now employ sophisticated market research techniques to determine the probable reaction of their customers to new products.

Long-term forecasting. In recent years, increasing effort has been devoted to long-range forecasting for periods extending five, ten, or more years past the normal "short-term" forecast period of one or two years. Business has come to recognize the usefulness of such forecasts in developing plans for future expansion and financing.

Labour force projections

Long-range forecasts usually are based on the assumption that activity toward the end of the period will reflect normal "full" employment. Given this assumption, the overall rate of growth depends on two principal factors: the number of people in the labour force and the rate at which productivity (output per worker) increases. The number of people of working age is known, barring some natural disaster, far into the future; they have already been born. Forecasters usually assume that productivity will continue to grow at the typical rates of recent decades. Expected technological developments, however, may alter the projected rate of change. The combination of changes in the labour force and productivity produces an estimate of the total growth rate for the economy.

A measure of total economic activity arrived at by such methods as these serves, in effect, as a control total for making long-range forecasts of the constituent elements of the economy. If estimates for spending by consumers, government, and business add up to more than the total of goods and services that can reasonably be expected, then the projection for one or more of these elements must be reduced. If the sum of the projected parts is less than the probable total, the analyst is likely to assume a shift in economic policy that will move the economy up to full employment by the end of the forecast period and adjust his various projections up to the appropriate total.

Long-range forecasts for individual parts of the economy depend on many of the same factors as do short-range forecasts, except that cyclical factors are usually ignored. Over the longer range, however, additional factors enter. Among the most obvious of these are growth in the population and shifts in its age composition. Changes in age composition—particularly the greater percentage of young people—have had a major effect on both consumer and government spending patterns in many countries since World War II. Young adults now constitute a huge market. They tend to buy large amounts of durable goods and also add to the need for home construction; on the average, they save less and borrow more in relation to their incomes than most older people do. This has major significance for financial institutions and financial markets.

In addition to population pressures, a number of other trends and assumptions influence long-range forecasts. Assumptions about war and peace are obviously critical. Assumptions must be made about government spending programs; expensive new programs may bring higher taxes and less consumer spending, whereas slower growth in government spending may lead to tax reductions. Over longer periods of time, technological discoveries or changes in financial institutions can affect the overall economy. When the forecast is made for an industry or a firm, the expected introduction of new products is also important.

FORECASTING TECHNIQUES

Economic forecasters have a vast array of information to work with and a growing variety of techniques. A few economists, believing that just one or two key factors determine the future course of the economy, limit their observations to these factors and develop forecasts based on them. A leading example of this is found in the school of thought that ascribes most importance to changes in the money supply. But most economists use a wider range of material.

Information on spending. Some elements of the future are known with reasonable accuracy. Government spending is reflected in existing budgets. These budgets indicate how much will be spent and how much money will be extracted from the stream of private spending by taxation. Similar information is available on some parts of the private economy. Periodic surveys conducted both by government and by private organizations measure business plans to invest in new plants and equipment. Increasingly, attempts are made to probe the mood and intentions of consumers concerning the possible purchase of automobiles, houses, appliances, and other durable goods. Regular surveys are also made to determine the general mood of the public—whether people are optimistic or pessimistic about their own economic future and thus whether their spending is apt to be relatively strong or relatively weak. In general, such information obtained from the various surveys of investment plans, spending plans, and attitudes has been highly useful to economic forecasters. Such information helps to limit the range of possibility. But plans and attitudes change, sometimes quite abruptly, and although the surveys are useful tools they are not clear and reliable guides to the future.

Surveys of business and consumer intentions

Selection of turning points. Probably the single most difficult economic forecasting problem is to pick the turning points in economic activity—the times at which the

economy turns from growth to recession or from recession to recovery. Because of the difficulty and importance of the problem, major efforts have been made to develop tools for this purpose. The National Bureau of Economic Research in the United States has identified a number of statistical series that normally turn up or down before the economy does. Common stock prices, business inventories, and changes in consumer installment debt are among these series, which are known as "leading indicators." Other statistical series normally move in line with overall activity ("coincident indicators"), and a third group changes direction after the economy does ("lagging indicators"). Although careful study of these groupings of statistics can be helpful, unfortunately there is no fixed relation between the movements of the economy and those of the various indicators. Although the "leading indicators" do ordinarily lead, the length of the lead varies. This reflects the dynamic nature of a complex economy that is constantly changing and in which strength or weakness may come from a variety of sources.

Some economists also use sets of statistics called diffusion indexes to calculate economic turning points. A diffusion index is a method of summarizing the common tendency of a group of statistical series. If a greater number of the series are rising than are declining, the index will be above 50; if fewer are rising than declining, it will be below 50. In effect, a diffusion index measures the degree to which either strength or weakness pervades the economy. If, for example, most of a group of industries are increasing their production rates, the economy as a whole is probably expanding; if the proportion of industries that are growing begins to decline and falls significantly below 50 percent for a period of time, the economy is probably in a recession, or at least moving in that direction.

Econometric methods

Economists frequently use mathematical equations to express the normal relations between various economic factors. As a simple example, a given increase in consumer income will ordinarily produce a certain increase in sales, saving, and tax revenue, and these developments can be expressed mathematically. With a sufficient number of equations, all the important interactions within the economy can be simulated in a mathematical model. With the advent of computers able to make millions of calculations in a few moments, economists have begun to construct more and more complex sets of equations, called econometric models (see ECONOMETRICS). These models, some of which include hundreds of equations, can be used to forecast overall economic activity (macroeconomic forecasting) or developments in particular parts of the economy (microeconomic forecasting). The success of econometric forecasting has so far been limited because the exact nature of economic relations is not fully known, and also because of the inadequacies of existing statistics. Nevertheless, the improvement of these techniques represents the greatest hope for more accurate economic forecasting in the future.

Input-output analysis

The computer has also stimulated development of another potential forecasting tool, input-output analysis. Input-output tables show the relations between the various industries and sectors of an economy. They show, for each industry, the amount of its output that goes to every other industry to be used as raw materials or semifinished products, as well as the amount that goes to the final markets of the economy. Input-output tables also show each industry's consumption of the products of other industries, as well as each industry's contribution to the production process. With such a table it is possible to trace the effects of changes in one industry or sector upon all the other industries and sectors.

The usefulness of input-output analysis for forecasting purposes has been limited by a number of factors. One problem is that it takes years to put such complex sets of statistics together; in a changing economy, relations may have shifted by the time the data for a base period have been assembled. Recently, however, progress has been made in developing methods to bring these relations (called technical coefficients) up to date, and input-output analysis shows increasing promise as a forecasting tool.

THE ACCURACY OF ECONOMIC FORECASTS

Major improvements have been made in the accuracy of economic forecasting. A competent economist can usually predict accurately enough to provide guidance to those who make policy decisions. Consensus forecasts—the average of a group of forecasts made by different individuals or organizations—have come closer and closer to the mark in recent years. Errors persist, nevertheless, and they occasionally lead to bad decisions.

Sources of error

The sources of error in economic forecasts are many. Some lie outside the realm of economic analysis; wars, agricultural disasters, or political upheavals are examples. Some forecasts go wrong for essentially ideological reasons: people who do not believe that an economic system will function tend to forecast its failure, which accounts for the many predictions of another great depression. Adherents of a political party in power have a notable tendency to optimism, whereas their opponents, including economists, tend to view the future with alarm. The student of forecasts must obviously consider their source; purity of motive is an important virtue for economists.

The most vexing sources of error, however, lie within the realm of economic knowledge. Many are statistical. Not only are some of the published data inaccurate but even the best statistics are available only after a period of time; the forecaster is forever predicting the future when he cannot be completely sure of the present. Statistics of inventories, among the most volatile economic elements, are noteworthy in this respect: for example, the published estimates of inventory growth in the United States for the last quarter of 1966 started with an annual rate of $14,400,000,000, were revised upward to $16,400,000,000, revised again to $18,500,000,000, and ended finally at $19,900,000,000. Forecasts based on the original figure could have gone seriously wrong.

The most persistent form of error in economic forecasting, however, is probably theoretical. Man's knowledge of his own economic institutions is limited. Good analysis is made more difficult by the fact that these institutions are constantly changing. This means that economic theory based on experiences of the 1950s may be of limited use in the 1970s. Some of the greatest contributions to the continued improvement of economic forecasting may come from economists who are not necessarily forecasters themselves but have the insight to understand the changing economy of today.

Economic Growth

The idea of economic growth is a modern one. Before the Industrial Revolution that began in the 18th century, most men had no notion that a whole country might grow richer within the span of a single lifetime. By the middle of the 20th century, the hope and expectation of this kind of progress had become important to public opinion in many countries. Much of this concern could be traced to political causes: the desire of statesmen for power and the desire to prove the superiority of one social system over another. Through rapid growth, it is argued, the economic base vital to defense can be kept large enough to deter any enemy. Another reason for the high importance given to growth is that it is easier to redistribute a rapidly growing national income than a slowly growing one, since in the former case nearly everyone may be made better off in some material way. Rapid growth also enables governments to spend more on public services.

Growth defined

Economic growth may be defined and measured in various ways. Most economists start with some indicator of overall economic activity, such as Gross National Prod-

uct (GNP), which measures a country's total production of goods and services. More often those concerned with measuring economic growth are interested in changes in the level of welfare of individuals; thus the rate of growth of consumption per capita is often cited as an index of the growth of welfare within a society. This measure can be objected to as misleading because it does not take account of expenditures by government on health, education, and other amenities, which in many countries are large and growing and should be considered in measuring human welfare. On the other hand, two countries may show the same rate of growth in per capita consumption; but the rate of growth of investment—*i.e.*, the growth of additions to the capital stock and therefore to productive capacity—may be higher in one than in the other. Thus the rate of growth of GNP per capita may be a better measure of an economy's long-run prospects. This indicator is closely related to another measure, the rate of growth of labour productivity, which is simply the rate of growth of output per unit of labour employed.

All these measures suffer from various shortcomings. Human welfare, for example, is a function of many things besides the consumption of goods and services. Estimates of consumption or GNP cannot take account of the importance of leisure or measure the quality of life. Another difficulty with statistical measurements of growth is the paucity of data for most countries before World War II.

HOW ECONOMIES GROW

Growth can best be described as a process of transformation. Whether one examines an economy that is already modern and industrialized or an economy at an earlier stage of development, one finds that the process of growth is uneven and unbalanced. Economic historians have attempted to develop a theory of stages through which each economy must pass as it grows. Early writers, given to metaphor, often stressed the resemblance between the evolutionary character of economic development and human life—*e.g.*, growth, maturity, and decadence. Later writers, such as the Australian economist Colin Clark, have stressed the dominance of different sectors of an economy at different stages of its development and modernization. For Clark, development is a process of successive domination by primary (agriculture), secondary (manufacturing), and tertiary (trade and service) production. For the American economist W.W. Rostow, growth proceeds from a traditional society to a transitional one (in which the foundations for growth are developed), to the "take-off" society (in which development accelerates), to the mature society. Various theories have been advanced to explain the movement from one stage to the next. Entrepreneurship and investment are the two factors most often singled out as critical.

Stages of growth

Economic growth is usually distinguished from economic development, the latter term being restricted to economies that are close to the subsistence level. The term economic growth is applied to economies already experiencing rising per capita incomes. In Rostow's phraseology economic growth begins somewhere between the stage of take-off and the stage of maturity; or in Clark's terms, between the stage dominated by primary and the stage dominated by secondary production. An aspect of the transformation of one economy, that of the United States, can be seen in Table 1, which describes changes in the percentage distribution of the civilian labour force over almost a century. The most striking fact is the enormous decrease in the proportion of the labour force employed in agriculture. Similar changes are apparent in the historical development of other industrialized economies. There are other aspects of growth. The decline in agriculture and the rise of industry and services has led to concentration of the population in cities, first in what has come to be described as the "core city" and later in the suburbs. In earlier years public utility investment (including investment in transportation) was more important than manufacturing investment, but in the course of growth this relationship was reversed. There has also been a rise in the importance of durable consumer goods in total output. In the U.S. experience, the rate of growth of capital goods production at first exceeded the rate of growth of total output, but later this too was reversed. Likewise, business construction or plant expenditures loomed large in the earlier period as an object of business investment compared to the recent era. Whether other countries will go through the same experience at similar stages in their growth remains to be seen.

Table 1: Occupational Distribution of the U.S. Labour Force
(percentages of total labour force)

year	agriculture	manufacturing	other (including services)
1870	50	17	33
1880	50	18	32
1890	42	20	38
1900	37	22	41
1910	31	22	47
1920	27	26	47
1930	22	23	55
1940	17	23	60
1950	12	26	62
1960	8	25	67
1968	5	24	71

Table 2 gives some comparative growth rates for a group of developed countries. It shows how uneven the process of growth can be. Partly this unevenness reflects the extraordinary events of the 1913–50 period, which included two major wars and a severe and prolonged depression. There are sizable differences, however, in the growth rates of the various countries as between the 1870–1913 period and the 1950–66 period. For the most part these differences indicate an acceleration in the rate of growth in more recent times. Many writers have attributed this to a relatively higher ratio of business investment in plant and equipment.

National comparisons

The relatively high rates of growth for West Germany, Japan, and Italy in 1950–66 have stimulated a good deal of discussion. It is often argued that "late starters" can grow faster because they can borrow advanced technology from the early starters. In this way they leapfrog some of the stages of development that the early starters were forced to move through. This argument is nothing more than the assertion that late starters will grow rapidly during the period when they are modernizing. As indicated by Table 2, Italy did not succeed in growing rapidly and thereby modernizing until after World War II. Together with Japan and Germany it also experienced a large

amount of war damage. This has an effect similar to starting late, since recovery from war entails building a stock of capital that will, other things being equal, embody the most advanced technology and therefore be more productive and allow faster growth. The other part of this argument is the assertion that early starters are actually deterred from introducing on a broad front the new technology they themselves have developed. For example, firms in a country that industrialized early may be inhibited from introducing a more modern and efficient means of transportation on a broad scale because there is no guarantee that other firms handling the ancillary loading and unloading tasks will also modernize to make the change profitable.

Related to this is the problem of whether or not growth rates of developed economies will eventually converge or diverge. For example, as per capita incomes of fast growers like the Italians and Japanese approach those of economies that developed earlier, such as the American and British, will the growth rates of the former slow down? Economists who answer in the affirmative stress the similarities in the changing patterns of demand as per capita income rises. This emphasis in turn implies that there is less and less chance to borrow technology from the industrial leaders as the income levels of the late starters approach those of the more affluent. Moreover, rising per capita incomes in an affluent society usually are accompanied by a shift in demand toward services. Therefore, so this argument goes, differences in growth rates between countries should eventually narrow because of the low growth in productivity in the service sector. The evidence is inconclusive. On the one hand, growth is a function of something more than the ability to borrow the latest technology; on the other hand, it is not clear that productivity must always grow at a slower rate in the service industries.

A rapidly increasing population is not clearly either an advantage or a disadvantage to economic growth. The American Simon Kuznets and other investigators have found little association between rates of population growth and rates of growth of GNP per capita. Some of the fastest growing economies have been those with stable populations. And in the United States, where the rate of growth of population has shown a downward historical trend, the rate of growth of GNP per capita has increased over the last century and a half. Another finding by Kuznets is that while GNP per capita in 1960 was substantially higher in the United States than in any European country, there was no significant difference in the per capita growth rates of all these countries over the period 1840 to 1960 as a whole. The conclusion is that the U.S. started from a higher per capita base; this may have been the result of its superior natural resources, especially its fertile agricultural land.

THE ANALYSIS OF GROWTH

Capital and labour

To explain why some countries grow more rapidly than others or why a country may grow more rapidly during one period of history than another, economists have found it convenient to think in terms of a "production function." This is a mathematical way of relating some measure of output, such as GNP, to the inputs required to produce it. For example, it is possible to relate GNP to the size of the labour force measured in man-hours, to capital stock measured in dollars, and to various other inputs that are considered important. An equation can be written that states that the rate of growth of GNP depends upon the rates of growth of the labour force, the capital stock, and other variables. A common procedure is to assume that the influence of the separate inputs is additive—*i.e.*, that the increase in the growth of output caused by increasing the rate of growth of, say, capital is independent of the rate of growth of the labour force. This is the starting point of a great deal of current empirical work that attempts to quantify the importance of different inputs.

Under certain assumptions, some reasonable and some patently false, it is possible to conclude that what labour and capital receive in the form of wages, profits, and interest is a fair measure of what they contribute to the productive process. Thus in the United States in the period following World War II the share of output going to labour was approximately 79 percent, while the share of output distributed as "profits" was 21 percent. If we assume that these proportions determine how much we should weight the rate of growth of the labour force and of capital respectively in determining their contribution to the rate of growth of output, we must conclude that the relative contribution of capital is slight. Alternatively, we may say that some given percentage increase in the rate of growth of the labour force will have a much larger influence on the rate of growth of output than the same percentage increase in the rate of growth of capital. This is a puzzling result and can be traced to the assumption that the influence of separate inputs is additive.

Quality improvements in the inputs. Much work has been done in an effort to measure the inputs in the productive process more accurately by taking account of improvements in the quality of both labour and capital over time. For example, it has been argued that the amount of a worker's time spent on his formal education is positively related to the income he receives and to his productive contribution. Measuring the number of man-hours worked from one period to the next will not give a true picture of the increase in labour input if the average amount of education received by workers is changing. Man-hour units must be converted to "efficiency" units. Thus if a labour force of 100 workers in the first year all had an eighth-grade education, while 20 years later each member had a tenth-grade education, then measured in efficiency units the labour force had grown. If the length of time spent on formal education increases over time, then the growth of the labour input will be larger if measured in efficiency units. There is, thus, an element of capital in the labour force.

Investment in human capital

Examples of investment in human capital are expenditures on health and on all types of education including on-the-job training. Expenditures of this sort increase the quality of the labour force and its ability to perform productive tasks. Many economists have argued that technological progress is really nothing but quality improvements in human beings. Some economists take an even broader view and speak of the "production of knowledge" as the clue to technological progress. The production of knowledge is a broad category including outlays on all forms of education, on basic research, and on the more applied type of research associated especially with industry. It is argued that fast-growing industries tend to be those having a high research and development component in their total costs. In addition, firms within an industry that have large research and development budgets tend to experience the most rapid technological progress. The argument is that technical change and improvements must originate in inventions that lead to innovations in the products produced or in the processes whereby existing products are manufactured.

A similar argument applies to the size of the capital stock. It can be maintained that design improvements increase the efficiency of capital goods so that a dollar's worth of machinery purchased today may be much more efficient than a dollar's worth of depreciated machinery purchased yesterday. The rate of growth of the capital stock measured so as to take account of quality improvements will be greater than the rate of growth of the capital stock measured in a way that neglects the differences between "vintages."

Some economists have stressed "economies of scale." For example, if an increase in the use of capital and labour leads to a greater than proportionate increase in output, this is said to result from economies of scale. Economies of scale may arise because an expansion of the market justifies a radical change in productive techniques. These new techniques may be so much more efficient that the returns in the way of increased output are much greater proportionately than the increase in inputs.

Another source of growth and of technical progress in

particular has been seen in shifts of demand from low productivity sectors to high productivity sectors, thus causing resources to be reallocated. The most notable movement has been the shift of resources, especially labour, out of agriculture—a traditionally low-productivity sector. Such shifts act to increase the rate of growth of output in ways that cannot be accounted for by simply measuring growth in total inputs. Historically, the allocation of both capital and labour have shifted during the growth process from low productivity sectors to high ones, causing the rate of growth of output to exceed the weighted average of the rates of growth of total inputs.

Entrepreneurship. This historical fact points to an element that has received little attention so far: the influence of entrepreneurship. If the allocation of resources changes during the course of growth and development, it does so under the leadership of an entrepreneurial class. The quality of entrepreneurship is seen by many economists as an important explanation of differences in the rate of technical progress between countries. Decisions must be made somewhere along the line as to whether a new product or process will be introduced. It has been argued that two countries undertaking similar amounts of investment leading to more or less identical rates of growth in the capital stock will not necessarily show the same rate of technical progress. In one country entrepreneurs may be undertaking enterprise investment that has as its aim the introduction of the most advanced types of production techniques, those that will lead to a rapid growth of labour productivity. In the other, because of hesitation or ignorance, the investment program may lead only to marginal changes in productive processes; the resulting growth in labour productivity and GNP will be small. For example, much has been said since World War II about the more aggressive nature of German businessmen as compared to their English counterparts. The emphasis on the role of the entrepreneur in economic growth stems from the theoretical work of the economist Joseph A. Schumpeter, but many others have echoed it.

Arguments about the significance of capital investment

The play of influences. Much thinking assumes, then, that contributions to output from growth of individual inputs are independent of one another. This assumption allows many growth theorists to conclude that capital investment is relatively unimportant as a growth factor. If there is interaction between the rates of growth of the different inputs, however, then it is possible to draw different conclusions. For example, over time there are likely to be improvements in the quality of capital goods. A machine that requires so much steel and so much labour to manufacture may be twice as productive as an older machine that required the same amount of raw materials and labour in its manufacture. Thus the rate of growth of technical progress and the rate of growth of the capital stock measured in natural units interact. Furthermore, the interaction between technical progress and capital formation is not necessarily in one direction. New knowledge opens up new production possibilities and gives rise to potential increases in technical progress and profits. Or the better educated the labour force, the more adaptable is it likely to be and therefore the better able to cope with new production techniques. At the same time, the higher the rate of growth of capital, the higher will be the growth of incomes and therefore the demand for education. The fact that much of the overall growth of technical progress stems from the transfer of resources and the positive association between the rate of transfer of resources and the rate of growth of the capital stock is another example of interdependence or complementarity between the growth of the inputs. But, again, capital investment undertaken to develop new lines of production will also be dependent on technological progress going on in those areas.

Conventional marginal productivity doctrine argues that as an input such as capital rises relative to labour, the additional output or marginal product that can be attributed to this extra amount of capital will be less than what a unit of capital on the average had been producing before. Marginal productivity doctrine also assumes that each unit of capital is identical with the next. This assumption is the basis for the argument that as more units of capital are utilized in production with a given amount of labour, it will push down the former's marginal product. There is the possibility, however, that additional units of capital may enhance the productivity of existing units: for example, an increase in the amount of capital resources devoted to the development of transportation and distribution may raise the productivity of capital employed, say, in manufacturing. The development of this kind of social overhead capital is certainly a prerequisite for a high return to capital in manufacturing, wholesaling, and retailing.

The analysis can be carried back one more step, to the basic determinants of growth. Economists ask why it is that capital, labour, or technical progress has grown more rapidly in one economy than in another or at one time than at another. Historically, the transition from a subsistence-level, underdeveloped state to a higher-level, developed one has been accompanied by a decline in the death rate followed by a decline in the birthrate. This naturally has the effect of first speeding up the rate of growth of the population and labour force and then reducing it as birthrates fall. Migration can greatly alter this picture, often in unpredictable ways. In the United States, for example, the rate of growth of the population and labour force during the 19th and early 20th centuries was higher than in most other developed countries, mainly because of high rates of immigration. From 1840 to 1930, the native-born U.S. population increased about 600 percent, while the number of those of foreign birth increased 1,300 percent.

The role of government. The differences in rates of growth are often attributed to two factors: government and entrepreneurship. The two are not mutually exclusive. In the early stages of sustained growth, government has often provided the incentives for entrepreneurship to take hold. In some economies the development of transportation, power, and other utilities has been carried out by the government. In others the government has offered financial inducements and subsidies. The land given U.S. railroad developers in the second half of the 19th century is a notable example of the latter. Another important role governments have played in the early stages is to help establish the sort of capital and money markets in which lenders could have confidence. Without financial intermediaries acting as brokers between lenders and business borrowers, it is difficult to envisage economic growth taking place on a sustained and rapid basis.

Government measures in the 19th century

In the 19th century, most liberal thinkers held that the main role for government in a developed capitalist system was that of a policeman: to preserve law and order, uphold the sanctity of private property, and give business as much freedom as possible. The depression of the 1930s persuaded many that a laissez-faire system did not automatically provide the necessary incentives to the innovation and risk bearing essential for economic growth. This led to a good deal of writing on the role that governments might play in stimulating growth. Economists have argued that, at the very least, governments can undertake to prevent serious and prolonged recessions. Only in this way can a general business psychology be developed that assumes growth to be the natural course of things, so that investment programs will pay off.

Growth theorists since World War II have gone further, arguing that it is not enough simply to achieve full employment periodically. Some maintain that it is necessary to maintain full employment over an extended period of time if high growth is to result. This argument relates to the earlier point that two economies may experience the same rate of growth of capital but that overall growth and technical progress will proceed at a much more rapid rate in one than in the other because of differences in the quality of new capital goods produced. The term enterprise investment has been used to describe the kind of capital formation that involves innovations and that by building ahead of demand generates rapid rates of growth of productivity or technical progress. But to get

such growth, it has been argued, an economy must be run "flat out," at full speed. While this has been subject to some dispute, there is a fairly general consensus that growth will be faster when unemployment fluctuates within a narrow range and at low levels.

Government intervention in expenditure

A variation on this argument is the question of how a government may intervene to determine the distribution of output between those types of expenditure that contribute to growth and those that lead to the immediate satisfaction of consumer demand. Here the choice lies between business investment, research, and education on the one hand and consumption on the other. The larger the first three, the more rapid will be the rate of growth. Governments giving a high priority to growth have various means at their disposal for influencing it. Consumption can and has been constrained through increases in income tax rates. The same is true of other tax rates such as the property tax—the chief revenue source for primary and secondary education in the United States. Tax credit for research and development expenditures is a common method for encouraging business outlays that may lead to innovations. The same method has been used to stimulate business investment outlays. "Easy money" policies on the part of the central bank, whereby the cost of borrowed funds and their availability are indirectly regulated in such a way as to encourage business borrowing, may lead to higher levels of real investment.

The true cost of stimulating growth will always be a temporary cut in current consumption. Only in the future can the economic benefits of the higher investment be realized. By the same token, current consumption can always be enlarged by a neglect of the future. It is even possible for current production to be so biassed toward the satisfaction of immediate needs that the productive capacity of an economy slowly declines as capital goods are not replaced. Between the extremes of total neglect of future generations and the paring down of current consumption to a bare subsistence minimum lie an infinite number of possibilities.

THE SOCIAL COST OF GROWTH

The belief that governments should have a large say in choosing the "right" rate of growth has also led some writers to challenge the social and economic value of economic growth in an advanced industrial society. They attribute to growth such undesirable side effects of industrialization as traffic congestion, the increasing pollution of air and water, the despoiling of the landscape, and a general decline in man's ability to enjoy the "real" amenities of life. As has been seen, growth is really a transformation whereby certain industries experience a rise in importance followed by an eventual decline as the market for their output becomes relatively saturated. Demand, relatively speaking, moves on to other types of industries and products. All of this naturally implies a reallocation of resources over time. The faster these resources move, other things being equal, the more rapidly can growth and transformation proceed. The argument can be recast in terms of this transformation. A slower rate of growth in per capita consumption will slow down the rate of transfer of resources, but it may also result in a more livable environment. The rate of growth of individual welfare may even be increased. Some argue that in a growth-oriented society wants are created faster than the industrial machine can satisfy them, so that people are more dissatisfied and insecure than they would be if growth were not given such a high value. It is held by some critics that, in modern industrial society, consumption exists for the sake of justifying production rather than production being carried out to satisfy consumer desires. These arguments are a powerful challenge to those who see growth as the most important economic goal of a modern society.

THEORIES OF GROWTH

In discussing theories of growth a distinction must be made between theories designed to explain growth (or the lack of growth) in countries that are already developed and those concerned with countries trapped in circumstances of poverty. Most of what follows will be confined to the former.

The savings–investment equation

As the British economist John Maynard Keynes pointed out in the 1930s, saving and investment are not usually done by the same persons. The desire to save does not necessarily generate investment. If savers attempt to save a larger share of their income than before (thereby consuming less) and if this is not matched by an equal increase in the desire of others to invest, total spending will decline. A natural reaction on the part of business will be to cut back on production, thereby reducing incomes earned in production. The final effect may be a cumulative movement downward as total demand becomes insufficient to employ all of the labour force. This break in the circular flow of income and expenditure suggests the possibility of a capitalist economy alternately experiencing periods of prolonged and severe unemployment (when desired savings at full employment exceed what the economy wishes to invest at full employment) and periods of serious inflation (when the inequality is reversed). This situation has not been the case historically. Since 1900 the unemployment rate (on an annual basis) has seldom remained outside the range of 3–6 percent for more than a year in the United States, if the war years and the Great Depression are omitted. While inflation has been serious at times, especially during wars or immediately after, it has not been of the prolonged, runaway type. For the most part growth has been a fairly regular process. The same can be said for other developed economies. In the following discussion, some attention will be paid to the ways in which the various theories of growth account for this important historical fact.

Modern growth theory can be said to have started with Schumpeter. Unlike most Keynesian or pre-Keynesian theorists, Schumpeter laid primary stress on the role of the entrepreneur, or businessman. It was the quality of his performance that determined whether capital would grow rapidly or slowly and whether this growth would involve innovation and change—*i.e.*, the development of new products and new productive techniques. Differences in growth rates between countries and between different periods in any one country could largely be traced to the quality of entrepreneurship. The latter in turn reflected certain historical and cultural values carried by the business class. Schumpeter also attributed much of the growth of technical progress and of the supply of labour to the entrepreneur. Thus, in more modern terminology, Schumpeter's explanation of why demand and supply have grown more or less at the same rate would be that supply adjusted to demand while demand in turn reflected the activities and investments of the entrepreneur.

Schumpeter believed that capitalism by its very success "sows the seeds of its own destruction." The American economist Alvin H. Hansen argued in the late 1930s that capitalism was in trouble in the U.S. for other reasons. According to Hansen, the closing of the geographic frontier, the decline in the rate of population growth, and the capital-saving character of recent innovations had all worked to increase the likelihood of stagnation by reducing the need for investment. The savings available in a mature economy would tend to exceed the amount that the economy would want to invest (at levels of full employment) and by increasingly larger amounts as time went on. This condition naturally would lead to increasing rates of unemployment as the discrepancy between demand and potential output widened. Hansen's views were very much coloured by the 1930s. The record since World War II has done much to overcome the pessimism generated by the great depression. As has already been observed, with the exception of the 1930s, most Western economies have not experienced prolonged and severe recessions. Demand and supply have grown more or less together in most capitalist countries, whether due to government policy or not.

The role of investment. In Keynes's *General Theory* investment played a key role in that it was the most important factor governing the level of spending in an econ-

omy, despite the fact that it typically was only one-fifth to one-sixth of total spending. This paradox can be understood in terms of a concept also developed in the 1930s, the multiplier. The multiplier was the amount by which a change in investment would be multiplied in achieving its final effect on incomes or expenditures. If, for example, investment increases by $10, the extra $10 of expenditures will generate, assuming unemployed resources, an extra $10 of production and subsequently incomes in the form of wages and profit. This increase, however, is hardly the end of the matter since most of the additional incomes earned will be respent on consumer goods. If nine-tenths of any change in income are spent on consumer goods and one-tenth is saved, consumption will increase by $9. But again, one person's expenditures are another person's income, so that incomes now rise by $9 of which $8.1 is respent on consumer goods. The process continues until expenditures, incomes, and production have increased by $100, of which $90 is consumption and $10 the original change in investment. In this case the multiplier is ten.

The negative aspects of investment

But investment may be a source of instability if it is not maintained at a rate sufficient to stimulate demand for the production it is creating. Is there any guarantee that supply or productive capacity will grow at the same rate as demand so that neither excess capacity nor excess demand results? The British economist R.F. Harrod and the American economist E.D. Domar put this question in a very simple mathematical form. In their equations, the rate of growth of supply (*i.e.*, the production function as defined above) is equal to the rate of growth of capital stock. Through investment this capital stock is augmented. The rate of growth of demand depends upon the rate of growth of investment or, more correctly, upon the rate of growth of nonconsumption expenditures. Thus investment affects both demand and supply. But the Harrod–Domar analysis still did not answer the question of what kept the system from becoming increasingly unstable.

Demand and supply. Much contemporary growth theory can be viewed as an attempt to develop a theoretical model that would bring the rate of growth of demand and the rate of growth of supply into line, since a model implying that capitalist systems are inherently unstable would not correspond to the historical facts. Models of growth may be classified according to whether they emphasize adjustments in demand or adjustments in supply, supply-determined models or demand-determined models. One of the better known examples of the supply determined model was developed by the British economist J.R. Hicks. Hicks assumed that the spending propensities of consumers and investors were such as to cause demand to grow at a rate in excess of the rate of growth of maximum output. This assumption meant that during any "boom" the economy would eventually run into a "ceiling" that, while also moving upward, was moving less rapidly than demand. The long-run rate of growth of the economy would be determined by the rate of ascent of the ceiling, which in turn would depend upon supply factors such as the rate of growth of the labour force and the rate of growth of technical progress or productivity. If for some reason these were to grow more rapidly, then output would also grow more rapidly as demand adjusted upward to the more rapid growth of supply.

An example of a demand-determined model of growth is one developed by the American economist J.S. Duesenberry. In the Duesenberry model, spending propensities of consumers and investors are such as to generate steady growth in demand. Assume that instead of spending nine-tenths of any change in income on consumer goods, as in the multiplier example above, they choose to spend 0.95. This increase will cause the rate of growth of demand to increase. The question is whether it will also cause the rate of growth of production to increase or whether it will merely result in price increases. If productivity or technical progress responds to a higher rate of growth of demand, as Duesenberry assumes, then production can grow more rapidly. Although in both the Hicks and Duesenberry models demand and supply grow at the same rate, the adjustment mechanisms are entirely different. In the Duesenberry model supply adjusts to demand; in the Hicks model demand adjusts to supply.

Other models of growth also illustrate this distinction between demand-determined and supply-determined growth. The British economist N. Kaldor assumes that there is a mechanism at work generating full employment. Simply stated, in his model an inadequate rate of investment will be offset by shifts in the distribution of income between profits and wages, which will cause consumption to change in a compensating manner so that overall demand is unchanged. While there are important differences between the Hicks and Kaldor models, both can be described as models of supply-determined growth.

Another model of supply-determined growth is that implicit in the traditional neoclassical analysis. The mechanism that adjusts demand to growing supply is the price mechanism, or Adam Smith's "invisible hand" of the market. This type of model assumes a world devoid of monopoly and uncertainty, in which the markets for capital goods and labour are free to adjust quickly so that "markets are always cleared" in the very short run.

Government intervention in demand and supply

A final example of a model of growth that illustrates the problem of adjustment between supply and demand is to be found in the work of the Dutch economist Jan Tinbergen and his followers. In contrast to neoclassical growth models where the market brings about an adjustment of demand to supply, the "target-instrument" models of Tinbergen assume that the government (as in the Netherlands and other European countries) undertakes to regulate demand and supply in an effort to achieve certain targets such as full employment or a predetermined rate of growth. For example, economists are expected to provide the fiscal authorities with a model that approximates the working of the economy and that indicates what will happen if the government, say, does not change its tax and spending programs in the coming period. These forecasts are appraised in terms of what the authorities consider desirable as a matter of social and economic policy. If it appears that unemployment will be too high and the rate of growth too low, the authorities take countermeasures. The government may, for example, cut taxes on corporate profits in order to stimulate investment. If investment is excessive and there is danger of inflation, the government may take other measures to reduce aggregate demand such as cutting its expenditures. This type of planning procedure has been tried with varying degrees of success. Sweden and the Netherlands are outstanding examples of attempts to offset fluctuations in private spending so as to realize full employment and growth. It should be noted that these models do not fit neatly into the demand-determined or supply-determined classification. In the example just given, both the rate of growth of demand and the rate of growth of supply are effectively determined by the fiscal authorities.

Foreign trade. Little has been said about foreign trade. Yet growth in most economies is very much dependent upon imports and the ability to export in order to pay for imports. The fact that some economies recovered relatively quickly from World War II and grew much more rapidly in the postwar period than others has stimulated a great deal of comparative analysis in growth theory. The exceptionally high growth rates in Japan and Germany compared to the general sluggishness of the British economy are related to foreign trade. Economists have pointed to the periodic balance of payments crises experienced by the British and the lack of such crises in Germany. During a boom, as incomes rise the demand for imports will rise also as a natural feature of prosperity. But if exports do not also rise at the same time, the authorities may be forced to take fiscal or monetary countermeasures and slow down the economy in an effort to bring imports and exports back into balance. Or exports may fail to grow sufficiently because labour costs are rising very rapidly and pushing up prices of exports faster than in competing countries.

A policy of encouraging growth has the effect of keeping the demand for imports high and making labour markets tight, thereby tending to push up money wage rates. At the same time, such a policy also tends to encourage innovations and investment projects that are very productive, particularly if the demand pressures are sustained. A "stop" policy naturally has just the opposite effects, both good and bad from the point of view of a country's balance of payments. The question is which policy will in the long run result in less rapidly rising costs and prices. Many writers have argued that if demand pressures are maintained the response or adjustment of productivity and therefore of supply to these pressures will be such that the country will soon find itself in a more competitive position. Running an economy "flat out," however, is likely to cause a short-run balance of payments crisis and lead to devaluation of currency.

Mathematical growth theories. In addition to the theories discussed above, a large body of literature has developed involving mathematical models. Because this field of analysis is so technical, only a general picture of the kinds of problems and questions discussed can be given. First, a set of equations is drawn up describing what the model builder feels are the important relations between economic variables such as output, capital, investment, and consumption. These equations must relate economic variables to one another at different points in time: for example, output last year determines consumption this year, which in turn helps to determine output this year and therefore consumption and output next year. It is possible to work out the movements of the variables over as long a period as desired. At the centre of much of this analysis is the concept of a steady-state rate of growth: one in which all the economic variables contained in the set of equations grow at the same constant rate equal to the growth of the labour force.

A related class of studies attempts to take account of the welfare of workers and consumers in the maximization of growth. These "optimal growth" models seek to maximize consumer satisfaction over time. In a model such as this the solution will not be the highest possible growth rate but one that will maximize the welfare of consumers. The importance of such models for planners would seem to depend on the realism of their assumptions as to consumer desires and technology.

The role of money in growth

Some mention of the role of money in growth is in order, although the field of monetary theory is too complex to be summarized here. Some theorists, such as the American economist Milton Friedman, advocate that in the interests of stability—and, by implication, growth—the monetary authorities should follow a simple rule in managing the nation's money supply. The supply of money has an important influence on the behaviour of an economy, it is argued, but this influence is felt only after some time. Consequently if the authorities try to control the economy through variations in the money supply, they may actually make matters worse, since the conditions they are responding to may have changed by the time their actions take effect. Friedman's prescription is to minimize the actions of the authorities; he would have the central bank confine its monetary intervention to assuring a steadily growing money supply.

At a much more abstract level, money has been introduced into mathematical growth models. These models treat money as an asset that has a certain return for one who holds it; for example, the return is positive if the price level falls and negative when the price level rises. An alternative to holding money in these models is to hold physical capital that has a return from its use in production. Changes in the money supply, through their effect on the price level, affect people's decisions to hold their wealth as money or as physical capital. The result will be changes in the rate of capital formation (investment), which in turn will affect the growth rate.

Model building and theorizing about growth has been proceeding on various levels of abstraction. Some of the work has to be considered of little practical value, in the sense that its explanatory value is negligible. Such studies, however, may stimulate other work that is helpful in an understanding of the growth process. Some models, while realistic, are not applicable to all economies. Thus a model that neglects international trade is of little use to a European economist trying to understand the more basic causes of differences in growth rates between countries. But model building will continue to be one of the more active fields in the study of economic growth.

Economic History Since 1500

This article covers the economic history of the industrialized world. It is divided into the following sections:

I. Economic development of the modern world before the Industrial Revolution
- The decline of the feudal system and the growth of commerce
- The rise of the entrepreneur and the labour market
- Capitalism and the Protestant ethic
- The voyages of discovery and the price revolution
- Nationalism and mercantilism
- Empire and the world economy
- The significance of early economic developments

II. The Industrial Revolution
- The Industrial Revolution in Britain
- Continental Europe
- Social consequences of the Industrial Revolution
- The course of industrialization, 1870–1914

III. Economic developments since World War I
- The aftermath of World War I
- The Great Depression
- The industrialization of the Soviet Union
- World War II and after in the industrialized nations
- The developing nations

I. Economic development of the modern world before the Industrial Revolution

THE DECLINE OF THE FEUDAL SYSTEM AND THE GROWTH OF COMMERCE

No sharp divide separates the economic life of the Middle Ages from that of the early modern world. But, in

retrospect, much of the 15th century in Europe displayed the symptoms of the decay of an old order. Population in many places was smaller than a century and a half earlier, and prices had generally declined. These changes were reflected in both the rural and the urban economies.

In those areas of Europe where a manorial type of agrarian economy existed, the links between lord and peasant were becoming either looser or tighter. The customary tenant, who held his land in return for services performed on the lord's demesne (estate), was in some places becoming a rent-paying tenant, even (in England, for example) turning into a tenant-farmer exploiting the disintegrating demesne lands. In eastern Europe, beyond the Elbe River, however, the reverse was happening. There the great lords were tightening their hold on the peasants' lands. Peasant was becoming serf and serf becoming slave. Thus, the old balance within feudalism was being tipped one way or the other.

Trade and industry were similarly changing in character. The traditional organization of the city crafts into guilds was breaking up, and companies of merchants, on the one hand, and of journeymen, on the other, began to assume responsibility for the specialized functions of their members. Germany in the 15th century suffered continual urban conflicts as the guilds struggled among themselves for power and privilege, and everywhere in Europe guild control over industry receded in the face of an almost universal tendency for individual urban capitalists, or groups of capitalists, to assume control, through mercantile capital, over the entire process of manufacture in textiles, leatherworking, mining, and the metallurgical industry.

The Hanseatic League

The structure and direction of international trade was also changing. The cities of the Hanseatic League (a league of towns in northern Germany that banded together in the latter part of the Middle Ages to protect and develop their foreign trade), which had long been dominant economically and politically in northeast Europe, had fallen into fratricidal war. Their conflict with the Scandinavian powers in the 16th century virtually brought about their final collapse, and this, in turn, had a depressing effect on those important sectors of economic life in such cities as Bruges, in Flanders, and London, which had been closely dependent upon the League. North Italy, which had long been the most advanced economic area, was also under severe pressure. The four great cities of Venice, Milan, Genoa, and Florence, which had dominated the life of the Po Valley, the Tuscan Plain, and large areas of the Mediterranean, were now faced with new competition and problems. The great voyages of discovery had opened up by 1500 an alternative route to the Orient around the southern tip of Africa, thus threatening the overland spice trade of Venice, although the effects of this were slow to be felt and their incidence was only intermittent until well into the 17th century. More serious was a slow but steady shift of the centre of European economic activity away from the Mediterranean toward the Low Countries. North Italy still remained an advanced area of wool and silk production and glass and porcelain manufacture and a centre for the great merchants in spices, grain, alum, wine, sugar, and other exotic products. Venice and Genoa also showed a sinuous flexibility in meeting the competition of the Portuguese spice traders. But the 16th century was to be the age of Antwerp, in the Netherlands, rather than of Venice, and its successor in the 17th century was a north Netherlands economy dominating the world from the great entrepôt of Amsterdam.

The influence of population on economic growth. Modern research has established almost beyond doubt that behind the new impetus stimulating the developments of the 16th century lies the reversal of the population decline of the 15th century. In its last decades there began the steady growth that may be detected everywhere in Europe throughout the 16th century and seems to level off only by the middle of the 17th century. By 1600 Europe had a population approaching about 100,000,000. Of these, perhaps one-half lived in countries bordering the Mediterranean. This probably represented between 20 and 30 percent more than in 1450 and was to increase by another 30 or 40 percent by the middle of the 18th century. Most countries shared in the 16th-century increase, especially Italy, England, the Low Countries, and France. By 1700 it was apparent that the increase was slowing down and even declining in some countries. The population of Germany was severely cut by the disease and poverty that followed the Thirty Years' War, and the population of Spain may have dropped from 8,000,000 to 6,000,000 in the 17th century. But, in general, the European economy reflected the buoyant increases in areas such as England and the Low Countries, especially in the area that today constitutes The Netherlands, where the population virtually doubled between 1500 and 1650.

The reasons for this increase have been much debated. Population movement must depend upon the balance between the birth rate and the death rate. Mortality, especially through the bubonic plague, which attacked everywhere sporadically, was extraordinarily high, but the incidence of plague seems to have slackened in the 16th century, and it finally disappeared from western Europe by the turn of the 17th century. The declining virulence of the plague, coupled with the removal or relaxation of restraints on early marriage, thereby facilitated a rise in the birth rate. This, in turn, was followed by urban growth, the decline of guild and apprenticeship laws, and the increase of individual farm holdings.

Bubonic plague

If the origins of this demographic revolution are obscure, its consequences, on the contrary, are quite clear. Everywhere it generated an increased demand for food and the necessities of life. This increase, in turn, not only became a major factor in the great inflation of the 16th century but also brought into being a new class of entrepreneurs, or middlemen, who seized the opportunities for trade and profit that it offered.

The rise of Antwerp and Amsterdam. The rise of Antwerp in the first half of the 16th century to the position of the leading entrepôt in the world vividly reflected this new movement. From about 15,000 in the mid-15th century, its population had passed the 100,000 mark by the middle of the 16th century. Antwerp was supreme during the half century from 1520 to 1576 as the warehouse and market of world trade. It not only absorbed the industrial production of its own textile centres, such as Ghent, Lille, and Ypres, but it also formed a sophisticated centre for merchant adventurers, bankers, and speculators from all over Europe. The merchant adventurers from England concentrated the largest part of the export trade in English cloth in Antwerp. The south German bankers (Fuggers, Welsers, Paumgartners) traded in cloth, spices, and metals with Germany and Italy. Italian merchants sold the produce of north Italy into northern Europe through the Antwerp market, while agents for the kings of Portugal sold great cargoes of Indian pepper, nutmeg, cinnamon, and cloves. Ships from Cádiz brought in cargoes of Spanish wool and wine and, later, of silver, to pay for purchases of cloth, iron, coal, and glass or to repay the financiers who fed, armed, and clothed the Spanish and Imperial armies.

Antwerp was not only a centre of trade but also of finance, where the European governments borrowed on a vast scale, especially for war purposes. Queen Elizabeth I's agent, Sir Thomas Gresham, acted as royal factor from 1553 to 1574, with the duties of raising long- and short-term loans for the Queen on the Antwerp money market. Most other kings and princes did the same. Among the great banking houses were those originating from south Germany, of whom the Fuggers were the greatest. Starting as weavers and manufacturers of cheap textiles in Augsburg in the late 14th century, the Fuggers had risen to be a world trading and banking house. They were now among the leading exponents of the arts of public finance, farming the revenues of the emperor and advancing capital against concessions of silver, copper, and iron mines in the Habsburg territories. They were thus the greatest subsidizers of European war and dynasticism, lending 500,000 florins to secure the election of Charles V as Holy Roman Emperor in 1519.

The Fugger banking houses

The sack of Antwerp in 1576 by Spanish troops added severely to the economic problems that beset Antwerp increasingly after the 1550s. Its capture by Alessandro Farnese, duke of Parma, in 1585 sealed its fate, for the Dutch blocked the approaches of the Scheldt River and virtually ended Antwerp's career as a world market for two and a half centuries.

The stream of refugees from the southern Netherlands began in the 1550s and continued for half a century but was at its peak in the 1570s and 1580s. Up to this time the northern Netherlands were much poorer than their southern neighbour, but, with the aid of the migrants, much wealth, enterprise, and skill was transferred across the great rivers from the vulnerable south to the more defensible north. Amsterdam, seceding from Spanish loyalty to the rebels in 1578, swiftly succeeded to the position lost by Antwerp. At Leiden immigrant merchants and textile workers from the area around Ypres launched a variety of woollen industries making the "new draperies." At Haarlem others set up bleaching centres that attracted great quantities of coarse linens from Germany. Other southern industries, such as silk weaving, glass blowing, paper making, sugar boiling, distilling, and printing, also moved to Amsterdam.

The growth of international trade. The great migration out of the southern Netherlands exported much talent and wealth also to London, Norwich, Colchester, and other English towns and cities, bringing the new textile skills and much mercantile and financial technique to England. But at this stage the Dutch republic was the greatest gainer, and between 1585 and 1620 Amsterdam became the centre of a world network of trade. This network was extended until it reached from the Baltic to the Mediterranean, from the British Isles deep into Germany, and throughout the 17th century it was increasingly linked to India and the East by the operations of the new Dutch East India Company (1602) and to America, the West Indies, and Brazil through the Dutch West India Company (1621). As a victualling station, the southern tip of Africa was settled with Dutch farmers, while Dutch slave traders built castles on the coast of West Africa. As merchants, financiers, shippers, and drainage engineers, the Dutch were as ubiquitous in the 17th century as were the Scots in the 19th.

Dutch East India Company

The Bank of Amsterdam (1609), the Loan Bank (1614), the Bourse (1609), the Marine Assurance Chamber (1598), and the Grain Bourse (1616) collectively formed the central machinery of an economy through which a large proportion of world trade passed. Except for the great herring fishery and the cloth industry of Leiden (the largest in the world), the Dutch were middlemen, carriers, and brokers rather than industrial producers, but their commercial skill, advanced financial techniques (including a fully developed stock exchange and company-share system), together with a low rate of interest, abundant capital, and a willingness to put it at risk overseas as well as at home, gave them a commanding position in the 17th-century world economy. The silver that represented the profit won in their trade with Spain was not hoarded but used to purchase goods from areas such as the East Indies and the Baltic, and these, in turn, were resold to the European nations, including Spain itself. Above all, the Dutch were the first to develop a purpose-built, oceangoing boat (the "flyboat"), which was unarmed and cheap to build and operate. With the cheap freight rates provided by the flyboat, the Dutch captured such great bulk trades as corn, timber, salt, and sugar.

Repression in the agricultural sector. The demand for Baltic grain, arising from the general increase in European population, which had everywhere turned food surpluses into deficits, was the greatest commercial opportunity seized by the Dutch. Throughout the 17th century a procession of Dutch flyboats passed through the Danish Sound carrying cargoes of grain from the southern shores of the Baltic Sea. To supply this demand, the large-scale farming system, based everywhere on the process that came to be known as *Bauernlegen* ("repressing the peasants"), spread throughout central and eastern Europe. Throughout eastern Germany, Austria, Hungary, Bohemia, Poland, and Russia, a process of increasing serfdom set in, culminating by the mid-18th century in Russia, where peasants were brought and sold like cattle. The rural population repressed thus had actually enjoyed more freedom than their counterparts in medieval western Europe, but now the great demesnes grew as prices rose and corn exports increased. Germans and Slavs were lumped together in virtual slavery in Mecklenburg and Pomerania. In Bohemia the German Catholic conquerors imposed brutal terms on the Czech heretic population. Conditions did not improve until the early 18th century in central Europe, and in Russia serfdom survived until the 19th century. Everywhere, the system produced economic stagnation, depriving trade and industry of capital and labour.

Increase in serfdom

Agriculture in western Europe. The agrarian system around the Mediterranean was less harsh, but, even there, the scarcity of fertile land, such as the Po Valley, the Roman Campagna, and the Tuscan Plain, gave rise to severe social problems. In Italy the limited areas of cultivable land demanded heavy capital investment, either for irrigation or drainage. The nobility or the municipality that provided the capital and carried out such works naturally demanded a lion's share of the profit. Hence the bitter comment of a 16th-century writer: "The plains belong to the lord, the mountains belong to the peasant."

Yet, sun, bread, and wine were not lacking. Rice and corn were among the crops that the enterprise of Venetian and Milanese landowners added to the Mediterranean scene. Italy therefore stood halfway between the stagnation of the East and the modest progress of the West, where some increase in productivity was discernible. England, northern France, and western Germany formed an area quite different from that in the East. In the West, lords tended to become *rentiers*. Peasants redeemed their quit rents, achieved the status of something like owner-occupiers in France, or became tenant farmers in England or declined into landless labourers. Providence offered a variety of fates; but all were free men, and the society of which they were a part could move on to a commercial or industrial future, exchanging feudalism for a reformed monarchy or constitutionalism.

Agricultural productivity. The consequences of the different agrarian economic systems and social structures adopted east and west of the Elbe were very marked. The social organization and capital investment in Western countries, together with modest improvements in plows, implements, drainage, manure, and enclosure, resulted in higher yields and a perceptible increase in productivity, especially by the second half of the 18th century. In east Europe, serfdom and stagnation produced an actual decline in productivity from 1650 onward.

THE RISE OF THE ENTREPRENEUR AND THE LABOUR MARKET

The 16th century was an age of industrial expansion that in some places, such as Britain, continued into the second half of the 17th century. Elsewhere, it levelled off by the middle of the 17th century, as, for example, in Holland. In Germany, progress was halted by the Thirty Years' War. This age of expansion resulted from many related causes: price inflation, population growth, the demands of governments in the new centralized states for war and court luxury (France, Spain, Sweden, and Britain).

Increased demand led to greater production. Since industry in this period most often meant production of consumer necessities, it relied for its raw materials everywhere on the countryside. Agriculture produced the wool, flax, and leather that formed the basis of the clothing industries supplying rich and poor alike. It also provided the corn for the baker and barley for the brewer. Brewing was one of the few great capitalist industries employing intensive capital equipment in the centuries before the Industrial Revolution, and the great brewers of London and the large cities of Holland and Germany were among the largest contemporary capitalists. Vineyards supplied the wine industries of France, Italy, Spain, and Germany. In addition, princes and noble landowners

Brewing

owned the rights over minerals that lay under the soil of their estates. They, therefore, exploited their mines and the deposits or (more commonly) sold concessions to urban capitalists to do it for them.

Role of the entrepreneurs. Increasing demand raised the incomes not only of urban entrepreneurs, who seized the opportunities offered by new demands, but also of those noblemen and gentry who, by luck or shrewdness, extracted opportunity from their estates. Throughout the enormously varied mining and metallurgical enterprises of western and eastern Europe (including coal, iron, tin, silver, copper, lead, and alum) and the glass and ceramics, chemical, textile, paper-making, and many other industries, there is clear evidence of the increasing role played by the capitalist organizers. These consisted mainly of city merchants whose capital was increasingly required to finance growing output and new technology. Such changes are most clearly reflected in the growth of these merchants in cities like London; Antwerp; Amsterdam; Cologne, Augsburg, and Nürnberg (Germany); Lyons (France); and, to a lesser extent, in smaller cities such as Norwich (England), Leiden, Haarlem, Hamburg, Barcelona, and Milan. In the Dutch cities they formed after a generation or two a merchant elite influencing the policies of the state at home and abroad. The philosophy of the Dutch republic is most vividly and accurately represented in *Het Interest van Holland* (1662; *Political Maxims of the State of Holland*), allegedly by Johan de Witt. In reality, this was the work of a great Leiden textile entrepreneur, Pieter de la Court. Its theme was the need for a context of peace, neutrality, tolerance, and economic freedom in which trade and industry could flourish. In London, a representative figure earlier in the century was Alderman Sir William Cokayne, confidant of the King and the contriver of 12 great commercial and industrial schemes, including a project for modernizing and expanding English textile manufacture. This came hopelessly to grief, however, and precipitated one of the greatest crises of the age by 1618. Another entrepreneur was Sir Hugh Myddleton, brother of a lord mayor of London, a mining contractor of Welsh origin with great enterprises in Wales and founder of the New River Company, which between 1609 and 1620 dug a freshwater channel 40 miles (60 kilometres) long to supply London with drinking water. In Europe the south German bankers performed similar functions as financiers and organizers for German industry. Dutch capitalists originating from Liège similarly exploited the iron and copper resources of Sweden. The Trips and de Geers were the most prominent of a large group of Netherlanders who settled in Scandinavia as agents of the monarchy to develop mining and metallurgy.

Early industrial schemes in London

Use of capital. The accumulated wealth of these new merchant princes was either saved and loaned as capital to borrowers, including the state, traders, and industrialists, or spent on personal consumption. In England a good deal of their wealth was spent on social advancement. Cokayne, for example, succeeded in getting all his daughters married to peers. Great merchants commonly moved out of the city and bought country estates for themselves in the counties surrounding London. Dutch merchants, though tending to remain in trade, also built themselves country palaces on the Vecht River near Amsterdam, just as Venetian merchants built great mansions along the Brenta River. Both invested capital in the countryside, purchasing farms and undertaking drainage and general improvement schemes. In the middle of the 17th century, Amsterdam capitalists financed and implemented the drainage of great areas of the English Fenland under the eye of the great Brabant engineer Cornelius Vermuyden.

Rise of the landowner-entrepreneur. Such enterprises were not entirely limited to the urban merchant. Everywhere in Europe, landowners joined in exploiting their own mineral deposits, such as the Lowther family in northwest England and the Dudleys in the English Midlands. At Stolberg in Germany, the counts encouraged mining and iron working on their estates, while Duke Julius did much to organize and modernize mining in the Ober Harz. One of the most famous woollen mills in central Europe was that of Count Waldstein at Oberleutensdorf. Many other nobles used the forced labour of peasants to develop textile production in Bohemia and Moravia. Others, in Silesia and Bohemia, exploited clay deposits on their estates to develop famous porcelain manufactures. Many a princely palace had a *Porzellan-zimmer* ("porcelain room") exhibiting products from the estate. Especially in England, but in many other countries also, there was intermarriage between members of these commercially oriented noble families and their aspiring bourgeois partners.

Technological innovations and improvements. The early modern period was not an age of revolutionary invention, but industrial expansion in some cases led to a number of improvements, mostly of an empirical kind. In mining, galleries and shafts were improved. Hoists brought up the ore and water. As early as 1550, in Bohemia, pumps worked by water power made possible shafts sunk to a depth of 1,300 feet (400 metres). Waterwheels were used to drive hammer forges and rolling mills. New methods of making brass and copper and lead alloy were discovered. Blast furnaces replaced open hearths. Coke was substituted for charcoal by 1700 to smelt lead, tin, and copper ores. Later, Shropshire ironmasters smelted iron similarly. In 1712, in England, Thomas Newcomen's newly invented steam engines were installed in Staffordshire mines to pump out surplus water. In the Netherlands windmills were improved and used for sawing timber. Everywhere textile industries developed improved equipment: fulling mills were driven by water; the Dutch at Leiden developed a multiple ribbon loom that was borrowed for English use; Haarlem improved techniques of bleaching linen in the early 18th century, substituting sulfuric acid for lactic acid; William Lee, an Englishman, had invented his frame knitting machine in 1589. In spite of opposition, mechanization slowly established itself in the succeeding centuries.

Use of steam engines and windmills

Need for commercial capital. These technological improvements that accompanied and made possible economic expansion had one thing in common: they cost capital; and these higher costs, mainly for working capital but also for fixed plants, equipment, tools, and buildings, explain the need for a new organization in industry and for a new type of entrepreneur to carry it on. Probably the most highly capitalized industry of all was brewing. By the end of the 16th century, the great London brewers, many of them of Dutch or German extraction, were producing beer in breweries that already bore a resemblance to a modern plant. To a lesser extent, this was also true of the great glassworks of London and the English Midlands. A late 16th-century Leipzig merchant of great wealth, Henry Cramer, had a textile factory, representing a large capital outlay, that included fulling mills, weaving sheds, a dye plant, and a complete residential area for the workers. In the Swedish iron and copper industries, capital was provided by the so-called *Brukspatroner* (proprietor), who provided the necessary credit. In England, the Netherlands, and in a rather less sophisticated manner in many centres of France, Germany, Switzerland, and Bohemia, the complicated processes needed to produce a piece of cloth—wool sorting, carding or combing, spinning, weaving, fulling, dyeing, and finishing—were organized under the control of an urban capitalist. His function was to provide credit, pay wages, set the standards and designs to be followed, and, finally, to seek markets for the product.

The spread of industrial skills. Much transfer of skill was involved in the rise of the pre-Industrial Revolution's manufacturing system. The nurseries of technology can be identified as north Italy, the Low Countries, and south Germany. The 16th century had no blueprints, so both capital and technology were transmitted across national boundaries in the most highly personalized way. Colonies of Italian merchant bankers showed Antwerp and Bruges the secrets of double-entry bookkeeping, and Italians dominated the London money market until well into the 17th century. One-third of the population of Norwich in 1600 was of Dutch origin. There, as in London, Colches-

Italian merchant bankers

ter, and many manufacturing centres in the east of England and the Midlands, Dutch, Flemish, and Walloon experts were to be found in textiles, brewing, glassblowing, printing and bookbinding, horticulture, and many other occupations. The Höchstetters and other south Germans bought concessions to develop the Cumberland mines of England, as they did in Spain and throughout the territories of the Holy Roman emperor. The process continued after the expulsion of the Huguenots from France in 1685, when another wave of highly skilled merchants, artisans, and professional men flooded into the Dutch republic, England, and Prussia, where they reinforced strongly (and in some cases originated) the processes of invention and development in such industries as linen and silk manufacture, clock making, paper making, and hat making.

The guild system and the labour market. Thus, nobles, merchants, and, in some cases, middlemen rising from the ranks of industry itself, inaugurated major changes in the early modern economy throughout Europe. Rising demands caused industry to outrun the supply of skilled labour (journeymen) controlled by the urban guilds. Therefore, the unskilled and unorganized rural workers were recruited into a new industrial system known as the "putting-out" system, or domestic system. Under this system, the capital, material, and, sometimes, tools were supplied by a merchant capitalist, who coordinated the different processes necessary to manufacture and disposed of the final product on the market. The processes (*e.g.*, combing, spinning, weaving, etc.) were carried on by a widely dispersed system of cottage labour.

This did not mean the guilds immediately disappeared. In some places, for example London, they changed their nature as the great merchant companies gained control of the craft guilds through their control of capital and power over the market. In other English towns, after a long series of amalgamations, the guilds weakened and finally disappeared. There were few left by the end of the 17th century, and industry increasingly was left to its own devices. The Industrial Revolution of the 18th century was able to spread all the more rapidly because only the vestigial remains of the old guild system were left.

Survival of the guilds

In France the economic reorganizations of Jean-Baptiste Colbert revived the guild structure largely to create revenue for the crown, but even in France guild power was weakened by the rise of the putting-out system in rural areas and the grant of licenses and exemptions by the crown to individual entrepreneurs in return for a fee. In Spain guilds actually increased—a characteristic symptom of Spanish backwardness. Likewise, in Germany and central Europe, the roots of the guild system lay deep and withered away only slowly as the enlightened despots of the 18th century introduced liberty of craftsmanship. In Italy the situation varied. In Rome guilds grew in number, whereas in Tuscany local rulers subordinated guilds to themselves. In Venice their power seems to have constituted a major obstacle to technological progress, as in textiles, for example. In Poland, as in Germany and Spain, the guilds remained strong. In Russia, oddly enough, there was far less regimentation until Peter I the Great reinforced the guild system as part of his westernization program.

Broadly, guild power was undermined most easily in the great entrepôt ports of northwest Europe, where capital and enterprise were relatively plentiful and where sea and water transport enabled economic change to come about most easily. The putting-out system, which had existed here and there in the medieval economy, now spread to many branches of production—such as mining, metallurgy, textiles, printing, and paper making. These were all industries demanding capital for equipment, raw materials, the payment of a large labour force, and a knowledge of marketing. Under the new system, guild and free labour might be combined. Spinning and weaving could be done in the countryside; combing and dyeing, in the towns. Thus, hierarchies of workmen grew up appropriate to each individual industry. In the metal industry of Solingen (Germany) the swordsmith, the temperer, and the sword furbisher all took part in the manufacture of a sword, but only the last (the *Reider*) was allowed to market the product. The same tendency for the man who was nearest to the market to assume control of the industry can be seen throughout the Birmingham and Sheffield industries making small ironware.

Emergence of large-scale enterprises. Large-scale production was not typical of the 16th century. Here and there an entrepreneur might concentrate production under one roof, as the famous Tudor manufacturer Jack of Newbury (John Winchcombe) is said to have done, employing some 500 or 600 adults and another 400 or 500 children. Less spectacular instances were to be found in late medieval Florence and Flanders. In the late 17th and 18th centuries such examples multiplied, however, not only in western Europe but also in Bohemia and Russia. A sailcloth factory in Moscow employed over 1,000 workers in 1729. The van Robias textile factory at Abbeville, France, employed many thousands of workers living and working in a large compound. A Bavarian copper mine had 1,000 workers, and a Tirolean silver mine employed 4,000. Some English coal mines had between 500 and 1,000 workers in 1700. The Swedish ironworks at Stiernsund made a variety of ironware, using machinery and a large labour force, as did the London and Zaandam (Holland) shipyards and the Amsterdam, Hamburg, Liverpool, and Bristol (England) sugar refineries. The French Royal Plate Glass Company was employing 1,000 men in its workshops by the mid-18th century.

Such examples are exceptions to the general rule of a small unit of production, but they show how industry was everywhere trying to burst out of its medieval straightjacket and assume the forms of organization most appropriate to the relatively economic and efficient use of capital, labour, and technology. Transport problems tended to restrict industrial location to the places where raw materials, labour, fuel, and power were available, but, where goods could be carried by sea or canal or where workers could be attracted by better pay or conditions of life, industries grew up despite such locational restrictions. The desire of governments for greater income or more power likewise reinforced the tendency to set up industries in places not naturally suitable for them. Such examples were to be found in countries like Spain and Prussia, the 18th-century rulers of which emulated the models of Holland, France, and England.

Factors influencing industrial locations

Unemployment and social problems. This new economy, larger but more flexible than its predecessors, provided greater opportunities for employment but had greater social consequences. The estimates of Gregory King, the late 17th-century English social statistician, suggest that at least one-third of the English population was unemployed or underemployed. This phenomenon was remarked on increasingly by many observers in England, Spain, Germany, and Italy in the 17th and 18th centuries. It is a central theme of Sébastien Le Prestre de Vauban, the great French soldier turned social commentator, in his *Projet d'une dixme royale* (1707). It accounted for the attempt to gather the poor together in workhouses that were supposed to combine the functions of poor relief and larger national production. The movement was strongest in 18th-century England. Much criticized and only fitfully effective, it served as a model for the more efficient deployment of resources by private enterprise in factories that was to characterize the Industrial Revolution itself.

CAPITALISM AND THE PROTESTANT ETHIC

Historians and sociologists who have looked for the deeper motivations of 16th- and 17th-century capitalism have sometimes suggested that they may be found in Protestantism, especially Puritanism. In 1904 the German sociologist Max Weber put forward the proposition that the linked phenomena of capitalism, laissez-faire, and the justification of business as a "calling" all derived their warrant from these sources. In 1922, Richard Henry Tawney, an English economic historian, tried to substantiate this thesis. Calvinism, in particular, was designed for a rising bourgeois class that was "conscious of the contrast between its own standards and those of a

The Weberian thesis

laxer world, proud of its vocation as the standard-bearer of the economic virtues" (*Religion and the Rise of Capitalism* [1926]). In spite of counter-arguments, such theories have had wide influence. Yet, they now need to be re-examined in the light of the knowledge that has emerged since they were first put forward. This includes the realization that the growth of capitalism in the early modern world received many stimuli unknown to Weber and Tawney, including the growth of population. Some of the changes that were supposed to be specifically linked with north-European Protestantism also involved no real innovations, being rather a shift to northern Europe of economic practices well established in north Italy, the cradle of the modern European economic system.

Calvinism. Further examination of the basic theology of Martin Luther and John Calvin suggests a medieval rather than a modern economic outlook, containing little to appeal to a rising bourgeoisie. Even Calvin gave his views on problems of economic morality with caution and reluctance. They occupy only a few pages in his 20 volumes of printed works. What Calvin did was to remove the question of usury from the complex of theological pedantry and place it on a basis of simple morality. Reasonable interest on a loan was no more unjust than a reasonable rent for land, but extortionate interest squeezed from the poor was "evil and foul." His disciples took a similar line. (The doyen of Dutch Calvinist theologians, Gisbertus Voetius, excommunicated a God-fearing woman in his congregation because her husband was a pawnbroker.) Generally, Protestant countries adopted attitudes to these problems very similar to the Catholic tradition, fixing maximum rates of interest, controlling prices, and setting up public pawnshops.

The Puritan societies of such areas as the Netherlands, East Anglia in England, New England in the United States, and Huguenot France likewise contradict the assumption that Calvinism was particularly associated with merchant capitalism. The Protestants who fled from the southern Netherlands before Spanish persecution into Holland and eastern England seemed to have been mainly skilled artisans. The capitalists among them, however, constituted only a small minority of the whole. Calvinist influence is clearly discernible among the personnel and policies of the Dutch West India Company, but, in general, dogmatic Calvinism was not characteristic of the rich merchant elite of the Netherlands. They were, for the most part, liberal and anticlerical in outlook, no more inclined to trust dynasticism or theocracy in Protestant form than in Catholic form. Indeed, in the 17th century, Dutch politics turned largely on the conflict between these "libertine" merchant princes of the Dutch republic and the party known as Orangists, led by the Calvinist ministers but composed largely of the humbler social orders in support of the House of Orange. The Orangists wanted to continue the religious crusade against Spain, which the great merchants realized would be disastrous to their business.

Protestant refugees from the Netherlands

The settlement in New England in North America was theologically Puritan and socially medieval. It was not until the middle of the 17th century that newer immigrants from the City of London began to challenge the older ideals of social stability, order, and discipline inherited from the Pilgrim Fathers. Like their London or Amsterdam contemporaries, these new capitalist elements wanted mobility, consumption, even luxury, all thoroughly deplored by men of the old dispensation, such as Gov. John Winthrop.

Similar conflicts may be found among the Huguenots of the areas around Bordeaux and Marseilles in France. Probably the majority of Huguenot support came, here as elsewhere, from the lower orders together with the lesser gentry, both hard hit by rising prices. Rich merchants may certainly be found, but they were probably no more important as an element than professional lawyers or doctors.

Origins of the Weber thesis. Such observations throw considerable doubt on the Weber thesis, which may have received some of its plausibility from later evidence of the predominance of Dissenters in 18th- and 19th-century British economic life. But much of this was Quaker or Methodist and based on a theology totally different from that of Calvin. It may well have been the result of the exclusion of Dissenters from many spheres of public life after 1660. In general, it looks as if the majority of the adherents to radical forms of Protestantism came from the ranks of displaced persons from the lower orders of society. The new economic developments tended to take place beyond the control of the old medieval towns and guilds. In what is now Belgium and, later, in Holland, there was a floating population from the ports and the countryside, much at the mercy of the economic cycles of alternating prosperity and depression. Religious persecution was another force turning thousands of artisans adrift in search of new places of settlement. The enforced mobility and restlessness of the times seemed to have given a special attraction to class, status, or wealth. Radical religions that emphasized the importance of character and conduct and that even preached socially egalitarian doctrines seemed to give purpose even to humble occupations. The doctrines of election and predestination had a special appeal to those who could believe that economic success based on thrift and sobriety was clear evidence of God's favour. It seems probable that in the casual, easy-going society of the early modern world, men thus motivated toward steady and methodical work would inevitably tend to rise in the social scale. On this interpretation, while the initial attraction of the new religions to capitalists may have been exaggerated, the practice of their beliefs and social habits may have contributed to the rapid growth of a class of capitalists later on. At the upper end of the social scale also, it has been argued that the appeal of Calvinism was not so much to the prosperous gentry as to those who were in difficulties through price inflation.

The Dissenters

THE VOYAGES OF DISCOVERY AND THE PRICE REVOLUTION

The age of discovery. Between the mid-15th and the mid-16th century, Portuguese, Spanish, Italian, and English navigators provided signposts to vast areas of the world previously unknown. In 1490 the world familiar to Europeans was limited to western Europe, the Middle East, Scandinavia, and North Africa. Hazier ideas based on myth and tradition intimated the existence of a continent across the Atlantic and of Arabia, India, and China (where there had been Muslim penetration and trade). A century later, this known world had undergone a vast expansion. Spain had discovered and claimed as its own much of the coastal regions of South America, Central America, and the West Indies. French and English voyages had reached the eastern coast of North America. The Portuguese had seized many places on the west coast of Africa, discovered Brazil, rounded the Cape of Good Hope, and reached past India into the Moluccas (Spice Islands). East Africa, Arabia, Cathay, the Philippines, and Japan had thus been made known incidentally to the explorers. Here was a vast new world open to trade and enterprise and offering a treasure house of spices, exotic goods, and precious metals to those with capital, stamina, and the will to trade.

Discovery of the Americas

The development of chartered companies. The late 16th century saw the nations of western Europe—Spain, Portugal, England, and the emergent Dutch republic—locked in the first scramble for trade and empire. Some of the contestants were individual merchants who attempted to conduct their business in the new areas in the traditional way, either as individual adventurers or at most loosely associated with other merchants in a fellowship or society. This was the way the merchant adventurers had conducted a large part of England's export trade in cloth to northwest Europe. It was an association of individuals in which every member traded alone with his own stock and employees, subject only to the regulations imposed by the company in order to secure benefits for all members. This was what was called the "regulated company," and it did not represent any accumulation of common capital. Such an institution had serious defects when it came to organizing and financing the much longer voyages, employing larger armed ships with larger

crews and with larger cargoes at stake. Voyages to the new areas of discovery often necessitated heavy outlays on defensive forts and equipment to protect the adventurers against hostile attacks. Such ventures were more than an individual investor could finance, and they required the collection of capital from many investors and its professional management. Such methods had occasionally been employed in the Middle Ages. These joint-stock methods now became far more common. In the second half of the 16th century, London capitalists, aristocratic and mercantile, raised money jointly to finance Sir John Hawkins' slave journeys, Sir Martin Frobisher's search for the Northwest Passage, Sir Francis Drake's raids on Spanish America, Sir Walter Raleigh's colonization of North America, and the trade enterprises to Russia and the Levant. Similar methods were followed by the adventurers of France and Holland, but very few of them succeeded.

The enterprises most significant for the immediate future were those to the East Indies. In Holland 12 groups of investors in the 1590s joined to finance such voyages by a separate parcel of capital, but the profits were sadly reduced by the competitive buying and selling of the valuable spices by the rival entrepreneurs. In 1602, therefore, they were amalgamated into the United East India Company. Like most Dutch institutions, this was a federation—six "chambers" situated in six different towns or provinces, each with its own organization and capital and subject only to general control from the central body. The need for permanent fixed capital for forts, ships, and arms suggested that the capital should also be permanent. A stockholder who wanted to get his money back could only do so by selling his claim on a share of the capital to somebody else at the price it would fetch on the market at the time of selling. Thus, the East India Company shares became one of the first and largest blocks of share capital to be traded on the new Amsterdam Bourse.

The United East India Company

Anglo-Dutch rivalry. The English East India Company obtained its charter on the last day of 1600. A company of 220 adventurers was established, which sounded very like a regulated company, but they recognized that India was too far away to be exploited by individual enterprise. Therefore, there was to be "a joint and united stock," though each voyage remained a separate capital investment. It was more than 50 years before the English adopted the Dutch method of a permanent capital fund.

The Dutch were the pacemakers under the vigorous, ruthless leadership of Jan Pieterszoon Coen, governor in the East Indies until 1629. By 1680 they had a monopoly of the spice-producing regions of the Malay Peninsula and Archipelago. They held Ceylon and many points on the mainland of India, the Persian Gulf, the Red Sea, China, and Japan. They employed every device to maximize profits on the cargoes of Japanese copper, silk, and porcelain; Chinese tea, pottery, and wallpaper; Indian cottons and spices; Persian carpets; Arabian coffee; Malayan tin; but, above all, the precious spices of the Malayan Islands, which left Asia at Christmas each year.

The English company was less successful. It managed to make high profits on the early voyages and set up many trading posts in the East, but it was evicted by Japan and driven out of the Spice Islands by the Dutch. On the Indian mainland the costs of defense were high. Lacking the expertise and the resources that enabled the Dutch to organize a self-balancing trade in many Eastern areas, the English company was always under pressure to export much larger quantities of silver to pay for its Eastern purchases than the Dutch. Throughout the 17th and 18th centuries it faced constant criticism for draining England of silver. Its reply was that it resold a large proportion of the spices, textiles, tea, coffee, and porcelain that it brought back from India in other European markets, thereby winning a net surplus of treasure.

North American trade

The Dutch were also active in North America, where colonists had settled in the New Netherlands, along the Hudson River, trading with Newfoundland, Virginia, and the West Indies. Their hold was not strong, and it was easily broken by the English in 1664. Nor were their enterprises in the West Indies and South America completely successful. The Dutch West India Company was formed as much to fight Spain as to develop trade. Large areas of Brazil were annexed but lost again to Portugal. The sugar market was a dangerously fluctuating one. Dutch Guiana, with its coffee, cacao, and cotton, produced better results, as did the slaving ports on the coast of West Africa, which were a main source of supply to America and the West Indies. But the West India Company was not, in the main, successful.

Success and failure of the companies. Indeed, many of the European chartered companies suffered results varying from barely successful to disastrous. The Virginia Company was a costly failure. The 30 or more French companies set up in the 17th century, including an East India, West India, and Senegal, did little but consume French capital. The English Royal African Company had a checkered career, as did competing companies formed in Denmark and Prussia to exploit Africa and the East Indies.

Somewhat late in the field, France managed to retrieve an otherwise dismal string of failures in the Caribbean. In spite of the collapse of Colbert's West India Company, individual French traders did well in what was known as the Sugar Bowl, developing sugar plantations on Martinique, Guadeloupe, Haiti, and other smaller Caribbean islands.

By 1700 a century of company activity by the Western nations in America, India, Asia, and Africa had left indelible marks. South America and the West Indies had been designated forever as "Latin" America. With the Dutch trading stations eliminated, North America's future was poised between England and France. England was firmly entrenched on the Indian subcontinent, while to the East the Dutch were equally the masters of the Malay Peninsula and Archipelago, with regular trade connections to China and Japan. It is likely that the Dutch East India Company had the best record of profit. None of the other company enterprises had anything but a patchy record, and some had lost enormous sums of capital and seen little, if any, profit. Some individual merchants in Amsterdam, Middelburg (Holland), Rouen and Nantes (France), London, and Bristol (England) had made personal fortunes. Others had lost them.

Success of the Dutch East India Company

But, if the colonial trades were by no means the easy gold rush they have sometimes been thought, it must be remembered that the capital investment they represented was still only a small part of the total trade of the Western world. The bulk of trade and shipping was still inter-European. The spices, sugar, cotton, and other goods were commodities that leavened the lump, but they were far from being the dominant influence.

The price revolution. *The influx of silver and price inflation.* One commodity produced in the New World nevertheless had a direct bearing upon an economic movement that, in turn, had incalculable effects upon the economy and society of the 16th and 17th centuries. The relationship between the flow of Spanish-American silver and the price inflation of the 16th century is still a matter of debate, but many historians still maintain that the major cause of the price inflation lies in this addition to the monetary supply of the world; and most others would agree that it played at least an important role. The precise dimensions of the inflation are not easy to establish, but in Spain, for example, prices at the end of the century were between three and four times greater than those at the beginning; elsewhere in France, England, Holland, Alsace, Italy, Germany, and Poland, they ranged from two to three times their 1500 level at least. The movement was not uniform or smooth. It began about 1480 in Germany, England, and Poland, about 1500 in Spain, and about 1530 in Italy (which generally experienced a smaller rise than most other places). Everywhere, the sharpest rise came between about 1540 and the 1570s. The inflation ended, as it began, at different times in different places: in Germany as early as the 1620s and in England and Poland by the 1640s. After the mid-17th century the price level almost everywhere remained steady or even declined for more than a century.

Imports of silver from Spanish America

Basing their arguments on the theory that prices move broadly in relation to the volume of money in circulation and the velocity of that circulation, some observers from the 16th to the 20th century have seen a major cause of inflation in the swelling stream of silver from Spanish America. They include Francisco López de Gomara, a Spanish historiographer, writing in 1558, Jean Bodin in his dispute with Malestroit in 1568–78, the author of the famous English *Dialogue of the Common Weal* (1581), and the followers of Earl Jefferson Hamilton, a U.S. scholar who has done most to reveal the dimensions of the problem in the 20th century.

The sequence of events was that the conquistadores, finding silver and gold plates and statues relatively common in Spanish America, began very soon after their arrival to mine precious metals. Boom levels were reached by 1550, after the discovery of rich silver fields in Bolivia and Mexico coincided with a new method of extracting silver through the use of mercury. Up to the 1630s large supplies of silver were mined and sent to Europe. The peak years, about the turn of the century, saw an annual flow of about 36,000,000 pesos. Thereafter, the flow began to dwindle until it fell to a relative trickle by 1660. During this whole period some 18,000 tons of silver (roughly the equivalent of one year's output from present-day South African mines) was added to Europe's monetary stocks. Of the total, about one-fifth was taken by the Spanish crown, some circulated in Spanish America, while the rest was convoyed twice a year to Seville, from where it was distributed throughout Spain and ultimately throughout Europe and to the East.

Opinions on the causes of inflation. The relationship of this flow to the inflation nevertheless raises certain difficulties. It has been noted, for example, that in some countries the price rise began at least 75 years before 1570, yet Hamilton himself is inclined to minimize the export of bullion from Spain before the latter years of the 16th century. Again, the dimensions of the price rise varied not only between countries but also between commodities. Thus, in general, every price investigation has confirmed that grain and other food prices rose a good deal more than metals, textiles, industrial goods, and colonial commodities, such as spices.

Clearly the influx of silver from the New World does not answer all the questions about the inflation. The growing output of the mines of Germany between 1480 and 1540, which reached its peak in the early 1540s, may help to explain why German and Polish prices rose earlier than Spanish prices, but it is still necessary to explain the impetus behind the continental mining of silver itself; and the demand for silver detracts from the purely monetary and supply side of the problem. Turning to the demand side of the equation, the important increases in population and changes in income distribution obviously played a role. Everywhere in Spain, Germany, Poland, Holland, and England, the larger cities show a rapid growth. Recent research has tended to suggest that the most important nonmonetary change that made it possible for increased supplies of bullion to infiltrate the economy and drive up prices was a general increase of population, associated with growing demand, larger capital investment, and larger national incomes.

Effects of the price inflation. All over Europe landlords' profits grew and with them rural investment and consumption. Customary tenants and freeholders also frequently enjoyed the benefits of rising prices. Entrepreneurs, businessmen, and speculators reaped some harvest from the gap that often opened between prices and costs, though wages sooner or later caught up with prices.

Debasement of the coinage

Everywhere governments had to face increased expenditure, and, since their incomes were slow to grow, they often added to the inflationary pressures by debasing their coinage, as did the English Tudors in the 1540s and 1550s. Such debasements reached their climax in the notorious monetary manipulations known as the *Kipper und Wipper Zeit* (see-saw time) of the early 17th century. Larger rural incomes together with larger urban incomes promoted the production and consumption of more luxury goods. Thus, any satisfactory explanation of the inflation must include these demand factors as well as the changes in monetary supply.

Few contemporaries grasped the underlying causes of the inflation. Naturally, they tended to blame it all on human wickedness and greed, passing legislation to hold down prices, rents, and wages, all to little effect. The inflation and its social consequences continued. Generally, those who could adjust their incomes to the changing price level benefitted most, such as landlords who could force or persuade their tenants to accept flexible commercial leases or tenancies; tenants with security of tenure, who could enjoy higher profits if they had surplus produce to sell, while still paying fixed rents; and tradesmen, who could put up prices and keep costs down. The sufferers were landowners, whose *rentier* incomes were limited by custom, and wage earners whose wages stuck at customary levels while the price of necessities rose. It must be remembered, however, that the wage earner completely reliant on a money wage was still the exception rather than the rule in most societies. Much payment in kind was still in force. Many workers were still rural peasants with a small holding to provide them with at least a subsistence living.

The decline of Spain. It has been argued that the decline of Spain in the 17th century from its 16th-century peak of power and prosperity was fundamentally due to economic causes. The silver influx is claimed to have brought about a high degree of inflation, and, since costs rose with prices, Spain suffered a loss of economic strength that brought about political decline. This theory is not universally accepted, and other historians have argued that Spain's problems arose from the misguided determination of Philip II and his successors to burden Spain with such heavy costs of war and extravagance that the consequential high taxation and poverty drove out all enterprise and large numbers of valuable skilled workers until Spain was to become a proud but arid desert, inhabited by bankrupts, monks, and paupers. This picture, though in some respects exaggerated, gains some credibility from comparisons with other countries, such as the Dutch republic; for there is a fair measure of agreement that the same price inflation that is alleged to have ruined Spain was, at the very same time, exerting a powerful natural influence that added daily to the wealth of the Dutch.

NATIONALISM AND MERCANTILISM

The growth of nationalism. The early modern age was a time of conscious state building. One after another, governments attempted to assert control over larger areas, and the new absolutisms tried to combine economic policies designed to achieve increasing national wealth with political programs aimed at increased power at home and abroad.

England. England was quick to achieve a high degree of unification, and this was confirmed as the Tudors strengthened their hold on Wales, Ireland, and the northern counties. Dynastic union with Scotland came with the Stuarts; and full legislative union in 1707. It cannot be claimed that the economic policies that were promulgated for this increasing area were always satisfactorily implemented, but a national policy was, at any rate, outlined in matters of tariffs, employment and poor relief, price and wage regulations, and the subordination of local authorities, municipalities, guilds, and companies to the will of the national government.

Union with Scotland

France. Elsewhere, progress was slower. During the reign of Henry IV in France, a significant practical contribution was made (in the shape of road and bridge building) to a concrete national economy. Under Colbert, principal economic minister to Louis XIV, something was done to unify weights and measures, to continue Maximilien de Béthune, duc de Sully's work of transport improvements, and to reduce divisive local tolls on roads and rivers. Even so, and in spite of French absolutism, France remained, in many respects, a large collection of provinces representing a great and varied wealth of natural resources but much divided by internal economic obstructions.

Other European countries. Even the Dutch republic, the model of economic modernity of the period, deferred to much local option in the shape of powerful cities and provinces. Real economic unity was achieved only by the predominance of the powerful and wealthy province of Holland. Both Spain and Italy faced insuperable geographical obstacles to any real economic unification, both countries being divided by mountain ranges. In general, the farther east the countries were, the more backward were their economies and societies. Germany in the 17th and 18th centuries still consisted of some 2,000 independent states of widely varying size, each with its duke, count, landgrave, bishop, or abbot among others. Russia, in spite of some rapid but exceptional projects of industrialization by Peter I the Great, was not modernized until after the Crimean War. Central and eastern Europe remained a society of lord and peasant (almost lord and slave), much of its business still conducted on the basis of barter or payment in kind.

Backwardness, however, was itself the stimulus to economic change. The examples of north Italy and the Netherlands—especially the Dutch republic—were constantly before the eyes of princes, bureaucrats, and even merchants struggling to cope with natural obstacles to transport, compounded by the remains of man-made obstacles surviving from years of fiscal impositions. In France and Germany, in particular, trade was constantly obstructed by internal tolls on roads, rivers, and canals. In 1685 it was calculated that out of a cargo of 60 logs, floated down from Saxony to Hamburg, only 6 remained after the customs officers at innumerable points had taken off their share as a tax contribution. Everywhere petty fiscalism obstructed the free flow of goods, and only at sea did cargoes move relatively freely (though even these were frequently subject to the attentions of privateers, pirates, and enemy warships).

Customs and tariffs

The development of mercantilist theories. The 17th and 18th centuries nevertheless saw the rulers of these imperfectly integrated territories evolving a set of ideas with a remarkably high degree of common content. The theories were those that have come to be called mercantilist, though in practice they were as much the creation of ministers and administrators as of merchants, and their objectives were political and strategic as much as economic. In an age when war was almost continuous (the 17th century is said to have enjoyed only four years of peace), economic principles that rested on the assumption that wealth could be pursued in the abstract, without regard to the means to procure it, maintain it, and protect it by force, had little appeal to rulers. The mixture of politics and economics in mercantilism varied from state to state according to the resources, situation, and mode of government in force. In the Dutch republic the power of the state was most subordinated to the needs of trade. In England, France and, later, in Prussia and Russia, the economic initiative of the state was seen essentially as the indispensable other arm of the military and, often, aggressive intentions of the state toward its neighbours.

The balance of trade. In spite of such differences of emphasis, however, mercantilist programs in most countries came to turn upon the concept known as the balance of trade. This concept was most clearly analyzed in the large volume of economic literature that appeared in England between the mid-16th and the mid-18th century. It may be discerned in the *Dialogue of the Common Weal* (1549–81) and is stated clearly by Thomas Mun in his *England's Treasure by Forraign Trade* (1664). The central theme is that, if the nation's exports exceed its imports, the nation will grow rich by reason of the influx of bullion that will result. But if the nation's imports exceed its exports, the nation will grow poor because of the loss of bullion that will necessarily follow. The next 150 years saw many refinements in the presentation of this simple proposition, as Mun's essay was discussed by scores of English writers and translated into French, German, Spanish, and Italian. But the basic concept of the "balance," supported by new bookkeeping practices and even by the notions of the new physics and mathematics, remained central to economic thought and policy down to the emergence of the classical economists and the ideas of the self-regulating economic mechanism introduced by David Hume and Adam Smith.

Mercantilist policies. From this concept emerged, in turn, a series of economic measures designed to expand and adjust the national economy to meet the needs of the state and society. In its fully fashioned version, the mercantilist program aimed at encouraging the maximum influx of raw materials for industry by the removal of import duties and the imposition of export duties on local raw materials, wool being a frequent object of attention. Local manufactures, on the other hand, were to be encouraged by the imposition of protective tariffs against foreign competition and the grant of subsidies and export bounties to assist local manufacturers. An abundant supply of skilled labour should be provided by a large population, and, as the difficulties of calculating an exact monetary balance became fully appreciated, the main practical objective of mercantilists everywhere tended to become the employment of a larger and better-trained labour force.

Export duties

This central core of ideas is common to the English mercantilists and to French writers such as Barthélemy de Laffemas and Antoine de Monchrétien in the time of Henry IV, the two most notable forerunners of the greatest French mercantilist, Colbert. They are repeated in the writings of the Austrian and German economists Johann Joachim Becher, Wilhelm Freiherr von Schröder, Philippe Wilhelm von Hörnigk, and the German cameralists, whose ideas powerfully influenced the ambitious economic programs of Frederick II the Great of Prussia. They appear constantly in the writings of the Spanish neomercantilists, Jerónimo Uztáriz and Bernardo de Ulloa, toward the middle of the 18th century.

In all these states successive attempts to turn mercantilist ideas into legislative form may be found between 1600 and the French Revolution in 1789. In France and in England such programs were most concentrated in the century between 1660 and 1760. The years from the Restoration to 1714 in England have been called the age of commercial and financial revolution. The emphasis there was on the regulation of trade (especially foreign), while industry was increasingly left to its own devices and largely freed from guild or government interference. The most important group of laws were those passed between 1660 and 1663, which developed in practical, enforceable form the ideas behind the Navigation Act of 1651—basically encouraging the growth of the mercantile marine by the compulsory channelling of trade between England and the outside world (especially British colonies) into English ships manned by English officers and crews. The use of foreign-built (mostly Dutch) ships was prohibited in order to boost English shipbuilding. Specified commodities of economic or strategic importance (sugar, cotton, timber, dyestuffs, naval stores) were enumerated so that their illegal carriage in foreign ships could be easily checked. At the same time, shipping was encouraged and agriculture boosted by the grant of bounties on exported corn (1673), and subsidies and protection were granted to a large range of industries including woollen textiles, linen, sailcloth, paper, metal manufactures, and many other products. Thus, a whole program of import substitution was launched and developed well before the Industrial Revolution. Between 1660 and 1700 exports and re-exports rose from rather more than £6,000,000 annually, while imports rose only from about £4,000,000 to £5,000,000 annually. This increase in export values continued, though at varying rates, until 1760, when they reached a figure of nearly £15,000,000.

English mercantilist legislation

Colbert's economic policies. The French program of Colbert was very different. Colbert was essentially the royal servant, ministering to royal needs, and his major task was to reform the tax system to improve the royal revenues. This he aimed to do by promoting manufactures through tariffs, privileges, and the import of skilled artisans, so that industry should be a source of national wealth and social contentment. It would be regulated

through a universal guild system that would bring not only discipline to industry but also revenue to the crown and a reputation for high quality to French producers of luxury goods. Colbert was by no means the pacifist he has sometimes been thought, and he placed the whole of his regulated economy behind his master's aggressions in Europe, believing, as he did, that the amount of world trade was fixed and that France would only enlarge its share at the expense of the Dutch and English by force.

Financing of French wars

Effects of mercantilism. The results of mercantilist policies remain debatable. England certainly enjoyed a century of economic development. French industries likewise spread and, in some cases, seem to have benefitted, as did their English competitors, by the vigorous application of intelligence to their promotion. In an age when invention was limited and the price level stagnant or declining, it is impossible to deny that the mercantilists seem to have brought great stimulus to economic development. In Russia, the imitative mercantilism of Peter the Great has been seen by recent scholars as a remarkable example of state-promoted economic advance. In the Prussia of Frederick the Great, many attempts at unsuitable industrial development, such as silk manufacture, copied slavishly from French models, proved hopelessly unsuccessful, but the works of improvement to harbours, roads, and canals, the clearance of forests, the drainage of marshes, and the settlement of colonies of thousands of industrious Huguenots laid the basis for the industrial future of a united Germany.

It is no longer possible to write off mercantilism as an ignorant contradiction of self-evident economic truth as revealed by orthodox economic theory. Its political, military, and fiscal preoccupations were nevertheless dangerous, and, in an age when public opinion had only limited means to challenge the vested interests of bureaucracy, authority, and private monopoly, mercantilist institutions could easily become a hindrance to further economic progress. The French economy, in particular, was to suffer from the growing burden of ossified institutions, obsolete laws, and harmful privileges corruptly bought and sold.

EMPIRE AND THE WORLD ECONOMY

Decline of Italy and the Dutch republic. The first half of the 18th century saw the completion of certain momentous developments. Internationally, trade moved away from north Italy and the Low Countries to centre more positively around the two foremost expanding nation-states, France and Britain. By 1700 there was no doubt that, commercially and industrially, Italy was in a state of relative decline. The great cloth-producing centres at Florence, Venice, and Como had all virtually ceased production, though silk manufacturing continued, often outside the old cities. Venice had finally ceased to be an entrepôt of world importance. In north Europe, the Dutch republic, heir to the Italian legacy, had lost its former dynamism. Essentially a middleman economy, it was now feeling the draft of competition from Britain and France. Merchants from these and other countries, who had formerly relied on the intermediary services of Amsterdam, were now trading directly with one another. Dutch foreign trade, while not positively collapsing, remained at about its mid-17th-century level. Agriculture even prospered, but the once-great industries of Leiden and Haarlem suffered badly. Although no longer the leaders of trade and manufactures, the Dutch continued to finance an important part of the needs of other states, especially for war. Dutch investors held an important stake in the rapidly growing English national debt, and there were few smaller governments that did not at one time or another turn to Amsterdam for loans.

Anglo-French competition

Italy and Holland may be regarded as examples of relative decline. Only Spain seems to present a picture of absolute decline from which there was to be no significant recovery even in the 19th century.

British economic and industrial growth. True expansion was evident only in Britain and France, and even there the early 18th century was punctuated by hesitations and losses. Everywhere population growth had slowed down. Cities frequently seemed to have reached the limits of expansion for the time being. London, for example, after a period of unprecedented population growth to over 500,000 people, had reached a point of overcrowding that threatened health and a point of general congestion on the Thames River that threatened profits. The new century brought about little expansion of its activities and with its stagnation went a levelling off of London demand for food and drink, necessities and luxuries. Breakneck expansion gave way to consolidation and more intensive development. These changes had their effects on agriculture, industry, and population throughout the Home Counties and East Anglia, and until 1750 landlords and tenants alike faced more years of depression than of prosperity.

Population growth

The total population of England and Wales may have grown by perhaps 1,000,000 to its 6,700,000 figure of 1760. It now seems probable that this continuing, though still modest, increase was due to a fall in deaths (33 per 1,000 in 1730 to 27 per 1,000 by the 1760s), whereas the birth rate rose from a low figure of 28 per 1,000 in 1710 to over 33 per 1,000 in the 1760s. In contrast to the deceleration of London, provincial cities had begun to grow. Norwich flourished on agricultural progress and its "new draperies," but the most significant vigour was to be found on the west coast, where Bristol, Liverpool, Whitehaven, and Glasgow in Scotland were all growing rapidly on the profits of the Atlantic trade—American and West Indian sugar, cotton, and tobacco and the provision of African slaves for the plantation economies of those areas. There was also a marked shift of manufactures, especially cheaper and lighter textiles such as linens, cottons, and fustians into the hinterlands of Lancashire and Scotland to meet the demand for exports to the new colonies. Ironware, hardware, nails, tin, glass, and small arms also filled the holds of Bristol ships sailing for West Africa, America, and the West Indies.

The western ports therefore accounted for a good proportion of the total increase in British shipping, which rose from about 320,000 tons in 1700 to just under 500,000 tons by the 1760s. Another important contributor to shipping demand continued to be the coal trade. Colliers taking northeastern coal from Newcastle to London had provided a major natural stimulus to English shipping and shipbuilding from 1550 to 1700. This cheap transport had, in turn, stimulated British coal production to a 14-fold increase by 1700. This expansion continued in the 18th century and was unparalleled in Europe; however, it took a new direction. Northeastern coal production, based on the London demand, grew less rapidly, while new coalfields, especially in the Midlands, ministered to the needs of an expanding pattern of output from a range of industries of widely varying type: sugar boiling, salt refining, brewing, and many small manufactures based on iron, such as tool making and lock, chain, nail, gun, and sword making. Abraham Darby discovered how to smelt iron ore with coke in 1709, but it took between another 50 and 100 years for the invention to penetrate widely throughout the iron industry.

Nevertheless, by the midcentury there were already signs that the growth of home and overseas demand were beginning to interact. As machines and engines called for more metal and fuel, coal output, in turn, responded, and this drew forth more demand for transport and labour. There was a notable increase in labour-saving mechanization everywhere, but, in spite of a few large-scale enterprises utilizing true factories, such as the Lombe's silk mill at Derby (1724), Wedgwood at Burslem (1759), and Boulton at Soho (1762), the new industries still grew by multiplying the number of relatively small units of production, employing new labour, and exploiting established technologies, such as dyeing, that were capable of improvement and expansion. All this new growth tended to provoke manufacturers and traders to challenge the older ideas of state paternalism and company monopoly, which now seemed to be a brake on output and profit rather than a help to their efforts.

Mechanization

Expansion of French trade and industry. In spite of the pattern of technical conservatism that state and guild

control imposed on the French economy during the post-Colbert period, France also shared in the general expansion of trade and industry in the 18th century. From Labrador down to the Caribbean, the French participated in the trans-Atlantic trades, importing fish, furs, tobacco, sugar, coffee, indigo, and cotton. The French ports of Saint-Malo, Nantes, and, above all, Bordeaux rose on the new trades. Even Marseilles, though centred on the Levant and Mediterranean trade, benefitted from the re-export trade in West Indian sugar and coffee.

Certainly in the first half of the 18th century, the output of French cotton and iron was also greater than that of the rival industries of Britain. Some French industries were hindered by the rigid, monopolistic, secretive, and legalistic guild system that cramped enterprise and made it impossible to follow fashion. But elsewhere, French industry, like its English rival, sought expansion through rural development and the putting-out system. It enjoyed the great advantage of a large domestic market (three or four times the population of Britain and more than ten times that of the Dutch republic) and rich natural resources. Probably the expansion of the French export trade was even greater than that of the English, before the 1789 Revolution. French capacity for invention, especially in industrial chemistry and such ancillary processes as textile printing, was truly remarkable. Yet, in certain respects, French development may be seen in retrospect to have had less potential than its English rival. Shipping and shipbuilding were less closely geared to industry, and the same was true of the relationship between coal output and coal-using industries. The French pattern of manufacture was therefore less adaptable to the growth of mass demand. The custom known as *dérogation*, which penalized aristocrats who participated in trade or industry below the level of the great state colonial trading companies, may well have deprived the French economy of valuable financial aid and initiative of the kind that came from the shrewder members of the British nobility, such as that of Francis Egerton, 3rd duke of Bridgwater, the great canal promoter, or of the coal-owning Lowthers.

Anglo-French rivalry. Two other related weaknesses may be discerned in the French economic structure. England between 1688 and 1750 had developed a surprisingly well-balanced system of public finance, based on a well-managed public debt, an evolving system of taxation (both direct and indirect), the Bank of England, and the great trading companies, together with a widespread system of private banking. French financial institutions, on the other hand, did not succeed to anything like the same extent. Indeed, some contemporary observers saw in the weakness of French public finance and its inability to raise the great masses of capital represented by the growth in the English national debt (£12,000,000 to £132,000,000 in 1763) a major reason for British military and economic superiority that was to emerge decisively at the Treaty of Paris, which brought an end to the Seven Years' War in 1763. Militarily, France suffered in its overseas possessions—in the West Indies, North America, and India—by reason of this financial weakness, and military defeat was certainly reflected in overseas trade, not least in India, where sea power, especially, gave England the whiphand by 1761.

The national debt

The observer of these events in historic retrospect must nevertheless be careful. By 1750 the future of world power and of European control of trade both within Europe and in the colonial world beyond was still in suspense between the two great powers, France and Britain. It is not easy to determine how much of Britain's success in overtaking its rivals was inherent in the situation in 1750 and how much was enveloped in the events and developments that took place subsequently.

THE SIGNIFICANCE OF EARLY ECONOMIC DEVELOPMENTS

Modest though the advance of these two and a half centuries seems compared with what was to follow, it was by contemporary standards truly momentous. Europe's population very nearly doubled, to reach 140,000,000 by 1750. The growth in the area and volume of international trade and shipping was without precedent. The roles of capitalists and capital in the changing industrial system were as revolutionary as those of entrepreneurs and factories in the next phase of development. Finally, the men of the 17th century had begun to grasp how scientific method could be applied not only to the problems of agriculture and industry but also to those of society itself, a realization pregnant with possibilities for the future. (C.H.Wi.)

II. The Industrial Revolution

From the mid-18th century until World War I, economic history centres around a group of changes known as the industrial revolution. The term industrial revolution is commonly used to denote those changes in the processes and organization of production that mark the passage from an agrarian, handicraft economy to one dominated by industry and machine manufacture, from what is sometimes called a premodern or traditional economy to a modern one. The term, when capitalized, refers specifically to the first historical instance of this transformation, which began in Britain in the 18th century, spread from there to the Continent and to offshoots of Europe overseas (the United States, in particular), and transformed in the span of a century the life of Western man, the nature of his society, and his relationship to the other peoples of the world.

At the heart of the Industrial Revolution was a cluster of innovations in the technique and mode of industrial production: (1) the substitution of inanimate for animal sources of power (in particular, the introduction of steam power fuelled by coal), (2) the substitution of machines for human skills and strength, (3) the invention of new methods for transforming matter (in particular, new ways of making iron and steel and industrial chemicals), and (4) the organization of work in large, centrally powered units (factories, forges, mills) that made possible the immediate supervision of the production process and a more efficient division of labour. These innovations in industry promoted and were, in turn, supported by major changes in the technology of agriculture and transport.

Underlying all of this was the systematic application of knowledge to the devising of more efficient production. In the first part of the Industrial Revolution, the knowledge was mostly the result of practical experience and informed empiricism. With time, however, beginning in such industries as chemical manufacture, applications were derived from pure science, and, by the end of the Industrial Revolution, the relationship was reversed. Theory had moved ahead of practice in most domains, and inventors were tapping the pool of scientific knowledge for usable ideas and information.

The Industrial Revolution was essentially completed in the first industrializing countries by the late 19th century. By then they had made their passage to the new technology and were pursuing new paths of change. Again, there was a clustering of innovations that gave the impetus to this further growth: electrical power, the internal-combustion engine, petroleum fuel, the automobile, and science-based chemical manufacture (the first synthetics). Some have called this array of changes a second Industrial Revolution. In the second half of the 20th century, a similar clustering of innovations (*e.g.*, atomic power, electronics, and computers), is effecting perhaps a third Industrial Revolution. Each of these stages has been marked by important gains in the production and delivery of energy; in the speed, precision, and convenience of tools and machines; and in the effectiveness and usability of final products (standardization of parts, refinements of tolerances, miniaturization of components).

All of these technological advances translated into economic growth—that is, increased productivity and income per head. Productivity is measured by the ratio of output to one or more factors of input (labour, capital, materials). As a result of the Industrial Revolution, labour productivity increased thousands of times in some branches of industry (cotton spinning, for example), hundreds of times in others (weaving, steelmaking, chemicals), with corresponding decreases in the cost of manu-

Changes in productivity

facture. By contrast, those activities little affected by the new techniques—skilled arts and crafts, for example, or barbering—showed almost no gain in productivity and little reduction in costs. The effect was a massive shift of demand in the direction of those products and services the costs of which fell the most and an increase in the numbers of persons and amount of capital employed in the branches furnishing these products and services. This shift was reinforced by the gains in income per head, which made it possible for the populations of advanced industrial countries to devote a smaller portion of their income to necessities, and to spend more of it on luxuries or "extras." This expenditure over and above the requirements of subsistence is especially responsive to the changes in relative prices entailed by changes in relative costs of production. The effect was a substantial growth of those branches most affected by the new technology and, in general, a shift of resources (including labour) out of agriculture into industry and services and a movement of population from the countryside into the cities and towns.

THE INDUSTRIAL REVOLUTION IN BRITAIN

Advantages of Britain. The first country to make the transition to modern industry and economic growth was Britain. The reasons for this precocity were partly material, partly social and institutional. Britain was favoured by its oceanic position, which gave the country easy access to markets and suppliers overseas; by its modest size and highly indented coastline, which placed most of the country within easy reach of water transport; and by the abundance of those natural resources that proved to be particularly important for the new industrial technology. These included water (for waterpower, chemical processes, textile finishing, and, in the form of high humidity, for the spinning of yarn); salt, for the manufacture of industrial alkalis and acids; china clay; iron and nonferrous ores; and, above all, huge, accessible deposits of coal, for use as fuel and as a source of carbon in the smelting of iron. The one resource Britain lacked was timber, but this very handicap was turned to an advantage by the precocious recourse to fossil fuel.

The internal free trade of Britain

At the beginning of the 18th century, Britain was a medium-sized nation. Its population of nearly 6,000,000 people was less than one-third that of France; yet, Britain constituted the biggest single market in the world, not only because of the island's compactness but also because the movement of goods through the country was unimpeded by man-made obstacles. France, Britain's chief political and economic rival, was divided into three major customs areas, and traffic was further trammelled by a multiplicity of special tolls and by customary restraints on the shipment of critical commodities such as grain. Most of central Europe was even more fragmented, and the burden of feudal tolls was such as to make traffic shun the rivers (though they were more navigable than those of France and Britain) and opt for the costly and uncomfortable alternative of land transport.

This large market was also the richest in purchasing power per head. Insofar as one can estimate the incomes of mid-18th-century Europe, the average Briton would seem to have been receiving some £12 to £13 per year (perhaps $300 in today's money), half again as much as a Frenchman and more, in proportion, as one moves eastward or southward to the poorer nations of the Continent. The greater purchasing power of the Englishman was shown in his diet—he ate white wheaten bread and much meat, where the Frenchman ate dark bread and soup; and in his consumption of manufactures—he wore leather shoes rather than clogs, wool rather than linen, and used some 13 kilograms of iron per head (as against 2.7 kilograms in France) in the late 1780s. This was far more than even the rapidly growing domestic industry could supply, and the difference was made up by imports from Russia and Sweden.

The purchasing power of the British population was, in its mass, an important stimulus to agricultural and industrial production. The effect was reinforced by the relatively wide distribution of wealth, both socially and geographically. Unlike most European nations, Britain was not polarized between a small class of wealthy consumers of highly individualistic, labour-intensive luxury products and a large mass of poor peasants with little to spare for manufactures and those only the highly differentiated products of local industry. British society was more complex in its structure, with a large and heterogeneous middle class, and the peasantry was, in many parts, fully integrated into the national market. This, in turn, reflected the precocious commercialization of agriculture, which learned early to specialize in cash crops, above all for the great London market. Specialization means dependency on the outside, and one of the striking features of the English countryside in the 18th century was the extent to which not only itinerant peddlers but even fixed shops (which, of their nature, are evidence of a substantial and continuing trade) were catering to the rural population. All of this conduced to the breakdown of regional peculiarities and the homogenization of taste, which promoted a demand for the kind of standardized product that lent itself to machine production.

Social homogeneity

Coal and iron. This domestic demand, reinforced by a large and growing demand for British products abroad, placed heavy strains on the existing techniques and organization of production. One of the first industries to feel the pressure was mining, where the deeper one dug, the more difficult it became to drain the infiltrating underground water from the pits. Coal mines especially were in trouble. In one colliery, 500 horses were required to raise the water, bucket by bucket. The solution was to replace the animals with tireless machines. In 1698 Thomas Savery introduced his "fire engine," a steam pump rather than a true prime mover; and then, in 1705, Thomas Newcomen invented his atmospheric steam engine, which worked a piston up and down a cylinder, alternately raising and lowering another piston that did the actual pumping. By 1767 there were 57 of these in the Newcastle coal basin alone, supplying some 1,200 horsepower, and there were probably hundreds of them in operation throughout the kingdom. The Newcomen engine was simple and sturdy. Some of them remained in use for half a century or more. But it was wasteful of energy, and as thus largely confined to the coal pits, where fuel was almost a free good. James Watt's invention of the separate condenser (patent 1769; first commercial application, 1776), cut fuel consumption 75 percent, freed steam power from this constraint, and made possible the industrial city; and it was Watt again who first succeeded (patents of 1782 and 1784) in converting the reciprocating (back-and-forth) movement of the piston into rotary motion, so that steam could be used not only to pump mines or blow furnaces but also to drive the wheels of industry.

Another industry that felt the strain of increased demand was ironmaking. Here, the most acute bottleneck was the shortage of cheap fuel and carbon. Since England had long since cut down most of its timber, repeated efforts were made to use coke in smelting, but the necessity of mixing the fuel with the ore in the furnace made it difficult to cope with the impurities in the coke. It was not until 1709, when Abraham Darby, a Quaker ironmaster at Coalbrookdale, Shropshire, had the good fortune to work with a fairly clean mix that coke smelting became a commercial possibility. Even so, other ironworks found it hard to follow suit, and it was not until more powerful bellows became available in the 1760s that the technique spread widely. By the end of the century, the old charcoal smelting had almost entirely ceased, and British production of pig iron, once also stagnant, was growing rapidly: approximately 25,000 to 68,300 tons from 1720 to 1788 (1.5 percent per year) to about 244,000 in 1806 (7.3 percent per year).

Effect of the use of coke on ironmaking

Pig iron, the product of the blast furnace, has serious limitations for industrial use. It is brittle, cannot be worked, and must be cast. It is suitable for objects such as pots or pipes that need not take pounding or stress, but it cannot serve to build machines, frame buildings, or carry vehicles. For these purposes, before the age of cheap steel, only wrought iron would do—that is, iron

refined to eliminate the carbon imparted by the smelting process. The Industrial Revolution in iron manufacture, therefore, was not possible until a way was found to use coal here too. The breakthrough came in 1783–84, when Henry Cort patented the combined technique of puddling followed by rolling. The first decarburized the pig; the second squeezed out the remaining dross and forced the hot metal into the desired shapes.

The putting-out system. The scale of enterprise in coal mining and iron manufacture was already substantial even before the Industrial Revolution. The dependence on bulky raw materials required these branches to concentrate in those areas dictated by nature, and the technology called for a heavy investment in fixed plant and equipment. By contrast, light industries, such as textiles, were widely dispersed and relied extensively on the distribution (putting out) of raw materials to cottage workers, who turned them into semifinished and finished products. The so-called putting-out system offered the merchant-manufacturers two important advantages. First, it shifted the burden of fixed costs to the workers. All the merchant needed was a room to stock materials and finished goods. When the market was bad, the putter out simply held off, with few overhead charges to pay. Second, it gave the merchant-manufacturer access to a large pool of cheap labour. Country dwellers would work for far less than urban, not only because the cost of living was lower but also because the rhythm of agricultural labour was uneven and left long periods of relative underemployment that could be profitably used to eke out the income from the land.

The putting-out system marked a major advance over the artisan workshops of medieval towns. By freeing enterprise from the constraints of town guilds, it opened the way to growth and technological innovation. Britain's precocity in this regard (by 1400, over half the wool cloth made was woven in the countryside) changed what today would be called an underdeveloped country, exporting its raw wool to manufacturing centres abroad, into Europe's biggest producer of cheap textiles for export.

Textiles and machine technology. The growth of demand in the 18th century pushed rural putting out to its limits, especially in spinning, where it took four or five persons to keep one weaver supplied with yarn. Given the high cost of land transport, the extension of the radius of labour recruitment increased disproportionately the cost of distribution of materials and collection of finished work. Nor was it possible to get more work from those already engaged by increasing wages; on the contrary, the worker tended to set his task by his need, and increased payment only meant that he could earn what he needed with less work. At the same time, the temptation to embezzle the raw materials increased, at the expense of the quality of the final product.

It was in this context of frustrated entrepreneurial opportunity that manufacturers sought for some way to bring the labour force under control. One way was to concentrate work under one roof, so that the employer could supervise performance. This solution, however, was not feasible in the context of the old technology. So long as enlarged workshops had to rely on human power and on the same machines used in rural cottages, they could not compete, for they were burdened with higher fixed costs and had to pay their workers more to lure them into a disciplined environment. The answer was found in the invention of machines that grew to be too large and costly for cottage work—so big, indeed, that they had to be driven by animal or inanimate power: the spinning jenny, by James Hargreaves in 1765; the water frame, by Richard Arkwright in 1769 (the prototype of all modern ring spinning devices); and the mule (so-called because it was a hybrid of the two), by Samuel Crompton in 1779.

Machines for spinning

This sequence of inventions shifted the bottleneck from spinning to weaving, and, for a short while, weavers lived in unaccustomed affluence trying to keep up with the output of cheap yarn. But in 1787 Edmund Cartwright invented a machine loom, which, though it took some two decades to perfect, inexorably displaced the handloom weaver. The power loom was applied first to the coarser fabrics, for only the tougher yarns could stand up to the irregular motions of the shuttle. The machine builders, however, learned to solve this problem; and by the 1820s handloom weaving was a dying craft, and its practitioners were among the most pitiful victims of technological obsolescence.

The innovations in textiles were applied first in cotton, primarily because cotton fibres lend themselves well to mechanical handling. Wool, an animal fibre, is less uniform and tractable. It also was more costly than cotton and constituted a much larger share of total costs; so that the potential cost reductions offered by mechanization were smaller. Even so, the innovations in spinning offered gains in labour productivity of the order of over 100 to 1; those in weaving, up to 10 to 1; so that mechanization came to wool also, lagging about two decades behind cotton, and eventually extended to all the textiles. The effect of prior mechanization in cotton is shown by the change in the relative position of the two industries. Between 1769 and 1829 the value of wool exports increased from £3,897,000 to £5,362,000, while that of cotton grew from £212,000 to £37,269,000.

Similar changes took place in other industries: paper manufacture, metalworking and woodworking, chemicals, machine building itself. The principles of mechanization were susceptible to wide ramification, and the factory context tended to promote change by restoring the link between enterprise and actual production that had been broken by putting out. In chemicals, more than in other branches, the lessons of science found application in industry. Here, too, the initial motivation came from a bottleneck: the high cost of washing, dyeing, and finishing the flood of fabrics engendered by mechanized spinning and weaving. The great innovations here consisted of the substitution of abundant mineral for scarce vegetable or animal resources: the French chemist Nicolas Leblanc's substitution of coal and salt for seaweed and wood in the manufacture of soda; bleaching by chlorine compounds instead of milk and sunshine; washing of wool with soap rather than urine. The manufacture of these new industrial compounds gave rise to considerable waste; the effort to dispose of these noisome by-products without damage to litigious neighbours, plus the desire to recover some of the potentially valuable components of the waste, proved one of the most powerful incentives to innovation in the chemical industry. Seen together, these technical changes made possible substantial gains in industrial output, overall product, and per capita income (see Table 1).

Table 1: Indicators of Economic Growth in Great Britain (1801–51)

	national income (£000,000; current prices)	population (000)	per capita income (£)	income from manufacture, mining, and building (£000,000)	share of manufacture, mining, and building (percentage)
1801	232.0	10,686	21.7	54.3	23.4
1811	301.1	12,146	24.8	62.5	20.8
1821	291.0	14,206	20.5	93.0	32.0
1831	340.0	16,368	20.8	117.1	34.4
1841	452.3	18,551	24.4	155.5	34.4
1851	523.3	20,879	25.1	179.5	34.3

Changes in transport. The growth of a modern industry in Britain generated a rapid increase in goods traffic. For all of Britain's natural advantages, the Industrial Revolution could not have taken place had there not been a concomitant improvement in facilities of transportation. Canals can be traced in Britain back to the 16th century, but the first truly industrial canal was the Sankey Canal (1757) from the Mersey to St. Helens, Lancashire, cut to bring Cheshire salt to Lancashire coal. This was followed in 1761 by the waterway that usually marks the beginning of the so-called canal age. This was the canal of Francis Egerton, the 3rd duke of Bridgwater, from

Canals and land transport

his coal mines at Worsley to Manchester. By 1815 a network of some 2,200 miles crisscrossed the country, along with 2,000 miles of improved river navigation. The most prosperous links in the network were those that carried the heavy, bulk commodities of industry—coal, above all.

For many commodities, however, as well as for persons, only land transport was fast enough. The road network inherited from the pre-industrial economy was manifestly unable to handle the increase in traffic, and restrictions on vehicles (the imposition of wide wheels, for example, that would cut less into the road surface) were at best a palliative. Here, the answer was found, as in canals, in private enterprise. In the first half of the 18th century, Parliament averaged eight road acts a year, most of them authorizing new turnpikes; from 1750 to 1790, almost 40 acts a year were passed; and, from 1791 to 1810, the figure jumped to 55. Even so, the wear and tear played havoc with traditional road surfaces, and it was not until John Loudon McAdam and Thomas Telford introduced their new hard-packed surfaces in the 1790s that roads began to be built that could stand industrial traffic. By 1815 there may have been 1,000 miles of highway built to this standard.

All this time, the pressure built up to speed communication and travel. Coaches were built to make better times; horses were driven harder; connections were improved so that the trip from London to Birmingham, which took two days in the 1740s, was cut to 19 hours in the 1780s. By the early decades of the 19th century, these efforts had reached a limit, and the newspapers of the period are sprinkled with gruesome stories of horses snapping their legs or dying of exhaustion on the fast routes.

Railways

It was this apparently insatiable demand for speed that made the railway an instant success for passengers as well as goods. The use of rails to facilitate the movement of heavy vehicles went back centuries in mining districts; rails diminish considerably the force required to haul a given load. What made the modern railway, however, was the invention of locomotive traction introduced in 1825 on the Stockton and Darlington Railway line (primarily for coal haulage) and then, triumphantly, in 1829 on the new Liverpool and Manchester Railway. This was the beginning of the railway era. The new line had been intended for the transport of goods; but to everyone's astonishment passenger revenues exceeded freight receipts. By 1845, 1,000,000 persons were using the London and Birmingham Railway line alone; by 1850, 6,559 miles of track were in service.

The railway was probably the most impressive and significant technical innovation of its time. Not only did it enable the economy to move the unprecedented volume of goods required and produced by the new techniques, but also its demand for iron (for rails, engines, rolling stock), coal, wood, brick, and other materials stimulated other industries. The special requirements of a railway roadbed, in particular, the need for level track, inspired some of the most spectacular engineering achievements of the age. The construction of the roadbed, including tunnels, bridges, viaducts, and similar works, called for large gangs of labourers and proved to be a laboratory for new techniques of industrial management. Similarly, the unprecedented costs of railway construction called for new methods of mobilizing capital and pushed Britain in the direction of corporate business enterprise with limited liability.

All of these connections of the railway with the rest of the economy made it the most important single determinant of the level of business activity. At the peak of the railway boom of the 1840s, the industry employed some 300,000 men in construction alone—more than in the entire cotton industry—and absorbed about half the country's total investment; that is, between 5 and 7 percent of the national income. It was also a potent force for geographical mobility and contributed thereby to the efficiency of the labour market and the democratization of society—this, in spite of segregation of passengers into different price classes.

Improvements in agriculture. The revolution in industrial technology was accompanied by important changes in the agricultural sector. Indeed, these were indispensable to the expansion of manufacturing; the new industrial work force was cut off from the land and depended for existence on the production of a food surplus and on such victuals as could be purchased abroad. The problem was aggravated by a rapid growth of population, beginning in the middle of the 18th century, and by the constriction of overseas supplies during the period of the French Revolutionary and Napoleonic Wars (1792–1815).

At the start of the 18th century, Britain, in years of good harvest, was still able to send food abroad. Agriculture was highly commercialized and specialized, and the techniques of cultivation were among the most advanced in Europe. Some scholars have even argued that the innovations of the previous period—water meadows plus mixed farming, new crop rotations, marling—were more important than the better-publicized advances of the so-called agricultural revolution of the 18th century.

New farming techniques of the 18th century

Over the course of the 18th century, the techniques of agriculture continued to advance. Certain names stand out: Jethro Tull, who advocated drilling seed rather than sowing it broadcast and who also advocated light iron horse-drawn implements instead of cumbersome wooden tools drawn by slow oxen; Charles ("Turnip") Townshend, 2nd viscount Townshend, who learned about turnips and clover in Holland and helped popularize them in England; Robert Bakewell (1725–95), the most prominent livestock breeder of his day, the creator of four new breeds of sheep selected for meat instead of wool; Thomas William Coke of Holkham, the personification of the gentleman farmer and chief exponent of the so-called Norfolk system of rotation. But what really made an agricultural revolution possible was not these few public figures but the large number of anonymous improvers, adopting and adapting the new methods with an alacrity and vigour that reflected both the enhanced market incentives and a veritable agronomania, which found expression in and was nourished by a flowering of agricultural societies and publications. In all of this, the emphasis was on rational accounting procedures that could provide the basis for an exact comparison between old ways and new: the reports of a contemporary observer such as Arthur Young consisted in large part of records of outlays and receipts, county by county, farm by farm.

The introduction of these new techniques encountered a serious obstacle in much of England in the prevailing pattern of dispersed, fragmented land tenure and open fields subject to common rights of usufruct. These arrangements went back to the Middle Ages or even beyond. They reflected, no doubt, an effort to equalize the quality of soils allocated to the different members of the village community: each received a piece of each of the different kinds of land cleared for cultivation. The common rights of usufruct followed: this was the only feasible way to permit each man to pasture his livestock on the stubble after harvest. Common rights of pasture, in turn, implied concurrent sowing and harvesting, hence a common pattern of crop rotation, which usually entailed one year of three in fallow. This wasteful system locked the farmer into a vicious circle of low yields—insufficient food for wintering livestock—low output of dung—inadequate fertilizer—low yields. By contrast, introduction of clover or root crops not only did away with fallow but provided additional food to keep the animals over the winter, to build up the herds and flocks, and to accumulate stocks of dung for the growing season.

The enclosure movement

The attempt to free land from these communal servitudes and regroup holdings gave rise to what was known as the enclosure movement. In village after village, in an area covering perhaps one-third of the arable land in England, the major landholders agreed to regroup holdings into contiguous parcels that could then be "enclosed" by hedges or ditches and farmed as the owner saw fit; at the same time, meadowland and wastes held in common were divided among the landholders in proportion to their holdings. This was not the first such wave of enclosure in English history: perhaps half of the arable land had already been converted by 1750. These earlier

enclosures—in the 16th century especially—had aimed at converting arable land into large sheepwalks, to meet the growing demand for wool. The enclosures of the 18th century, however, were intended to increase cultivation.

Although enclosures were perhaps the greatest single factor in permitting and encouraging the diffusion of the new agricultural techniques, they entailed a heavy charge on the smaller landholders, who could not easily afford the legal costs and outlays for surveying, hedging, ditching, and the like. Even worse was the situation of the landless cottar or bordar, who lived by a kind of tolerance on common land, was permitted to pasture a few animals, and worked as a day labourer in the fields of his propertied neighbours. Enclosure settlements were scrupulous in their protection of the rights of those who owned land but were equally rigorous in their exclusion of those who did not. As a result, many small holders were forced to sell their parcels to those who could afford the costs of enclosure; and many more landless labourers had to leave their homes and take service elsewhere. For a long time, it was thought that these uprooted victims of enclosure provided the basis of the factory labour force. This has been disproved by the census data, which show the population of areas of enclosure growing throughout this period. This is exactly what one would expect of an institutional change that increased the demand for farm labour. Even so, agricultural employment could not keep up with increasing manpower, and it was the surplus population of the countryside that flowed to the cities. Enclosure selected many of those who chose to go; but, on balance, the agricultural revolution it helped make possible slowed the course of rural emigration.

There are no official figures on British farm output in this period, but it is estimated that wheat production, for example, almost doubled from 1700 to 1820—13 million to 25 million quarters. Even so, the agricultural sector could not supply the growing food needs of the country, and, from the 1770s on, Britain was on balance an importer of grain. To be sure, imports represented a small fraction of overall wheat consumption—less than 5 percent of home demand in the period from the end of the French Revolutionary Wars to the abolition of the Corn Laws (tariffs on imported grain) in 1846. Yet, the proportion would have been significantly larger had it not been for these protective duties, which constituted a subsidy to British farming and kept British prices higher than they would have been in a free market.

Abolition of the Corn Laws

The abolition of the Corn Laws and the introduction of almost complete free trade in manufactures in 1845–49 marked the substantial completion of Britain's Industrial Revolution and its economic pre-eminence at midcentury. The first signalled the victory of the manufacturing interest over the agricultural: as early as the second decade of the century, employment in industry exceeded that in agriculture; by 1851 it was twice as large, as was the share of manufacturing in the national product. If one added trade, transport, and other predominantly urban activities to the balance sheet, the disparity would be much greater. Understandably, the modern sector refused to go on paying tribute to the land.

The second was testimony to Britain's confidence and superiority in the world market; no one could undersell its wares (some 93 percent of British exports were manufactures). At this point, this small country, with less than 10 percent of the population of Europe, accounted for two-thirds of the coal mined in the world, half the make of iron, half the market of cotton cloth, and over one-quarter of the goods in international trade. It was a moment of dominance without parallel before or since.

CONTINENTAL EUROPE

The Continent until 1815. The other countries of Europe actually took a long time effecting their industrial revolutions. The rapidity with which some of them moved once the new technology took hold—Germany is the usual example—is deceptive. The hard job was to start moving. By comparison with Britain, the Continent was severely handicapped: geography, political boundaries, and a legacy of medieval tolls were barriers to the movement of persons and goods; forests were relatively abundant but coal scarce; incomes were lower; labour was cheaper and labour-saving devices were thus less advantageous; society was more rigidly divided by status and occupation; it was more rural, and country dwellers made poor or tight-fisted consumers; social attitudes were less favourable to business enterprise. In the lands east of the Elbe, the persistence of serfdom locked the greater part of the population into agriculture, so that the potential supply of labour to industry was drastically curtailed; moreover, since unfree men do not work so well as free, productivity was low, and the people were impoverished. Even in the freer lands to the west, however, the rural economy could not be compared with that of England. Subsistence farming predominated; there was considerably less regional specialization; techniques were less productive, and there was nothing like England's fascination with improvement. Commerce and industry had scarcely begun to penetrate the countryside.

Government sponsorship of manufacture

By the mid-18th century, even earlier in some countries, the governments of Europe were seeking systematically to promote industrial development. The reasons were primarily political: industrial growth and economic prosperity generated revenue and employed men, and money and men were the sinews of war, hence of power. The measures varied with and are a good reflection of the needs and shortcomings of these economies: subsidies in the form of money, gifts, low-cost loans, exemptions from taxes, use of public buildings, or free machines; technical assistance and the imposition of compulsory standards and quality control (particularly important in France); monopoly privileges to innovators of new products or techniques; an assured supply of labour, by assignment of serfs, prisoners, vagabonds, or such public charges as orphans and the residents of poorhouses (especially in central and western Europe); exemption of the work force from military service and the plant itself from the burdens of quartering troops; special privileges to immigrant artisans and entrepreneurs (Huguenots in Berlin, Germans in Russia, Jews throughout central Europe); an assured market via government or army orders or compulsory purchase by such unfree subjects as Jews (Germany especially); the award of places and honours to industrialists and of patents of distinction to their products. In some fields, particularly those linked to armament (powder works, arsenals) and to the supply of luxuries to the court (glass and mirror manufacture, tapestries and carpets, porcelain), the state itself became entrepreneur. In other branches, the state relied on private initiative and, when this failed to respond to the incentives offered, might order aristocrats or court purveyors or Jews or such others as were in no position to refuse to start putting their money and efforts into manufacture.

Much of this development from above was misdirected. Technical knowledge and managerial talent were in short supply, and the effort to force progress inevitably led to misallocation of resources and the manufacture of goods of poor quality at high cost. Subsidies only encouraged waste and inefficiency, while monopoly privileges eliminated the competition that might have compelled better performance. The difficulty was compounded by the preference of most rulers and their officials for large, centralized establishments—visible symbols of industrial achievement. The "manufactories," so called to distinguish them from true factories, were not centrally powered and were ordinarily equipped with the same devices used in conventional workshops. They had, therefore, no technical advantage over dispersed cottage manufacture yet were burdened with higher capital costs and were far less attractive to workers, who resented supervision and discipline—hence the need to assign labour, which was invariably sullen and unproductive. Most of these hothouse enterprises collapsed as soon as the state withdrew its support, and the setback was proportional to the amount of support. In Prussia, which was the greatest exponent of forced development, the death of Frederick II the Great, in 1786, was followed by a hecatomb of bankruptcies and liquidations.

This is not to say that the whole effort of state sponsor-

ship of industry was pointless. The privileged manufactories left behind a legacy of knowledge and skills. Many of the men who were trained in them constituted a second generation of entrepreneurs, less spoiled, more hardheaded, and far more successful.

On the Continent, as in Britain, the real progenitor of modern industry was the putting-out system. It had always been inhibited by the privileges of urban manufacturing centres and the efforts of the state to control the standards of production; but, beginning in the late 17th century, industry gained a foothold in the French, Walloon, Rhenish, and Swiss countrysides. In France, the prosperity and influence of this partially illicit industry was recognized by a law of 1762, which legalized the fait accompli. By this time, the efforts of merchant-manufacturers to reach farther afield for their labour (Norman clothiers were drawing some of their yarn from as far away as Picardy) were producing the same kinds of bottlenecks that had moved British manufacturers to turn to machinery and the factory, and there is no doubt that the same changes would have occurred on the Continent had the economy simply continued to develop along these lines. But this process was interrupted, first, by the British innovations and, then, by the French wars of 1792–1815. The first changed completely the conditions of international competition. It was at once apparent that any nation that wanted to maintain itself as a power, political as well as economic, would have to learn the new technology. The second, however, worked against this by cutting much of the Continent off from Britain for a generation and diverting resources into familiar but profitable techniques rather than more hazardous innovations.

The spread of British techniques

The extension of the Industrial Revolution to the Continent may be viewed as a process of cultural diffusion. The continental countries already had a pool of skilled artisans who might learn and apply the new techniques—clockmakers, instrument makers, millwrights, joiners, metalworkers. Even so, they needed considerable help to bring them to the British level. This was accomplished by missions of inquiry to Britain or by placing workers in British plants, by a certain amount of industrial espionage, by the purchase of British machines (usually illegally), and by engaging Britons to work in continental enterprises.

The first fruits of this diffusion were already seen before the French Revolution: a few steam engines, including some built in Europe; some thousands of mechanized spindles for spinning cotton; the first, abortive attempt at smelting iron ore with coal at Le Creusot in France (1785). During the French wars, the interruption of British imports permitted certain branches, textiles especially, to develop in a kind of splendid isolation—that is, to modernize with old-fashioned equipment. Such crucial branches as engineering and iron manufacture, however, made little headway. The one area in which isolation paid was chemicals, where the French responded to the shortage of alkalis by developing the Leblanc soda process.

The continental revolution, 1815–50. The return of peace brought both opportunity and peril: on the one hand, communications with Britain were open once again, and, on the other, British manufactures were so much cheaper and often better than continental wares that the infant industries of the Napoleonic era were menaced with liquidation. Most of the continental countries responded by setting up prohibitive tariff barriers; at the same time, both government and private enterprise bent every effort to import British skills and experience or to spy out the secrets of British technology. To combat this potential loss of superiority, the British had long since passed laws against the migration of skilled artisans or the export of machinery; but these could do no more than impede the process. By 1825 Britain's attempt to maintain a monopoly of the new technology was clearly a failure, and the ban on the emigration of artisans was lifted. Machines took longer, but in 1842 pressure from a machine-building industry whose capacity had outstripped home demand persuaded the Parliament to annul the prohibition on exports.

Determinants of continental changes

The rate of assimilation and adoption of the new technology in continental Europe varied widely. Among the more important determinants were (1) the degree of economic and technological backwardness; (2) the degree of exposure to British competition (too much could be fatal, but a certain amount could be stimulating, as in Belgium and Switzerland); (3) relative factor costs (if labour was cheap enough or capital too scarce and dear, it did not pay to install machines); (4) the political pressures for modernization (the rulers of smaller states, such as Belgium, Switzerland, and Sweden, not caught up in the competition for power, were willing to let economic development take its course); (5) the political pressures for conservatism (old-fashioned landed magnates in such countries as Austria and Russia correctly perceived industrialization as socially and politically subversive); (6) the resource base (other things equal, a goodly supply of coal, as in Belgium and Westphalia, was a potent incentive to the adoption of the new technology); (7) the size of the market (the unification of most of Germany into a customs union [Zollverein] by 1833 gave a powerful impetus to trade and regional specialization of industry); (8) the character of demand (peasants made poor customers for manufactures); and (9) the ability of the society to generate entrepreneurs (weakest in eastern Europe but also constrained in countries such as France by hostility to unbridled competition and by the conservatism of family enterprise).

The years from 1815 to 1850 saw several of the continental countries initiate their own industrial revolutions. Belgium was first, in the 1820s and '30s, with a marked emphasis on coal mining and metallurgy. France followed and, being poor in coal, concentrated on textiles and other light industries. From the 1830s on, the Swiss moved along the same path. Finally, Prussia, with large coal resources in Silesia and Westphalia, developed from the 1840s on a pattern similar to Belgium's. In all of these, railway construction was an important stimulus to development. Belgium, compact and densely populated, built its trunk network by the early 1840s. Germany was almost as quick, so that by midcentury one could cross the entire country by rail, east–west or north–south. France, by contrast, had only stubs of lines radiating from Paris and isolated stretches in the provinces. In the rest of Europe, the new technology was still exceptional, stunted by material and institutional obstacles.

The middle decades, the 1850s and 1860s. The decades of the 1850s and '60s were a period of catching up for continental Europe—not that Britain was standing still. Easy money favoured expansion: the effect of the gold discoveries in California and Australia (1848–49) was multiplied by the readiness of credit institutions to lend in a highly liquid market. The contrast was especially marked with the crisis years of the 1840s, when bad harvests, the collapse of a speculative boom in railway shares, and, finally, an epidemic of political revolutions in 1848 had first contracted the economy and then just about brought it to a standstill. Now confidence reigned everywhere, and promoters hastened to bring new commercial and industrial enterprises to the attention of investors. A striking feature of this renewed expansion was the role played by joint-stock, limited-liability corporations. These were not new; they went back to the chartered trading and colonial companies of the 17th century. But they had always been exceptional, subversive of a commercial morality that held a businessman personally liable for his losses "to the last shilling and acre." They had required the express authorization of the state and had been reserved for those few activities that could not be handled even by the collective resources of a partnership. Railway construction was one of these, and the railway did more than anything else to naturalize the limited-liability corporation. The principle was susceptible, however, of much wider application, the more so as technological advance and economies of scale increased the threshold investment required to found competitive enterprises. The contribution of limited liability was far more important on the Continent than in Britain, which had built its industrial establishment from

The role of limited-liability corporations

the ground up, plowing back profits into firms that began small and grew with the changing technology. Britain was also richer and possessed the most efficient money and capital markets in the world, so that industrial enterprises could count on generous bank credit, nominally short-term, but, in fact, renewed to cover medium- and long-term investments. By contrast, the follower countries across the Channel, which had to bridge the technological gap, were confronted with the task of paying for costly installations, not only with the industrial profits of yesterday but also with such resources as could be mustered from outside the industrial sector. In such circumstances, limited liability and joint stock were indispensable, and institutions had to be developed to take up the task of mobilizing capital and channelling it to potentially profitable ventures—hence, the importance of the corporate investment bank, already successful in Belgium but taking a new departure in the 1850s with the establishment of the Crédit Mobilier in Paris (1852) and the Bank für Industrie und Handel in Darmstadt (the Darmstäder Bank, 1853). These were followed by (and, in numerous instances, helped found) similar development banks throughout Europe. Some of them concentrated more on speculative promotions than on industrial development; the Crédit Mobilier itself, eponymous model for the new species, foundered in 1867 because of its vain effort to keep up profits and appearances by stock-market coups. Others worked better, especially in Germany, where the rapid growth of capital-intensive heavy industry, above all in metallurgy and mining, provided a large field of opportunity.

Free trade

The rapid economic expansion of these years set the stage for a major departure from the conventional wisdom of high protection. The key move was not Britain's unilateral step toward free trade in 1845–49 but rather the Anglo-French Treaty of 1860, which was swiftly followed by a series of similar agreements between the leading European economies, including the Zollverein. These were accompanied by reciprocal legislation to facilitate capital movements across national borders and by international monetary agreements providing for standardization and simplified exchange of currencies. This was not yet complete free trade, but it did bring closer the kind of international market that would, in turn, promote technological rationalization and diffusion. The Cassandras who predicted that the protected industries of France and the Zollverein would simply be crushed under the weight of British imports were proved wrong; the most efficient and strongest continental enterprises invested heavily in new plants and did better than ever. There was, however, a purge of smaller, marginally inefficient firms unable or unwilling to meet the new competition.

Improved transport

This purge of the old technology was further hastened by the vast improvement in transport technology that marked these years, in particular, by the competition of the trunk rail network of western and central Europe. The track mileage rose sharply (see Table 2), but more important than this was the completion of key connections and the consequent growth of passenger and goods traffic: 65,000,000 to 169,000,000 tons in Britain from 1855 to 1870; 4,000,000 to 44,000,000 in France from 1850 to 1870. Nothing did more to break down the autonomy of regional markets and promote the mobility of persons; internal migration, up to then confined largely to short intraregional movements, began now to develop along interregional routes. The railway, in combination with the steamship, also moved a rising current of transoceanic migrants—108,000 per year from Europe to the United States, 1830–49; 218,000 per year, 1850–69. This exodus, as much as modern market competition, hastened the demise of old trades in low-wage rural areas.

Table 2: Growth of Railway Networks in the 19th Century, Selected Countries
(in kilometres)

	1840	1850	1860	1870	1880	1890	1900

Although the middle decades of the 19th century were dominated by the extension of known techniques to new enterprises and areas and within existing enterprises, technical advance did not cease. For one thing, considerable improvement was built into the very process of expansion; it is hard to build a new edition of an old model without incorporating improvements. For another, no technique or machine is usable without some adjustment to the specific conditions in which it is to be used, and this adjustment often entails improvements. In the meantime, the pressures of demand continued to stimulate invention. An excellent example is steelmaking, where the traditional cementation and crucible techniques could produce only small pieces at high cost, used in shears, razors, swords, watch springs, and the like. The development of high-speed machinery and vehicles, however, created a need for steel in far greater sizes and amounts than customary. From the 1830s on, then, metallurgists in several countries bent their efforts to the problem. The definitive solution was found at about the same time by William Kelly of the United States (*c.* 1851) and Henry Bessemer of England (*c.* 1854), who was looking for a way to make a better cannon: by blowing air through a furnace containing molten pig iron, the oxidation of the carbon would proceed without the application of any external heat; hence, Bessemer's claim to make steel "without fuel." Though taken up eagerly, the new technique needed some additional touches before it was susceptible of general application: first, Robert Mushet's clever trick of burning off all the carbon and then adding it as desired made possible a standardized product, and, much later, the Thomas–Gilchrist process (1878–79) enabled steelmakers to work with phosphoric iron ores and opened the greater part of the world's iron resources to the new technique. In the next decade, a second way was found to produce cheap steel, this time with even closer quality control: first, a new "regenerative" oven invented by William Siemens (mid-1850s) yielded much higher temperatures, so that iron could be refined in huge open hearths; and here again, it was a second inventor, Pierre Émile Martin of France, who worked out the technique of adjusting the mix by the admixture of scrap so as to yield a standard product (1864). The whole story of cheap steel is almost an ideal case study in the dynamics of invention: (1) the importance of serendipity, (2) the role of multiple invention, and (3) the incompleteness of initial solutions and the indispensability of subsequent improvement.

Cheap steel

The chemical industry also moved ahead; in the 1850s and 1860s artificial, synthesized dyes were developed, first in England, then in Germany. Much more than in steel-making, however, technical advance in chemistry depended on scientific knowledge and systematic experiment: artificial dyes were only the first application of the new science of organic chemistry. These first dyes, then, were a promise not only of what would rapidly become one of the most creative and flourishing branches of industry but also of a new approach to invention.

The chemical industry

By 1870 the more advanced industrial countries of continental Europe had reached a point at which they could compete with Britain on reasonably equal terms. The scale of their enterprises was still smaller, as was the place of industry in the larger economy. Yet, they had assimilated the essential techniques of machine manufacture and adapted them to their circumstances; and, where before they had been almost exclusively learners, they were now generating innovations of their own.

SOCIAL CONSEQUENCES OF THE INDUSTRIAL REVOLUTION

The question of the social consequences of the Industrial Revolution has been hotly debated since its effects were

first noted in the early 19th century, and the issue is still alive. The split has been political, with the right usually giving a favourable judgment, the left a negative one. The question is beset by difficult problems of interpretation, value judgments, and criteria, but the following general observations may be made concerning the impact of the Industrial Revolution in Britain.

Standards of living

First, wage data indicate that, on balance, those workers who shifted out of agriculture or pre-mechanized industry into the modern branches of industry improved their earnings significantly. The gap was largest for those who came from the most backward rural areas in western and southern Ireland or the Highlands of Scotland. Those who stayed behind in agriculture benefitted to the extent that labour could easily take advantage of job opportunities in manufacturing: rural wages were highest in those parts of England adjacent to the great industrial centres.

Second, the worst losers were those workers who hung on in bypassed trades, such as handloom weaving. By 1830, tens of thousands of these were living on the very edge of survival.

Third, real earnings fluctuated with prices, particularly food prices, and the level of employment, as they always had. Real wages were thus at their lowest during the period of the French wars, when wheat prices reached record heights, rose over the next 15 years, fell again in the depression of the late 1830s (despite falling prices), then moved back up from the trough of 1842. There is no agreement on what the composite trend was from, say, 1790 to 1850, though no one would argue for a marked shift either up or down; the consensus, however, is that real wages rose substantially from the middle of the century on.

Fourth, consumption of the major food staples seems to have increased, partly owing to new sources of nourishment (potatoes and fish, in particular). Consumption of textiles grew even faster, and the generalization of the use of washable undergarments thanks to cheap cotton fabrics constituted a major advance in comfort and health.

Fifth, on the other hand, housing deteriorated as thousands of migrants poured into swollen urban centres that could not grow fast enough to accommodate the influx. The population of 103 cities of over 20,000 (including London) rose from 3.5 million in 1821 to 6.8 in 1851 to 9.5 in 1871. (This, it should be noted, is a general characteristic of all industrial revolutions: because construction technology does not advance as rapidly as that of other branches, investment in housing is less profitable than other investments or can be made profitable only at the sacrifice of quality and space—this, both for systems of private enterprise and state planning.) The poor either jammed into old structures, filling every vacant space by building sheds in courtyards or converting cellars into dwellings, or moved into little jerry-built row houses that were slums before they were finished. Water supply and sewage disposal were grossly inadequate: the life of the urban poor was a compound of damp, filth, and nasty smells. All of these inconveniences were an old story; rural housing was often even more primitive; but 100 hovels scattered over the hillsides were a much less serious problem than back-to-back tenements. Density bred discomfort, disease, and neurosis. Urban death rates actually rose in Britain in the 1820s and 1830s.

Working conditions

Sixth, the conditions of work in the modern industrial sector varied widely. Generally, the larger and more modern the enterprise, the roomier, clearer, and safer the workrooms, the shorter the hours, and the higher the wages. The weaker, less-efficient firms had to save on their wage bill in order to compete. Over time, therefore, the construction of new plants and increasing scales of production yielded as a by-product a substantial improvement in working conditions. The worst feature of the new mode of production was the extensive reliance on women and children. In itself, this was not new: women and children had always worked hard and long in cottage industry. Nevertheless, the discipline of the factory (a discipline often imposed by strangers), the remorseless monotony of many of the tasks, and the physical hazard and discomfort of some of the new processes took a heavy toll.

By the first decade of the 19th century, the abuses of factory labour were already a cause of public concern in Britain. The government was at first reluctant to intervene, for fear of breaching the sanctity of private contracts, but, beginning with parish apprentices in 1802, then continuing with other children in 1819 and 1833 and with women (in mines) in 1842 and (in textile factories) in 1847, Parliament gradually increased its purview. The most important step was the passage of the Factory Act of 1833, which set a minimum age of nine years, limited the hours of children to eight per day, required employers to provide schooling for their young workers, and, most decisive, established the principle of official inspection to ensure compliance. Unfortunately, the law aimed at first to protect only workers in centrally powered textile factories, so that older modes of production were enabled to persist in abusive working conditions until the passage of more comprehensive legislation later in the century.

In general, the social consequences of the Industrial Revolution were not so uniformly bad as they have been made out but were far worse than they had to be. They reflected the unpreparedness of British society, the ideological commitment to laissez-faire, and the natural indifference of most beneficiaries of industrialization to the sufferings of those who paid the bill.

Across the Channel, observers of the British scene were inclined to congratulate themselves on being spared the "white slavery" of the cotton proletariat. Yet, their poverty problem was even more severe—though more widely distributed, hence, less visible. Their industrial labour force was paid less and worked harder, and more of their children died younger. On the other hand, data on the consumption of necessities, such as wheat, potatoes, and textiles, show substantial increases per head over time; and, since these gains could not have been confined to the well-to-do, one must conclude that people were eating more and dressing better. Housing, as always, was a dark spot, with death rates varying widely between rich and poor neighbourhoods. As in Britain, much depended on the level of economic activity: the late 1830s were hard years, and the mid-1840s, with their conjuncture of bad harvests and business contraction, produced in some areas (Flanders, Silesia) a Malthusian peak in mortality. Things picked up thereafter.

Another test of the effects of industrialization is the hypothetical question: what would have been the condition of the population had there been no Industrial Revolution? It is nearly impossible to conjecture an answer. One approach is to consider the fate of those parts of Europe, or even of the United Kingdom, that did not keep pace with the new technology. These proved invariably to be the poorest areas—sloughs of overpopulation, endemic underemployment, and underdevelopment. Like Silesia in 1844 or Flanders and Ireland in 1846, they had no reserves in time of want and fell easy prey to famine and disease. There was an autonomy to the population growth that began in the mid-18th century that made some kind of revolution in productivity indispensable if Europe was not to lose the slow gains of a millennium and sink back to the poverty of the Middle Ages.

THE COURSE OF INDUSTRIALIZATION, 1870–1914

Industrial proliferation, 1870–1914. The last part of the 19th century saw the further ramification of the Industrial Revolution into the peripheral European lands, the offshoots of Europe overseas, and—for the first time—a non-Western society, Japan. The result of this geographical extension, combined with differing national rates of productivity change and industrial growth, was a drastic revision of the international balance of economic and political power.

The United States

A new industrial giant appeared across the Atlantic. The United States was especially favoured for economic growth. It was a rich land, with varied climate and abundant natural resources. Population density was quite low, so that land could often be had for the settling, and the

return of labour was high and increasing. The existence of an open frontier was in the long run a stimulus to industry, because land could compete for labour at high wages and costly labour was a spur to technological innovation. U.S. industry early won a reputation for ingenuity, for example, in the precocious recourse to interchangeable parts—what came to be known as the U.S. system of manufacture.

The course of the U.S. Industrial Revolution may be summed up by a few key variables. From 1839 to 1899, value added in the industrial sector (manufacturing, mining, and construction) rose from $310,000,000 to $7,830,000,000 (at fixed 1879 prices)—that is, over 25 times or 5.53 percent per year. Deflating for the size of the labour force and the change in average man-hours per year, the increase was from about $385 per capita to $1,022, a gain of 2.65 times or 1.64 percent per year. Consumption of mineral fuels, a good indicator of both industrial activity and capital stock, grew 65 times from 1850 to 1910, or 7.2 percent per year; deflating for population change, the gain was still 16.4 times or 4.77 percent per year. The effect was to make the United States the greatest industrial power in the world: the U.S. passed Britain in steel output in 1890, in coal in 1898, and in raw cotton consumption at the turn of the century.

Russia

Political seers of the late 19th century were wont to pair the Russian Empire with the United States as the two giants of the future. Yet, Russia, big and populous though it was, lagged at that time far behind the United States in industrial development: in 1913 Russia (including Poland and Finland) produced some 34,000,000 metric tons of coal; the United States had reached that level in 1869 and by 1913 was extracting over 500,000,000 tons. Russian economic power was still potential—latent in the high land–man ratio, the rich natural resources, the large and rapidly growing population, and the existence of a small native cadre of highly educated scientists and technicians, reinforced by immigrant entrepreneurs and workmen. The similarity with U.S. conditions is striking. But, where the United States was enabled by its institutions and attitudes to make the most of its means and opportunities, the political and social constraints of tsarist Russia—a parasitical aristocracy, nationalist objections to Westernization, serfdom to 1861, and communal obligations and passport controls after 1861—all of these were serious impediments to innovation and to the efficient allocation of human resources. Moreover, the country was as poor as any country in Europe, and modern techniques cost far more at the end of the century than at the beginning. Government intervention and assistance were therefore indispensable to the development of social overhead capital (railroads, above all) and heavy industry. The key figure was Count Sergey Yulyevich Witte (minister of finance, 1892–1903); this was the period of Russia's most rapid growth, with a second spurt just before the war. The greatest gains were in metallurgy: once the railway opened the Donets Basin to exploitation, output of pig iron rose from 69,000 tons in 1887 to 1,507,000 in 1901—an increase of 22 times (25 percent per year). Even so, this was still a pre-industrial society; the work force in "large-scale" manufacture numbered less than 3,000,000 in a population of 170,000,000.

Japan

In many ways Japan was less prepared than Russia to undertake a technological revolution. It was much poorer in natural resources, at least as poor in income and accumulated wealth, and far more ignorant of modern science and technology. On the other hand, this was a much freer society, with a peasantry responsive to economic opportunity and a high degree of social and political cohesion that was to make possible the enlistment of loyalty and effort on the scale of both nation and enterprise. It was also an exceptionally literate society that was capable of learning quickly. The Japanese campaign to industrialize—and it should be seen as that—reflected the conviction of the leaders of the society that only by adopting Western technology could the nation maintain its independence vis-à-vis Western encroachment.

The success of modern technology in Japan owed much to government expenditure on social overhead capital (especially transport and education), to selective and moderate tariff protection, and to official support for those branches of industry that called for heavy investment and were slow to generate profit. This program, in turn, depended on gains in productivity and a growing surplus that could be converted into tax revenues. Advances in agriculture were crucial, with output rising 1.93 percent per year from 1885 to 1917. The first major industrial gains were characteristically in light industry—

silk textiles to begin with but, very quickly, cotton. From 1880 to 1913, cotton spindles increased from 13,000 to 2,287,000, or 176 times. By the latter date, the Japanese export of cotton yarn and thread was worth twice that of Germany and about 40 percent of that of the United Kingdom. Heavy industry, by contrast, was still in a state of tutelage, dependent on military orders and artificial stimuli; the payoff in technical training, managerial experience, and labour skills would come later.

The changing balance of economic power. Within Europe, these decades brought an important realignment of economic power as the first follower nations (Germany, France, Belgium) completed their industrial revolutions and new entrants (Sweden, Italy, Holland, Hungary) made their appearance. Britain, the first industrial nation, continued to develop and grow, though more slowly than its rivals. By the 1890s Germany had passed Britain in iron and steel manufacture, and, from then on, the gap between the two countries widened steadily. The result was a shift in the balance of political power that generated international anxiety and conflict and contributed to the outbreak of World War I.

The relative decline of Britain

The reasons for the relative decline of Britain have been a subject of extensive controversy. Some have tried to minimize the weakness of British performance, but this is unpersuasive, since most of the major economic variables give evidence either of a slowing down or of smaller gains than elsewhere, especially in the newer branches, such as electric power, electrical engineering, and organic chemicals. What is more, British technique was now lagging, even in industries such as steel, in which the key innovations were of British origin.

It has been argued that British technology, for all its shortcomings, represented a rational, optimal response to the relative costs of the factors of production; that is, that, if British productivity in certain industries was lower than that of competitors, this was unavoidable, implicit, among other things, in Britain's deteriorating natural endowment for industry. Britain, on this interpretation, was no longer able to compete. If true, this is a discouraging judgment and one that would no doubt have deterred such raw-materials-poor countries as Japan from ever entering the international market. It is far more plausible to see Britain's relative decline as the result of

economic reverses and human shortcomings than as inexorable destiny.

There were, first, the consequences of industrial proliferation: where once almost the whole world had been open to British goods, now the home markets of manufacturing rivals were closing through tariff restrictions (Germany, 1879; France, 1892; United States, 1890 and 1897). Competition in third markets was intense. The cotton industry furnishes the best example: from 1885 to 1913, British sales of yarn to China fell from 20,000,000 to 2,000,000 pounds, while India and Japan were selling hundreds of millions of pounds between them.

Second, Britain found itself handicapped by its priority in industrialization. To go first is both an advantage (entrepreneurial profits, accumulation of capital) and a disadvantage (costly mistakes, expenses of experimentation, related costs). The British, who had built much of their industrial plant and transportation system to the requirements of a smaller economy, now found that younger countries, building to new specifications, were better able to adopt more efficient techniques and operate on a larger scale.

Even when the British built a new plant, however, it was usually not so efficient as in Germany; and, in such areas as electrical engineering and organic chemicals, the British were not even building plants to the extent that market demand and natural-resource endowment warranted. In this case the explanation seems to lie in social values and institutions. The newer branches of industry, especially, and the older branches, to an increasing degree, demanded a high level of scientific training and a willingness to invest in research and development with a delayed payoff. The day of the inspired tinkerer was past. In this circumstance, the Germans were at a significant advantage, for their educational system was far ahead of the British in the production of graduates in science and applied science; and the society conferred a value on these activities that was wanting in Britain. To some extent, Britain compensated for this knowledge gap by importing continental technicians and entrepreneurs—a significant reversal of the earlier pattern; yet, this was, at best, a palliative. The difficulty was compounded by the great emphasis on experience and seniority in British works, by practical men's suspicions of "book learning," and by the scarcity of ambitious, tradition-free management. Too many British entrepreneurs were heirs of earlier achievers, industrialists by inheritance and duty and more concerned with spending than getting.

The "great depression" of the 19th century. The pressure of international competition was felt most keenly in Great Britain, which, as the dominant industrial power, had most to lose. The sense of loss was the stronger because these were decades of slow growth of manufactures (1.8 percent a year), declining prices (the wholesale index for manufactures fell from 127 in 1873 to 71 in 1894), protracted slumps, and small profits—hence, the traditional designation "the great depression."

Business cycles

Some scholars have viewed the great depression as a European phenomenon, but the course of economic activity in the continental countries was quite different from what it was in Britain. German industry did suffer a severe setback after the crash of 1873, a typical catharsis after some three years of enthusiastic company promotion (the *Gründerjahre*) fuelled by the large French war indemnity. Beginning in the 1880s, however, rapid growth resumed, and profit levels picked up, with no further serious interruptions until the crisis of 1900–02. Over the period 1873–1913, mining output rose 4.3 percent per year; manufacturing output, 3.4 percent. France, by way of contrast, had much less trouble in the 1870s, was hard hit by a financial crisis in 1882, had another, smaller shock in the mid-1890s, and then another, more protracted, in the first years of the new century. On the whole, these were years of below-average growth for manufactures (2.3 percent a year between 1873 and 1895). In the United States, the troughs of industrial activity came about every ten years, with especially severe conditions in the 1870s and 1890s. For the U.S., however, as for Germany, these were decades of sustained growth of manufacturing output (4.9 percent per year 1869–1913) and could in no way be described as depressed.

Even so, it would be a mistake to place too much reliance on indexes of aggregate production, which of their nature soften the pattern of economic fluctuations. The periodic depressions that were afflicting the economies of all advanced countries were real enough to their victims. The near regularity of these contractions gave them an appearance of inevitability, and economists bent their efforts to understanding them and predicting their timing. Much of the difficulty was linked to the increasing commercial and financial interdependence of nations. The world volume of trade had grown spectacularly (three times between 1850 and 1880, three times again from 1880 to 1913), in spite of the late-19th-century tendency to higher tariff protection. Trade entailed credit, so that every major commercial centre held large amounts of commercial paper, secured in principle by real commodity transactions but often resting on personal arrangements (accommodation paper) and mutual confidence. With the development of the limited-liability corporation and large-scale trading in company shares and debentures, a new field of speculation and credit opened up, the fortunes of which were closely linked with those of the commercial sector. The potentialities for enrichment were much enhanced, but so were the dangers of overoptimism and the penalties of miscalculation. Typically, the upswing of the cycle was marked by a rapid rise in the volume of trade and investment, with a concomitant increase in commodity prices (including the rate of interest) and a growing reliance on credit. When demand, however, was no longer able or willing to meet these prices, orders would fall off; stocks would accumulate; bills of exchange and other instruments of credit would not be paid; and a downward spiral of diminishing confidence would produce a general contraction. This process could not be limited to one area or country; all its trading partners would necessarily suffer in turn.

The international monetary system

The communicability of these fluctuations was enhanced by the workings of the international monetary system, which rested on the gold standard and generally free convertibility. The primary concern of the central banks was to protect specie and bullion reserves, thereby ensuring continued convertibility. In time of contraction, however, the calls for credit drew heavily on these reserves, for, when confidence failed, only hard metal would serve as payment. To counter this drain, the central banks tightened credit and the money supply when they were most needed and loosened them when the emergency had passed. By raising interest rates in time of crisis, moreover, each money market strained the resources of the others by siphoning off funds. To be sure, if matters became desperate, one central bank would rescue another by direct loan. More often, however, it was *sauve qui peut*, with each country defending its reserves at the expense of its own citizens.

The international gold standard depended, in the last analysis, on the maintenance of a stable balance of payments among the economic powers. To some extent, convertibility conduced to that result by imposing restraints on all: any nation that bought more than it could afford would see the rates of exchange turn against it, lose reserves, and have to stop overspending. Yet, the tacit acceptance of this discipline would never have survived any real imbalance of international exchange. Even in the 19th century, those countries, such as Austria and Russia (or even Britain during the Napoleonic Wars and the United States during and after the Civil War) that could not back their paper currency with sufficient metal simply eschewed convertibility; and, with World War I, the gold standard became a matter of history and, for some, of ideological adoration. There were several attempts to restore it subsequently, but none succeeded, for the simple reason that no sovereign nation was prepared to accept the self-privation that it implied.

A second Industrial Revolution. Insofar as the Industrial Revolution spread during these decades to newly industrializing countries, its outlines were substantially the

same as they had been earlier; that is, the first advances typically took place in food processing and textiles (cotton especially), with further extension into metallurgy, machine building, and chemicals. Within each of these branches, the techniques and equipment introduced were largely the classic elements: spinning machines and power looms, coke blast furnaces, and rolling mills. But the equipment itself had grown bigger, faster, more accurate and dependable, while the array of techniques had vastly proliferated, so that newly industrializing nations adopted, alongside these classic items, such newer ones as the steam hammer (an invention of the 1840s), the sewing machine, the milling cutter (for metal as well as wood), and the new technology of steelmaking. As a result of these changes, the threshold scale of production had grown considerably, and each piece of equipment cost substantially more. To be sure, it was sometimes possible, and sensible, to start new enterprises with the second-hand machines and equipment of more advanced economies. More often, however, one took what machine manufacturers and industrial engineers were prepared to deliver, and few of them were ready to build for their customers outmoded plants and equipment. In short, though the lineaments of these later industrial revolutions were the same as earlier, the content was quite different.

In the meantime, the technology of the advanced nations continued to evolve in the same direction, although the gains achieved in the older branches were shrinking relative to previous advances. The spindles could turn a little faster; the furnaces could be built higher; but the increment entailed a smaller proportional increase in profit than the radical changes of an earlier era. The place of the old staple industries was shrinking, and the rate of growth of a given economy depended on its ability to develop newer lines of production.

These constituted, toward the end of the 19th century, an innovational cluster important enough to warrant perhaps the designation of a second Industrial Revolution. As before, the critical advances occurred in the fundamental sphere of energy conversion and distribution: on the one hand, the production and use of electricity as a source of motive power and, on the other, the invention of the internal-combustion engine as a prime mover. The first had revolutionary consequences both for industrial technique and domestic life. Not only was electrical transmission of energy more efficient and safer than conventional direct drive by shafts and belts but it also could be effected over long distances, so that the production of energy could be centralized and power distributed to small units (households and shops, as well as mills and forges) as needed. Electrical current, moreover, was far more versatile than steam power, for it could be used not only to produce motion but also light, sound, and heat and made possible a revolution in communication (telegraph, telephone, radio, television, radar, telex, etc.), as well as some notable advances in chemical manufacture. By the end of the century, almost two-thirds of U.S. factories were using electrical power equipment to some degree; by 1914, three-quarters. Whereas steam power was necessarily concentrated in large production units, hence, in a few power-intensive industries, electric motors were useful and profitable in a much wider range of activities; thus, in 1889, the five leading power-using branches (lumber, food, iron and steel, textiles, paper) held 73.5 percent of total primary-power capacity in manufacturing; by 1929 this share had fallen to 58 percent. In Europe, Germany took the lead both in production and use of electrical power and the production of electrical equipment. German industry was marked by thorough exploitation of by-product energy produced by heat-generating industries, such as metallurgy, large distribution nets with high-use factors, and early standardization of current characteristics.

Electrical power

The second major innovation in the generation of power was the internal-combustion motor, so called because the driving force is obtained by controlled explosions within the motor itself. The first such device was Étienne Lenoir's gas engine of 1859, but the critical conceptual advance came with Alphonse Beau de Rochas' four-stroke cycle, which found application in Nikolaus August Otto's "silent" gas engine of 1876. This was a tremendous success from the outset, for it was far more efficient than the steam engine when working intermittently or at less than full load, conditions typical of small industry. Its principal shortcoming was that it was tied to its source of fuel, whereas the promise of the internal-combustion motor lay in its compactness and potential mobility. These possibilities were realized with the adoption of oil fuel. The result was a revolution in transportation (marine engines, the airplane, and, above all, the automobile), which liberated land transport from rail routes and the individual traveller from dependence on common carriers. The impact of the automobile was only beginning to be felt in the period before World War I; but the introduction of the cheap passenger car (Henry Ford's Model T, from 1908) was a promise (or warning) of things to come. The automobile quickly became the most important single product of the manufacturing industry, generating investment and growth by its demand for raw materials and highways (including bridges and tunnels) to match the burgeoning volume of traffic. Output of petroleum products, rubber, cement, asphalt, steel, glass, and even textiles (for upholstery) waxed (and sometimes waned) in sympathy with the demand for and use of automotive vehicles of all sorts, to say nothing of a large service sector (insurance, law and litigation, medical repair, auto repair, garages, and parking lots) devoted partially or exclusively to meet the needs and correcting the misdeeds of auto users. At the same time, the process of manufacturing automobiles called for innovations in materials and techniques important in themselves and susceptible of application in other industries: line assembly, new alloys, special-purpose tools, advances in grinding and stamping, and standardization of parts. By 1913 there were 1,258,000 motor vehicles registered in the United States, 208,000 in Great Britain, 125,000 in France, 93,000 in Germany—a total of 1,700,000. Twenty-five years later, on the eve of World War II, the total for those four countries had reached almost 36,000,000, a gain of over 21 times (13 percent per year).

Internal-combustion engine

As important as the automobile industry came to be, two other new branches of manufacture can be compared to it in range of influence and potential for growth. One was organic chemicals and the manufacture of synthetics. Again, the pre-World War I years gave just a hint of what was to come: celluloid (John Wesley Hyatt, 1868); artificial silk or rayon (Hilaire, comte de Chardonnet, 1889–90); bakelite, the first synthetic resin (Leo Hendrik Baekeland, 1909); cellophane (J.E. Brandenberger, 1912). These artificial fibres and plastics were the first fruits of what would be a new kind of industry, based on increasingly heavy investment in laboratory research and turning out new products to order, primarily for consumer use.

The second was the equally versatile electronics industry, in its infancy in the early years of this century, when its only application was still wireless communication. The key innovation here was the tube or valve, so called because it channelled the flow of electric current in one direction and made possible the construction of complex circuits. Synthetics and electronics did not fully develop until the interwar years and the post-World War II period and might better be seen as part of a new major cluster of innovations (including atomic energy and computers) constituting a third Industrial Revolution.

Along with these and other innovations in technique and product went new patterns of industrial and business organization. The old trend to bigness continued as better but costlier production equipment raised the price of entry and offered new economies of scale, while improvements in communication enhanced the possibilities of centralized management. In the United States, capitalization per manufacturing establishment increased from $4,334 in 1849 to $10,992 in 1879 to $153,278 in 1919. Economies of scale—in marketing and administration as well as production—were only part of the story, however. Equally important were market considerations, in particular, the desire to stabilize profits and minimize competition, either by absorbing or eliminating competitors

The trend toward bigness

or by organizing cartels, trusts, and similar combinations in restraint of trade. In Europe, the merger and cartel movements were especially strong in Germany, first, because the close ties of German manufacturing with investment banks allowed the latter to play the broker's role in combinations (which usually generated substantial fees and promotional profits); second, because German managers were usually bureaucrats who identified with their functional role and took well to group discipline; third, because the German government was, on balance, favourable to developments that it viewed as promoting stability and control. By 1905 there were some 366 industrial cartels operating in Germany; some controlled prices, others output, many both. So powerful was the trend to bigness and combination and so influential the role of the so-called great banks (themselves the result of numerous mergers) that contemporary observers thought they saw the appearance of a new stage in economic development, the era of finance capitalism.

Finance capitalism

The term was somewhat premature. Although similar trends were to be found in the other major European industrial economies, they were substantially weaker. In both Britain and France, for example, the stress on family ownership and identification posed a barrier to both financial intervention in industrial management and to disciplined participation in cartel agreements. In Britain, when mergers did come, they were often a response to contraction rather than an act of expansion: independent firms reluctantly combined their resources to meet falling prices and profits and then spent years fighting over the appropriate allocation of authority and returns.

In the United States, giantism was to a certain extent the expression of a national style, an aspiration to bigness on the part of industrial tycoons, such as Andrew Carnegie in steel, the Guggenheims in mining, John D. Rockefeller in oil, the brothers James and Benjamin Duke in tobacco, Philip Danforth Armour and Gustavus Swift in meatpacking, Edward Henry Harriman in railroads. Financial interests also played their role: Kuhn, Loeb & Co. in railroads and, most prominently, J.P. Morgan and Company, the bank that founded the General Electric Company, the International Harvester Company, and the United States Steel Corporation—to cite its three largest creations. The usual technique in these promotions was to "water" the stock—that is, to issue shares for an amount far beyond the real assets and cost of the component companies. The difference, which is said to have been as high as $62,500,000 for U.S. Steel, went into the promoters' pockets. Not that the stock was not worth its watered value: if the amalgamation was well planned and yielded sufficient control of the market and (more rarely) savings in costs, the new combine might well make enough money to justify the price of its shares; in most instances, thus, it was the consumer who paid for the "water." By the Sherman Anti-Trust Act of 1890, combinations in restraint of trade were prohibited. Nevertheless, it took decades of litigation to dissolve the largest trusts, and, even then, the giant corporations that remained found ways to cooperate informally.

Industrialization on the eve of World War I. The position of the different nations in this process of social as well as economic transformation may be measured by the position of industry relative to agriculture and the ratio of urban to rural population. In regard to the first, one can discriminate among four categories.

First, there were countries in which the industrial labour force was already greater than that in agriculture: Great Britain, which had reached this position by 1820, is the best example, but Belgium had pushed its industrialization almost as far. The United States and Germany, in spite of substantial advantages in agriculture, had long since entered this group. France had not quite made it and would not do so until after World War II. Each of these countries had increased product per head by three to five times over the course of the preceding century (see Table 3).

Second, there were countries whose agricultural population was still about twice as great as its industrial: Sweden, Italy, and Austria all fell into this category. Each nation had developed by this time a large, modern industrial sector, and Sweden and the Czech lands, particularly, had enterprises that were technologically at a level with the best European practice.

Table 3: Growth of National Product, Selected Countries and Periods (Constant Prices)

	rate of growth per decade (percent)		coefficient of multiplication in a century	
	total product	product per head	total product	product per head
England and Wales				
1700 to 1780	5.3	2.0	1.7	1.2
1780 to 1881	28.2	13.4	12.0	3.5
France				
1831–40 to 1861–70	26.3	21.6	10.3	7.1
1861–70 to 1891–1900	15.7	13.5	4.3	3.6
Germany				
1850–59 to 1910–13	29.2	16.3	12.9	4.5
United States				
1839–43 to 1910–14	48.2	16.8	58.9	4.9

Third, there were countries that had entered on the Industrial Revolution but were still primarily pre-industrial. Russia was a good case in point, with a few completely modern plants, especially in the young iron-and-steel industry of the Donets Basin. Hungary also had, in the Ganz electrical works of Budapest, one of the more progressive enterprises in Europe. But these were predominantly peasant societies; skilled industrial labour was scarce; and industry was still dependent on strong tariff protection and artificial support.

Fourth, there were countries almost exclusively dependent on agriculture: such Balkan nations as Greece and Bulgaria, the colonial lands of Asia and Africa, and the more backward countries of Latin America—in short, what would later be called the Third World. With rare exceptions (*e.g.*, India's cotton manufacture), industrial production consisted almost entirely of domestic handicrafts and artisanal work.

Concomitant with the shift of resources to industry went a movement of population to urban centres. The development of a predominantly urban society entailed substantial costs to physical and psychic health, while the convenience of concentration was offset by the impediments of high density of living and movement. Even so, urbanization contributed to the increase in productivity and wealth by intensifying contacts and information flows between innovators in knowledge and its applications and by nourishing and propagating new attitudes toward family size and population control.

This last was of the greatest consequence, because it reinforced what was already a wide gap between the industrial nations and the rest of the world. By the beginning of the 20th century, the very size of the gap between industrial and pre-industrial nations constituted a barrier to development by the latter, while the differential accessibility of the new technology made their task harder by bestowing on them those benefits that translated into lower mortality rates rather than higher output. Just when the industrial nations were completing their "demographic transition" from high death rate cum high birth rate to low death rate cum low birth rate and winding up their population explosion, the undeveloped parts of the world were entering on theirs.

In sum, the Industrial Revolution, though consisting in a cluster of changes in technique in a small part of the productive system, ramified throughout that system and, transforming it, transformed the quality of life and the values of society; starting in one country, it proliferated throughout the world—a far more ecumenical movement than even the most successful religious faiths. It did so unevenly, for better or worse. Those countries that have become rich in the process (though they have pockets of poverty) are now having second thoughts; technology is much decried as an enemy of man. The poorer nations cannot afford the luxury of renunciation; they have noth-

ing to renounce. They are all, or almost all, striving to effect their own industrial revolutions. (D.S.La.)

III. Economic developments since World War I

THE AFTERMATH OF WORLD WAR I

The outbreak of war in 1914 ended a distinct era in economic history and ushered in a period of instability, uncertainty, and unexampled change that could hardly have been foreseen before the conflict began. Trends that might have been gradual were telescoped into a few years. A further impetus was given to the concentration of production in large-scale units and to the decline of competition. State intervention in the economy, prominent for the first time under modern conditions during the war, was to assume a more definite and permanent character. Technological change became more firmly linked to the giant advances in the physical sciences and permanently molded life in the advanced regions of the world.

To write the economic history of this great transformation poses many problems, for, despite statistical and literary evidence on a scale unprecedented for any previous period, it is no easier for historians to agree, the very nearness of the phenomena being observed provoking controversy rather than consensus. It is, moreover, inadequate to consider only the advanced countries of western Europe and North America when observing the development of the world economy. New light may be cast on the economic past of the now advanced countries by considering the history of the developing countries.

Only the most technologically and industrially advanced nations could wage wars of the type of 1914–18 and 1939–45. Germany's ability to hold out so long was a tribute to its industrial strength as much as to its military competence in both wars. The decisive role of the United States as an arsenal and its rapid industrial growth in both wars is again highly significant. France held out in World War I thanks to its allies' economic support; its collapse in World War II was economic as well as military. With or without the atomic bombs, Japan would have been defeated because of its overstretched resources.

In this period, economic history cannot be separated from military history, and into both the major wars there entered deep economic rivalries. War also provided an overwhelming stimulus to maximize production and make full use of scientific knowledge. Mechanization, rationalization, and standardization were imposed by the conditions of war production, and the interruption of normal trade channels intensified the search for substitute materials and the development of synthetics, from which are descended some of the fast growing industries of the period. The "new industries" early in the century expanded rapidly. In the United States as well as Europe new plants had to be erected both in existing industrial areas and in areas little touched by industrialization.

The conditions of war production

The increase of government control. Once they realized that modern economies could engage in long wars, the belligerents had to intervene rigorously in the economic arena. Market forces were superseded or supplemented by state direction and coordination. The overriding aim became the equipping of the armed forces, and, since their needs rapidly became voracious and unlimited, output at any price became the watchword and contracts were placed on a cost-plus basis to encourage maximum production. Trade unions and employers' associations were drawn in, and controls had to be extended to the distribution of necessities to the home front. The overall problem was one of acute shortage and the substitution of administered priorities for free market forces.

This greatly affected politicians and administrators accustomed and disposed to an automatically operating market economy. Not even in Germany had a comprehensive apparatus of controls been envisaged at mobilization. It was assumed that, when the fighting ended, a speedy return to the market would be possible. From 1918 the state relaxed its hold on the economy—prices surged forward in a burst of inflation, and a short postwar boom began, to end in mid-1920.

Postwar reconstruction. Destruction resulting from the war on land was chiefly confined to the main battle zones in Belgium and France. The victorious Allies expected that Germany would pay for this destruction, but this turned out to be a vain hope: reparations caused bitter controversy in the coming years and animosity between the victor powers. What was, however, of greater significance was the ability of the advanced industrial countries rapidly to reconvert their industries and rebuild devastated areas. French reconstruction endowed the northern and eastern *départements* with a new infrastructure and re-equipped and modernized agriculture and industry within a few years. Likewise, German industry recovered rapidly.

The diminution of European power. It was the world economy that experienced the most profound changes. The most outstanding was the financial and industrial upsurge of the United States and the decline of Europe, transformed from a creditor to a debtor. The world monetary and trading system centred on Europe had been seriously dislocated, and frontier changes had increased the tariff barriers dividing the Continent; and there was political uncertainty in central and eastern Europe. The Bolshevik Revolution had taken Russia out of world capitalism and threatened to spread westward in the postwar atmosphere of discontent and near chaos. Finally, industrialization had gone ahead in other parts of the world, closing old markets and rearing up new competitors. Most ominous of all was the emergence of Japan as a vigorous competitor in world markets.

Of major and immediate significance in the postwar decade was the need to restore the old pattern of trade and payments. This was taken to mean, first, the restoration of the gold standard upon which prewar currency stability and convertibility had been based. But war finance had everywhere caused inflation in the belligerent countries, and there could be no return to gold without currency stability. Second, Europe was quite unable to resume its prewar position as an international creditor. U.S. capital played a vital part in European reconstruction and subscribed heavily to the international loans that enabled Germany to make scaled down reparations payments. Stabilization and expansion in the 1920s was thus underpinned by an outflow of funds from the United States to Europe. This proved to be a most unstable arrangement. Funds returned to take advantage of the capital gains realizable on Wall Street and when the crash came in 1929 one of the main props of the central Europe banking structure was removed, and the stage was set for the financial collapse of 1931.

The role of U.S. capital

Inflation. War finance had been inherently inflationary, and, once controls were removed, prices began to soar. Moreover, social breakdown in eastern Europe and Russia had resulted in money printing and inflation. The occupation of the Ruhr by French troops in 1923 in an effort to enforce reparations payments precipitated a hyperinflation in Germany that broke all records. In the final stages Germany resorted to the printing press on a massive scale, and the rise in prices was such that workers collected their wages in suitcases and spent them at once before the paper marks became worthless. In November 1923 a determined and successful effort was made to stabilize the currency, and Germany entered a new period. Industry had meanwhile wiped off its debts and made considerable windfall profits. Thanks to this and to the inflow of American funds, industry was modernized and expanded. Inflation had disastrous effects for those who held their savings in state bonds or fixed interest securities or who lived on fixed incomes. At the same time, speculators and profiteers did well, and some made fortunes overnight. The "new rich" of the inflationary years prospered; their social juxtaposition with impoverished middle class people helps to explain the political upheavals that followed. The outstanding feature of the inflation was its arbitrary effect: undermining the old virtues of thrift and savings, which had been capitalism's most valuable moral supports.

Countermeasures. As governments sought to control inflation they prepared to return their currencies to a gold base. This was done with a greater measure of international consultation than hitherto. Britain returned to gold

—at the prewar parity—in 1925 in an effort to "look the dollar in the face" and permit the City of London to resume its prewar financial pre-eminence. It required a conscious effort to deflate prices and incomes, and the effort ran into stiff working class resistance. Its effect on exports was highly adverse, and it was an important factor behind the General Strike of 1926. The French, with the franc only four-fifths of its prewar value, were unable to return to gold at the old parity. When the franc was stabilized in 1926 and the move was legalized in 1928, to avoid unemployment it was slightly undervalued, which favoured exports and the tourist industry.

In the 1920s something like currency stability and convertibility were restored on the basis of a modified gold standard. Reconstruction was completed in war-damaged areas; industries were restored and modernized; old trade links were re-established and new ones opened. Industrial expansion was resumed. American capital flowed into Europe, and by 1930 a number of countries were enjoying boom conditions. But there were some shadows. The British economy was suffering from the loss of export markets. The traditional industries were ailing, and the overvalued pound had harmed the export trade. Germany, like Britain, had a seemingly intractable unemployment problem with almost 2,000,000 persons jobless even before the slump.

The changing world picture. The primary producing countries had boomed during and immediately after the war and had increased their capacity. The recession that began in 1921 after the postwar restocking boom was a sign that things had changed. Most of the producing countries were in a colonial or dependent relationship to the advanced countries, and in a number of them a nationalist movement had appeared on the scene. Where some industrial growth had taken place, as in India, it called for protection of the home market and government encouragement of industrialization. The seeds of change were being sown. Some economists have linked Europe's interwar difficulties with the disappointing performance of primary producers. Had the European countries adapted to changes in technology and world demand, they would have increased their demand for primary products and enabled their producers to buy more manufactured goods. As it was, world trade was the worst sufferer from the war and the biggest casualty in the Depression of the 1930s. To make matters worse, the industrial countries protected their own producers, and, when the slump came, there was a general retreat to the home market with higher tariff barriers, quotas, and administrative devices to keep imports down. Primary producers responded by encouraging their own industries as well as keeping up prices by restriction schemes.

Nationalist movements

Outside Europe, Japan, the only Asian country before 1914 to have begun to lay the foundations for an advanced industrial economy, experienced rapid economic growth in the 1920s. Japanese businessmen seized the opportunity afforded them by the cutting off of European exports to Asian markets, and, despite the recession of 1921–22 and the Tokyo earthquake of 1923, the industrial sector expanded rapidly. The economy was dominated by a few giant, monopolistic firms peculiar to Japan, but much industry continued to be organized in the old forms in workshops or on the domestic system. Wages were low and labour abundant. Creating technologically advanced industries necessary to carry on the war with China was typical of the 1930s in Japan. The economy depended intimately, however, upon foreign trade. In the 1920s it had benefitted from the demand for silk, and Japanese industry was later able to undercut its competitors in textiles and cheap consumer goods.

Technological and industrial progress. The introduction of industries based on new technologies was to have profound effects on the relative economic development of the industrial countries and particular regions in each country. During the 1920s the United States took the lead in the new fields. It was favoured with vast natural resources; a large, varied, skilled, and educated labour force; a large and expanding internal market; and a high average income. Such conditions encouraged production of standardized articles on a large scale and continuous improvement in technology to keep down labour costs and to take advantage of expanding markets. The accumulation of capital and its concentration into giant business units had proceeded rapidly from the latter part of the 19th century and took a further giant leap as a result of the war. U.S. productivity was the highest in the world and that country's system of manufacturing became a model. U.S. industry pressed into new fields opened up by technological advance, and a whole range of machine-made products passed into general consumption. This transformation was seen in the widespread use of the automobile, the telephone, the consumption of electricity, and the kitchen equipped with electrical appliances. The new consumer durables, symbols of modern living, were most fully developed and most widely used in the United States. Correspondingly, innovations of no less importance appeared in complementary fields: merchandising, advertising, packaging, retail selling, and consumer credit. The United States mirrored the prosperous future of the other advanced countries, although the full flood of Americanization was delayed until after World War II.

The U.S. in the 1920s

Compared with urban U.S., even the most highly developed areas of Europe seemed archaic. Their incomplete industrialization had left in existence parts of the traditional culture that moderated the operation of market forces. In Europe, a successful businessman might retire early or endeavour to pass his children into the ranks of the still highly regarded leisure class. Most European countries except Britain still had a large peasant sector, with which was associated many activities still in an artisan stage, and a cluster of petty capitalist activities in the small towns that dotted the rural landscape. The structure of agriculture, the distribution of income, the whole character of the market did not yet favour the mass production typical of the 20th century. The main emphasis of European industry in the 1920s was on textiles, iron and steel, coal mining, heavy engineering, and shipbuilding. Economic historians have pointed to the slow shift of resources from the old declining sectors to industries based on the new techniques of the kind that were growing in the United States as being a fundamental weakness of Europe's interwar economy. This drag on Europe's growth also limited the demand for raw materials and foodstuffs from the less developed countries.

The slow shift of resources

Market forces seemed powerless to effect the kind of transformation needed, and state intervention often merely confirmed acquired positions. In any case, the conditions favouring the growth of the new industries in the United States could not be produced in other environments. A further shift of resources out of agriculture and toward urban living was necessary. Only a general rise in incomes could open a mass market for such new products as automobiles and domestic appliances. New systems of distribution and consumer finance had to be adopted, and capital had to be attracted by the prospect of profits. These changes came about slowly as output recovered and began to expand with increased productivity; but the obstacles were not simply within the range of economic policy: they were more broadly sociological and cultural. Changes in social structures and life-styles, accelerated by World War II and helped by time passing, were vital and perhaps decisive.

The beginnings of social welfare. The economic experience of the war years did not shake the general assumption that, in peacetime conditions, state intervention was unnecessary and harmful. But it had been shown that in certain circumstances business might benefit from the activities of the state. Only in the United States was belief in the virtues of rugged individualism still unchallenged, and even there it was more myth than reality. Until the Depression of the 1930s, however, there was no desire, even in Europe, to see the state permanently endowed with more extensive economic powers. It was not the success of state intervention in the war but the breakdown of market forces in the 1930s that opened the way for regulated capitalism.

The extent of state intervention varied greatly; some countries had operated the railway system for many

years, and there were state monopolies for fiscal purposes. But the main economic intervention continued to be the tariff. Even Britain had imposed protective tariffs on luxury items during World War I and in the 1920s began "safeguarding" industries from unfair foreign competition. At the same time, there was a steady underlying trend toward greater state involvement in the economy, influenced by the growing Socialist and trade union movements. The way was being prepared for the wider intervention by the state characteristic of the Depression decade.

The use of tariffs

State provision for social welfare had a much wider measure of acceptance in the 1920s and steadily became more systematic. It was understood that the sanctity of private property and the pursuit of profit might be threatened if society did not make adequate provision for its casualties. By the 1920s most states had social security or insurance systems of various degrees of comprehensiveness. Increasingly, such welfare provision became a matter of legislation laying down minimum standards rather than the old haphazard mixture of charity, poor relief, and mutual insurance. Wartime experience, in which all members of a society were taken to be in solidarity against a common enemy and thus entitled to its support, exercised an important influence on the development of social security systems.

The state's tendency to assume social responsibilities was persistent and continuous in the period after World War I, and, with the establishment of the International Labour Office in Geneva, a beginning was made in establishing uniform standards between countries. Partly under labour union pressure, industrial regulation became more comprehensive and better enforced. Public and local authorities were also assuming greater responsibility in transport and the provision of water, gas, and electricity; in education; and in housing, made necessary by the chronic and widespread postwar shortage. Investment in human capital, if not yet a common phrase, was being taken more seriously than ever before; but, like all similar trends, it was uneven; practice often lagged behind legislation, especially in the poorer countries.

Paradoxically, the richest country of all lagged far behind. In the United States, where the new technologies were most profoundly altering social life, where business structures and patterns of consumption earliest assumed the characteristics of modern capitalism, social security was neglected until the Depression. Apart from some accepted regulatory functions, neither the federal nor the state governments did much in the social and economic arenas. The whole American tradition—and the majority of public opinion, including organized labour—upheld the principles of laissez-faire liberalism. The most advanced capitalist country lacked a system of social security that every advanced industrial country in Europe took for granted, and it was also without an independent political party of the working class.

During the 1920s, as recovery and inflation took place, production and productivity again began to grow in the advanced countries, and incomes rose. Meanwhile, the new technologies began to influence social life more fully. Road transport made its effects felt through the bus and the truck; rural areas were brought into closer contact with urban influences; and personal and labour mobility increased. Marketing and distribution changed as farm produce could be collected more regularly and moved more quickly to urban markets. Electric power brought new flexibility to industry and opened an industrial vocation to hitherto predominantly agrarian areas. The cinema and the radio transformed entertainment patterns as well as the supply of information or propaganda. Professional sports became a growing industry. Service trades of all kinds grew most rapidly in the advanced countries with high incomes.

The new technologies

This expansion of the "tertiary sector" was one of the most notable trends of this period. Consumers, with increased incomes, spent more on services. Former household activities became specialized marketed services; retail outlets multiplied; old-style services expanded, and new ones appeared. As the activities of governments, national and local, became more complex, so their employees increased; and even business employed a growing bureaucracy of its own. In other words, the white collar element in the labour market grew and was symbolic of changes in life-style in societies with a relatively high and growing per capita income. Expectations grew, too, even faster than possibilities for their realization. Workers became better organized and more demanding, installment selling enabled people to spend ahead of their incomes, and the Depression caught all these developments in full flood.

THE GREAT DEPRESSION

The stabilization of capitalism after World War I was short-lived, for the world economy plunged into the worst depression in its history. Although heralded by the Wall Street crash in the autumn of 1929, it was some years before it became apparent that this was no ordinary cyclical downturn. It afflicted every capitalist country, and its depth and length still challenge those seeking its explanation. Even on the outbreak of World War II, despite the recovery from the trough of 1932–34, the Depression had not been conquered, and capitalism had not found new long-term forces of expansion sufficient to overcome the trends toward depression and stagnation. So far from new government policies for full employment and economic growth being effective, it seemed rather that purely national remedies, the resort to beggar-my-neighbour policies and, more especially, the drive to rearm—which arose out of the political upheavals of the Depression—prepared the way for the new war.

What does seem to be accepted is that, although depression was centred in the United States, it was the special and intimate relationships established between the U.S. and other capitalist economies after World War I that accounted for its rapid diffusion and harsh impact. It is equally apparent that the stabilization that had taken place in the other countries and the boom conditions of many, in the late 1920s, concealed serious weaknesses. The British economy's failure to resume capital exports in the old way, the decline of its basic industries, the consequences of the overvaluation of sterling—all weakened the world economy and thrust greater responsibilities upon the United States. The investment boom in European countries following reconstruction could only continue so long as markets could be found; a cyclical downturn was inevitable sooner or later. The problems of the primary producers (now weak sellers as a result of overproduction) reduced the market for manufactured goods and slowed their growth rate.

In the return to gold, some currencies had been overvalued, others undervalued, and the Depression came before adjustments could be made. Moreover, international financial relations were no longer on prewar lines. War debts and reparations weakened capitalist countries, leaving the United States as the major creditor. The 1920s' boom in Europe had been financed by an outflow of U.S. funds, much of the investment being on a short-term basis and already being withdrawn in the last phase of Wall Street speculation before the crash. Any investigation of the causes of the Depression must consider the changed role of the United States as now the main support of prosperity in the capitalist world. Once the U.S. economy had slumped, there was no prospect of maintaining prosperity elsewhere.

The effects of Wall Street speculation

The collapse of the world market. The reversal of the dollar outflow exposed the deficiencies in the economies of the other capitalist countries. What was striking, above all, was the disintegration of the world market as each country sought its own salvation. The contraction of world trade was the most general expression of the crisis, hitting hardest the primary producers and those industries depending upon exports. Thus, outside the United States, the Depression was worst in Germany and Britain. The sharpest contraction was in the export trades and the capital goods industries, as well as in shipping and shipbuilding. Activities turned mainly toward the domestic market suffered less, and so "sheltered" and "unsheltered" industries were distinguished. The former, least affected by de-

pression, were also the easiest to help. The recovery of the export and capital goods industries was much more difficult to engineer, and in many cases permanent contraction was the remedy used.

For most countries, the more prosperous conditions had been before 1929 the sharper was the decline in the following years, but a large agrarian sector—as in France—could provide some shelter from the blizzard. Germany was the worst hit European country, and there, as in the United States, the Depression was a social and political calamity. In Britain, however, the abandonment of gold and the devaluation of sterling; the adoption of protection that stimulated home industry; a delayed development of the technologically more advanced industries; a building boom assisted by cheap money; and the ability to take advantage of the low prices of imported foodstuffs and raw materials while using accumulated reserves to avoid a balance of payments problem—all enabled it to weather the Depression better than some other advanced industrial countries.

The United States was the home of the Depression, and it persisted there longest. The prolongation of the Depression is linked with its causes. Although the stock market crash had acted as a detonator, there were powerful forces in the U.S. economy that made the crisis more than a cyclical decline. Moreover, the collapse of the boom raised doubts about the long-term prospects, hitherto viewed optimistically. The Depression was thus traumatic because it contradicted deeply held beliefs in unlimited expansion and also brought poverty, hardship, and hopelessness to millions in the world's richest country.

That the United States was particularly slump prone was not a popular view in the 1920s, when the country seemed on a course of boundless expansion. Indeed, optimistic forecasts were made up to and even after the crash of 1929. U.S. economist John Kenneth Galbraith, in *The Great Crash, 1929* (1955), ascribed the Depression diffidently to five main factors: (1) unequal income distribution, which limited the consumer goods market and made investment and luxury spending erratic (bad news from Wall Street sent both down); (2) fraudulent business, which abounded in "a kind of flood tide of corporate larceny"; (3) the banking structure, which contained too many independent units, causing bankers to yield to overoptimism or to act foolishly—and once one bank failed the whole system collapsed; (4) the new creditor position of the United States, which, besides resulting in unwise foreign lending, was coupled with high tariffs so that foreign countries could not service their debts by increasing exports to the United States, resulting in default and the inability of foreigners to continue to pay for U.S. exports; and (5) the poor state of economic intelligence.

Five causative factors of the Depression

Government response. The historian must give due weight to the social consequences of economic fluctuations and the way in which governments, by their response to the situations thereby created, may complicate matters further. It was generally assumed by economists, at least well into the 1930s, that government intervention should be minimal, the assumption being that government intervention could not correct, and might aggravate, a market disequilibrium. Indeed, some felt the slump was partly a consequence of government interference. Even when governments did perforce begin to intervene, the orthodox majority continued to be suspicious of the trend or even to blame it for the economy's failure to recover more quickly and completely. Since the 1930s economic opinion has moved to the view that governments should have intervened with appropriate weapons to remedy what was seen as the basic cause of depression—a deficiency in demand.

What is clear is that the Depression had such severe social consequences that even reluctant governments could not stand aside. The price of nonintervention was social revolution, and intervention was, or could be, a weapon of counterrevolution, as under the Nazi regime in Germany. Intervention, therefore, took place pragmatically, and its forms were at first "orthodox" in that they consisted of old, well-tried methods. First, the tendency toward economic nationalism was reinforced as governments imposed tariffs or raised existing ones and added quotas and other devices to protect home producers. As the Depression continued, protection tended to be used increasingly aggressively to bargain with other countries and penetrate foreign markets. The disintegration of multilateralism, which was often replaced by bilateral trading agreements, accompanied the decline of world trade. The immediate effect of all these measures was to reduce the volume of international trade and create conditions of trade war.

Parallel to this went the breakdown of the gold standard. In the autumn of 1931 the overvalued pound sterling was driven off gold, starting a succession of devaluations as countries learned that an undervalued currency gave a temporary advantage in the struggle for markets. With their objective base for parity destroyed, currencies became subject to government action, and some form of exchange control had to be established if balance of payments difficulties were not to be exaggerated by speculative currency movements. Countries like France, which delayed establishing exchange control, did so to their cost. Nazi Germany, on the other hand, by means of rigid controls, could operate parallel exchange rates to its advantage and at the expense of weaker trading partners.

The conditions of recovery. The Great Depression of the 1930s shook capitalism to its foundations and was the major formative influence on political and social as well as economic life. Already undermined by World War I and its aftermath, many of the old certainties derived from 19th-century liberalism disappeared. Despite millions of unemployed throughout the decade—in many of the most advanced areas of the world—and the triumph of Fascism in Germany and the subsequent drive to war, most years of the 1930s were, however, years of recovery, though recovery from a very low level. Indeed, the slump itself had prepared the conditions for recovery through the normal cyclical process: after a few years, in which investment falls to a low level or even becomes negative; when stocks are used up; when equipment grows obsolete and has to be replaced; when prices reach bottom, the possibilities for profitable investment begin to improve. Unsound firms have disappeared, the financial excesses of the boom have been liquidated, a shift of resources from the unprofitable sectors has been affected, old plant has to be renewed, and confidence revives. Thus, the classic conditions for recovery began to operate independently of government action.

Recovery came slowly and in many countries was far from complete by World War II. Until there was a revival of world trade, the primary producers could not raise their incomes. On the other hand, in the advanced countries, even those as export dependent as Britain and Germany, it was possible to find a substitute for exports. In Germany this was chiefly war production. In Britain, although rearmament in the late 1930s helped recovery, it had earlier depended upon an expansion of the home market, the shift to new industries, and the continuous rise in service activities, even in the "depressed areas."

As a major importer of foodstuffs and raw materials, Britain was able to take advantage of the deterioration in the terms of trade of primary products. This enabled consumers to spend more of their income on nonfood items and expanded the consumer goods and services market, creating new opportunities for profitable investment and employment. It assisted manufacturers directly and consumers indirectly through the relative cheapening of imported raw materials. Given that this took place with a resumption of technological advance and innovation, Britain could enjoy a limited recovery. Almost all persons could thus improve their real income, at the expense, in part, of primary producers abroad. Where those primary producers were to a large extent at home, as in France, these conditions for recovery did not exist.

All governments realized that something had to be done to relieve what amounted to a national catastrophe. The Soviet Union's example had begun to turn thoughts toward planning, even of capitalism, as a possibility. In the early years of the Depression the instinctive reaction of

The orthodoxy of political reaction

politicians was still strongly orthodox. In Britain, proposals for positive steps to overcome unemployment through public works, were rejected by a Labour government. The watchword virtually everywhere was to keep the budget balanced and avoid interference with free market forces. Policy was thus generally deflationary: government expenditures were vigorously reduced, and the more consistently such remedies were applied, as in France, the more they aggravated the disease. In some cases, however, governments did inadvertently run budget deficits through emergency action, and where they did so they began, possibly unwittingly, to assist recovery. The real innovation came when what was done in some cases by accident was pursued systematically.

The German remedy. Two experiments are worth noting as of particular importance. Both had the character of models—to be emulated or to be avoided—and both have preoccupied economists and historians since, though a definitive account of neither has yet been written. One is the National Socialist policy adopted in Germany on Adolf Hitler's assumption of power in 1933, which prepared the most powerful industrial nation in Europe for a new war. The other is the New Deal, which Franklin D. Roosevelt proposed to the American people after his inauguration at almost the same time. These two experiments can also be considered as alternative ways of saving capitalism. Both shed light on the nature and efficacy of remedies for unemployment and depression that, during and after World War II, were to acquire immense prestige both among professional economists and the general public.

In Germany, the recovery and expansion of the 1920s were abruptly ended by the Depression, when American investment was cut off and short-term funds withdrawn, and when the collapse of world trade drastically reduced exports. Between 1929 and 1932 national income fell by 40 percent and unemployment soared to more than 6,000,000. All of the weaknesses of the German economy were exposed, particularly its unhealthy dependence on foreign loans and credits. As German governments followed each other in rapid succession, grappling halfheartedly with insurmountable problems, the National Socialist movement gained increasing support from the middle class and the peasantry. Blaming Germany's ills on the Versailles settlement and international Jewish finance and promising to save property owners from Bolshevism, Hitler's party came to power in January 1933 and implemented a new and energetic policy to save German capitalism. It is difficult to separate Nazi economic policy from its political and international policies, but there is little doubt that it was supported by the leaders of German big business and banking. It destroyed the free trade unions and political parties and abandoned the "socialist" elements in the National Socialist program.

In some respects Nazism continued old policies. The mark's exchange value was upheld, and much trade was conducted through bilateral bargaining. The state supported the depressed sections of the economy in consultation with business leaders. To relieve unemployment the Nazis initiated a policy of public works, including the famous *Autobahnen* ("expressways"). But such measures were but the prelude to much bigger rearmament expenditures that Hitler launched in defiance of the Treaty of Versailles. With state control of wages and, later, prices, unemployment was absorbed and idle resources used without significant inflation. The opening up of a new market for heavy industry in armaments production restored profitability and confidence in German capitalism but at the price of increasing militarization of the economy and to the accompaniment of an aggressive external policy that made war inevitable.

Foreign trade and exchange dealings controls were tightened to enable vital raw materials to be obtained on favourable terms. Exports had to be increased to pay for these imports. At the same time, militarism led to the development of new industries producing armaments irrespective of costs. Domestic consumption was held back by pegging wages at about their 1933 level. Prices rose rather more, despite controls.

It was no secret that German recovery was based on a war economy. All participants in World War II experienced a similar process: but the German experience was novel and, by some, held up as an example. The Nazis established a full employment economy but one geared to war and with war as its inevitable outcome. Nor did the Nazi leaders try to disguise their intentions, which they rationalized as a need to acquire for Germany more *Lebensraum* ("living space"). The Nazis did not establish a new economic system; they simply imposed greater state control on an economy that still rested upon private ownership and private profit. Industrially, however, it was a highly concentrated economy, and it was big business that benefitted most directly from Hitler's policies.

Hitler's quest for *Lebensraum*

The New Deal policy. The urgent situation created by the Depression in the United States and the blow inflicted on cherished ideas about rugged individualism imposed striking departures in that country's government policy. To say that they were imposed is to emphasize the fact that they did not arise from the application of an economic theory but were in the tradition of American pragmatism. Not until near the end of the 1930s did the doctrine of the economist J.M. Keynes begin to influence policy, and the measures that were taken until then fell considerably short of the Keynesian prescription.

When the Depression struck, a Republican administration under Pres. Herbert Hoover held office and met the catastrophe with puny relief measures to help farmers and the unemployed. Tariffs were raised in 1930, and, when these measures failed, Hoover set up the Reconstruction Finance Corporation to make loans to banks, financial institutions, and other enterprises in trouble. In the first year the economy continued to decline, and, when Franklin D. Roosevelt took office in 1933, average income was about half what it had been before 1929; 90,000 businesses had failed; banking was on the verge of collapse; and 15,000,000 people were unemployed. American capitalism seemed headed for collapse if not revolution.

Roosevelt's economic ideas, such as they were, were purely orthodox. During his presidential campaign he had repeatedly attacked Hoover for permitting a budget deficit. Thus, the electorate did not vote for the New Deal, which is best seen as the sum of pragmatic measures the new administration enacted to grapple with the emergency. It was intended to sustain capitalism while recovery took place through the operation of market forces. In part it consisted of a huge relief program financed by public funds and organized by a host of ad hoc bodies. It did not establish a planned economy but aimed to restore the profitability of business so that idle resources and manpower could be used. But so minimal had been the role of the state heretofore that a series of reforms had to be enacted to enable the government to carry out its task. Once Roosevelt declared that he was offering a New Deal, the program was pushed through with dramatic swiftness. U.S. public opinion was prepared to try anything that offered better prices, profits instead of losses, and more jobs. Each section of the economy was dealt with by a special agency. The gold standard was abandoned and the dollar devalued. The Agricultural Adjustment Act helped farmers through price supports, subsidies, and the restriction of production. The National Industrial Recovery Act embraced a series of measures based on a code of "fair competition" for each industry. Again, the intention was to raise prices by reducing competition. At the same time, wages were also to be raised.

Budget deficits

The New Deal included large public works outlays that brought the federal budget into deficit, but these deficits were too modest to account for the recovery of the economy that slowly began. Although Roosevelt set out to save U.S. capitalism—and succeeded—his policies were strongly opposed by many businessmen and by conservative opinion, possibly because he was supported by organized labour and most wage earners and appeared more radical than he was. In return for this support the administration made concessions to trade unions and authorized a modest social security program. It seems

that once the worst of the Depression had passed, business confidence may have been weakened by Roosevelt's policies, or by the menace that many businessmen believed these policies held over them.

In any case, U.S. recovery received a severe setback in 1937, when government expenditure declined. The lesson was learned, and by 1938 the doctrines of Keynes had made headway, both among economists and in the administration. Pump priming and countercyclical spending were making their way as respectable fiscal practices, but unemployment remained high, and tendencies toward stagnation persisted until World War II began to have its effects.

The New Deal enabled the dire emergency that confronted Roosevelt on his inauguration to be overcome without disaster and without making inroads into private property rights or political freedoms. It did not fully succeed in bringing about recovery. In fact, it took the colossal expenditures of World War II finally to overcome the Great Depression. In this respect the New Deal can be contrasted with Nazi policy, which found the complete answer to the Depression: arms expenditure limited only by physical resources. This was the answer, too, that American capitalism found after 1940.

THE INDUSTRIALIZATION OF THE SOVIET UNION

The Bolshevik Revolution, which in 1917 took Russia out of the capitalist world, and Russia's transformation into a leading industrial power have had enormous significance in the 20th century. In the early years the very existence of the new regime weakened capitalism; and later the viability of the alternative system was demonstrated in the carrying out, through nationalized property relations, of planned large-scale industrialization. Whether or not Premier Joseph Stalin's tyrannical methods were necessary to the process, the results were impressive, indicating to less developed countries that there was an alternative to capitalist industrialization. Elsewhere, too, planning was turned from vague concept to practical reality, acquiring exceptional prestige even in capitalist countries.

The early days: War Communism and the NEP. When the Bolsheviks took power they could hardly have confronted a worse economic situation. When the revolutionary wave in Europe subsided, they were left with a situation unforeseen in Marxist thinking: a workers' party held power in a predominantly backward peasant country ringed by hostile capitalist states. The country was torn and divided by civil war; industry and the transport system were virtually in ruins; famine and disease stalked the land.

When World War I broke out, Russia had a small but advanced industrial sector, and capitalism had made deep inroads into agriculture. In the industrial centres were large concentrations of workers on which the Bolsheviks drew for support. The countryside was experiencing severe social strain as the old village society was undermined by the spread of capitalist relations. The Stolypin reforms, begun after the Revolution of 1905, hastened this process by enabling peasants to withdraw from the *mir* (village commune) and favouring the better-off peasants, or kulaks. The considerable advances, before 1914, in both industrialization and in modernizing agriculture made the tsarist autocracy and its officialdom increasingly anachronistic. The old order was drifting toward a crisis that the war brought to a head once the strain of battle losses began to tell.

The Stolypin reforms

It was in this situation that the February Revolution of 1917 took place, leading to a Provisional Government dominated by the middle class. As the economic situation deteriorated, the masses came into increasing conflict with the Provisional Government, enabling Lenin and the Bolsheviks to lead a successful insurrection and to establish "the dictatorship of the proletariat" in November. Workers and soldiers under Bolshevik direction had been the spearhead of the revolution in the towns, but in the countryside the peasantry had acted independently to seize land owned by the nobility. While endorsing this peasant revolution, the new regime also proclaimed the nationalization of the land. For the moment, control of agriculture remained in the hands of the peasants, and the feeding of the towns then, and for something like a decade, depended upon extracting a food surplus from a mass of peasant holdings still largely cultivated in the old way.

The economic steps taken by the Bolsheviks in their first year included nationalization of all industries employing more than five people, of banks and foreign trade, and of the land. A large part of the country, however, was outside the new Soviet government control, and civil war continued until 1920. There was, in fact, virtual economic breakdown, with many factories closed or producing only a trickle. Priority was given to the front for supplies available in what was substantially a siege economy named "War Communism." The government appropriated what revenue it required either by requisition or by printing money. The black market engulfed supplies, stocks were hoarded, and galloping inflation began.

War Communism was born of an emergency situation in which the economy had collapsed and all efforts were concentrated on survival. Market relations were sharply curtailed, and wages and other payments were made in kind. Grain surpluses were requisitioned, if necessary by force. As production fell and goods disappeared from the shops, workers who had not been drafted into the army or employed in the new administration drifted back to the villages. The hardships of the period were only made bearable by promises of a better life in the future. Discontent, already growing, now became more open. The mutiny at the Kronstadt naval base in February 1921 was the final danger signal. War Communism was abandoned and replaced by the New Economic Policy (NEP).

The NEP was generally admitted as a retreat. Its basis was that it permitted private enterprise in internal trade and to some extent in industry. It also encouraged the peasants to produce a surplus for sale and offered opportunities for their enrichment. Nepmen (private businessmen) and kulaks accumulated capital. The debate in the Communist Party was about how far this should be permitted and, more fundamentally, how fast Soviet industrialization should proceed.

Central planning. It was axiomatic that the U.S.S.R. could only overcome its historical backwardness through industrialization and that this should take place under the control of a central planning agency and on the foundation of a nationalized industry. The NEP stood by this principle. In fact, the State Planning Committee (Gosplan) was set up in February 1921 to "work out a single general state economic plan and methods and means of implementing it." What was at issue was the rate of industrialization, the tempo of growth, which could not in practice be separated from the path that was to be chosen.

The establishment of Gosplan

During the "industrialization debate" of the 1920s, all the great questions about economic growth that interested Western economists a quarter of a century later were thoroughly discussed. After Lenin's death in 1924, Joseph Stalin strengthened his hold on party and state apparatus and formulated the theory of "Socialism in one country"—concentration on building up the Soviet economy at the expense of the international goals of Communism. He was supported by Nikolay Ivanovich Bukharin and others on the right wing of the party, which assumed that NEP would last for a considerable time. Industrialization, therefore, could take place only by slow stages in which the peasantry was encouraged to market its surplus and nationalized industry produced the consumer goods it required in exchange. These perspectives were opposed by the left opposition, whose leader was Leon Trotsky. "Socialism in one country" was rejected as a revision of Marxism because it placed internal interests before those of world revolution. The policy of concessions to the kulaks and the adoption of a slow industrialization tempo were equally condemned, and a program for more rapid industrialization and planning and the encouragement of voluntary collectivization was substituted. Finally, the left opposition was defeated, and Stalin emerged as the master of the party apparatus. Free debate was stifled,

and the dead hand of orthodoxy gripped Soviet political economy.

Meanwhile, the New Economic Policy enabled recovery to proceed fastest of all in agriculture but also in industry. Once the prewar levels had been attained (from about 1925), decisions had to be made on the rate of growth. This depended upon how much grain surplus the peasants were prepared to part with. And that in turn depended upon the ability of industry to supply industrial goods. The main emphasis would have to be upon consumer goods production, and capital formation would be a dependent variable and not the main determinant. If, however, economic policy continued along these lines, industrialization would be slow, and the U.S.S.R. would be vulnerable to capitalist pressure or even attack. Meanwhile, the growing prosperity of the kulaks and the Nepmen would undermine the nationalized property relations upon which the state was founded.

Stalin's change of course

These dangers prompted Stalin to make a brusque alteration of course, taking over much of the policy of the defeated left opposition and applying it with a brutality they had never advocated. From 1928, therefore, the Soviet Union suffered a new period of strain and sacrifice in which, under conditions approaching civil war, agriculture was collectivized and the first stages of planned industrialization were forced through. From this cauldron the U.S.S.R. emerged to face the German attack of 1941 with a much more powerful industry than before. The basis had been laid for it to become the second largest industrial power, but the social and human price had been tremendous.

The drafting of the First Five-Year Plan was begun by Gosplan in 1927; the starting date was from October 1 of the following year, but the campaign did not get under way until 1929. At the end of that year, the plan targets were revised upward at about the same time that Stalin ordered forced collectivization.

A whirlwind descended on the Soviet countryside. The peasants were forced into new collective farms set up without adequate technical means or experienced leadership, and kulaks were forced off the land and deported in large numbers to Siberia. Their resistance was shown by their mass slaughter of their animals, which set back the production of meat and milk products for years. Soviet industry was unable to supply enough equipment, fertilizers, and insecticides to raise the technical level of the new collective farms above that of the former peasant holdings, so agricultural production declined sharply, and bitter resentment long remained among the peasantry.

In industry there was certainly more enthusiasm for the change; but the emphasis of the first and subsequent plans was upon endowing the Soviet Union with heavy industry, not with increasing consumer goods production. This made high growth rates possible, since a large part of production went into new investment. Sacrifices were imposed not only on the peasantry but also upon the working class, including the huge new labour forces drained from the countryside into overcrowded industrial towns. Propaganda explained that these sacrifices would provide a better life in the future.

Social upheaval and oppression. At the price of a gigantic social upheaval the economy was transformed and entered upon a long period of expansion. The First Five-Year Plan, only unevenly fulfilled, was followed by a second in 1933 and a third still incomplete when war came. These plans maintained the priority of heavy industry, with a shift toward defense. While the capitalist world was plunged into depression, the Soviet Union grew rapidly. The growth record was impressive. Although per capita consumption may have declined and agriculture stagnated, industry—and especially heavy industry—showed a formidable advance. The development of social and community services supplemented real wages. Large numbers of people acquired new skills, as well as literacy, while a new managerial and technical elite was trained.

The Second and Third Five-Year Plans

Industrialization was achieved without foreign capital. The expected revolution in Europe had not taken place, and the isolation of the U.S.S.R. was intensified with the rise of Nazi Germany and the growth of armaments in the capitalist countries in the late 1930s. It remained economically inferior to the advanced capitalist countries despite the five-year plans.

Soviet life in the 1930s was lived under the shadow of political repression and terror unjustified by the pressures of industrialization. The arbitrary arrests, purges, trials, prison camps, and mass executions were necessary instruments for Stalin in maintaining his personal ascendancy over the new ruling stratum and the masses. But Stalinism was a burden on the economy; and it is no accident that the height of the purges is paralleled by a dip in the indexes of industrial production.

Purges and executions

Industrialization in the Soviet Union was consciously planned with the whole economy centrally controlled. Material balances, not prices, determined the allocation of resources, and the plan targets were fixed in quantitative terms. Anomalies and abuses, sometimes gigantic, did not prevent the main objectives of the plans from being realized. But the type of planning used—virtually, production at any cost—showed its weaknesses as the output pattern became more sophisticated. Its defects were most apparent in the sectors closest to the consumer, in light industry and retail distribution. After the ravages of World War II had been repaired, the planning methods inherited from the Stalin era came under more critical scrutiny, and modifications and reforms were introduced.

Many criticisms can be made of Soviet planning. The priority given to heavy industry and armaments meant that the Soviet consumer had to suffer. Labour discipline was severe. The high output encouraged in the 1930s by the Stakhanovite Movement made for inequality of earnings. Complaints of wasteful use of productive capacity and materials and of mismanagement and corruption have frequently been made by the leaders themselves. Especially during the purges, initiative and responsibility were impaired by the fear of punishment. Bureaucratic heavyhandedness, unevenness of production and work loads made necessary by sudden spurts to achieve plan targets, production of goods not really required, and difficulties in coordinating the requirements of different enterprises—these are among the criticisms made of Soviet planning.

The later stages of Stalinism. By the time Germany attacked the U.S.S.R. in June 1941 the five-year plans had given the Soviet Union a powerful industrial base. Whatever the revulsion against Stalin's crimes and the excesses and mistakes of the plans, it had been shown that an alternative to a privately-owned economy was viable. But the Soviet Union was still considerably behind the advanced capitalist countries in per capita output and labour productivity, although the gap had been narrowed. Nevertheless, without the accelerated industrialization that the plans made possible the defeat of the U.S.S.R. in 1941 or 1942 would have been certain.

At the end of the war the Soviet Union faced a tremendous task of reconstruction that again postponed the improvement in consumer goods output; but the war had spurred industrial and technological advance, and the planning apparatus was well able to meet the postwar challenge. Within a few years, however, resources were once again being diverted by the Cold War. Stalin's death in 1953 initiated a period of economic reforms. With consumer needs still generally receiving a low priority, the Soviet Union showed its strength in other directions. The sustained and rapid growth of the 1950s, the development of nuclear weapons, and finally the launching of a space satellite caused concern and even alarm in Western countries: the Soviet Union did seem to be catching up to the West. The Soviet economy displayed a number of weaknesses, some inherited from the Stalin era, others arising from its continued separation from the world market and from the difficulties of providing a larger quantity and variety of consumer goods.

Reforms after Stalin's death

The postwar years saw the establishment of nationalized and planned economies in eastern European countries. East Germany and Czechoslovakia apart, these countries had been predominantly agrarian, though, except for Albania, they had some industrial towns or areas. Yugo-

slavia broke with the Soviet Union in 1949; Albania adopted a pro-Chinese policy after the Sino-Soviet schism of the 1960s; and Romania has tended to pursue its own course. Each of the east European countries adopted an economic policy closely following the Soviet example, even when inappropriate for its particular circumstances. The Stalinist model of "Socialism in one country" was applied in literal detail in what appeared to be an attempt to establish replicas of the Soviet Union in the "Peoples' Democracies."

The strains and tensions in Soviet society after Stalin's death were even more pronounced in a number of the east European countries. When the East European Council for Mutual Economic Assistance (CMEA) was established in 1949, much was heard about the need to develop "an international Socialist division of labour." In fact, the economic development of Czechoslovakia, Poland, Hungary, Romania, and Bulgaria had been adversely affected not only by a fundamental change in their international economic relations—away from Germany and western Europe and toward the Soviet Union—but also by their comparative isolation from each other. Even in the 1960s, the degree of coordination and integration provided for by CMEA left each country very much a separate economic entity. While achieving rapid rates of growth and overcoming their former underdevelopment to a considerable extent, development of these countries was uneven.

The economic history of the Soviet Union and the east European countries must be viewed against events in the capitalist world. The Cold War reduced the volume of exchanges with the capitalist countries and thus the possibility of remedying their deficiencies through trade. The United States, in particular, imposed an embargo on strategic exports to the area. Although the output of consumer goods did increase, partly under the threat of such popular uprisings as occurred in Berlin in 1953, in Hungary and Poland in 1956, in Czechoslovakia in 1968, and in Poland again in 1970, the boom in the capitalist world had increased the supply of consumer goods available to the masses of the population in western Europe still faster. In shop-window competition the east European countries continued to be outclassed. Automobiles and many consumer durables were only for a privileged few. Necessities might be in adequate supply, cultural goods—such as books and records—cheap, social services adequate, and accommodation cheap if not abundant, but the range of goods the Western consumer could spend his money on was still not available.

WORLD WAR II AND AFTER IN THE INDUSTRIALIZED NATIONS

The improvised character of the economic policies of the belligerents in World War I was almost entirely absent in World War II. War experience had been digested, and further lessons had been learned from the Great Depression. Perhaps most important of all, World War II had been anticipated with some deliberation by the main participants. In the end, it was the sheer weight of resources that the Allied powers were able to bring to bear that stopped the German military machine and demolished the Japanese "New Order" in Asia.

The impact of economic mobilization

In the capitalist states, economic mobilization imposed unprecedented centralized control and planning directed to maximize output for the war effort while distributing sufficient civilian supplies to maintain efficiency and morale. Production was regulated by a priorities system, labour was directed, and scarce commodities rationed. Prices and wages were controlled and foreign trade curtailed to strategic needs. The market mechanism was largely superseded, but private property rights were preserved, although they might be interfered with on a compensatory basis when the war effort demanded it. Although some war factories were state owned, military contracts were generally fulfilled by private industry on a profit-making basis. The war economy thus required considerable state control, but it remained, in Germany as in Britain and the United States, a capitalist economy.

The desire to knock out the enemy's economic nerve centres and to demoralize, or even destroy, the workers upon which the armed forces depended account for much of the destructiveness of World War II. Modern technology provided supremely powerful weapons that, even before the atomic bomb, could reduce whole cities to rubble in a few hours. The wide-ranging nature of the fighting on the Western Front after the Allied landings in June 1944, as well as in the East, together with the effects of bombing, extended the area of destruction far more than previous wars as well as making it more complete. At the end of the war, therefore, the European countries and the Soviet Union faced an unprecedented mass of destruction. To this were added the losses from the sea war and the dislocation and disruption of prewar trade patterns.

The recovery. The recuperative powers of advanced industrial societies, however, are equally remarkable. The effect of bombing on machines and industrial equipment was less severe than on dwellings and other buildings. Given the human skills available and an abundant supply of people with the incentive to reshape shattered lives and earn enough to buy necessities, it was possible to restore industry and reconstruct the social infrastructure comparatively quickly. From the ruins emerged, in fact, a larger and more advanced industry than in peacetime. It was even claimed that the more devastated regions, such as western Germany, had the advantage over the less battered industries in Britain, which brought much obsolescent equipment and plant intact into the postwar years. Such an explanation of British industrial problems, which were to limit its growth in the period after 1945, was, however, too facile.

The European belligerents endured very severe upheavals and hardships in the later stages of the war and the first years of peace. This was a period of general penury, of rationing and the black market, during which, in some places, money virtually lost all value, and people returned to a barter economy. Only United States loans and aid prevented economic and social breakdown. Meanwhile, large transfers of population took place, particularly from eastern Germany and Czechoslovakia to the West, and large numbers of displaced persons had to be resettled. The many millions of rootless and penniless people provided, however, a mobile and adaptable labour force. German recovery, particularly, benefitted, but in the first years of postwar reconstruction Europe as a whole was helped by labour from this and other sources. Growth was not held back by labour scarcity, and the bargaining power of workers was held in check until full employment levels were reached.

At the end of the war a tremendous disparity existed between the United States and the dislocated economy of impoverished Europe and Asia. Only the United States could supply the foodstuffs, raw materials, semifinished products, machinery, and machine tools that were in scarce supply. The capacity of the belligerent countries to earn foreign exchange, particularly dollars, had been greatly impaired; and they needed loans or aid if reconstruction was to be carried through without balance of payments difficulties. U.S. lend-lease, under which supplies had been made available during the war, ended shortly after Japan's capitulation. The subsequent U.S. loans to France and Britain proved inadequate. Finally, spurred by the growing tension of the Cold War, the European Recovery Program, or Marshall Plan, was launched in 1947 to continue reconstruction and rescue capitalism in western Europe.

The Marshall Plan

The outstanding fact was that the reconstruction boom was succeeded, not by a crisis of overproduction and a return to high unemployment but by expansion that continued through the 1950s and 1960s. The explanation of this latest phase of capitalist development is not made easier by the fact that the period of the Great Depression has not yet been adequately explained. It is possible only to trace the main lines of development and indicate some of the major problems.

Postwar monetary systems. The governments of the Allied countries in the postwar world saw that the currency chaos and beggar-my-neighbour policies of the 1930s must be avoided. First, the reconstruction of the world monetary system was needed, and the United Na-

tions Monetary and Financial Conference held at Bretton Woods in July 1944 sought to do this through the establishment of the International Monetary Fund and the International Bank for Reconstruction and Development (World Bank). The former set out to establish monetary stability and to remove exchange restrictions that hampered world trade. It established new rules for adjusting exchange rates without a return to the old gold standard. Although each national currency was to be expressed in terms of gold, it was the dollar price of gold and the convertibility of the dollar that together provided the essence of the postwar monetary system.

Bretton Woods set the postwar international monetary scene, but there were also important new factors. The recovery of the world market was much more rapid than after World War I. In an atmosphere of expansion international trade was liberalized through the General Agreement on Tariffs and Trade (GATT), and other agencies on an international or regional basis made possible a greater degree of international economic cooperation. Some, such as the Organization for European Economic Cooperation (OEEC), set up by the countries benefitting under the Marshall Plan, were mainly consultative bodies. More important was the movement toward economic integration in Europe that led to the Treaty of Rome in 1957 and the setting up of the European Economic Community (EEC, or the Common Market) in 1957.

Whatever its inherent problems (which emerged in the 1960s), the new monetary system did make possible the recovery and world expansion of the quarter century after World War II. It permitted an increase in the monetary supply on a scale impossible under the pre-1914 gold standard or the interwar gold bullion standard. The new gold exchange system was seriously criticized, particularly by France under Charles de Gaulle, when, in the 1960s, successive international currency crises and the weakening of the dollar were calling it into question. There was, however, no agreement on a substitute, apart from tinkering or modifications to suit the changing conditions created by the growth of western Europe and Japan's economic power. In particular, for the U.S. government, the gold parity of the dollar, established in 1934, appeared to be sacrosanct. It was this continued overvaluation of the dollar upon which U.S. capitalism's world position seemed to depend during the 1960s.

The Bretton Woods agreement confirmed the pre-eminence of the dollar, backed by the huge gold holdings in Ft. Knox, which lasted until the end of the 1950s. Sterling, despite Britain's diminished role, remained a key currency, which, like the dollar, could be used by other countries as part of their reserves for international payments. During the postwar period of dollar scarcity the dollar was as good as gold, in demand all over the world; but the new arrangements allowed a worldwide inflationary trend assisted by the outflow of dollars from the United States. This outflow, beginning as reconstruction loans and then Marshall Aid, was continued in other ways: as military expenditure, by military and economic aid to countries threatened by "Communist aggression," and by direct and portfolio investment. Much of this huge American foreign spending and capital outflow assisted the rebuilding of European capitalism and then its powerful resurgence from the mid-1950s as well as the remarkable upsurge of Japan. In the long run, as the U.S. balance of payments became increasingly unfavourable, the dollar scarcity turned into a dollar surplus; and the mark, the yen, and other currencies became strong currencies. At that point, the Bretton Woods system was doomed.

The first years after World War II were years of reconstruction, and progress on the whole was rapid. Industrial capacity had been built up during the war, and it was often possible to restore production quickly. Governments injected new demand into the economy, and this, together with the pent-up purchasing power of consumers and the reserves accumulated by business, fuelled the postwar boom. The war had shown that government spending could have positive economic results.

Expansion and full employment. From the early 1950s a long-term expansion began in the industrialized countries. Particularly rapid growth rates were achieved by advanced countries that were incompletely industrialized. Western Germany made a spectacular recovery and resumed its place as the hub of industrial northwest Europe. Japan exploded into an industrial giant, showing an astonishing versatility in exploiting the most advanced techniques and production methods. The Scandinavian countries continued with their solid prosperity. The fringe countries of southern Europe, still relatively backward, began to speed into the 20th century. Such older industrial areas as Britain and Belgium experienced growth, too, but at a rate that compared unfavourably with that of the rest of western Europe. The United States also grew less rapidly, thus causing some concern, especially in the years after the launching of the Soviet space satellite, but the huge size of the economy meant that continuing growth produced a steady increase in a per capita income well above that of western Europe and Japan.

Background of postwar expansion

The roots of the sustained growth of the advanced industrial countries in the 1950s and 1960s seem to have been laid in the war and even as far back as the Depression. A long period in which investment was at a low level and, in some fields, actually negative had cleared the way. In some countries the war had added to industrial capacity; machines and machine tools were available to produce new consumer goods. Japanese firms, for example, turned from producing range finders and bombsights to cameras and photographic equipment. Despite the destruction in Germany, there was more plant and equipment available for production than in the 1930s. The United States had considerably increased its industrial capacity. British industry, which had not entirely thrown off the Depression in 1939, entered the postwar world in a sellers' market, and unemployment was minimal until the late 1960s.

Interrelated developments in varied fields tended to make industry much more science based than ever before. This enabled the logic in the industrial system to be worked out more fully, culminating in the fully automated computer-controlled process. But highly sophisticated machines had only a partial application and represented an enormous outlay of capital. Perhaps more important in raising total output was the steady increase of productivity levels over almost the whole of industry. Into this there entered not only straight technology but also changes in business organization, administration, and management, and a better educated and more adaptable labour force. The workers were geared by the incentive of the increased range of goods available to the needs of the industrial machine that produced them. New methods of wage payment were devised to obtain increases in productivity.

Postwar capitalism was characterized by almost uninterrupted output and productivity growth and high levels of investment. As the expansion continued its momentum, workers had to be mobilized from further afield. Germany and France each attracted some 3,000,000 immigrants from southern Europe, Turkey, Algeria, and even sub-Saharan Africa to meet a chronic labour shortage. In particular, steady and prolonged employment became as much a part of the expected order of things as insecurity and unemployment had been in the 1930s.

Full employment greatly enhanced trade union power as well as making employers compete for labour. Some economists claimed that "wage push" was a main factor in the inflationary pressures of the 1960s; but the whole situation was inherently inflationary, and governments that attempted to deal with it merely checked expansion and created a recession. It was generally accepted, therefore, that some inflation was unavoidable if growth and full employment were to be maintained. Government expenditures, especially on armaments, when financed by credit expansion, fed the inflationary trend and were probably its basic source.

The return of inflation

Inflation was undoubtedly linked to the increase in the money supply that government policies required. The ability to increase the money supply was made possible by the currency arrangements established by Bretton Woods and particularly by the outflow of dollars from
